Electronic Medical/Health Records. Studies of EMRs and EHRs have described the use of databases to get accurate information about patients (e.g., arrests, medications, diagnoses), including refusals and concerns (among those agreeing) of patients to have their paper records entered into electronic media. In general medicine, physicians report a decline in productivity while adapting to EMRs, followed by practicing medicine differently with higher quality and safety and noticing a decline in paperwork and wasted communication time. Only 10% of physicians using electronic records abandon them to return to paper records. Many reports of electronic records are being harvested for previously uneconomic investigations (e.g., substance abuse–related mortality in 169,051 veterans over 7 years).

In Boston, a cardiologist at Massachusetts General Hospital described their frustration on Twitter (X): “Why are nearly all notes in Epic … basically ‘useless’ to understand what’s happening to a patient during a hospital course?” Another doctor’s reply says, “Because notes are used to bill, determine the level of service, and document it rather than their intended purpose, which was to convey our observations, assessment, and plan. Our important work has been co-opted by billing.”

The promise of bringing medical record keeping into the digital age was to maintain a live record of a live patient, enabling clinicians to track patient care across hospital systems and over time. Instead, we have been saddled with systems that cut into patient care (clinicians typically

Telegram: @medical_k

www.konkur.in

spend an hour feeding documentation for every hour they spend with patients) and, often, are too fragmented to allow a patient's file to follow her from one medical center to another. The EMR, as a colleague of mine put it, is "electronic in the same way your grandfather's radio is electronic." The energized, improvisatory role of medical Twitter (X) inevitably draws attention to what our bulky, billion-dollar systems should have been providing—to the cost, in dollars and lives, of the rapid clinical learning that we have foregone.

It is hardly news that our EMR systems have failed medicine. However, an executive order from New York State, issued at the end of March by Governor Andrew Cuomo, amounted to a grim epitaph: "Health care providers are relieved of record keeping requirements to the extent necessary for health care providers to perform tasks as may be necessary to respond to the COVID-19 outbreak … Any person acting reasonably and in good faith under this provision shall be afforded absolute immunity from liability. A system designed to expedite and improve the delivery of health care was officially recognized as an obstacle."

7.10 Cultural Competency in the Organization and Delivery of Psychiatric Care

Carole E. Siegel, Ph.D., Helena B. Hansen, M.D., Ph.D., and Jonathan Michel Metzl, M.D., Ph.D.

Cultural competency (CC) is a notion borne from considerations of nondiscrimination that has been applied in various contexts, including national and international affairs, education, the workplace, and health care. In all these venues, it speaks of productive ways to achieve equitable ends in situations where a mainstream or majority group–sometimes a power group–interacts with "other" cultural groups–usually minority or possibly disadvantaged groups–who have values and views and sometimes languages that are appreciably distinct from the "mainstream." The specific contextual issues and the positions taken can substantially differ from venue to venue. For example, while debates can ensue as to whether or not immigrant children in the United States should be educated in their native languages and in specially designed educational courses, there is no analogous debate in health care. In the United States, Western medicine is predominantly delivered in English, but there is wide agreement that language accommodations are required for persons from cultural groups who have limited English proficiency.

Since 2014, several events of notoriety have occurred in which law enforcement agents were involved in adverse community situations, and Black lives were lost. A collective response to this which has had a substantial national impact is the "Black Lives Matter" movement which aims to eliminate the occurrence of such events and to raise public awareness of innate biases in the population and prejudicial treatment of Blacks, as these factors may have played contributory roles. Organizations both private and public used by diverse groups, including educational and medical settings, have responded and actively put in place activities to ensure that their settings are open and respectful of its

Telegram: @medical_k

www.konkur.in

diverse community members. At NYU Langone Hospital, an Office of Diversity Affairs was established within which activities to fulfill the goals of diversity and inclusion were put in place. There is a roadmap and timeline for promoting an inclusive and equitable culture of medicine. This includes hiring and placement at all institutional levels and particularly in leadership positions, a diverse faculty and staff, as well as the establishment of a greater array of diversity training activities in the School of Medicine. Medical education now includes a curriculum on systemic racism and its impact on health outcomes. Many of the activities that have been suggested are the same as those endorsed under organizational CC that aim to accommodate diversity and promote equitable care.

Here, we explicate the notion of CC, providing background on mental health disparities, some formal government responses through the years, and some proposed solutions for organizations, their programs, and their staff to improve their CC in the delivery of care. In part II, structural competency is introduced, which addresses the societal influences and social determinants of health that can cause disparities in treatment and care outcomes. Specific recommendations for clinical care that integrate social awareness of these factors are exposited.

Suggestions are made to move the discussion of CC in health care–with a focus on mental health care–beyond a rehearsal of compliance issues and the rhetoric of political correctness to a description and justification of the CC activities that can be used to promote patient-centered care. While it is critical to apply these activities in all health areas, it is particularly crucial in mental health care, where diagnoses are made and many treatments delivered strictly based on verbal communication. Operationalizing the activities of CC has remained challenging, but the landscape of the ‘80s, when these notions were first introduced, has considerably changed based on the broad recognition that for CC to move forward, greater specificity was required on how to do this. Recent societal events of negative import reinforce the need to have specific activities in place that will have an impact.

DEFINITIONS: CULTURAL GROUP; CULTURAL COMPETENCY

Telegram: @medical_k

www.konkur.in

A cultural group has shared activities, ideas, and traditions, which are reinforced by its members. The group is a dynamic entity as the views and values of its members can change over time and are influenced by where people live as well. Thus Chinese and Chinese American cultures in 2014 differ from each other, and each group differs from itself pre- and post-Chinese economic reforms. Federal policies for health care to date have been framed to ensure nondiscrimination only for minority racial/ethnic groups, but CC is intended to apply to any cultural group that encounters limitations in service access or in participation in services. While clearly including underserved racial/ethnic groups, it also encompasses groups disadvantaged in health care such as lesbian, gay, bisexual, and transgendered communities, the born Deaf, and even rural communities, each having distinct lifestyles. Anthropologists have recently questioned the value of culture in understanding a persons' behaviors, as monolithic constructs fail to account for variations in expression and experiences within cultures. The notion of a cultural identity attempts to address this deficit by recognizing that persons belong to multiple cultural groups, and the intersectionality of these groups is what shapes a worldview. Cultural groups are defined by more than race, ethnicity, country of origin and go beyond to encompass socially defined groups for which membership impacts daily living, such as groups defined by socioeconomic status, professional roles, gender, and stage of life roles. Thus a Black, unmarried, inner-city male will differ in world view from a Black father who lives in suburbia. CC training materials for clinicians take cognizance that persons' views of their cultural identity are fundamental to understanding how they make sense of the world and hence how they respond to and interact with a health care provider.

Many definitions of CC in health care have been proposed, of which the most commonly cited in mental health care is that of Terry Cross. He defines CC as "a set of congruent behaviors, attitudes, and policies that come together in a system, agency, or among professionals and enables that system, agency, or those professionals to work effectively in crosscultural situations." This definition first appeared in a monograph on ways to work with severely and emotionally disturbed minority youth written for the Georgetown University Child Development Center (now the National Center for Cultural Competency), an early promoter of CC in the delivery of children's services. A less proscriptive definition defines Cultural Competence in an individual or organization as having the

Telegram: @medical_k

www.konkur.in

capacity to function effectively within the context of the cultural beliefs, behaviors, and needs presented by consumers and their communities. While these definitions are all-encompassing, to better understand their implications, it is helpful to parse them into the distinct ways they apply to organizations and to caregivers.

When considering healthcare organizations that broadly include structural entities such as departments of mental health, managed care companies, hospitals, agencies, and programs, CC is referential to the policies and procedures that should be endorsed and promoted throughout an organization to enable caregivers and other staff under the purview of the organization to work effectively and efficiently with different cultures and within multicultural situations to provide high-quality services. On the clinical level, CC refers to the desirable personal attributes of clinicians encompassing their attitudes (affective domain), knowledge (cognitive domain), skills, and actions (behavioral domain) that enable them to work effectively and efficiently across cultures and in multicultural situations to produce clinically and culturally appropriate service outcomes. This latter definition addresses clinician values, overt and covert biases, as well as the knowledge and skills guiding the ways to act. There has been notable clinical resistance to the concept of CC as many believe that it is already addressed or implied in clinical competency or feel it is already adequately addressed when a clinically competent clinician practices patient-centered care. The Institute of Medicine defines clinical competency as the ability to use clinical skills and knowledge to identify each consumer's unique health state and diagnosis, individual risks and benefits of potential interventions, and personal values and expectations. In working with persons with severe mental illness, some curricula endorse core competencies to address recovery, rehabilitation, and empowerment. The argument goes, if these notions are fully operant, CC will be embedded in clinical competency. But for now, CC is not treated as a distinct construct in clinical training or adequately represented in its curriculum, so that CC needs to be viewed as a distinct competency.

It is well documented that clinicians' misunderstandings of cultural sensibilities can lead to failed treatment alliances. Many psychiatric training programs around the country have instituted CC didactics and curriculum that explicate one or more of the attributes of CC identified by Derald Sue and others of attitudes, knowledge, and skills. For example, the New York University psychiatric CC curriculum has included three

Telegram: @medical_k

www.konkur.in

modules, two of which address attitudes (and awareness): Perceiving the Other and Perceiving Self. In the former, residents learn how sociocultural influences impact clinical presentations, and in the latter, residents experience their own cultural backgrounds and examine their influence on the doctor–patient relationship. Action skills are taught through a third practicum module where residents practice conceptualizing culture in the doctor–patient encounter using a culturally interpretive clinical approach. Other models have been proposed for guiding clinical competency, and one such other is discussed later.

STRUCTURAL COMPETENCY: ADDRESSING INSTITUTIONAL DRIVERS OF INEQUALITY

Jonathan Metzl and Helena Hansen have introduced a construct called structural competency that addresses the institutional and policy-level (i.e., structural) drivers of disparities in treatment and health outcomes. These drivers shape the social determinants of mental health in populations, as well as mental health care delivery systems and the practice environments of clinicians who deliver care. The premise of structural competency is that health inequity results from and reflects institutionally embedded inequalities, including systemic racism, that sicken marginalized groups of people through such social determinants as unstable housing, unsafe polluted neighborhoods, lack of access to fresh food, unemployment, substandard education and high levels of police surveillance and incarceration. Clinical practitioners are traditionally trained in individual patient-level interventions, but as health experts they can, when taught the relevant skills, work with institutional stakeholders to reorient policies and practices toward health promotion. Clinical practitioners are in a privileged position not only to redesign clinical services to address structural barriers to care (such as by providing transportation and social services) but also to collaborate with community organizations, nonhealth sector agencies such as housing assistance, education, and legal aid, as well as policymakers, to promote health through community-based programs. Structural competency frameworks also emphasize the mental health effects of particular health policies, and increasingly clinicians can help to develop and implement policy solutions to some of the most pressing social and political issues of our time, including gun violence and mass incarceration.

Telegram: @medical_k

www.konkur.in

A growing number of medical schools are developing structural competency curricula and community practicums (see structuralcompetency.org). They provide classroom and community-engaged experiential learning based on three fundamental principles: (1) understanding patients' experiences in terms of their structural drivers; (2) intervening to address those drivers at institutional levels (through community organizations, nonhealth agencies, and public policy); and (3) practicing structural humility, which means seeking out multidisciplinary collaborators with other types of expertise, including community organizing, and having patience with the slow pace of structural change. Some psychiatry residency programs have worked with faculty members who are social scientists and community organizers to create structural competency trainings that specifically address barriers mental health.

FIGURE 7.10–1. Hierarchical levels of health care system.

Figure 7.10–1 displays the hierarchical levels of a health care system in which CC activities need to be introduced. Structural competency is added as a meta-level to the Terry Cross view of CC as structural competency impacts operations and behaviors at all of the displayed levels.

WHY CC IS IMPORTANT: DIVERSITY, DISPARITIES

Telegram: @medical_k

www.konkur.in

The Percent non-White of the U.S. Population is Growing

According to the most recently published U.S. Census figures (2021), 40.7% of the U.S. population is non-White. 18.9% report themselves as Hispanic/Latino, 12.6% as Black/African American, and 5.9% as Asian. The Hispanic/Latino group in the United States is even larger as many in this group have entered the country as illegal immigrants and are not counted officially in any of the U.S. Census counts. Nevertheless, many of these persons will avail themselves of emergency rooms in hospitals and use hospital clinics when confronted with mental health problems. Racial/ethnic groups that require special attention from psychiatric practitioners comprise an ever-increasing proportion of all persons served. For example, in NYS in its public mental health system (which excludes private practice practitioners), in 2013, 24.3% were Black, non-Hispanic, 23.3% were Hispanics, and 1.9% were Asian American.

Continuing Evidence of Disparities

In 1978, the first report of the President's Commission on Mental Health explicitly recognized critical disparities among racial and ethnic minorities. President Jimmy Carter and especially his wife Rosalynn became strong advocates for rectifying these disparities. A series of reports originating with the Western Interstate Commission on Higher Education commissioned by the Substance Abuse and Mental Health Services Administration focused on the four broadly defined racial/ethnic groups identified as underserved and underrepresented in managed mental health care—**Americans of African Descent, Asian and Pacific Islanders, Latinos, and Native American Populations—and compiled into a comprehensive volume a great depth and breadth of knowledge about the mental health needs of these cultural groups.** The Surgeon General's 2001 Supplemental Report reported on the mental health care of these major underserved racial/ethnic groups finding disparities in availability and access to needed services. The report endorsed CC in care delivery as a key approach for the reduction of these disparities, although there was no elaboration on how to do this.

There is strong evidence of sustained disparities in mental health. Researchers continue to find disparities for racial/ethnic minority groups in service accessibility, service utilization, as well as inpatient satisfaction. Asians remain less likely to access care than other groups. There are also still notable disparities in the reported prevalence of mental health

Telegram: @medical_k

www.konkur.in

conditions among groups, with reasons for this at best only speculative. Several authors have linked prevalence differences to a misunderstanding of cultural presentations of symptoms resulting in both over and underdiagnoses. Papers still speculate on reasons for higher rates of diagnoses of psychosis in Black adults, ADHD in Black children, and lower rates of diagnoses of depression in Latinos. Mechanisms of disparities are often linked to social determinants, for example, poverty, and to structural factors such as federal and economic health policy, operations of the health care system, provider factors, and environmental contexts. Residential segregation of services and providers and provider shortages may also account for access and use disparities. For example, for Native Americans, in 2018, it was noted that the Indian Health Service (HIS) remains understaffed and underfunded. A review of disparities across the country based on some recent studies conducted from 2010 to 2015 is presented in Table 7.10–1.

While it is hard to evaluate whether disparity rates have been increasing or decreasing over time, an effort has gone into producing services likely to eliminate disparities for cultural groups. This includes culturally adapted assessment instruments, norming these instruments for racial/ethnic groups and training psychiatrists on how to make more culturally sensitive diagnoses, adapting evidence-based services to better fit the styles and mores of cultural groups, and introducing alternate services more acceptable to certain cultures, such as those that incorporate religion and spirituality into a therapeutic approach. A recent effort to increase the success of therapeutic alliances between persons with disorders and their therapists directly encourages peers to present to their caregivers the aspects of their cultural identity that can influence their receptivity and the success of the care they are being prescribed. It is described below.

CULTURAL AWARENESS OF CAREGIVERS

Growing Recognition of the Role of Cultural Competency in Care Delivery

Some authors locate the roots of a concern with cultural awareness in clinical training in the 1950s to 1960s postwar social sciences. A group of medical sociologists and anthropologists, Talcott Parsons among them, studied the professional acculturation and socialization of doctors during clinical training. What had been taken for granted as primarily technical

Telegram: @medical_k

www.konkur.in

education was revealed to be a rich cultural milieu, replete with rituals, key symbols, rites of initiation, and social dramas, which led researchers and clinicians to a growing awareness of the “culture of medicine” as opposed to the culture of patients. There is a consensus, however, that the term “cultural competence” was not widely used in medical journals or clinical training until the 1980s when the Association of American Medical Colleges and the Accreditation Council of Graduate Medical Education called upon medical schools and residency programs to train clinicians to address their patients’ “culture,” which largely referred to their patients’ ethnic and racial identity. The term “cultural competency” and the concern with outcome disparities came from the field of education, which had used the term with regard to addressing educational attainment disparities by ethnicity and race.

In psychiatry, this awareness of cultural differences between practitioners and patients as relevant to clinical practice was codified in the DSM IV, published in 1999. Psychiatrist-anthropologist Arthur Kleinman led a special committee of the DSM IV Task Force devoted to cross-cultural psychiatry that introduced new diagnostic frames and clinical tools to the DSM IV appendix. These included “culture-bound syndromes” and the Cultural Formulation, a guide to interviewing and diagnosing patients using questions that took the patients’ cultural understanding of their problem into account, using Kleinman’s Explanatory Model. This contrasted with the symptom checklists of the DSM III, which had aspired to use universally applicable symptom descriptions, descriptions that soon proved to be interpreted differently across ethnic and language groups, and which some practitioners argued led to misdiagnosis. At about the same time, Derald and Stanley Sue were advocating for the cultural competence of clinicians, particularly in their work in counseling and psychotherapy. They emphasized the need for a greater understanding of psychiatric symptoms that could be misunderstood across the cultural divide between Western medicine and Chinese patients. They emphasized the need for addressing cultural beliefs, attitudes, knowledge, and skills and developing new counseling competency standards when working with multicultural populations.

By 2000, as the DSM IV Cultural Formulation gained visibility, and as increasing numbers of medical schools adopted some form of training in cross-cultural patient care, competing models of training in cultural issues emerged. The first might be called cultural expertise, in reference to the

Telegram: @medical_k

www.konkur.in

goal of having medical trainees gain knowledge of the beliefs and behaviors of their patients' cultural groups. In practical terms, this led medical schools to emphasize language translation services and, in some cases, "cultural consultants" who are members of minority ethnic groups employed by medical centers to assist healthcare providers in communicating with their patients. The second approach might be called cultural sensitivity, in which the goal is not to master bodies of knowledge about the cultural groups from which patients come, but rather to understand the broader psychosocial context of each patient, to ask each patient's guidance in learning what is relevant to them, and to heighten the cultural self-awareness of clinical practitioners so that they can take their own biases into account in their exchanges with patients. These two approaches, cultural expertise and cultural sensitivity, are not mutually exclusive, but many medical training programs emphasize only one.

Expanding on the cultural sensitivity approach, the term "Cultural Humility" was introduced by pediatricians, who offered "humility" instead of "competency" because it conveys the attitude a doctor would need to adopt in order to learn from the unique circumstances and thinking of each patient. The practical elements they proposed were (1) self-evaluation of the health care provider to root out cultural assumptions that might reinforce their stereotypes of and discrimination against patients, (2) empowering patients to have a voice in their own decision making; and (3) forming partnerships with communities to advocate for more locally responsive health care.

Table 7.10–1. Selected Disparity Literature Review: 2010 to 2014

Authors (year)	Title	Objective	Sample	Conclusion
Service Accessibility and Utilization				
Wu P et al. (2010)	Mental health service use among suicidal adolescents: findings from a U.S. National Community Survey	Assess patterns of mental health service use among adolescents who had attempted suicide and examine service at individual and community level	877 adolescents (12–17) who attempted suicide in the past 12 months	▶ Mental health needs of minority, lower-income families are unmet ▶ Larger race/ethnic disparities in use of in and outpatient services than in school-based services ▶ School-based services more accessible to suicidal adolescents who may experience barriers in receiving standard care
Alegria M et al. (2011)	Disparities in treatment for substance use disorders (SUD) and co-occurring disorders for ethnic/racial minority youth	Review literature on racial/ethnic disparities, focusing on SUD services and comorbid behavioral health disorders in children and adolescents	N/A	▶ Compared with non-Hispanic-Whites, Black adolescents with SUD reported receiving less specialty and informal care ▶ Latinos reported receiving less informal care ▶ Mechanisms of disparities identified in federal and economic health policy, operations of health care system, provider factors, environmental context, patient factors, etc.
Cummings J et al. (2011)	Racial/Ethnic differences in mental health services use among adolescents with major depression	Examines difference in mental health services use in NH-Whites, Black, Hispanic and Asian adolescents experiencing major depression	7,704 adolescents (12–17) with major depression in past year–nationally representative	▶ Black Hispanic and Asian adolescents significantly less likely than non-Hispanic Whites to receive prescriptions medication, to receive treatment for depression from specialist or provider, and receive outpatient treatment, after adjusting for family income and insurance status
Akincigil et al. (2012)	Racial and ethnic disparities in depression care in community-dwelling older adults in the United States	Investigated racial/ethnic disparities in diagnosis and treatment among community-dwelling older adults	Medicare Current Beneficiary Survey, n = 33,708	▶ Blacks significantly less likely than non-Hispanic Whites to receive depression diagnosis from provider and if diagnosed less likely to be treated
Cook B et al. (2013)	Assessing racial/ethnic disparities in treatment across episodes of mental health care	Investigating race and ethnic disparities in decisions to start and terminate care and decisions during treatment	Whites, Blacks, and Latinos with probable mental illness	▶ Blacks and Latinos initiated care less frequently ▶ Black and Latino episodes were shorter ▶ Black and Latino had fewer psychotropic drug fills
Kim G et al. (2011)	Limited English proficiency (LEP) as a barrier to mental health service use: a study of Latino and Asian immigrants with psychiatric disorders	Examine the effect of LEP on mental health service among immigrant Latino and Asian adults with psychiatric disorders	372 immigrant adults (18–86) with any instrument-determined mood, anxiety, and SUD	▶ LEP of Latinos but not of Asians significantly reduced odds of mental health service use ▶ Asians less likely to access care
Jimenez D et al. (2012)	Disparities in mental health service use of racial and ethnic minority older adults	Apply the IOM definition of health disparities, to measure disparities in different episodes of mental health care	1,658 adults >60 with likely mental health care need	▶ Treatment initiation is significantly lower and the adequacy of treatment is significantly poorer for Black and Latino older adults than White counterparts ▶ Latinos had significantly longer treatment duration, more visits, and higher expenditures
Merikangas K et al. (2012)	Service utilization for lifetime mental disorders in U.S. adolescents: results of the National Comorbidity Survey–Adolescent Supplement (NCS-A)	Examine rates and sociodemographic correlates of lifetime mental health service use by severity, type, and number of mental health disorders	6,483 nationally representative adolescents (13–18)	▶ Black and Non-Hispanic Black were less likely to receive mood and anxiety disorder services than White counterparts
Siegel C et al. (2013)	Access to and use of noninpatient services in New York state among racial-ethnic groups	Report on differences in use of noninpatient services in Hispanics, Asians, and non-Hispanic Blacks and Whites using NYS public mental health system	NYS OMH 2009 Patient Characteristic Survey	▶ Higher treated prevalence for Latinos and Blacks compared to Whites ▶ Lower prevalence rates for Asians ▶ Lower treatment intensity among Black youth with disruptive disorders, Hispanic adults with anxiety, and Asians <65 with depression compared to White counterparts ▶ In upstate metropolitan areas, Black youth and Hispanic adults had lower treatment intensity than Whites ▶ In NYC, Whites >65 had higher treatment intensity than other groups

Patient Satisfaction				
Huang B et al. (2011)	The Effects of discrimination and acculturation to service seeking satisfaction for Latina and Asian American women: implications for mental health professions	Provide full description of Latina and Asian American women's experiences in mental health seeking service and identify ways to improve satisfaction	4,649 women from National survey of Latino and Asian Americans (NLAAS)	▶ Perceived gender and race/ethnicity discrimination in Latina and Asian American women negatively predict satisfaction in mental health service seeking ▶ Older age, higher education level, duration in the United States, and better mental health positively predicted satisfaction
Risk for Disorder or Condition				
O'Donnell S et al. (2011)	Increased risk of suicide attempts among Black and Latino lesbians, gay men, and bisexuals	Assess whether major depressive and substance use disorders mediates higher prevalence of suicide attempts among LGB minority youth than White counterpart	388 Latino, Black, and White LGB New York City residents (18–59)	▶ Black and Latino LGB youth had significantly increased risk of suicide even without depression and SUD markers
Huang K et al. (2012)	Physical and mental health disparities among young children of Asian immigrants	Examine physical and mental health functioning among Asian-American children of U.S.-born and immigrant parents	7,726 Asian and U.S.-born White children	▶ Asian children of foreign-born families at greater risk than children of U.S.-born White families of poor physical health, internalizing problems, and inadequate interpersonal relationships
Morgan P et al. (2013)	Racial and ethnic disparities in ADHD diagnosis from kindergarten to eighth grade	Identify racial/ethnic disparities in diagnosis and treatment of ADHD in children from kindergarten to 8th grade	17,100 national representative sample from Early Childhood Longitudinal Study	▶ Minority children are less likely to receive ADHD diagnosis than White children ▶ Among children with ADHD diagnosis, minorities less likely to be taking prescription medication
Siegel C et al. (2014)	Why are racial/ethnic rates of childhood attention-deficit/hyperactivity disorder in national studies highest among Whites?	Examine race/ethnic differences in ADHD treatment of children in large public mental health system and compare with national rates	Children 3–17 receiving care in NYS public mental health system	▶ Contrary to national findings, ADHD prevalence rates in public mental health system are higher in White children except for Hispanic females ▶ Authors reason that White children have greater access to private providers through private insurance and make greater use of general practitioners
Provider Shortage				
Gone J et al. (2012)	American Indian and Alaska Native mental health: diverse perspective on enduring disparities	Investigate mental health disparities unique to AI/An community	N/A	▶ Little oversight of mental health services in Indian Health Service (IHS) ▶ IHS remains understaffed and underfunded
Cook B et al. (2013)	The role of provider supply and organization in reducing racial/ethnic disparities in mental health care in the United States.	Identify factors such as county-level provider organizations and SES characteristics associated with MH services and differences across race/ethnicity	12,241 respondents from the National Latino and Asian-American Study, National Comorbidity Survey Replication, and National Survey on American Life	▶ Significant racial/ethnic disparities in use of any and specialty MH care after controlling for geographic variation ▶ Latino residential segregated areas had shortages of psychiatrists and Black residential segregated areas had shortages of medical specialties
Dinwiddie G et al. (2013)	Residential segregation, geographic proximity, and type of services used: evidence for racial/ethnic disparities in mental health	Examines role of residential segregation in differential access and mental health service utilization	9,738 Whites; 3,362 Blacks, and 5,053 Latinos living in Metropolitan Statistical Areas	▶ High Latino isolation and centralization areas had shortage of psychiatrists ▶ High Black concentration areas had access to psychiatrists in their area ▶ Respondents in Black neighborhoods treated by nonpsychiatrists and general doctors ▶ Respondents in Latino neighborhoods treated by general doctors ▶ Respondents living in High Latino isolation and centralization areas more likely to utilize nonpsychiatrist

Another expansion on the idea of provider self-evaluation was introduced by psychiatrist-social scientists Elizabeth Bromley and Joel Breslow in an approach to clinical education that develops "Critical Thinking Skills." They propose heightening trainees' self-awareness of the culture of medicine by teaching them the history of medicine and

Telegram: @medical_k

www.konkur.in

sociocultural research on medicine. They argue that this prepares trainees for leadership in medicine through understanding their own role in the larger institutions that are constraining patients' care and options. For example, trainees learn from this material that the U.S. health care system locates disease in the individual, rather than the community or the environment, which explains its focus on "compliance/adherence" rather than on the patient's milieu, their resources, and supports. Another example, clinicians are trained to tell diabetics to limit their intake of sugar and processed foods, but not to ask if they live near grocery stores with fresh foods or if they know how to cook.

Cultural Activation of Consumers to Provide Cultural Information to Their Caregivers

Carole Siegel, Lenora Reid-Rose, and Gary Haugland have posited that since the health activation of consumers has been documented to improve health outcomes, "cultural activation" of consumers might do so as well. Cultural activation was framed as a consumer's recognition of the importance of providing cultural information to providers about their cultural affiliations, challenges to receiving care, views about and attitudes toward behavioral health and general medical health care, and the ability to transmit such information. In conjunction with several consumer groups, they developed prompts for consumers to use to help them culturally represent themselves, thus promoting shared decision making as part of the therapeutic alliance and acting as a form of consumer empowerment (Table 7.10–2).

The prompts help consumers transmit to providers cultural information about their identities, their views of their mental health challenges, and the supports and barriers that they may encounter. They draw on the domains covered in the *DSM-5* Cultural Formulation Interview and on the "three C's" of Kleinman's explanatory model of illness: call, cause, and course. YouTube videos made by the Substance Abuse Mental Health Administration, are available that explain and support the use of these prompts. It is not intended to replace the Cultural Formulation Interview but rather to serve as a portable aid for consumers to transmit culturally relevant information to caregivers whenever the consumer feels it is needed to do so.

GOVERNMENT RESPONSE: STANDARDS, REGULATIONS, AND LEGAL REQUIREMENTS

The civil rights movement of the sixties heightened concerns about discrimination in health care. Title VI of the Civil Rights Act of 1964 states that "no person in the United States shall, on the grounds of race, color or national origin, be excluded from participation in, be denied the benefits of, or be subjected to discrimination under any program or activity receiving Federal financial assistance." A primary focus at the federal level has been to remove language barriers that can prevent access to both general and mental health care. The Americans with Disabilities Act of 1990 mandated accessibility to facilities and programs for persons with disabilities, and this included psychiatric conditions. It also provided an impetus for introducing principles of CC into federally funded mental health programs. In 2000, President Bill Clinton signed Executive Order 13166 "Improving Access to Services for Persons with Limited English Proficiency," which requires federal agencies and those receiving federal funding to identify service needs of persons with LEP and implement systems to ensure persons have meaningful access to services without unduly burdening the mission of the agency. Guidance issued by the Department of Justice spells out compliance standards to be followed to ensure programs and activities provided in English are accessible to persons with LEP. Ensuring that language is no barrier to health care, this action addresses discrimination on the basis of national origin, which was prohibited by Title VI. In 2000, the U.S. Department of Health and Human Services, through the Office of Minority Health, published National Standards for Culturally and Linguistically Appropriate Services in Health Care referred to as the CLAS standards. However, while provisions for culturally competent care and administrative and organizational supports were encouraged, only the provisions for linguistic assistance were made a mandated requirement. Neither the metrics to measure compliance to these standards nor enforcement guidelines accompanied the standards, although these came at a later date. The CLAS standards were revised in 2013 and augmented with an extensive set of guidelines for an organization to employ these standards (see Table 7.10–3). The new CLAS standards are organized into overarching themes. Communication and language access; engagement, and continuous improvement and accountability encompass the original standards, and a new standard,

Telegram: @medical_k

www.konkur.in

governance, leadership, and workforce, is included to ensure that CLAS standards are integrated and implemented throughout an organization.

Table 7.10–2.
Cultural Activation Prompts for Consumers

Telegram: @medical_k

www.konkur.in

Cultural Activation Prompt	Explanation
1. How would you like to be called 2. The kind of person you would feel good about getting care from 3. Your cultural identity 4. Any negative or traumatic experiences you have had because of your cultural identity.	These first prompts are suggested to be used when a consumer and provider first meet and get to know one another. These prompts help create the foundation of a respectful, honest, and open relationship. These set the stage for future conversations about cultural identity. They give providers a baseline understanding of how consumers view themselves from a cultural perspective. The fourth prompt can begin a discussion on how the consumers may have experienced events in relation to those outside their cultural identity groups.
5. The names you and people from your cultural groups give for why you are seeking care. 6. What you and people from your	Prompts 5–8 are also suggested to be used when a consumer and provider first meet and get to know one another. These prompts give consumers a way to articulate the importance of their cultural norms. Finally, they can begin a conversation to help clarify the nature of their challenges in a cultural context.

Telegram: @medical_k

www.konkur.in

cultural groups think may be the cause(s) of your health challenges

7. Why people from your cultural groups think you need care
8. What people from your cultural groups feel about you seeking care
9. Who from your cultural groups might help you while you are in care
10. Kinds of different care you have had that were helpful
11. Care that you have had that

Prompts 9–11 are suggested to be used when a care plan is being made. The prompts help consumers articulate their preferences from a strengths perspective. They can be used to identify social supports that may not typically be considered.

Telegram: @medical_k

www.konkur.in

	was not helpful	
12.	Things you like to do where you live, worship, shop, socialize, etc. with people from your cultural groups	This final prompt is suggested to be used when planning for recovery in the community. This prompt helps identify activities that relate to their cultural identity that can help consumers maintain good outcomes while tapping on cultural community strengths. Additionally, it can begin or continue a conversation on building additional social supports in the community.

The CLAS standards have been tied to the review criteria of the Joint Commission (formerly Joint Commission Accreditation of Hospitals/Healthcare Organizations) for the accreditation of hospitals and other health care organizations that have been expanded to include more explicit cultural and linguistic elements. The Joint Commission is essentially the gatekeeper for hospitals to obtain federal funds for inpatient care and has focused its reviews on an organization's safety and quality of care standards. Accreditation of hospitals and medical schools requires adherence to these standards. Additionally, the National Committee for Quality Assurance has standards for cultural competence that health care organizations and managed care plans must address as part of their accreditation process.

Some recent government-mandated changes in insurance coverage for health care and the way in which individual insurance plans pay for mental health services need to be considered to examine whether they have influenced the receipt of mental health care by racial/ethnic groups. The Affordable Care Act, passed in 2010, has been shown to have increased access to care for lower socioeconomic groups, which include many racial/ethnic persons most positively affecting those living in states in which there was an expansion for Medicaid recipients who could enroll because of more liberal criteria. Effects on outcome have not yet been well studied, particularly on racial/ethnic groups, and outcome evidence that exists is mixed to date, but access has been documented to have

Telegram: @medical_k

www.konkur.in

improved. The Mental Health Parity and Addiction Equity Act of 2008 require large-group employer insurance plans to cover mental health services at the same level as medical and surgical services if they offered them in order to make mental health service payments more equitable across illness categories; the effects of this on racial/ethnic minorities would thus only apply to those in the workforce and has not yet been studied.

BEYOND THE RHETORIC: DEFINING THE ACTUAL ACTIVITIES OF CC

On a clinical level, there is skepticism as to whether or not CC can be defined precisely enough to operationalize its aspects into clinical training and best practices. On an organizational level, many feel that CC is achieved once language accommodations are made, such as having interpreters available when needed and having key forms in translated versions. Hospital signs in multiple languages are now commonplace. While certainly necessary, these steps are not sufficient. But substantial progress has been made in isolating specific activities and defining and developing tools and products to promote activities of CC. We begin by making clear that CC activities need to occur on the multiple levels of a care organization in order to achieve quality outcomes.

Telegram: @medical_k

www.konkur.in

Table 7.10–3.
National Standards for Culturally and Linguistically Appropriate Services in Health Care (HHS, Office of Minority Health, 2000)

Telegram: @medical_k

www.konkur.in

Principal Standard:

1. Provide effective, equitable, understandable, and respectful quality care and services that are responsive to diverse cultural health beliefs and practices, preferred languages, health literacy, and other communication needs.

Governance, Leadership, and Workforce:

2. Advance and sustain organizational governance and leadership that promotes CLAS and health equity through policy, practices, and allocated resources.
3. Recruit, promote, and support culturally and linguistically diverse governance, leadership, and workforce that are responsive to the population in the service area.
4. Educate and train governance, leadership, and workforce in culturally and linguistically appropriate policies and practices on an ongoing basis.

Communication and Language Assistance:

5. Offer language assistance to individuals who have limited English proficiency and/or other communication needs, at no cost to them, to facilitate timely access to all health care and services.
6. Inform all individuals of the availability of language assistance services clearly and in their preferred language, verbally and in writing.
7. Ensure the competence of individuals providing language assistance, recognizing that the use of untrained individuals and/or minors as interpreters should be avoided.
8. Provide easy-to-understand print and multimedia materials and signage in the languages commonly used by the populations in the service area.

Engagement, Continuous Improvement, and Accountability:

9. Establish culturally and linguistically appropriate goals, policies, and management accountability, and infuse them throughout the organization's planning and operations.
10. Conduct ongoing assessments of the organization's CLAS-related activities and integrate CLAS-related measures into measurement

Telegram: @medical_k

www.konkur.in

and continuous quality improvement activities.

11. Collect and maintain accurate and reliable demographic data to monitor and evaluate the impact of CLAS on health equity and outcomes and to inform service delivery.

12. Conduct regular assessments of community health assets and needs and use the results to plan and implement services that respond to the cultural and linguistic diversity of populations in the service area.

13. Partner with the community to design, implement, and evaluate policies, practices, and services to ensure cultural and linguistic appropriateness.

14. Create conflict and grievance resolution processes that are culturally and linguistically appropriate to identify, prevent, and resolve conflicts or complaints.

15. Communicate the organization's progress in implementing and sustaining CLAS to all stakeholders, constituents, and the general public.

From U.S. Department of Health & Human Services. Office of Minority Health. National CLAS Standards. https://thinkculturalhealth.hhs.gov/clas/standards

Figure 7.10–2 indicates that the policies and procedures of an organization impact the kind of staff employed and the limits placed on their therapeutic work. The composition of the clinical team, the kind of supervision that team members receive, and the approaches taken to coordinate care define the human resource boundaries of the program. The program's work is conducted within a palpable milieu that patients encounter and react to. Clinical work uses particular clinical tools and service delivery modalities that are constrained by reimbursement issues that impact service choices and the duration of delivery. The care that is ultimately delivered by clinicians is subject to their competencies.

Telegram: @medical_k

www.konkur.in

FIGURE 7.10–2. Factors in a care organization impacting care outcomes.

Figure 7.10–3 illustrates how CC needs to guide these activities. The policies of an organization that works with multicultural populations need to address CC deliberately. The starting point is the incorporation of CC into a mission statement of the organization, allocation by the organization of a budget to enable a person/group to be assigned to spearhead CC, and the development of an organizational plan for CC. The plan requires community, provider, and client input. The desirability of staff diversity needs to be addressed in hiring policies, and training activities need to be organized for all levels of the organization. The clinical team needs to address cultural strengths and challenges when managing a client's care and coordinating services. The milieu of the program needs to be welcoming to cultural groups and accommodate their special needs, for example, by having convenient hours of operation, policies on privacy, and child-friendly areas. When delivering services, cultural assessments need to be made in order to appropriately diagnose the client and develop a service plan that will act to engage and retain the client in services. Services need to be chosen that are culturally acceptable to a client, and if sufficient numbers warrant it, services specifically chosen or adapted for cultural groups. In service delivery, clinical competency needs to be

Telegram: @medical_k

www.konkur.in

augmented with a requirement for CC as the behaviors of clinicians, based on their attitudes and skills, can impact outcomes.

FIGURE 7.10–3. Cultural competency activities impacting care outcomes.

Specific Clinical Activities

Psychiatrists play a key role in the engagement and retention of persons from cultural groups in care. They often are the gatekeepers for entry into specific types of services, determine specific treatments and serve as arbiters in treatment team meetings. In the clinical hierarchy, they have a distinct power role, thus impacting other clinicians as well as clients. CC is, however, not a concept discussed in most training programs and not yet a focus of clinical care, particularly in programs that strongly endorse medical models as explanatory of illness and symptoms and medications as the primary modalities of psychiatric care. Being clinically competent and practicing patient-centered care is endorsed and could include CC, but to date is only addressed in a hand full of training programs. But buy-in to CC by psychiatrists is critical to good care, as, in order to engage persons from cultural groups in care and to have them remain in care, they need to trust their psychiatrists. Lack of trust and feelings of stigma can impact engagement in services and adherence to treatment

Telegram: @medical_k

www.konkur.in

regimens. Trust can only be engendered if clinicians are cognizant of cultural views on mental illness that can impact treatment.

Cultural Competency Curricula for Clinicians

There are several curricula that address ways to enhance the CC of psychiatrists, counseling practitioners, psychologists, and social workers. A comprehensive review of such training guides has been conducted by researchers at the Canadian Centre for Addiction and Mental Health Centre de Toxicomanie et di Santé Mentale. They found consistency across guides in the use of the Sue and colleagues framework of CC encompassing personal level awareness, knowledge, and skills. Awareness modules address understanding and conciliating a client's and one's own biases, beliefs, attitudes, and world views. Antiracist and antioppression conceptual models may be invoked. Knowledge attainment addresses understanding both the generic cultural factors that can impact care, for example, social determinants of illness, level of acculturation, immigration status, as well as specific cultural factors such as a cultural view of illness causation and expectations for recovery. Skill component modules in the more practical guides suggest approaches for engagement and problem-solving based on cultural views of clients, as well as on the tangibles of working with interpreters and seeking consultation from clients' natural caregivers such as clergy and traditional healers. Case studies and scenarios are often introduced here. In addition, several guides also address clinician-client power relationships and even system–client interactions. In the former, sensitivity to issues of power differentials that can engender either trust or mistrust are addressed. In the latter, the curricula cover areas overlapping with recent ideas on structural factors impacting relationships.

We review in greater detail one curriculum developed by psychologists Deborah Altschul and Jeff Brooks-Harris for the broad swath of counseling practitioners. The multicultural skills training model (MST) is a practice-based method of CC that aims to enable providers to adapt their current practices to meet the needs of culturally diverse populations. It is applicable across a broad array of service modalities, including psychotherapy, psychoeducation, and skills training. It also draws upon the Sue and Sue tripartite seminal model of training offering practical approaches for understanding, in addition to the cultural views and biases of clients, one's own views and suggests ways to conciliate clinician-

Telegram: @medical_k

www.konkur.in

patient views. It addresses the need for practitioners to integrate into their therapeutic approach ways to empower clients to deal with the high likelihood of impacting social determinants of health such as housing needs.

MST is arranged as six clusters of culturally based activities to help better match the individuals' needs to therapeutic care. To illustrate, the module Becoming Aware of Your Own Multiple Worldviews, a prerequisite to working with multicultural clients, recommends confronting your own personal culture-based worldview as it influences views of mental health and the etiology of mental illness and appreciating your own multiple cultural identities and their impact on your thinking and treatment decisions. When working with clients, Creating a Culturally-Sensitive Working Relationship includes knowing the cultural norms and customs of a cultural group as they manifest in a particular individual and determining the style of collaboration that is most comfortable for the consumer. Understanding the Individual's Worldviews and Facilitating Cultural Identity Development parallels the work of the first caregiver module for the client and suggests exploring with clients the historical backgrounds of their cultures, as well as the current placement of the client in that culture. There is a focus on understanding cultural norms about help-seeking, problem attribution, and expected outcomes. On the client's part, it is helping the client to value their own cultural background but also to become open to other worldviews as well. Open discourse is suggested to help clients deal with experiences that they may have had that they perceived as racist or biased in social and work interchanges. In Responding to Societal Structures and Value, counselors are encouraged to work with consumers to confront their feelings of being undervalued because of cultural identity and social status. This could be based on having received slurs, felt racial discrimination, or having felt undervalued as transmitted to others in ambient societal messages. Empowering consumers through social activation and encouraging them to make greater use of cultural resources such as religious affiliations is recommended. A final cluster Utilizing Complementary Roles beyond Psychotherapy suggests ways to incorporate nontraditional healing methods of their cultures into the therapeutic work.

Clinician Self-Assessment of Cultural Competency

Telegram: @medical_k

www.konkur.in

There are several practitioner-level CC self-assessment scales. While self-assessments can be pointless because of their subjective structure, if appropriately used, they can serve further as educational tools. One with established psychometrics that is widely used is the Multicultural Counseling Inventory. It addresses the three domains of awareness, knowledge, and skills. It is comprised of 40 items on which the provider rates his/her self-perceived cultural competence across the subscales Multicultural Counseling Skills (Sample Item: “When working with minority clients, I am able to quickly recognize and recover from cultural mistakes or misunderstandings”), Multicultural Awareness (Sample Item: “I am involved in advocacy efforts against institutional barriers in mental health services for minority clients”), Multicultural Counseling Relationship (Sample Item: “When working with minority clients, I find that differences between my worldviews and those of the clients impede the counseling process”), and Multicultural Counseling Knowledge (Sample Item: “When working with minority clients, I make referrals or seek consultations based on the client’s minority identity development).

Domains of Organizational and Program Activities

Except for that provided by psychiatrists or other professionals working entirely independently, most mental health care is organized as programs, bundles of available services, and treatment strategies geared toward ameliorating psychiatric distress. Programs, in turn, are components of mental health care agencies, centrally administered entities that provide policy and procedural guidelines for the programs under their purview and obtain and allocate resources. From an organizational or program perspective, CC activities should take place in the domains illustrated in Figure 7.10–4. Needs assessments refer to gaining an understanding of the diverse cultural groups using a care system, their possible service gaps, and specific service needs. Information exchange refers to mechanisms for receiving and transmitting information on community needs to persons responsible for planning and delivering services. Reflexively, deliberate efforts are required for communities to receive information on services available and ways to access these services. CC tools need to be disseminated to caregivers to improve their ability to provide CC services. Services that are offered need to be appropriate for community cultural groups and modifications to existing services made and/or new services introduced. Language accommodations may need to

Telegram: @medical_k

www.konkur.in

be made. Organizations need to promote and sustain recruitment, hiring, and retention procedures of culturally competent bilingual and bicultural staff, as well as to educate and train existing staff in CC. Linkages to other systems need to take into account the cultural needs of clients. Outcomes related to disparities in access and quality of care to cultural groups, desirable cultural group outcomes, and satisfaction with services need to be distinctly monitored. These activities are expected to improve outcomes and need to be monitored to see if they are taking place and the impact they may have. They need to be endorsed through the policies and procedures of the organization.

Telegram: @medical_k

www.konkur.in

FIGURE 7.10–4. Cultural competency domains.

Both an organizational-level instrument and a program-level instrument to assess CC have been developed by the Nathan Kline Institute Center of Excellence in Culturally Competent Mental Health. The guiding

Telegram: @medical_k

www.konkur.in

principles were to have objective measures that demonstrated the importance of the concept of CC, for which it was feasible to collect appropriate data that were reliable and accurate. While clinicians can be assessed on their self-perceived attitudes and beliefs, organizational and program-level items were selected to be verifiable.

The organizational level scale items were selected based on a review of recommendations, standards, and guidelines. A 27-site study succeeded in establishing the predictive validity of the several language accessibility items of the scale, showing they correlated with better engagement and retention. The program level scale was based on an ethnographic study of three long-standing programs that defined cultural groups in which deliberate and culturally grounded steps had been taken to make them acceptable. Key and common elements were observed across these programs and used to define domains of CC. It is informative to review these instruments as they were designed in form not only for assessment purposes but intended to serve as roadmaps for introducing CC activities into organizations and programs. Each criterion is scored with an ordered scale of whether or not an activity is accomplished, reflecting an increasingly complex degree of activity related to CC. A score indicates that the listed activity and all those below it are carried out. We use the scale items to step through specific activities that should be undertaken to promote CC.

Organizational Activities

The first set of criteria is meant to ensure that a procedure for setting up a CC presence in an organization is established. Fundamental is that an organization has an articulated commitment to CC evident in its mission statement. By creating a position with an assigned budget and having this person/group part of the governance of the organization, there are tangible assurances that CC activities can take hold. Strategies for obtaining information about and working with members of diverse cultural groups include establishing a committee that includes members of the largest cultural groups in the community and empowering that group to review current CC work and communicate its concerns and ideas directly with management. The organization needs to identify which cultural groups are being served, what their language needs are, and which members of the community are not being seen in order to target its outreach efforts. Particular data items need to be collected for all clients in

Telegram: @medical_k

www.konkur.in

a consistent manner so that they can be aggregated to assess the cultures and language needs of the population being served by the agency. Information on the target community allows the agency to tailor its outreach and services to the needs of its cultural groups.

Several criteria relate to staff. Hiring, recruiting, and retaining staff that is from prevalent cultural groups or who have experience working with these groups is often noted as ideal. This diversity should extend beyond clinical staff to include administrative and supervisory staff as well. Organizations can have policies in place that seek culturally representative employees and strategies to identify suitable candidates. Staff training, if related to the work of staff, might be an effective way to enhance the CC of all, both members of cultural and mainstream groups.

Literacy level and English proficiency can be barriers to accessing services. Several criteria address language accommodation. This could be accomplished through hiring bilingual staff or, if not able to do so, having interpreter services available for all service users from the point of the first contact with the organization. Additionally, organizations need to recognize that key forms and documents need to be translated into commonly encountered languages in order to work effectively with persons having Limited English Proficiency. Furthermore, service descriptions and educational materials also need to be translated, and for persons with limited reading skills, alternate formats can be introduced (e.g., novellas, videos, and items in simplified English). Finally, services that do not appear to be effective for persons from certain cultural groups may need to be adapted for use with that cultural group, or new services introduced that have been developed specifically for prevalent cultural groups (Table 7.10–4).

Program Activities

The program-level CC assessment scale identifies activities that are more directly associated with delivering care than organizational activities. The criteria address strategies for engaging consumers from cultural groups into a program, measures program capacity for meeting the language needs of clients, including gaining an understanding of and working with communication styles of clients. The appropriateness of the services offered to the cultural groups served, the use of support groups including peers, family, and kin, and utilizing cultural community resources to sustain a consumer's recovery are also measured. The scale examines

Telegram: @medical_k

www.konkur.in

program outcome goals and prods a program to include in outcome measurement cultural groups' understanding of and desirability for different modes of recovery. Finally, keeping in mind the health care reform goal of population health, community outreach to cultural groups is assessed.

Engagement in a program means that the client will receive a sufficient dose of the program so that the maximum benefit of the services can be realized. If appropriately engaged, it is likely that participants will adhere to treatment regimens and complete the work of a program. Programs need to understand the cultural needs of their clients to engage them. A welcoming milieu in the program is essential as well. The scale measures whether assessments go beyond the collection of standard demographic information such as age, gender, race/ethnicity, and preferred language to include more detailed information on cultural group identity, level of acculturation, and religious/spiritual beliefs. Primary to engagement is addressing language needs and ensuring effective communication with clients through an understanding of and adjustment to their possibly different styles of communication. Examining ways to increase trust in the staff and addressing the experience of stigma from the perspectives of different cultures also increase engagement.

The scale examines whether services have been culturally modified or new culture-specific services have been offered. Certain service modalities may not be suitable for cultural groups. This is true even for some highly endorsed evidence-based practices. Exploring the possibility of making modifications to services to make them more culturally relevant can be accomplished with the input from members of the cultural groups and further ensures a connectedness of the program with the cultural groups it serves. For example, group therapy that requires sharing of personal information with strangers is not an acceptable mode of care for older adult Chinese populations. However, a mahjong group run by an experienced therapist can combine the positive aspects of both a culturally enjoyable experience and a profitable therapeutic encounter.

Utilizing various support groups available to the client can enhance the possibility of positive outcomes. The scale examines the extent to which the program includes peer staff from the cultural group. These are both paid employees and volunteers who have mental health experience. Staff from the same cultural groups of clients enrolled in the program who have mental health experience can facilitate engagement of cultural clients in

Telegram: @medical_k

www.konkur.in

the program by enhancing consumer trust in the program and providing role models of recovery. They can also provide other program staff with information on cultural views impacting mental health treatment and acceptable treatment strategies. Family and social networks–as identified by the consumer–can play a large role in the lives of members of cultural groups, particularly in immigrant groups. Some consumers may rely heavily on particular family members for their supports and for maintaining their ties to their communities, while others may rely more heavily on close friends and members of their social network. The extent to which these persons participate in assessment, care planning, and providing ongoing supports is assessed. The scale also measures the extent to which a program identifies community resources that are acceptable and responsive to cultural values and preferences of consumers as referrals to promote healthy community living.

The scale identifies three ways to measure outcomes, a critical aspect of any assessment of health care programs. Service delivery outcomes such as patterns of use and program completion rates, while not measuring the quality of care, should not differ among cultural groups and act as basic markers of disparities. Satisfaction surveys need to be formulated with members of cultural groups as their desirable recovery outcomes may differ from those of clinically comparable consumers from other groups because of different beliefs, relationships, and resources to achieve goals. Finally, a program's outreach efforts are measured. In order to increase the enrollment of cultural groups into programs that might be of benefit to them, outreach efforts should be undertaken that include identifying these groups in the community and informing them about what the program offers to people from these cultures (Table 7.10–5).

Telegram: @medical_k

www.konkur.in

Table 7.10–4.
Organizational CCAS Criteria and Their Rationale

Telegram: @medical_k

www.konkur.in

Criterion	Description	Rationale
1. **Agency's Commitment to Cultural Competence**	The agency (or its parent organization [PO]) has a management-level person responsible for CC and a dedicated budget for CC activities, a CC plan, and procedures for updating the CC plan.	A management-level person who has primary responsibility for CC ensures that CC will be addressed. Without a dedicated budget, only limited activities can be conducted. A written plan concretizes the agency's commitment to CC. Review and updating ensure that there is a feedback loop and that corrective actions can be taken.
2. **Assessment of Service Needs**	The agency obtains current data on its service users and its target community that enable identification of their cultures and language needs	Particular data items need to be collected for all clients in a consistent manner so that they can be aggregated to assess the cultures and language needs of the population being served by the agency. Information on the target community allows the agency to tailor its outreach and services to the needs of its cultural groups.
3. **Cultural Input into Agency Activities**	The agency (or its PO) has a CC Committee or other group that addresses cultural issues and has participation from cultural groups of the target community	A committee dedicated to CC will enhance the likelihood that activities appropriate to the cultures served are introduced and carried out. The committee can go under many names or be part of the functions of existing boards, advisory groups, and committees.

Telegram: @medical_k

www.konkur.in

			Input is sought from representatives of the most prevalent cultural group of the target community. Having more than one representative from a cultural group makes active participation more likely.
4.	**Integration of CC Committee or Other Group with Responsibility for CC Within Agency**	The CC Committee or other group with responsibility for CC is integrated within the agency evidenced by the following activities: ▶ Reviews services/programs with respect to CC issues at the agency ▶ Reports to Quality Assurance/Quality Improvement program of the agency/PO ▶ Participates in planning and implementation of services at the agency ▶ Directly transmits recommendations to the executive level of agency/PO	The extent to which the functions of the CC Committee are reported and used in the agency provides a measure of the likelihood of change with respect to CC. Four key committee functions are expected to take place, but they may be introduced at different stages.
5.	**CC Staff: Training Activities**	The agency (or PO) offers to staff educational	Training and educating staff in CC enhances the likelihood of the delivery appropriate

Telegram: @medical_k

www.konkur.in

	activities in which cultural issues are addressed and requires staff to have an adequate amount of specific training on CC	services to cultural groups. Ideally, educational activities should take place every year, and all staff members who have face-to-face contact with and provide direct clinical care to agency clients receive CC training. Administrative staff should also be knowledgeable about CC.
6. CC Staff: Recruitment, Hiring, and Retention of Staff from/or Experienced with the Most Prevalent Cultural Groups of Service Users	The agency is committed to hiring and retaining CC staff who are from or who have had experience working with the most prevalent cultural groups of its service users	Having direct service, supervisory and administrative staff with relevant experience with the most prevalent cultural groups enhances the likelihood of the acceptability and use of CC practices. Hiring and retaining professional staff members who are from the cultures of service users provides positive role models for clients of the agency and affords additional opportunities to increase knowledge about the cultures.
7. Language Capacity: Interpreters	The agency (or PO) accommodates persons who have limited English proficiency (LEP) by using interpreter services or bilingual staff	Language needs of persons with limited English proficiency must come to the attention of the agency at the point of first contact in order to identify their needs and link them to the appropriate services. Once a person has agreed to

Telegram: @medical_k

www.konkur.in

		receive the services offered by the agency, language needs must continue to be addressed. Ideally, interpreters are formally trained and certified or are bilingual staff members who have received CC training.
8. Language Capacity: Bilingual Staff	The agency has staff who speak the language of the most prevalent cultural group of service users with members who have LEP	Having bilingual staff members who can work directly with persons with language needs is ideal–and likely to be cost-effective as well.
9. Language Capacity: Key Forms	The agency has translated versions of key documents and forms in the language of the most prevalent cultural groups of its service users	Legal documents and critical care information must be understandable to persons with limited English proficiency to ensure that such information is provided equally to all service users.
10. Language Capacity: Service Descriptions and Educational Materials	The agency accommodates persons with LEP by translating service descriptions and accommodates persons with limited reading skills (LRS) by providing service descriptions or educational materials in formats	Using different formats and media for descriptions of available services and for educational materials ensures that literacy level is not a barrier to accessing services. Service-related materials translated into the most prevalent non-English language will be especially helpful to overcome treatment barriers for

Telegram: @medical_k

www.konkur.in

	they can understand.	service users and family members.
11. Assessment and Adaptation of Services	The agency (or PO) reviews and adapts or introduces services suitable to the most prevalent cultural groups of service users	A comprehensive CC-based assessment of services may result in the adaptation of existing services and the introduction of new services to better serve members of the most prevalent cultural groups.

Table 7.10–5.
Program Level CCAS

Telegram: @medical_k

www.konkur.in

Criterion	Description	Rationale
1. **Cultural Assessment of Consumer**	Program obtains a detailed cultural assessment of each consumer that is additional to collecting standard (age, gender, race/ethnicity; preferred language) demographic information	Information that provides a view of beliefs, values, and world views of the consumer that can be used to improve diagnosing and the therapeutic alliance of staff with cultural groups. Information is recommended to be collected at the initial clinical assessment but can be updated throughout the course of the program. Cultural information should be made available to all clinical staff and care workers.
2. **Engagement: Spoken language capacity**	Program has procedures and staff to facilitate working with consumers/families with limited English proficiency or with consumers who are Deaf	If staff can communicate with consumers/families in their preferred language, the therapeutic encounter will be enhanced.
3. **Engagement: Communication styles**	All levels of program staff communicate with persons from cultural groups in ways that are respectful to them	Barriers between staff and consumers are reduced when modes of communication are respectful, acceptable, and familiar to the consumer.
4. **Engagement: Trust building**	Program intentionally and actively works to build and maintain the trust	Retention and engagement in the program are likely to increase if consumers feel their personal information

Telegram: @medical_k

www.konkur.in

	of consumers and family members from cultural groups	is held confidential and that staff care about them by being responsive to their values and preferences as they relate to the program.
5. Engagement: Culturally framed stigma reduction	Program intentionally conducts activities to reduce stigma of mental illness as experienced by a cultural group	Stigma can impede engagement in services. Persons from cultural groups who might benefit from mental health services often delay seeking treatment or drop out of services because of the cultural group's views of mental illness, including their attribution of its causes, its impact on other family members, and their social standing in their communities.
6. Culturally friendly service delivery environment	Program is conducted in physical spaces that are made appealing and familiar to the cultural groups served	Features of surroundings that are familiar, welcoming to families, and celebratory of a cultural group enhance consumer and family feelings of comfort and a sense of connectedness while participating in the program.
7. Culturally modified or new services	Program has strategies for making their services responsive to values and preferences of persons from	Services need to be reviewed and modified for applicability and their responsiveness to the values and preferences of the cultural group. New services may need to be developed.

Telegram: @medical_k

www.konkur.in

	cultural groups with the aim of improving their effectiveness	
8. Inclusion in program of staff from cultural groups who have mental health experiences (consumer peers)	Program includes staff, both paid and volunteers, who have mental health experience and are from the cultural groups served by the program	Staff from the same cultural groups of clients enrolled in the program who have mental health experience can facilitate engagement of cultural clients in the program by enhancing consumer trust in the program and providing role models of recovery. They can also provide other program staff with information on cultural views impacting mental health treatment and acceptable treatment strategies.
9. Family member involvement	Program engages persons that are identified by the consumer from their family, including from social networks, to take part in care planning and providing ongoing support	Family and social networks can play a large role in the lives of members of cultural groups, particularly immigrant groups. Some consumers may rely heavily on particular family members for their support and for maintaining their ties to their communities, while others may rely more heavily on close friends and members of their social network.
10. Community resources	Program utilizes community	Consumers from cultural groups benefit from

Telegram: @medical_k

www.konkur.in

	resources acceptable and responsive to cultural values and preferences of consumers to promote health outcomes	interventions that involve the use of community resources.
11. Satisfaction with Program	Program conducts activities to measure consumer and family member satisfaction with the services provided	Program improvement for cultural groups needs to be based on consumer and family member appraisals of the program.
12. Service Delivery Outcomes	The program examines disparities in service delivery outcomes related to engagement and retention in the program	Service delivery outcomes for cultural groups should not differ from those of clinically comparable consumers from other groups. Consumers from cultural groups may have particular difficulties in engagement in and retention of services. Differences in service delivery measures on engagement and retention could reflect these difficulties. These need to be identified and monitored by the program.
13. Recovery Outcomes	The program examines disparities in service process outcomes and	Recovery outcomes for cultural groups may differ from those of clinically comparable consumers from other groups because

Telegram: @medical_k

www.konkur.in

	identifies and monitors recovery outcomes that are desired by consumers from cultural groups	of different beliefs, relationships, tools, and resources to achieve goals. These need to be identified and monitored by the program.
14. Program Outreach	Program identifies cultural groups in the community/service area who underutilize services and might benefit from the program and conducts outreach to increase their access	To increase the enrollment of cultural groups into programs that might be of benefit to them, outreach efforts should be undertaken that include identifying these groups and informing them about what the program can offer.

IN CONCLUSION

The mental health field has grappled with the complexities of psychiatric disabilities in an increasingly multicultural population. Clinicians need to be aware of and respond to more and more inclusive federal legislation focusing on nondiscrimination and the national standards for the promotion of CC in hiring practices and health care delivery. Current health care reform efforts are resulting in new models of integrative care that address Donald Berwick's triple aims for the improvement of population health, higher quality care, and cost reduction. Clinicians can work from the ground up to incorporate CC into the new models providing an opportunity to better fulfill the triple aims. Population health requires knowing and understanding the needs of diverse cultural groups; higher quality care requires CC of organizations, programs, and clinicians. Cost reductions will follow if care is more appropriately targeted to cultural groups resulting in reduced use of expensive and inappropriate services. Systemic changes, as alluded to in organizational CC and structural competency, provide an outline for the necessary systemic changes. Clinicians, including psychiatrists and other mental health professionals,

Telegram: @medical_k

www.konkur.in

are the critical lynchpin in successful treatment encounters, so along with systemic change, clinician changes in attitudes and behaviors may act to shift the entire system toward the goals of CC.

7.11 Medical Error

NORA C. OBERFIELD, M.D.

Telegram: @medical_k

www.konkur.in

Doctors and the medical systems within which they practice strive for perfection in patient care. Nevertheless, as humans and technology are imperfect, medical errors occur in spite of this dedication to excellence. A landmark 1991 Harvard Medical Practice Study estimated that as many as 1.3 million injuries occurred nationwide to patients receiving hospital care. In 1999, the IOM warned the public that between 44,000 and 98,000 Americans may die each year as a result of medical errors. In 2013, in the *Journal of Patient Safety*, John T. James gave updated estimates of deaths associated with medical error during hospitalization based on studies published between 2008 and 2011. He estimated that more than 400,000 premature deaths occurred in hospitals per year related to preventable patient harm. That number is far greater than the estimate previously reported by the IOM, suggesting that there continues to be much room for improvement in this area. In 2016, the *British Medical Journal* noted medical error as the third leading cause of death in the United States. In 2019, the World Health Organization (WHO) reported that there is a 1 in 300 chance of a patient being harmed while receiving medical care. Too often, inherent bias related to race, ethnicity, gender, sexuality, and socioeconomic status also impacts who is more likely to experience a medical error. In 2018, in the *International Journal for Equity in Health*, researchers concluded that women and African-Americans were affected more than other groups.

Although a number of congressional actions have led to legislation requiring mandatory national or state reporting by hospitals of medical errors, reports of such documentation have been scarce. Issues to contend with are the need to protect doctors and hospitals from frivolous lawsuits resulting from public disclosure and failure to maintain confidential information about patients. While more hospitals are engaging in patient safety initiatives, a 2021 *Journal of Patient Safety* study found that these interventions have only been minimally effective in medical error risk reduction.

The topic of medical error has been complicated by the use of confusing and often conflicting terminology. The IOM separates medical errors into two main categories: errors of execution and errors of planning. An error of execution occurs when there has been a “failure to complete a planned action as intended,” and an error of planning occurs when there has been “the use of a wrong plan to achieve an aim.” Thus, by definition, medical errors require that there be a component of negligence. When

Telegram: @medical_k

www.konkur.in

they do occur, there is a desire for attribution to try to understand why the errors have happened. Did the error occur because the physician departed from an accepted standard of treatment? Was the error avoidable, or the result of poor training? Or was it unintentional—an accident—and better considered a close call or a borderline case?

It is important to distinguish medical errors from adverse events. The latter are related to a particular disease process and are most often predictable or, if not predictable, are known risks. Medical errors usually lead to adverse events and may harm the patient temporarily or permanently, may increase the time for recovery from disease, or may result in patient death. Adverse events may occur in the absence of medical errors, and medical errors may not be associated with an adverse event.

At Johns Hopkins University, the term medical mistake is used instead of medical error and is defined as follows:

> A medical mistake is a commission or an omission with potentially negative consequences for the patient that would have been judged wrong by skilled and knowledgeable peers at the time it occurred, independent of whether there were any negative consequences. This definition excludes the natural history of disease that does not respond to treatment and the foreseeable complications of a correctly performed procedure, as well as cases in which there is reasonable disagreement over whether a mistake occurred.

Types of Error in General Medicine

The current literature highlights five main types of medical errors: errors of commission, errors of omission, errors of communication, errors of context, and diagnostic errors.

1. An error of commission occurs when something done by a member of the medical team leads to patient harm either because it was the wrong thing to do or because it was the correct thing to do, but it was not performed correctly.
2. An error of omission occurs when something that was clearly needed for the patient's healing process was not done.
3. An error of communication occurs when information is not conveyed effectively, either between at least two providers of care or between a provider of care and the patient.
4. A contextual error occurs when a member of the health care team does not recognize social factors in the patient's life, which could

Telegram: @medical_k

www.konkur.in

create barriers to the implementation of effective postdischarge treatment.

5. Diagnostic errors occur when a wrong diagnosis is made, which could have sequelae such as inappropriate or delayed treatment.

Errors may also be categorized as systematic or individual. Systematic errors are caused by flaws in the hospital system or in the transfer of information from one unit of the hospital or from one group of doctors to another. In general, no one person is to blame. An example would be the unavailability or inability to retrieve a patient's medical records or a mismatched blood transfusion. The failure is in the health care delivery system as a whole rather than in the individual.

Individual errors are attributed to a particular physician or to a specific member of the treatment team. Examples include prescribing the wrong medicine or operating on the wrong leg. The physician bears the responsibility, even if the error is made by a person under his or her supervision. Research at John Hopkins Medical Center involving an examination of 25 years of U.S. malpractice claim payouts from 1986 to 2010 indicated that diagnostic errors were the most common type of medical error. A 2020 report from AHRQ suggests that diagnostic errors remain prominent at this time. While the predominant focus in recent years has been on reducing medication and surgical errors, the importance of improving the error rate in the diagnostic area is equally important.

Types of Error Specific to Psychiatry

While there is increased discussion of medical error generally, errors occurring in patients with primary psychiatric diagnoses are an area often excluded from the literature. S.W. Cullen and colleagues separated errors in inpatient psychiatry units into four categories: treatment errors, diagnostic errors, preventive errors, and other errors.

1. Treatment errors are defined as "…failures in the formulation or delivery of an appropriate intervention, therapy, or procedure."
2. Diagnostic errors are not only inappropriate psychiatric diagnoses but also mistaking a physical illness for a psychiatric condition or vice versa.
3. Preventive errors were the most common and have been defined as "any failure to offer indicated prophylactic treatment, as well as

Telegram: @medical_k

www.konkur.in

inadequate or inappropriate monitoring of an initiated treatment plan." Preventive errors include inadequate or disruption of safety protocols "…such as fall precautions, locked unit doors, break-away bars in closets, or 15-minute checks for patients with suicidal ideations."

4. The "other errors" category included problematic transfers and discharges.

In the Cullen study mentioned above, it was found that nonpsychiatric staff members felt ill-prepared to deal with referrals of patients with a history of psychiatric treatment or hospitalization or of patients who were in a state of emotional distress. There was often an inadequate or cursory medical examination in patients who were disruptive or otherwise uncooperative. In order to reduce the error rate among such patients, it will be necessary to decrease stigma about mental illness and educate all health care providers about the complicated presentation of some psychiatric patients with active symptoms such as psychosis. In addition, compliance issues may be a factor in the management of psychiatric patients with a medical illness which may cause difficulties implementing safe and appropriate discharge plans.

Causes of Error in General Medicine

As mentioned above, the causes of medical errors are multifactorial. In general medicine, they include medication errors, transitions of care errors, errors stemming from the use of EMRs, errors related to the challenges of treating a growing geriatric population, and errors related to job overload, fatigue, and physician burnout, among others discussed below. In most instances, medical errors correlate with inexperience. For example, first-year house officers make more errors than second- and third-year residents. Junior attending physicians make more errors than senior attending physicians. Clearly, the aphorism of experience being the best teacher seems to apply in these instances, but experience or the lack thereof is not the only factor.

Medication. According to statistics from the IOM, medication errors in the United States contribute to 1 out of every 131 outpatient deaths and 1 out of every 854 inpatient deaths. The U.S. Food and Drug Administration (USFDA) reports that over 770,000 patients are injured each year due to medication errors. In France, a 2007 study on adverse events in inpatient

Telegram: @medical_k

www.konkur.in

healthcare noted that 50% of serious adverse events were caused by medication errors. At the Mayo Clinic, medication errors are separated into three categories: medication factors, patient factors, and health care professional factors. Medication factors include medications with names that sound similar or medications with low therapeutic indexes. Patient factors include metabolic challenges related to poor hepatic or renal function, patient cognitive status, and polypharmacy. And, lastly, health care professional factors include poor handwriting and the use of abbreviations in prescriptions and progress notes. A 2019 study out of Sao Paulo, Brazil, indicates that electronic medical record usage in the emergency room setting led to a decrease in medical errors. Several studies found that interruptions during rounds and pressure to complete rounds were also potential contributors to medication and other errors.

Transitions of Care. It is important to note the role that transitions of care can play in a medication error. One study found that nearly 50% of patients had at least one medication error when discharged from inpatient units.

Working Hours. Concerns about resident overwork, which may contribute to medical error, generated a new set of duty-hour regulations recommended by The Accreditation Council for Graduate Medical Education (ACGME) that took effect in July 2011. Those recommendations limited the maximum shift length for first-year residents (also known as interns) to 16 hours a day. Although the particulars of duty hours are discussed further in the section *Regulating Working Hours of Interns and Residents,* they are mentioned here in order to examine how this change affected medical error. The change in duty hours was enacted by the ACGME based on research that demonstrated that long duty hours harm both patients and residents. Decreased shift lengths for interns led to a decrease in the incidence of serious medical errors in intensive care units. Longitudinal studies of duty hour restriction, however, did not show that house staff used that time to sleep more hours than previously, nor was there a lessened incidence of burnout. Working shorter shifts may have had the unintended consequence of increasing stress by requiring residents to complete the same amount of work but in less total time. Increased work compression has been associated with poorer clinical performance and decreased satisfaction among residents.

Telegram: @medical_k

www.konkur.in

HANDOFF ERROR. Shorter shifts have also led to more handoffs (when hospital staff who are going off shift communicate information about their patients to the hospital staff coming on shift), and there is a growing literature indicating an elevated rate of medical errors with more handoffs. Different hospitals perform handoffs in different ways, and even individual departments within the same hospital perform handoffs differently. While some hospitals may use a handoff system combining verbal and paper sign-out, other hospitals use an electronic document that is continuously updated. But there is room for error in these frequent transactions. For example, one study found that there were 24 unique handoff mnemonics used in one hospital. In addition, many doctors have never been given formal training in handoff communication. With the rise of errors attributed to handoffs, there is a growing call for a need for a systematic algorithm to be followed by all departments in all hospitals. Efforts are currently being implemented in some hospitals across the United States, focusing on training both medical students and residents to improve handoff communication in order to decrease medical errors.

Electronic Medical Records. The use of EMRs has generally been met with a favorable response, particularly in terms of how electronic documentation decreases medical errors related to illegible handwriting in progress notes and prescriptions. However, some physicians are concerned that EMR may lead to an increase in medical errors because the EMR has replaced face-to-face or phone communications.

James Bernat was among the first to point out the ethical and quality problems associated with the use of EMR. He pointed out the hazards of

> …copying and pasting data obtained from other clinicians, authorship ambiguities, inadvertent inclusion of unobtained data in templated notes, misleading history, and physical exams, failure to review prepopulated data, inadequate discharge summaries, impairments to patient-physician communication, and the transformation of the purpose of the medical record to billing documentation.

In addition, many clinicians have commented on the fact that EMR is making patient care less about the patient and more about record keeping. One study found that medical interns spent only 12% of their time with patients and 40% of their time at computers. Patient encounters have become experiences where the expectation of eye contact between doctor and patient can no longer be guaranteed, with the physician often having to fill out automated checkboxes on the computer screen while

Telegram: @medical_k

www.konkur.in

speaking with the patient. Paying less direct attention to the patient could lead to medical error by missing pertinent details of the history or missing subtle nonverbal communication signs, which could be diagnostic clues. Physicians should meet the patient before entering information into the computer.

Population Demographics

In 2021, there were 55.9 million people in the United States who were 65 years old or older. Estimates suggest that by 2030, there will be roughly 73 million people in this age category. In the United Kingdom, there were 5.9 million people listed as 75 years old or older in 2020, with an expected rise to 8.7 million by 2033. Through improvements in scientific understanding of disease pathology, people are living longer than they did previously, often due to taking medications that slow or halt the progression of several comorbid medical conditions. Given the growing size of older adult populations internationally, in order to reduce medical errors, there must be an increased understanding of the types of medical errors that occur in the older adult population. Polypharmacy, taking several medications daily, can be a significant contributor to medical error, given that medications may have negative drug–drug interactions, and increased care must be taken to administer particular medications at specific times of day to avoid such interactions. In one study from the United Kingdom examining 13 long-term residential homes, polypharmacy is evident, with the average resident receiving seven or more medications. Age-related metabolic changes in how the body responds to medications must also be taken into account, with a need for greater education on renal and hepatic dosing of medications.

Job Overload, Fatigue, and Physician Burnout. Job overload, in which doctors are required to care for too many patients, is a major contributor to medical error. In the hospital setting, interns are assigned to too many patients with too few supervisors. In the outpatient setting, too many patients are cared for by too few doctors. Private practitioners are under pressure from managed care companies who often reward doctors financially for productivity, which translates into a high caseload of patients that leads to overwork. Similarly, some managed care and insurance companies reward doctors who order few laboratory tests, thus lowering cost; however, this may result in misdiagnosis, especially in

Telegram: @medical_k

www.konkur.in

complex cases with atypical presentations. Fatigue and burnout interfere with doctors' judgment and lead to mistakes. While studies report rates of burnout in medical students from 31% to 49.6%, among medical residents, this percentage increases, with some specialties reporting rates as high as 76% (internal medicine). Among practicing physicians, the rates vary by specialty, with emergency medicine physicians reporting burnout at a rate of 51%, while psychiatrists are on the lower end of the spectrum, reporting burnout at 33%. In 2018, ACGME introduced several wellness initiatives into medical education and residency training programs in an attempt to decrease burnout.

Causes of Error in Psychiatry

As within general medicine, the causes of error in psychiatry are multifactorial. Areas to examine include the specifics of the inpatient psychiatric care setting, medication errors, suicide, and restraint and seclusion practices.

Inpatient Psychiatry Unit Characteristics. One of the most striking ways in which inpatient psychiatry units are distinct from most other inpatient units in hospitals is that they are locked units. While the primary purpose of this locked structure is to maintain the safety of the patients and those around them, the fact that the units are locked has the potential to make emergency treatment logistically more challenging. Additionally, again with safety in mind, most inpatient psychiatry units do not allow for any sharps on the unit (with the exception of very small needles used for blood draws, which are often kept off the unit until needed). This means that if a patient is at a level of medical distress requiring the use of IVs, delays in getting the patient to a secure environment, which allows for IV access, are inevitable. These delays may lead to patients not receiving emergent care in the most appropriate time frames, which could lead to an increased error rate in this patient population. Overall, more medication errors occur in hospitalized psychiatric patients than in psychiatric outpatients.

Medication. Most mistakes in psychiatry occur in the area of medication. A wrong prescription may be written, the wrong medication for a disorder may be prescribed, or the wrong dosage of a drug may be administered. A common cause of medication error is poor handwriting by

Telegram: @medical_k

www.konkur.in

physicians, which is then misread by a pharmacist or nurse. A potential remedy is to insist that all prescriptions be typed and transmitted to pharmacies via computer (electronic prescribing has been increasingly adopted by most medical practices throughout the United States). Similar-sounding drug names have also been to blame for medication mistakes, for example, citalopram (Celexa) and celecoxib (Celebrex), buspirone (BuSpar), and bupropion (Wellbutrin) (Table 7.11–1). Drugs with similar phonemes lend themselves to miscommunication in writing or in speech.

Table 7.11–1.
Examples of Drug Name Confusion

Psychoactive Medication	Confused With
Metadate CD (methylphenidate)	Methadone (Dolophine)
Levoxine[a] (levothyroxine) (thyroid preparation)	Lanoxin (digoxin)
Serzone (nefazodone)	Seroquel (quetiapine)
Lamictal (lamotrigine)	Lamisil (terbinafine) (for nail infection)
Zyprexa (olanzapine)	Zyrtec (cetirizine) (for allergies)
Celexa (citalopram)	Celebrex (celecoxib) (for arthritis)

[a]Name changed to Levoxyl after U.S. Food and Drug Administration report in 1994.

Wrong drug administration, that is, giving a drug to a patient that was not the drug prescribed for that patient or giving the correct drug but at the wrong dose, is the most common type of medication error. Wrong drug administration occurs more frequently on units with either fewer registered nurses or two or more patients with the same (or similar) name staying on the same unit. Most prescription errors in psychiatry are with antipsychotic medications followed by anxiolytics and antidepressants. Increasingly, studies are showing that the use of computerized medication orders decreases errors related to drugs. There is a growing consensus that the current dispensing of drugs as needed (the so-called PRN medications) ought to be re-examined. One recent study found an increased risk of error by 15% each time a PRN medication was given on medication rounds. As-needed directions are often ambiguous and do not always

Telegram: @medical_k

www.konkur.in

indicate when or how often, or at what dosages they are to be used. While doctors are placing the orders, nurses are often on the front lines of decision-making as to when and how these medications should be dispensed, and in some instances, are not trained sufficiently to thoroughly assess how these medications may interact with other medications the patient is taking. Therefore, in an effort to decrease medication error rates, PRN orders should always be written with clear identification of indication, frequency, and dosage.

Suicide. Unlike most physicians, psychiatrists rarely have to deal with the death of patients. Exceptions may be made for geriatric psychiatrists who deal with the aged or for consultation-liaison psychiatrists who deal with the seriously medically ill; however, when death occurs in those instances, it is often expected and part of the disease progress.

Suicide is unexpected. It is also viewed by many persons as preventable. On the basis of that expectation, family members may sue for malpractice after the event. Suicide is not always preventable, however. Some persons who have a strong desire to kill themselves will do so despite the many advances that have been made in the treatment and management of suicidal patients. When mistakes occur, they are usually the result of the psychiatrist having underestimated the suicidal risk or if the psychiatrist has appraised it accurately, the nurses and attendants not taking the necessary steps to ensure the patient's safety (e.g., constant observation).

Litigation is more common for suicides that occur in a hospital than for those that occur in an outpatient setting, presumably because one-to-one coverage is the standard of care for the actively suicidal hospitalized patient. Of all the suicides that occur in the United States, approximately 5% occur during hospitalization. The most common methods of suicide in the hospitalized patient are jumping or hanging. In most cases, safety protocols such as one-to-one monitoring or 15-minute checks were not followed assiduously.

Courts have not penalized psychiatrists for honest errors of judgment in clinical practice. One court stated: "The accurate prediction of dangerous behavior, and particularly suicide and homicide, are almost never possible. Thus, an error of prediction or even of judgment does not necessarily establish negligence." In spite of this, however, psychiatrists are expected to evaluate patients properly for suicide risk and to establish

Telegram: @medical_k

www.konkur.in

a rational treatment plan to ensure that the risk of a patient successfully killing themself is minimized as much as possible.

The effect of having a patient commit suicide can have profound effects on the treating psychiatrist. There is an initial sense of disbelief and shock upon being informed of the event, often followed by feelings of guilt. Common questions asked are: Did I overlook anything? How could this have been prevented? What should I have done differently? Some psychiatrists are so traumatized that they give up practicing altogether or never again work with patients who are suicidal. More commonly, however, they seek to talk about the experience with other clinicians, especially clinicians who have gone through a similar experience of losing a patient to suicide. This process can be very salutary, allowing the psychiatrist to realize that they are not alone, that others have gone through the same experience, and as in all branches of medicine, including psychiatry, not all illnesses are curable and some suicides, even when care and treatment are exceptional, can neither be predicted nor prevented.

Restraint and Seclusion

Errors in the area of restraint result from not using these devices correctly; this results in physical injury or, in some cases, death by strangulation or cardiac arrest. Patients in seclusion rooms may injure themselves by banging their heads into the walls or exhaust themselves as a result of agitated behavior that can lead to dehydration and death. In both situations, constant vigilance is necessary. In 2006, the Centers for Medicare and Medicaid Services (CMS) mandated more training for health care workers in the area of restraint and seclusion in an effort to promote safer practices and greater acknowledgment of patients' rights. They later released a revised set of guidelines related to restraint and seclusion, which included "face-to-face examination by a physician, nurse, or physician's assistant within 1 hour of placement in restraints or seclusion." Some hospitals have initiated policies in which patients in restraints and seclusion must be on one-to-one constant observation with vitals checks every hour, with physician review for the necessity of restraints every 4 hours. Seclusion rooms must be designed to be environmentally protective, for example, padded walls, ventilation. In New York State nursing homes, efforts have been made to reduce the use of physical restraints, with a decrease from 6.14% in 2011 to 1.86% in 2014.

PREVENTING MEDICAL ERROR

Practice Guidelines

Practice guidelines have been developed by the APA for a variety of disorders. These include delirium, dementia, substance use disorder (SUD), depressive disorder, panic disorder, borderline personality disorder, suicide, and schizophrenia. Guidelines for other psychiatric disorders will be forthcoming. According to the APA, the term *practice guideline* refers to a "set of patient care strategies developed to assist physicians in clinical decisions." They are careful to point out that guidelines are not meant to be standards of care:

The APA practice guidelines are not intended to be construed or to serve as a standard of medical care. Standards of medical care are determined on the basis of all clinical data available for an individual case and are subject to change as scientific knowledge, technology advance, and patterns evolve. These parameters of practice should be considered guidelines only. Adherence to them will not ensure a successful outcome in every case, nor should they be construed as including all proper methods of care or excluding other acceptable methods of care aimed at the same results. The ultimate judgment regarding a particular clinical procedure or treatment plan must be made by the psychiatrist in light of the clinical data presented by the patient and the diagnosis and treatment options available.

Although few studies have been done, common sense indicates that guidelines will improve the quality of care and diminish medical errors in psychiatry. They are works in progress, however. As new methods of treatment develop, they have to be revised and updated, lest they become fossilized and irrelevant. Other risks are their possible misuse by third parties such as managed care companies and health maintenance organizations (HMOs). Many guidelines are prepared by third-party payers and may be compromised by conflicts of interest of cost versus quality of care. Some HMOs pay bonuses to their doctors based on high scores on how closely they adhere to a set of guidelines in the treatment of a specific disorder. This may influence psychiatrists in the choice of therapy or the length of the patient's hospital stay if they are not in keeping with the set of guidelines being used.

There is no indication that there has been an increase in malpractice suits against psychiatrists since their introduction; however, published

Telegram: @medical_k

www.konkur.in

guidelines are often brought forward in litigation as standards of care. Psychiatrists and other physicians should not be intimidated by this practice. Psychiatrists may legally and ethically deviate from guidelines; however, the decision to do so and its rationale should be documented in the chart.

As mentioned previously, the APA guidelines do not include all proper methods of care for a particular disorder, nor do they allow for ambiguity, controversy, or dissent. For this, the practitioner must turn to a textbook, such as the *Comprehensive Textbook of Psychiatry,* in which such differences are discussed.

Electronic Medical Records, Medication Reconciliation, and Electronic Prescribing

The EMR is fast becoming an integral part of most hospital and outpatient clinic settings, with several notable advantages over paper records. According to Dr. Michael Houston, these advantages include "…the ease with which information can be shared among providers, thereby improving the efficiency of health care delivery by reducing redundancy, simplifying billing, and improving quality, and safety." EMR became more commonplace following the 2009 Health Information Technology (HIT) for Economic and Clinical Health (HITECH) Act, part of the American Recovery and Reinvestment Act of 2009, as well as the 2010 Patient Protection and Affordable Care Act, national legislation which included bonuses for medical sites participating in EMR.

The advent of EMR led to improvements in medication reconciliation, defined by the Institute for Healthcare Improvement as "a process of identifying the most accurate list of all medications a patient is taking—including name, dosage, frequency, and route—and using this list to provide correct medications for patients anywhere within the health care system." One study polling patients who were about to be discharged from inpatient hospitalizations noted that 27.9% of the patients were unable to list their discharge medications, and even a smaller percentage had an understanding of what their medications were for. Acknowledging that medication-related errors are frequent contributors to medical error, the Joint Commission declared medication reconciliation a 2005 National Patient Safety Goal. Notably, 2021 NPSGs include decreasing wrong-site surgeries, misidentification of patients, and medication errors. Stephanie Mueller and colleagues have found medication reconciliation to work most

Telegram: @medical_k

www.konkur.in

effectively when two particular conditions are met: close communication between physicians and pharmacists and ensuring that patients at higher risk of medication error are more closely monitored. This latter category includes the elderly, individuals taking multiple medications, and individuals with multiple medical comorbidities.

In an effort to eliminate medication errors occurring due to illegible handwriting, most medical centers throughout the United States now use electronic prescribing (frequently referred to as e-prescribing). This practice allows prescriptions to be electronically transmitted directly to pharmacies. EMR systems are now used by most hospitals. However, different hospitals often utilize different EMRs, which can pose challenges in sharing patient information when needed. This lack of ease of patient information sharing can lead to more medical errors. On the other hand, however, for hospital systems that share EMRs, facilitated information sharing can theoretically lead to less medical error. Further research on this topic is needed since universal EMR use has only been in practice since 2016.

Blame and Medical Error Reporting Structures

The Royal Australian and New Zealand College of Psychiatrists raised an interesting argument when they suggested that for improvements in medical error to occur, modern medical culture must undergo a significant frameshift. In particular, they recommended moving away from a model of individual blame toward one of acknowledging systems failures. They found that “a “no blame” culture is essential to voluntary reporting, dispassionate analysis, and correction of systems failures.” Although the blame is diffused in this model, accountability is not. Every member of the medical community has a responsibility to their colleagues and their patients to take part in telling the story of what went wrong as the first step in determining how to ensure this error is not repeated. Assurances of confidentiality and ease of reporting are the most pertinent factors leading individuals to freely report errors. In one study, it was found that clinicians and other members of the hospital staff were most likely to tell a member of the medical error report team about an error in person (53%), followed by phoning in the error (35%), using the online data reporting system (6%), submitting a written form (4%), and lastly, by email (2%).

www.konkur.in

Regulating Working Hours of Interns and Residents and Improving Handoffs

Teaching hospitals often rely on interns and residents to perform services such as phlebotomies and intravenous (IV) therapy and to serve as messengers and transporters, tasks that are more appropriately performed by ancillary personnel. In addition, house staffs are often required to work long hours, and sleep deprivation can impair their judgment and clinical skills. The average resident works more than 80 hours per week, with a shift of 30 hours every third or fourth night. As mentioned above, a limit on the number of hours interns and residents may work was set forth by the CMS. Their work rules were (1) residents were limited to no more than 12 consecutive hours per assignment in emergency services, (2) residents could not work more than 80 hours per week over a 4-week period, and could not be scheduled to work more than 24 consecutive hours, and (3) scheduled rotations had to be separated by not less than 8 hours of nonworking time, provided for each week. Nonworking time is time away from training and patient care activities. In 2000, 8% of residency training programs nationwide were cited by the Accreditation Council for Graduate Medical Education for violating the CMS work hour requirements.

In response to the death of a patient at a New York hospital in 1989, the New York state legislature enacted the Bell Commission Report, which implied that resident work hours contributed in part to that accidental death. The state responded by establishing rules for resident work hours, including 80-hour week limits and 24-hour consecutive call limits.

The impact of these limits on the continuity and quality of care remains to be seen. Legitimate concerns have been raised about shorter shifts leading to more handoffs, which could lead to more opportunities for error.

The Joint Commission has reported that “Communication and handoff failures are among the root causes in nearly two-thirds of “sentinel events,” which are serious, often fatal, preventable adverse events in hospitals.” Acknowledging the need to address handoff failures with a greater scope, the ACGME now mandates that all “…residency training programs provide formal instruction about patient handoffs and that faculty monitor handoffs and ensure adequate handoff skills through direct observation.” Unfortunately, despite this mandate, many residency training programs still do not consistently train their residents in how to perform proper handoffs. In one recent study, roughly half of the residents polled

Telegram: @medical_k

www.konkur.in

believed that critical patient information was lost during resident shift changes. From June 2010 through February 2014, a comprehensive handoff curriculum, known by the mnemonic I-PASS (Illness severity, Patient summary, Action list, Situation awareness and contingency plans, and Synthesis by receiver) was piloted in nine different pediatric residency programs throughout the United States. In developing this curriculum, it became evident that the key ingredients for an effective handoff include: dedicated time for verbal exchange in a HIPAA-compliant location, the active use of templates for accessing and recording information, priority given to discussing ill patients, and highlighting action items. Use of the I-PASS curriculum was associated with a 23% relative reduction in the medical error rates across all nine study sites, as well as a 30% relative reduction in the rate of preventable adverse events. Importantly, the study found that the use of a comprehensive handoff curriculum did not elongate the handoff process in any way, nor did it cause residents to spend less time with patients. A 2020 review of I-PASS utilization in *Pediatric Quality & Safety* has shown I-PASS to be effective in reducing medical errors.

In an effort to eliminate mistakes that might occur-related to medical student involvement in patient care, the CMS defined medical student responsibilities as follows: (1) Students can take histories and perform physical examinations with the approval of the patient's attending physicians; (2) they may write in the patient's chart, but all entries must be countersigned by the attending physicians; and (3) medical or surgical procedures may be performed if they are under direct inpatient supervision.

Many medical educators believe that the current CMS rules do not go far enough and that interns and residents are not used properly by many teaching hospitals. It is not uncommon for a resident in cardiac surgery to assist with an operation for 14 hours and then to stay on duty for an additional 10 hours. Similarly, a pediatric resident may be in the emergency room for 24 hours without sleep. Even though their hours fall within the CMS guidelines, they are not conducive to the resident's education in view of the inevitable fatigue when a person is without sleep for 24 hours. For residents with families, especially those who are parents, current work schedules disrupt relationship harmony and child-rearing. This added stress interferes with optimal functioning. It has been suggested that chronic sleep deprivation may put residents at increased

Telegram: @medical_k

www.konkur.in

risk for motor vehicle crashes, medication errors, and decreased mental clarity. There are no easy answers to these problems, but the current situation clearly requires resolution.

Emergency physicians commonly experience sleep deprivation because of the need to work shifts during the evening and late-night hours. The negative effects of this problem are compounded by job stress and traditional methods of scheduling work shifts. Sleep deprivation may be reduced by schedules designed to lessen interference with normal sleep patterns and circadian rhythms. Pharmacologic treatments for sleep deprivation exist in the form of alertness-enhancing agents such as caffeine. Sleep-promoting agents may also help treat the problem by helping physicians to sleep during daytime hours. Minimizing sleep deprivation may help prevent job burnout and prolong the length of an emergency physician's career.

Coping with Medical Errors and Adverse Events

Doctors have a long tradition of examining adverse events and of learning from their mistakes. The case presentation (also called the *clinicopathologic conference* [CPC] or morbidity and mortality conference [MMC]) is a group exercise attended by clinicians, researchers, educators, and students who examine all aspects of patient diagnosis, treatment, and outcome. Ideally, CPCs/MMCs do not attempt to cast blame on a practitioner; however, if negligence has occurred, then it becomes evident in the open discussion of those in attendance. A 2012 study examining how MMCs are used to improve the quality of medical care found that a lack of structure in the approach to MMCs frequently led to few clear action plans with definitive timelines. While CPCs/MMCs also could be a useful time to address the emotional impact of having made a medical error, there appears to be less comfort spending time on this topic. As the perception of having made a medical error can lead residents to experience significant personal distress and decreased empathy, it is perhaps time to incorporate elements of self-care and coping strategies as part of CPCs/MMCs. A 2020 article in the *Western Journal of Emergency Medicine* suggests that changing the name from CPCs/MMCs to a case-based error reduction conference (CBERC) may eliminate the propensity for the "blame game" and lead to actual systemic improvements in medical error. Most hospitals also have risk management teams whose duty is to identify potential or actual instances of malpractice by

Telegram: @medical_k

www.konkur.in

physicians in the facility and to approach the patient and discuss the situation openly and honestly. Lastly, offices of quality assurance function to assess and prevent risks to patients in a continuous effort to eliminate adverse effects, as described in Table 7.11–2.

Ethics of Disclosure. There is an ethical duty on physicians to disclose medical errors, accidents, injury, or bad results to their patients who have an absolute right to understand what occurred during their course of treatment. An explanation is mandatory, and an apology is appropriate if an error was made. The American Academy of Pediatrics believes, “An atmosphere of openness and honesty leads to a culture of quality and safety.” If, as a result of a disclosure, legal proceedings ensue, then the physician has the opportunity to offer an explanation—but appropriate compensation for harm suffered as a result of malpractice is a patient’s legal right.

Telegram: @medical_k

www.konkur.in

Table 7.11–2.
Medical Documentation Requirements for Patient Adverse Events

These guidelines apply to instances of *adverse patient events,* which are defined as follows: "*A significant adverse patient event is an unplanned or unexpected occurrence that results in patient death, harms the patient, temporarily or permanently, or significantly increases the planned length of hospitalization.*" These guidelines are applicable, however, to all medical documentation and should be universally followed.

It is most important that the responsible attending physician (or covering attending) write a note as soon as possible after an adverse event, certainly within 24 hours. This note should clearly document their active participation in the care of the patient. Subsequently, an attending note must be written daily, for as long as appropriate to the patient's status. This is a supplement to the standard Medical Board documentation requirement, especially crucial in the first few days after an adverse event occurs.

All notes must be dated, timed, and signed.

The purpose of medical documentation is to promote patient care and safety, not to cast blame on an individual for an adverse patient event. When describing a patient adverse event, extreme care must be exercised to avoid implied blame for such an event by another caregiver. The note should clearly document the attending physician's participation in the care of the patient, and the discussion should be an objective analysis of the events that transpired, an assessment of the patient status, and a plan for subsequent management. An open disclosure approach to adverse event documentation must be followed.

Courtesy of NYU Langone Health.

Patient–Doctor Relationship. A good patient–doctor relationship is characterized by a sense of trust, respect, and honesty between the two parties. The better the patient–doctor relationship, the less chance for misunderstanding leading to litigation. Studies have shown that when a medical error or adverse event occurs within the context of a good patient-doctor relationship, litigation is rare. In its absence, however, litigation is likely in as much as 70% of cases of medical error, especially if a major

Telegram: @medical_k

www.konkur.in

mistake was made, regardless of whether or not death ensues. In surveys of patients, almost 100% desire that doctors report and discuss medical errors with them. Acknowledging a medical error, minor or major, may actually reduce the risk of a malpractice action.

Therapeutic Privilege. Therapeutic privilege is the physician's right to withhold information from a patient if, in their opinion, such disclosure would cause irreparable harm to the patient. Some patients do not wish to know the nature of their illness, and that right needs to be respected. Others may be so prone to anxiety or panic that even a hint of medical error (especially if no adverse outcome occurred) would be potentially dangerous to the patient's overall sense of well-being.

Duty to Disclose. There is a patient–consumer movement supported by some members of the legal profession that would require physicians by law to report medical errors. As mentioned previously, disclosure is currently an ethical, not a legal, obligation. Proponents of duty to disclose argue that self-policing by the medical profession is inefficient, and a legal duty to disclose malpractice would provide a remedy. Proponents of such laws would also require that they apply not only to the person committing the error but also to those who witness the error, for example, nurses and members of the treatment team.

Opponents of the duty to disclose law argue that it would harm the patient–doctor relationship and, in particular, weaken the trust and teamwork among health care professionals who would be required to be informants on one another. Adopting a rule of disclosure also suggests to the public that doctors, as a group, are not to be trusted. Opponents of the law also note that quality assurance and risk management programs that bring negligent acts to light are already in place and that further enforcement is unnecessary. Most experts take the position that physicians are the ones who ultimately must decide to disclose errors based on their professional and ethical beliefs.

Barriers to Disclosure. Some suggest that, rather than focusing on whether disclosure should be an ethical or legal obligation, the greater question to examine is why there is often a fear of speaking up when a medical error has been committed. A 2013 study out of Minnesota reports, "Medical students and residents may be concerned about retaliation in the form of poor grades and evaluations. Confronting an attending physician

Telegram: @medical_k

www.konkur.in

can be intimidating, and…the "hidden curriculum" (a set of influences that function at the level of the organizational structure and culture) may encourage…students and residents to remain silent." Work in this area is still ongoing, as evidenced by a 2019 study in *Academic Medicine* which highlighted that medical students experience distress and are unsure of what to do when they encounter or make medical errors. They are still not getting adequate training in error reporting and emotional support when doing so. A medical culture that embraces nonjudgmental systems of error reporting may be critical to decreasing medical errors from occurring in the first place.

Role of Apology. It is becoming standard practice for physicians to apologize to patients when disclosing unanticipated outcomes that fall within the category of medical error. For an apology to be successful, however, there must be a real sense of regret communicated to the patient or family. It is not sufficient to say "I am sorry" pro forma. There must be an empathic communication of concern and personal responsibility. Apologies have generally not been admitted in evidence in malpractice suits because it would have a chilling effect on the entire process. Juries could interpret an apology as an admission of guilt and be less objective about facts in the case that might otherwise be exculpatory.

Regulation of Privacy, Delivery, and Quality of Health Information Distribution in the Age of Electronic Medical Records

Health Insurance Portability and Accountability Act. The HIPAA was passed in 1996 to address the medical delivery system's mounting complexity and its rising dependence on electronic communication. The act orders that the federal Department of HHS develop rules protecting the transmission and confidentiality of patient information, and all units under HIPAA must comply with such rules.

Two rules were finalized in February 2003: the Transaction Rule and the Privacy Rule. The Transaction Rule facilitates transferring health information effectively and efficiently by means of regulations created by the HHS that established a uniform set of formats, code sets, and data requirements. The Privacy Rule, administered by the Office of Civil Rights (OCR) at HHS, protects the confidentiality of patient information. This means that a patient's medical information belongs to the patient and that the patient has the right to access it. Psychotherapy notes previously were

Telegram: @medical_k

www.konkur.in

the exception to this rule, which were deemed as property of the psychotherapist who wrote them. However, the 21st Century Cures Act, enacted on April 5th, 2021, requires that all notes are available to all patients in an effort to increase transparency. Hopefully, patients knowing more about their medical history will also lead them to take a more active role in their medical care and will consequently lead to a decrease in medical error. Individual hospitals are responding to this new ruling at an individual pace.

Table 7.11–3.
Transaction Rule Code Sets

Health care information: The Transaction Rule defines standards and establishes code sets and forms to be used for electronic transactions that involve the following health care information:

- Claims or equivalent encounter information
- Eligibility inquiries
- Referral certification and authorization
- Claims status inquiries
- Enrollment and disenrollment information
- Payment and remittance advice
- Health plan premium payments
- Coordination of benefits

Code sets: Under the Transaction Rule, the following code sets are required for filing claims with Medicare:

- Procedure codes
- American Medical Association Current Procedural Terminology codes
- Healthcare Common Procedure Coding System codes
- Diagnosis codes
- *International Classification of Disease* codes
- Drugs and biologic
- National Drug Codes
- Dental codes
- Code on dental procedures
- Nomenclature for dental services

Adapted from Jaffe E. HIPAA Basics for psychiatrists. *Psychiatr Pract Manag Care*. 2002;8:15.

Telegram: @medical_k

www.konkur.in

In 2002, the Transaction Rule was implemented, meaning that all entities covered under HIPAA must comply. The health care information involved and code sets are listed in Table 7.11–3. In 2003, the Privacy Rule was executed. Under this rule, patients have new statutory rights (Table 7.11–4).

Under the Privacy Rule, there are certain guidelines by which every practice must abide:

1. Every practice must establish written privacy procedures. These include administrative, physical, and technical safeguards that establish who has access to the patient's information, how this information is used within the facility, and when the information will and will not be disclosed to others.
2. Every practice must take steps to make sure that its business associates protect the privacy of medical records and other health information.
3. Every practice must train employees to comply with the rule.
4. Every practice must have a designated person to serve as a privacy officer. If it is an individual practice or private practice, this person can be the physician.
5. Every practice must establish complaint procedures for patients who wish to ask or to complain about the privacy of their records.

The OCR at HHS is responsible for making sure that the Privacy Rule is enforced. This enforcement is conducted by the government through a *complaint-driven* system in which the OCR responds to complaints made by patients concerning confidentiality violations or denials of access to records, all of which are covered under HIPAA. In such cases, OCR may follow up and audit compliance.

In 2009, the HITECH Act was signed into law as a subsection of the American Recovery and Reinvestment Act. The purpose of the HITECH Act was to "…promote the adoption and meaningful use of HIT" through incentive payments from Medicare and Medicaid for technology use. Examples of "meaningful use" include e-prescribing, completing electronic medication reconciliation, and updating electronic records on vaccination status. This act also led to strengthened breach notification requirements. In 2013, the final HIPAA Omnibus Rule was enacted, which increased penalties for HIPAA noncompliance to as much as $1.5 million per violation.

Telegram: @medical_k

www.konkur.in

Table 7.11–4.
Patient's Rights under the Privacy Rule

Physicians must give the patient a written notice of their privacy rights, the privacy policies of the practice, and how patient information is used, kept, and disclosed. A written acknowledgment should be taken from the patient verifying that they have seen such notice.
Patients should be able to obtain copies of their medical records and request revisions to those records within a stated amount of time (usually 30 days). Patients do not have the right to see psychotherapy notes.
Physicians must provide the patient with a history of most disclosures of their medical history on request. There are some exceptions. The APA Committee on Confidentiality has developed a model document for this requirement.
Physicians must obtain authorization from the patient for disclosure of information other than for treatment, payment, and health care operations (these three are considered to be routine uses, for which consent is not required). The APA Committee on Confidentiality has developed a model document for this requirement.
Patients may request another means of communication of their protected information (i.e., request that the physician contact them at a specific phone number or address).
Physicians cannot generally limit treatment to obtaining patient authorization for disclosure of their information for nonroutine uses.
Patients have the right to complain about Privacy Rule violations to the physician, their health plan, or to the Secretary of HHS.

APA, American Psychiatric Association; HHS, Department of Health and Human Services.

Adapted from Jaffe E. HIPAA Basics for psychiatrists. *Psychiatr Pract Manag Care*. 2002;8:15.

The APA has created a HIPAA educational packet, which can be obtained on the APA website (http://www.psych.org/). On the site, there are also recommendations for enabling physicians to comply with HIPAA.

In 2010, the IOM formed the Committee on Patient Safety and HIT to gain a greater understanding of the impact of HIT on patient safety. In 2012, this committee submitted a report, *Health IT and Patient Safety:*

Telegram: @medical_k

www.konkur.in

Building Safer Systems for Better Care, in which a disturbing trend was noted, which may negatively impact this goal. Specifically, it appears that some vendors—contracted by medical facilities to create EMR platforms—may be restricting the release of information regarding safety issues by citing contractual confidentiality clauses. This may, however, be leading to difficulties in determining where the problems currently are in HIT, and therefore, limits room for improvement.

Hospital Standards and Performance. A group of agencies, such as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) and the Liaison Committee on Medical Education (LCME), influence the standards of hospital care and performance. In addition, hospitals must comply with government regulations (city and state health rules). The JCAHO inspects hospitals at least once every 39 months and is also responsible for determining the requirements for hospital accreditation. Hospital reimbursements from Medicare and Medicaid are contingent on meeting these standards, but the accreditation is done on a voluntary basis. The LCME and the Liaison Committee on Graduate Education are charged with accrediting medical schools and residency training programs, respectively. The two accrediting committees review education and training programs every 4 years; the procedure is voluntary.

The JCAHO is also involved in preventing medical errors and developed guidelines to help surgical teams standardize safety systems. The guidelines, called "The Universal Protocol for Preventing Wrong Site, Wrong Procedure, Wrong Person Surgery," address the verification of documents, marking operative sites, and other issues related to patient safety.

The JCAHO issued a list of dangerous, unapproved abbreviations, acronyms, and symbols that accredited organizations must discontinue using as part of their National Patient Safety Goals requirements. The list of unapproved abbreviations pertains to all handwritten and electronic, patient-specific communication (Table 7.11–5).

The Institute for Safe Medication Practices (ISMP) released an updated List of Confused Drug Names in Feb 2019. To avoid medication errors, ISMP recommends strategies such as: "…using both the brand and generic names on prescriptions and labels; including the purpose of the medication on prescriptions; configuring computer selection screens to

Telegram: @medical_k

www.konkur.in

prevent look-alike names from appearing consecutively, and changing the appearance of look-alike product names to draw attention to their dissimilarities." The ISMP, along with the FDA, endorse the use of "tall man" (mixed case) letters as visual aids to avoid medication error (Table 7.11–6). The FDA has begun working with drug companies to select names for new products that differ significantly from those already on the market.

Table 7.11–5.
Confusing Medical Notations

Prohibited Abbreviation	Potential Problem	Preferred Term
U (for unit)	Read as a zero (0) or a four (4), causing a 10-fold overdose or greater (4 U seen as "40" or 4 u seen as "44").	Write "unit."
IU (for international unit)	Misread as "IV" (intravenous) or 10.	Write "international unit."
Q.D. and Q.O.D. (Latin for once daily and every other day)	Mistaken for each other. Also, the period after the Q can be mistaken for an I and the O can be mistaken for an I.	Write "daily" or "every other day."
Trailing zero (X.0 mg) and lack of leading zero (.X mg)	Decimal point is missed.	Never write a zero by itself after a decimal point (X mg) and always use a zero before a decimal point (0.X mg).
MS, MSO_4, and $MgSO_4$	Confused for one another. Can mean morphine sulfate or magnesium sulfate.	Write "morphine sulfate" or "magnesium sulfate."

Table 7.11–6.
List of Confused Drug Names Illustrating Tall Man Lettering Practices[a]

Drug Name	Confused Drug Name
MetaDATE CD (methylphenidate)	methaDONE (Dolophine)
LEVOTHYroxine	LANoxin (digoxin)
Serzone (nefazodone)	SEROquel (quetiapine)
LaMICtal (lamotrigine)	LamISIL (terbinafine) (for nail infection)
ZyPREXA (olanzapine)	ZyrTEC (cetirizine) (for allergies)
CeleXA (citalopram)	CeleBREX (celecoxib) (for arthritis)

[a]Note how the same drugs from Table 7.11–1 are listed, but using tall man lettering format that promotes more accurate drug identification.

Hospital Utilization Review. This in-house evaluation process was created to make sure that institutions provide efficient, quality health care that meets patients' needs. The members of the utilization review committee consist of hospital administrators, physicians, and nurses. The committee reviews each patient's chart within a specified number of days of admission. The appropriateness of the admission, treatment strategies, and the length of the hospital stay is reviewed to facilitate the patient's discharge. Through this process, the utilization review committee determines whether a particular admission was really indicated and whether the hospital stay was longer than necessary. A hospital must conduct utilization reviews to be eligible for JCAHO accreditation.

Professional Standards Review Organization. The Professional Standards Review Organization (PSRO) was set up by the federal government to review and monitor care received by patients whose care is paid for with government funds. PSROs are made up of physicians elected by local medical societies that have been established by local medical associations and serve several functions: They attempt to ensure high-quality care, control costs, determine maximum lengths of stay by

Telegram: @medical_k

www.konkur.in

patients in hospitals, conduct utilization reviews, and censure physicians who do not adhere to established guidelines. A PSRO may conduct a medical audit to evaluate the quality of care retrospectively by carefully examining charts.

Peer Review Organization. In the early 1980s, the peer review organization (PRO) replaced PSROs as the federal review organization for hospitals receiving Medicare funds. To promote compliance with federal guidelines for health and hospital care, PROs conduct independent utilization reviews and quality-of-care studies, validate diagnose-related group (DRG) assignments, and review hospital admissions and readmissions.

Federally mandated and funded, the PROs had greater authority than the PSROs. PROs were able to impose sanctions on hospitals for inadequate care; they could even recommend the termination of federal funding to hospitals that consistently violated federal standards. In addition, PROs could adjust or refuse payment for health services that they considered unnecessary.

Quality Improvement Organization. In May of 2002, quality improvement organizations (QIOs) replaced PROs. Funded by the federal government through the CMS, the QIOs are state-based organizations with three main aims: to provide safer and more effective care for patients, to improve the overall health of patients, and to make healthcare more affordable. IPRO, New York's QIO, released their Quality Improvement Report for New York State focused on the years 2011 to 2014. One goal which was achieved and highlighted in the report related to IPRO's success in helping medical practices integrate HIT for meaningful use and improved care coordination. In 2019, CMS awarded IPRO a 4-year contract to assist smaller hospitals with a number of initiatives, including patient safety.

Centers for Medicare and Medicaid Services. In an attempt to improve patient safety and reduce complications, Medicare stopped paying for some hospital-acquired conditions. These include errors such as an object left in the patient during surgery, blood incompatibility, decubiti, and air embolism, among others. In some states, such as New York, Medicaid has stopped paying for "never events," once described by the former New York State Health Commissioner, Richard Gaines, as "…a

Telegram: @medical_k

www.konkur.in

list of things that, frankly, should never happen." The New York State Never events list includes medication errors, patient disability from the use of restraints or bedrails, and surgery performed on the wrong body part. CMS believes that financial disincentives will influence hospitals to provide more aggressive quality reviews and be better able to address issues effectively. Critics of the program claim that some errors are really adverse events citing bed sores as an example of a condition that cannot always be avoided, even with the most highly skilled nursing care.

Clinical Manifestations of Psychiatric Disorders

ANU A. MATORIN, M.D., ANDRES A. AVELLANEDA OJEDA, M.D., ASIM A. SHAH, M.D., AND PEDRO RUIZ, M.D.

Manifestations of psychiatric disorders express themselves as variations of normal functioning from subtle to obvious, making it confounding for the clinician to integrate data into an accurate diagnostic picture. The Diagnostic and Statistical Manual of Mental Disorders (DSM-5) has placed a strong focus on integration of symptom data, including patients' self-assessments of symptom severity with a goal to improve patients' overall satisfaction and treatment outcomes.

The DSM-5 approach aims to provide an even more thorough evaluation and comprehension of the patient's interpersonal world, work role, family life, and culture than is typical in general medical practice. This dimensional model will introduce a greater amount of information for the clinician to assess, evaluate, and measure, including the severity of psychiatric conditions. Despite the introduction of DSM-5 a few years ago, the lack of scales to screen and assess psychiatry symptoms or conditions continues to be the same as 20 years ago and is therefore primarily driven by the clinician's individual clinical assessment.

Telegram: @medical_k

www.konkur.in

The nature and expression of psychiatric signs and symptoms are profoundly altered by the patient's strengths, coping capacities, psychological defenses, and situational context so that the clinical picture ultimately represents a balance between psychopathology and psychological strengths. It is important to integrate substance use and culture background as part of initial presentation and subsequent treatment planning and follow-up. The clinical symptomatology must also be understood as part of the individual's attempts to cope with the biologic, psychological, and environmental challenges that they face. When attempts to cope overwhelm the individual's capacity to respond, less adequate, more disorganized, and ineffective thoughts and behaviors emerge, and these comprise the impairments that present in clinical situations.

In addition, the coronavirus pandemic has led to the introduction of Covid infections with implications in different systems including neurosensory symptoms, long-term effects after being infected, as well as social isolation, depression, and anxiety with phobias, fears, and worries about getting infected with Covid-related illness.

NEED FOR A COMPREHENSIVE CLINICAL PERSPECTIVE

DSM-5, like other medical disease classifications, uses multidimensional approaches to mental disorders, as the previous too-rigid categorical system was unable to capture clinical experience or important scientific observations. The goal of this approach is to capture a more accurate description of patient presentations and for the diagnosis to be more valid.

The DSM-5 dimensional model addresses the longstanding concerns that clinicians often tend to limit their fields of vision and appreciate only part of the available information; the clinician's theoretical orientation and other personal and cultural factors also limit what is perceived. Research has demonstrated that clinicians tend to perceive primarily those signs and symptoms that are most in accord with their theoretical points of view and with the tools that

Telegram: @medical_k

www.konkur.in

they have available to treat psychiatric disorders, a phenomenon known as concept-driven perception. Such differences may lead one clinician to see a major mood disorder to be treated with medication, whereas another sees a pervasive personality problem with depressed mood to be treated with psychotherapy and to use different technical terms to label roughly the same phenomena. Psychodynamic-oriented psychiatrists might see psychomotor retardation, whereas a neuropsychiatrist sees bradykinesia; a psychodynamicist might see depressed affect and muted speech, whereas a neuropsychiatrist sees masklike facies and aprosodic speech.

The intermittent nature of many psychiatric signs and symptoms; the potential unreliability, selective recall, and false remembering of patients and others in reporting symptoms and events; differing interpretations of elicited information or observations; and subjective theoretically driven biases that influence the clinician's perception of signs and symptoms all contribute to potential errors in data collection. To help guard against misinformation and simplistic understandings and formulations, whenever possible, complete assessment of a psychiatric patient requires consultation with family, friends, coworkers, and other professional observers to enrich the history and to provide supplemental observations of the patient over time. Finally, via the DSM-5 dimensional assessment model, the comprehensive gathering of clinical symptoms will be the foundation for greater standardization, integration, and monitoring of treatment planning and outcomes.

THE CLINICAL CHALLENGES

DSM-5 development involved physicians, psychologists, social workers, nurses, counselors, epidemiologists, statisticians, neuroscientists, and neuropsychologists. This version even had feedback from patients, families, lawyers, consumer organizations, and advocacy groups. However, one of the costs of this increasing reliability has, in many instances, been the narrowing of the field of clinical vision. That is, clinicians who rely predominantly on

Telegram: @medical_k

www.konkur.in

structured interviews and checklists may become somewhat closed-minded and risk ignoring clinical phenomena that are very important but that may not be part of the structured interview framework or mental set. An additional related difficulty can be seen in the use of nonclinical research staff that are trained to interview individuals using structured interviews (as in large epidemiologic studies). In these instances, the need for interrater reliability is often achieved at the expense of a more nuance-based appreciation of the different meanings of subjective sensations, especially when the interviewer has no clinical experience with which to interpret the subject's descriptions.

However, in spite of these practical challenges, a thorough assessment of the clinical history and description of the psychopathology and detailed account of the patient's subjective experiences are important for the following reasons:

1. Significant diagnostic distinctions are made primarily on the basis of the historical information and elicited phenomenology. The more detailed, complete, and correct the diagnosis, the more rational and precise the treatment planning and the more reliable the prognosis. Consider, for example, the importance of accurately distinguishing between neuroleptic-induced akathisia versus anxiety symptoms related to psychotic thinking. On the basis of which of these diagnoses the clinician selects, the therapeutic strategy might be diametrically opposite.
2. The clinician's capacity to fully hear and communicate a comprehensive understanding of the patient's internal experiences helps to diminish the patient's sense of isolation so characteristic of many of these disorders and fosters the growth of a therapeutic alliance, increasing the likelihood of treatment adherence.

The Reliability Dilemma

As mentioned, for a given clinical manifestation of a psychiatric disturbance, different clinicians may arrive at different conclusions regarding the same clinical symptoms in the same patient. This

Telegram: @medical_k

www.konkur.in

reliability dilemma may confound an objective clinical assessment. Many factors contribute to this phenomenon. For example, some discrepancies may be due to differences in the patient's status or in information imparted by the patient from examination to examination, in the clinician's definitions of the symptoms or signs in question, and in perceiving and interpreting the patient's responses to general presentation or questions within the interview. A substantial amount of information variance in clinical practice reflects the impossibility of asking all questions within the time available for clinical evaluation. As an example, in one study, the rate of sexual side effects increased from 14% when depending on spontaneous patient report to 58% when the interviewer directly asked about these side effects.

A 52-year-old schoolteacher with recurrent major depression presented to her treating psychiatrist with her fiancé of 6 months. As part of the visit, the patient requested if she could stop her antidepressant medication, even though she had multiple severe relapses in the past. With her fiancé's encouragement, the patient disclosed arousal difficulties and anorgasmia after she started the medication. The patient had disclosed many painful memories related to past trauma to her psychiatrist, but she reported feeling shy and embarrassed to mention the sexual side effects. Upon further questioning, the patient reluctantly disclosed that she was terrified she would lose her fiancé if she continued taking her current antidepressant and did not know how to address this issue impacting her personal life.

Even when simply responding to direct questions about symptoms, patients may respond differently depending on the interviewer's manner, how the questions are asked, their personal sense of trust or safety, whether they have answered these questions before, the amount of cuing that may signal the "desired" response, their fatigue, or a host of other variables.

Most clinicians still rely heavily on their own clinical intuition and subjective responses to patients as part of a diagnostic assessment.

Telegram: @medical_k

www.konkur.in

However, these clinical inferences, whether accurate or not, are often based on nonconscious assumptions, comparisons with other patients not well remembered, or distortions based on the clinician's own personal experiences. When the bases for these intuitions can be identified and described clearly, they may prove to be reliable and valid. However, intuitions are often wrong—simple trust in intuition alone is not sufficient. Thus, a clinician's sense that a patient is angry and potentially violent may result from the patient's subtle (but verifiable) body language and tone of voice, or it may represent a countertransference distortion that is not prompted by any observable patient behavior. At times, clinicians often too quickly label behaviors as inappropriate when they do not appreciate and understand contextual or cultural considerations. Appropriateness depends heavily on context, and definitions of what is proper in a given context may also be highly subjective. Appropriate behavior (or dress) in some parts of California may be inappropriate in Boston. Furthermore, the rapid change and growth of the current multicultural society places cultural understanding and context in psychiatric history taking and assessment in the forefront. Even manifestations of low intensity of emotional expression leading to a clinical description of "constricted affect" may reflect cultural norms or a psychopathological state.

Ambiguity in the Assessment of Psychiatric Signs and Symptoms

Since, at the present time there are no clear-cut diagnostic, radiologic, or laboratory tests to make a psychiatric diagnosis, virtually all psychiatric symptoms can be ambiguous or nonspecific and are usually seen in many different disorders. Depressed mood, for example, occurs in a wide variety of diagnostic groups, including major depressive disorder, schizophrenia, some personality disorders, mood disorders secondary to medical or substance-related states, and so on. Even the so-called first-rank symptoms of schizophrenia described by Kurt Schneider are diagnostically nonspecific. They are seen with some frequency in otherwise classic

Telegram: @medical_k

www.konkur.in

depressive and bipolar disorders. Apathy offers another good example of an important nonspecific phenomenon. Although apathy is often part of depression, research has shown this symptom to be a clinically distinct syndrome. Apathy is marked by lack of spontaneity, initiation, and emotionality as well as lack of activity and interest in friends, family, and hobbies. Apathy and the associated symptom of amotivation may exist in their own right without the presence of significant depression, as in initial phases of abstinence from cocaine and in other syndromes characterized by reduction in dopaminergic tone, such as frontotemporal dementias, Parkinson disease, or progressive supranuclear palsy.

In general medicine, symptoms not recognized as part of a clearly defined syndrome are often described as being of unknown origin. Thus, a fever that cannot be ascribed to a known disorder, such as pneumonia, is described as a fever of unknown origin. Given the nonspecific nature of psychiatric symptoms, it seems wise to use similar conventions, referring to hallucinations of unknown origin or depressed mood of unknown origin when a symptom cannot be clearly linked to a well-described syndrome. In DSM-5, the “not otherwise specified” (NOS) is replaced by *other specified disorder* and *unspecified disorder.* In the first category, the clinician must specify why the diagnosis doesn’t fall under any specific category within a diagnostic class. If the clinician chooses not to specify the reason, then they will check unspecified class. Even though individual signs and symptoms may be organized into syndromes and disorders, they often have courses of their own. Thus, in the appearance or the resolution of a disorder, certain associated signs and symptoms may appear very early or may persist after all the others have waned. For example, in the restricting form of anorexia nervosa, excessive exercise is often the first symptom to appear and the last to abate even after dieting has stopped. In some cases, certain signs and symptoms that are commonly associated with a given disorder may not appear. Each sign and symptom may have its own pattern and variable response to treatment. In the treatment of schizophrenia, for example, some patients experience rapid resolution of hallucinations but have persistent delusions without

Telegram: @medical_k

www.konkur.in

ever having any other thinking disturbances, whereas others may have no residual hallucinations or delusions but still have prominent thinking disturbances.

Predisposition and Vulnerability in Psychiatric Symptomatology: Genetic and Intrauterine Considerations

Genetic factors are key in determining the expression of most if not all psychiatric disorders. Prominent among these are dementias of the Alzheimer type, schizophrenia, unipolar and bipolar mood disorders, anxiety disorders, alcohol use disorder, and some personality traits. For virtually all of these disorders and traits, what is largely unknown at this point is the nature of the inherited vulnerabilities.

Intrauterine factors contribute to many psychiatric disorders. For example, maternal starvation and influenza infections during the second trimester of pregnancy have been implicated in the pathogenesis of schizophrenia. Maternal smoking and low birth weight may be risk factors in the pathogenesis of attention-deficit disorders in children. Maternal alcoholism may lead to fetal alcohol syndrome, a major cause of developmental disability.

Fundamental Neurobiologic Factors

Investigational studies have shown that shortly after birth infants vary widely in temperament. For example, differences have been noted in spontaneous activity levels and thresholds, intensity, and duration of their reactions to external stimuli; the regularity or irregularity of certain biologic rhythms such as sleep; tendencies to approach or withdraw from new stimuli; the speed and degree of adaptation; attention span and distractibility; the persistence of behavior; and qualities of mood. On the basis of such early behaviors, children may be described as having easy or difficult temperaments, quick or slow to warm up. Nevertheless, these temperamental qualities correlate somewhat with behavioral problems, at least through early childhood.

Telegram: @medical_k

www.konkur.in

Aside from temperament, other persistent normal variations in personality development seem to be constitutionally related and may influence subsequent resilience or vulnerability. Traits, such as introversion, extroversion, and neuroticism, appear to be relatively enduring and stable personality dimensions. Other temperamental qualities that endure include novelty seeking, being relatively open to new experiences, and stick-to-it-iveness. Subtypes of intelligence, such as those related to conceptual, mathematical, musical, kinesthetic, and interpersonal abilities, have been postulated as having separate genetic determinants and patterns of development. The type A and B personality patterns, hardy and resilient personalities, high-strung, sensitive, fussy, irritable, and pessimistic characteristics have all been described as generally lifelong qualities that originate in early childhood. Even dimensions of character, referring to concepts about the self in relation to others that develop over time through social learning and maturation of interpersonal behavior, have been shown to have moderate heritability. These include such qualities as self-directedness, the ability to engage cooperatively with others, and the capacity to “transcend” the self by developing a sense of one’s place or purpose in the larger social context.

Other characteristics relevant to psychopathology but not diagnostically specific may also be inherited. These include psychosis proneness, cognitive styles (such as obsessionality or detail orientation), and emotional reactivity (which is part of the dimension of neuroticism). The relationship between the inheritance of these traits and the patterns of transmission of specific psychiatric disorders is unknown.

Impact of Physical Illness

All of the metabolic, toxic, infectious, and other causes of physical illness produce increased vulnerability to psychiatric disturbance. Studies have shown higher use of psychiatric services by those who are physically ill and higher than expected prevalence of physical disease among the psychiatrically impaired.

Telegram: @medical_k

www.konkur.in

Some children with obsessive-compulsive disorder (OCD) and tic disorders with symptoms that appear during the prepubertal period and whose course of illness becomes episodic have been found to have pediatric autoimmune neuropsychiatric disorders associated with streptococcal (group A β-hemolytic streptococcus) (PANDAS) infections. Accompanying symptoms during episodes of exacerbation are emotional lability, separation anxiety, nighttime fears and bedtime rituals, cognitive deficits, oppositional behaviors, and motoric hyperactivity. In PANDAS, patients' flare-ups of behavioral problems are commonly associated with documented group A β-hemolytic streptococcus infections or symptoms of pharyngitis and upper respiratory infections.

Human immunodeficiency virus (HIV) infection leading to acquired immunodeficiency syndrome (AIDS) vividly illustrates the multiple and complex ways in which stressors can lead to psychiatric disturbances. These patients' psychiatric symptoms may represent central nervous system (CNS) changes that are the direct effects of the virus on the CNS producing changes in cognition, personality, and mood, expectable psychological adjustment responses of the patients in response to an overwhelming life-threatening disorder, or the emergence of latent or quiescent primary psychiatric problems provoked by the psychological stress of the viral illness. Adding to the complexity, some individuals with cluster B personality traits may engage in excessive risk-taking behaviors, increasing the likelihood of viral exposure; they may then be at higher risk for developing psychiatric symptoms or disorders in response to being HIV positive because of their pre-existing cluster B traits.

Telegram: @medical_k

www.konkur.in

A 31-year-old accountant presented to the ER with report of "waves of anxiety," including "panic feelings," palpitations, and dizziness. He reported he had started a new job and was anxious and stressed out. Although he had no prior medical history, he reported new-onset headaches, nausea and "chest wall pain concomitant with 'waves of anxiety'." The psychiatrist on duty obtained a medical consult. The patient was eventually diagnosed with a pheochromocytoma.

Effect of Life Events

The impacts of life events, particularly those that are negative and outside of a given individual's control, have complex effects on the development and persistence of psychiatric symptomatology. In general, the likelihood of developing psychiatric manifestations is increased in those who have a pre-existing psychiatric disorder. After exposure to the same negative stressors, such as a serious accident or act of violence, individuals who previously had anxiety disorders are more prone than those without such histories to subsequently develop symptoms of posttraumatic stress disorder (PTSD). Other factors, such as gender, may also predict risk of developing PTSD, with women more likely to develop the disorder given the same exposure to stress. Although individual responses vary widely, truly catastrophic events, such as incarceration in a concentration camp, cause enduring psychiatric disturbances in a high percentage of survivors regardless of whether they had prior psychiatric problems. Similarly, the stress-related consequences of combat also vary widely, so that some heavily combat-exposed veterans develop long-lasting PTSD, whereas others develop very few persistent symptoms. The death of a parent or spouse, divorce, and major physical injury affect some people profoundly and others hardly at all in the long run. Significant stressors are likely to be more traumatic during early development rather than later or at certain critical developmental periods, compared with other times. For example, the loss of a parent at a very young age is likely to be more traumatic

Telegram: @medical_k

www.konkur.in

and have more profound and lasting effects than the loss of a parent as an adult.

The combined impact of negative life events and poor emotional and practical social support is important in predicting the emergence of at least some psychiatric disturbances. People who are ordinarily very competent in all role functions may fall apart completely when a supportive spouse who has bolstered them and taken care of many of their needs suddenly dies. Patients presenting with a major depressive episode have experienced more uncontrollable actual and threatened losses such as the death of a spouse in the year before onset.

A 65-year-old woman presented to her primary care physician with her daughter after her neighbors told her daughter that they had noticed that she was more withdrawn and staying in her house for days without checking the mail or watering her favorite flower garden. The patient reported fatigue, “heavy leaden” arms and body, poor appetite, and poor sleep. The patient’s husband of almost 40 years had suddenly passed away 1 year ago. The patient plaintively stated, “We had made so many plans in retirement, and now they are all gone.”

Nevertheless, not all psychiatric disturbance is attributable to easily identified, provoking negative life events; indeed, some major negative life events that at first glance appear to have preceded the onset of a serious psychiatric disturbance may, in fact, have occurred only after the psychiatric disturbance actually began. For example, someone who attributes the onset of depression to having been fired from a job several months previously may already have been functioning suboptimally at that time and may have been fired as a consequence of a depression-induced decline in role function.

Certain environmental features can counter the effects of environmental stressors and protect against psychiatric disturbances. Stable families and friends, good financial circumstances, and supportive religious and social communities offer

Telegram: @medical_k

www.konkur.in

some protection. Research has shown that individuals with psychiatric disturbances have fewer social supports than normal controls. This may be due to friends' and relatives' withdrawal from deviant behaviors or to the disturbed individual's withdrawal from deleterious family and social relationships. In contrast, physically ill people have more social supports than others, perhaps reflecting their ability to recruit help in times of need. Of course, the quality, as well as the quantity, of social supports is important. As has been demonstrated in schizophrenia and mood disorders, for example, negative relationships even in close families may have deleterious effects, both in developing and in sustaining psychiatric disturbance.

The negative impact of a physiologic or environmental stressor is closely related to its personal meaning. For example, the loss of a spouse who has been chronically demented, disabled, and burdensome ordinarily has a very different impact than the loss of a vital, supportive, loving spouse.

Finally, a relevant study has demonstrated the interaction of genetic vulnerabilities with adverse life events. In a study involving several hundred young adults followed prospectively, genetic vulnerability to depression was conferred by certain polymorphisms of the serotonin receptor. Over a period of several years, individuals with one or two copies of the short allele of the 5-hydroxytryptamine T promoter polymorphism exhibited more depressive symptoms, diagnosable depression, and suicidality in relation to stressful life events involving finances, housing, employment, and relationships than individuals homozygous for the long allele. This research provides strong evidence for gene–environment interactions, in which a person's responses to environmental insults are moderated by their genetic makeup.

DISTINGUISHING FEATURES OF PSYCHIATRIC SIGNS AND SYMPTOMS

Circumstance

Telegram: @medical_k

www.konkur.in

Psychiatric signs and symptoms are usually not static entities; depending on the circumstances, they often vary in intensity or even in their existence. The depressed mood of a melancholic depression may persist regardless of external situations, whereas the depressed mood in milder, reactive depression may vanish completely during certain situations—including a psychiatric interview—only to reappear at other times. Signs and symptoms that occur only in specific settings or with certain internal states are referred to as state dependent. For example, certain hallucinations or memories may be present only during states of drug or alcohol intoxication; in some patients, hives may erupt as a psychophysiological response only during states of anger. Interpersonal context is also important. Some people become violent only when involved in sadomasochistic relationships or in certain group settings such as adolescent gangs. In gangs, social pressures for conformity and expectations for aggressive behavior may provoke pathologic behaviors that might otherwise never be expressed by gang members individually.

Cultural Context

Psychiatric signs and symptoms cannot be assessed independent of an individual's background and culture. Many phenomena often considered to be symptoms of psychiatric disorders may not be experienced as psychiatric problems by patients. Hearing an angel's voice may represent a manifestation of a psychotic disorder, yet the patient may vigorously dispute that the experience is a psychopathological symptom. In mainstream American culture, for instance, any experience of thoughts being broadcast out loud is considered pathologic. These signs and symptoms must all be considered in context: exactly what constitutes normal varies from culture to culture and from situation to situation. As mentioned earlier, behavior or subjective experience that may be defined as symptomatic in one context may be perfectly acceptable and within normal bounds in another. A phenomenon should be considered abnormal only if it seems deviant within the patient's specific culture after its full physiologic and environmental context is taken into

Telegram: @medical_k

www.konkur.in

account and if it causes personal or interpersonal impairment. Too often, phenomena prematurely mislabeled as psychopathology turn out to be perfectly understandable and nonpathologic once the whole situation is appraised. Conversely, some examiners are loath to label certain phenomena as psychopathological even when they clearly are, for fear of stigmatizing the patient.

Within cultures, most interpersonal interactions are carefully regulated by tight sets of rules and controls and constrained by reasonably well-defined sets of expectations and acceptable limits.

An 18-year-old woman was brought to the emergency center by her youth minister. The youth minister stated that his youth group had returned from a week-long religious retreat. The young woman had been looking forward to the retreat for months. At the retreat, she volunteered to lead the singing of religious songs, had the “gift of tongues,” and spoke in tongues to lead the meeting. The youth group was entranced by her fervor and religious dedication. However, for the last 3 days, she had stopped sleeping, was found kneeling alone at night in the wet ground, had started “fasting” for repentance. Expressing concern for this change in her behavior, the youth minister had contacted her parents and immediately brought her to the nearest hospital.

Even slight deviations from these acceptable limits are quickly perceived by laypeople, as well as professionals, because behavioral deviances are often experienced as threats. Deviations in amplitude, duration, and intensity can occur in facial expressions, gestures, postures, vocalizations, language, and other expressions of emotion and thought. A small increase in the rate of speech, an intrusion into one person’s conversation by another who does not allow proper pauses, a gesture that comes just a bit too close to a face, an excessively rigid or distant stance, or a gaze that is too staring or too avoidant each signals social insensitivity and alerts the observer to deviant behavior.

www.konkur.in

Sign and Symptom Classifications

The classification of clinical signs and symptoms in psychiatry has been accomplished using several different schemas: state versus trait, primary versus secondary, and form versus content. The state versus trait distinction refers to whether the sign or symptom is an enduring characteristic of the person ("traits") or time-limited phenomena associated with specific Axis I disorders, which are usually state phenomena. While DSM-5 does not use a multi axial system for diagnosis, and while personality disorders are still included as they were in DSM-IV-TR, an alternative model in DSM-5 has been included as Section III in the new DSM-5. As in clinical practice distinctions are often fuzzy, and comorbidity among the so-called categorically distinct disorders is often the rule rather than the exception, DSM-5 uses a single axial approach.

DSM-5 has changed the classification of schizophrenia by deleting all subtypes, but has kept all other types, like schizoaffective in the diagnosis. In addition, a dimensional view of psychopathology fits much recent data better than the categorical view that is inherent in the DSM-IV-TR. That is the basis of DSM-5 changes for personality disorders also. For instance, personality disorders fit poorly into a categorical scheme, and the frequent "comorbidity" of these disorders likely reflects the descriptive overlap rather than the patient having two distinct disorders. Similarly, in the DSM-IV-TR, dysthymia and major depression are seen as two different mood disorders, while recent studies indicate that they are more likely manifestations of one disorder that differs in course and intensity. DSM-5 not only deleted the diagnosis of dysthymia, but also combined it with major depression, as persistent depressive disorder, with partial or full remission, early or late onset, and mild, moderate, or severe as just a few of its specifiers.

Impairments and Adversities

In addition to the traditional signs and symptoms of psychiatric disorders, recent focus has been on the impairments and adversities that psychiatric signs, symptoms, and disorders create in affecting

Telegram: @medical_k

www.konkur.in

specific role functions and causing social and economic burdens for the patient and others. These problems and impairments often cut across traditional sets of signs and symptoms of which categorical diagnoses are comprised, affecting, for example, basic abilities to care for oneself and one's family, marital functioning, child rearing, wage earning, school performance, and social behavior. They constitute the issues with which patients and families contend, and they need to appear on the problem lists that treatment plans and specific interventions target. Studies reveal, for example, that the impairments imposed by major depression are considerable with regard to physical functioning, role limitations, and social functioning. Furthermore, the relationship between symptoms and disorders on one hand and functional impairments on the other is not always straightforward. For example, in both bipolar and unipolar mood disorders, many patients recover symptomatically from episodes but achieve premorbid psychosocial function either months later or not at all. In one review of previously published studies on major depression, there was a consistent lag time between symptomatic and functional recovery. Whether this disparity between symptomatic and functional recovery reflects subtle residual symptoms, unrecognized cognitive disturbances, personality difficulties, or a combination of factors is unknown.

A 30-year-old woman with postpartum depression was reluctant to return to work as a fashion buyer. She felt she just "could not return to work this fast," in spite of marked improvement in her sleep, mood, energy level, and remission of her crying spells. She was treated with cognitive behavior therapy and an antidepressant, which she felt helped her very much. Yet, she felt "paralyzed" to perform in a job that she competitively had sought out prior to her pregnancy.

THINKING DISTURBANCES

Telegram: @medical_k

www.konkur.in

Normal Thinking

Thinking is defined as the mental activity and processes used to imagine, appraise, evaluate, forecast, plan, create, and will. Most thought involves complex rules that are probably best currently approximated (albeit inexactly) by fuzzy-logic decision-making algorithms that use neural net technology, increasingly applied by scientists and engineers in vague situations in which all-or-none, black-or-white thinking does not apply but in which multifaceted, contradictory, and competing possibilities and biases are the rule. Most of what is known about thinking derives from the study of language as the product (and reflection) of thought, yet a great deal of thinking takes place preverbally and nonverbally. Thinking occurs in images, music, and kinesthetic sensations and in symbols other than linguistic ones. Attempts to transmit preverbal and nonverbal thought using only words are frustrating and unsatisfactory. Creative artists have considerable difficulty describing the inner states of tension and inchoate awareness from which ideas are distilled.

Ordinary thought is far from logical. Streams of conscious thought are intruded on by competing thoughts and associations and by outside stimuli, and attention is easily distracted. Ordinary conversation is marked by recurring asides, interruptions, delays, and the loss of ideas. Decisions are often made on the basis of very few cues and inadequate evidence: people jump to conclusions. Beliefs are zealously held that are not supported by evidence. Thinking in stereotypes is more common than thinking in logical categories; from an evolutionary perspective, thinking in stereotypes and by approximation has probably been more adaptive than thinking in strictly defined categories. This tendency helps account for clinicians' tendencies to make diagnoses by approximation and intuition based on prototypes and to feel less comfortable using formal lists of criteria found in statistical manuals such as the DSM-IV-TR. Consistent with this notion, a recent study found that more than 60% of patients being treated for personality disorders by clinicians had diagnosable personality disorders when strict DSM-IV-TR criteria were applied, and the most common personality disorder

Telegram: @medical_k

www.konkur.in

diagnosed based on DSM-IV-TR was NOS. As mentioned previously, in DSM-5, the NOS is replaced by *other specified personality disorder* and *unspecified personality disorder* to minimize the vague and confusing diagnosis of NOS.

Considerable variation exists among individuals regarding predominant cognitive styles, and an individual's style of thinking also shifts considerably from time to time. Cognitive style refers to one's predominant manner of information processing and decision making; the particular biases and distortions thinking processes make by means of augmenting, elaborating, or minimizing incoming information; and the extent to which people use careful and deliberate logic versus intuition versus thoughtless, anxiety-induced impulsivity to guide decision making. In some individuals, a particular cognitive style may come to dominate that person's repertoire so completely as to interfere with the flexible, adaptive responses required to deal with the usual variety of daily needs. An obsessional style of thinking is marked by attention to detail and hypervigilance concerning the possible implications of a particular thought or event. This may take the form of preoccupation with strict adherence to established rules, values, or beliefs. An obsessional style may be highly adaptive in certain situations, as in professions requiring meticulous detail such as librarians, computer programmers, and surgeons. However, excessively rigid obsessionality may be maladaptive, as when someone scrupulously sticks to the rules even when such adherence is self-destructive and short sighted. A hysterical style of thinking is characterized by global, diffuse, impressionistic, emotionally laden evaluations of situations in which lack of attention is given to details and nuances. This style is poorly adaptive to detail-oriented work but may be useful in the arts, certain aspects of marketing and sales, and some social situations.

Telegram: @medical_k

www.konkur.in

A 35-year-old pharmaceutical sales manager had difficulty in managing work responsibilities in her new job. She reported spending long hours focusing on minute details of each task herself. She struggled to delegate responsibilities to her staff or to prioritize her workload for fear of missing any small detail. She was unable to meet deadlines for job reports or assigned tasks. Frustrated, she eventually asked for a job transfer.

Types of Thinking

Because of the different ways in which both normal and abnormal thinking expresses itself, differences that are apparent to even a casual observer, attempts have been made to subtype thinking by the extent to which logical versus nonlogical thought is used. Although less commonly used than before, Sigmund Freud's division of thought into primary and secondary process thinking provides a useful descriptive classification.

Primary Process. Primary process thinking, the more primitive type, is typically seen in dreams but is also prominent in young children and in psychotic states. This type of thinking disregards logic, permits contradictions to exist simultaneously, disregards the linear notion of time, and is dominated by wish and fantasy. It uses symbol, metaphor, imagery, condensation, displacement, and concretism in its organization, creating the jumbled and incoherent style of thinking characteristic of dreams. Primary process thinking represents what has been loosely and metaphorically called right brain thinking, associated with visual images and creative thought.

Secondary Process. Secondary process thinking is characterized by logic. In contrast to primary process thinking, the secondary process uses linear notions of time, clearly delineated abstract categories, and deductive rules of logic. The abilities to think abstractly and to think in detail about future plans are characteristic of secondary process thinking. Normal secondary process thinking is

Telegram: @medical_k

www.konkur.in

also characterized by predictability, coherence, and redundancy. Words, vocal inflections, and gestures provide important contextual cues and create a sense of overall coherence to the communication. Ideas follow one another in a sequence that is understandable to the listener.

A non-Freudian typology of thought divides thinking into three types: fantasy thinking, imaginative thinking, and rational or conceptual thinking. Fantasy thinking allows the person to escape from, or deny, reality and can be seen in normal as well as pathologic thinking. Everyone occasionally uses fantasy thinking when daydreaming. Some dissociative and psychotic phenomena illustrate the most pathologic manifestations of fantasy thinking. Imaginative thinking merges fantasy and memory to generate plans for the future. Rational or conceptual thinking uses logic to solve problems.

Regardless of how one categorizes thought, people can fluidly shift from linear/secondary process/rational thought to fantasy/primary process/nonlogical thought, as in the free associative method used in psychoanalysis. During this process, individuals willfully surrender the controls that maintain secondary process thinking and switch to the less controlled modes of primary process thinking in which thoughts are loosely associated by emotional associations or based on peripheral, concrete, coincidental, loosely similar, or trivial aspects of a thought. In addition, the fact that increases in primary process thinking can be induced in normal people under experimental conditions or with fatigue suggests that more primitive thought processes, such as those seen in psychosis, are usually inhibited by higher-order processes and that their appearance may be release phenomena—that is, nonlinear or psychotic thinking may indicate the functional absence of those overriding control systems that ordinarily sift, evaluate, and regulate the form and flow of thought before it reaches consciousness.

Flow and Form Disturbances

Telegram: @medical_k

www.konkur.in

Because the underlying processes that govern thought are not understood, current systems for classifying thought abnormalities are primarily descriptive. Conventional classification separates form and flow from the content of thought, yet many types of abnormal thinking include both form and content abnormalities. Thus, although delusions are usually classified as thought content disturbances, they are also marked by formal abnormalities, such as rigidity and imperviousness of thought to external influence or to information that clearly contradicts the delusional idea.

Although formal thought disorder typically refers to marked abnormalities in the form and flow or connectivity of thought, some clinicians use the term broadly to include any psychotic cognitive sign or symptom.

Normal variations in the flow and form of thought are considerable. For some people, thinking appears to be effortless, rapid and productive, exhibiting linear, goal-directed thoughts and creativity, with digressions and occasional leaps but always controlled and comprehensible. For others, thinking is a difficult exercise, a slow, painstaking process with low output, compared with other people, or "scattered," with difficulty staying with a topic or finishing a single thought. Most people experience admixtures of these extremes. Disturbances in the flow and form of thought occur with regard to rate, continuity, control, and complexity.

Thinking can be unusually slow or accelerated. Slowed (or retarded) thought, such as noted in depression, is typically goal directed but characterized by little initiative or planning. Patients experiencing retarded thought often describe feeling that even simple thought requires monumental effort, as if molasses were cluttering their thinking. These difficulties are expressed as slowness in decision making and as long latency of response, increased pause times when speech is initiated and during speech. Thought blocking, seen in schizophrenia, is experienced as the snapping off or as a sudden break in a train of thought, as if a wall suddenly comes down, interrupting thinking (and speaking) in midsentence. To an outside observer, without further explanation from the patient, thought blocking may appear identical to thought withdrawal, a

Telegram: @medical_k

www.konkur.in

disturbance in the control of thought in which the patient feels as if some alien force has intentionally withdrawn the thoughts from consciousness. The patient's further description and explanation of the inner experience is necessary to distinguish these two symptoms.

A 27-year-old man was brought to the emergency room by ambulance after being found at a gas station making bizarre hand signals at passing motorists. The man spoke in a slow, halting manner. During the interview, he would complete his sentence partially, then he would stare blankly with an odd smile. Eventually, he would complete the remainder of the sentence as if he had never stopped midway. He reluctantly disclosed that his thoughts were being programmed and controlled by powerful computer signals.

Accelerated rates of thinking, typically accompanied by fast talking, can be seen as a normal variant. Rapid rates of speech, influenced heavily by cultural and situational factors, only sometimes reflect truly rapid thought. Pressure of speech—speech that is rapid, excessive, and typically loud—is characteristic of mania (or hypomania), stimulant intoxication, and, occasionally, anxiety. Flight of ideas occurs when the flow of thought increases to the point at which the train of thought switches direction frequently and rapidly. The associative links between conceptual topics during flight of ideas are comprehensible to the listener, although not without considerable effort at times. Listening to a flight of ideas that is not overwhelmingly fast can be both a dizzying and enjoyable experience for the listener, as exemplified by the successful performance style of certain contemporary comedians.

Continuity

Disturbances in the continuity of thought may take several forms. In circumstantiality, the flow of thought includes many digressive turns

Telegram: @medical_k

www.konkur.in

and associations, often including a great deal of unnecessary detail. Transcripts of circumstantial thought or speech are marked by multiple commas, subclauses, and parenthetic asides. Nonetheless, in circumstantial thought or speech, the speaker eventually returns to the point that was initially intended without having to be prompted by the listener.

In contrast, in tangentiality, the person's thought wanders further and further away from the intended point, without ever returning, so that the person may not even remember what the original point was supposed to be. Tangentiality is a mild form of derailment in which there is a breakdown in associations. Loose associations exemplify more severe derailment, in which the flows of ideas are no longer comprehensible to the listener because the individual thoughts seem to have no logical relation to one another. Loose associations are classically a hallmark feature of schizophrenia. In extreme cases, the associations of phrases and even individual words are incomprehensible, and syntax—the rules of grammar by which phrases are organized into sentences and words into phrases—may be disrupted. Word salad describes the stringing together of words that seem to have no logical association, and verbigeration describes the disappearance of understandable speech, replaced by strings of incoherent utterances.

Clang association refers to a sequence of thoughts stimulated by the sound of a preceding word. For example, a manic patient said, "I'll kill with a drill or a pill—God, I'm ill—what swill." In echolalia, the patient repeats a sentence just uttered by the examiner. Repetition of only the last uttered word or phrase is called palilalia, a symptom found most often in chronic schizophrenia.

Perseveration and stereotypy are two other associative abnormalities in which the flow of thought or speech appears to get stuck. In perseveration, a sentence or phrase is repeated, sometimes several times over, after it is no longer relevant. Perseveration is commonly seen in delirium and other medical, substance related, and/or CNS disorders. Stereotypy refers to the constant repetition of a phrase or a behavior in many different settings, irrespective of context.

Telegram: @medical_k

www.konkur.in

Disturbances in the control of thought include delusional passivity experiences and obsessional thinking. In delusional thought passivity, patients experience their own thoughts as being under the control of other forces. Thought passivity may take several forms: in thought insertion, thoughts are experienced as having been placed within the patient's mind from the outside; in thought withdrawal, thoughts are whisked out of the mind; in thought broadcasting, patients experience their thoughts as escaping their minds to be heard by others.

A 20-year-old man presented for a psychiatric evaluation with his mother, noted to be wearing an orange hat with wires protruding through the cap. The patient had recently started wearing unique head gear. The patient stated that he had an elaborate plan to wear a different color cap with a feather or wires every day. Animatedly, the patient stated that unknown individuals were pulling thoughts out of his mind and broadcasting his business to everyone.

These experiences are often combined with specific delusions of control, seemingly to explain the passivity experiences. Several of these phenomena were included by Schneider among the so-called first-rank symptoms of schizophrenia. Today, these symptoms are viewed more broadly as nonspecific psychotic symptoms, more likely to be seen in schizophrenia but not pathognomonic of the disorder.

Telegram: @medical_k

www.konkur.in

A 36-year-old man with schizophrenia had placed silver duct tape tightly around every window in his home. He was convinced that his neighbors had a device connected to their TV satellite dish that could control his thoughts and actions. He calmly explained that the duct tape interfered with the satellite signal. He never ventured out of his home without headphones on so that no one could hear his thoughts or place bad thoughts in his head to control him.

Obsessional thinking is stereotyped, repetitive, persistent thinking that is recognized as one's own thoughts. Obsessional patients do not experience their thoughts as being controlled by outside forces. Nonetheless, they experience only partial control over the obsessional thoughts. They can, with great effort, stop thinking the obsessional thoughts but cannot prevent them from recurring. Thus, characteristic of obsessions are the subjective experience of compulsion and the resistance to it. In classic obsessional thinking, insight is retained, and, as bizarre as some obsessions are, patients know that these thoughts are irrational and their own. However, more recent studies have revealed that insight into obsessional thinking is more variable than had been previously believed, at times becoming delusional. At times, obsessions may be pervasive enough to dominate the patient's consciousness. Obsessions may be simple, a sequence of words, or elaborate, such as enumerating the possible consequences of a past behavior and elaborating a cascading sequence of typically catastrophic events. Typical obsessional themes in OCD involve preoccupations with dirt and contamination, fear of harming others, symmetry, and those related to health and appearance.

Telegram: @medical_k

www.konkur.in

A 33-year-old man would leave 2 hours plus early for every appointment. He had an obsession to park his vehicle exactly in-between two white lines, and it had reached the point that he would park his car, come out of the vehicle, and measure the distance on each side with a measuring tape to keep it equal. This would take him over an hour; therefore, he had to leave home couple of hours before each appointment, making him incapable to function and hold any job.

Obsessional thoughts are usually seen in conjunction with compulsive behaviors, which are rituals linked to the obsessions that are typically constructed to undo the effects of the thought. Thus, contamination obsessions are linked to cleaning rituals, fears of harming others lead to checking rituals, and so forth.

A 36-year-old woman was found standing in front of the grocery store counting backward rapidly in multiples of 10 with a chanting rhythmic quality for several minutes. Relieved, she then entered the store convinced that her chanting rituals would ward off mites that would otherwise infest her body. She spent several hours bathing and chanting numerically due to obsessions of contamination and infestation.

The most prominent disturbance of thinking complexity is an impaired capacity to think abstractly. Abstract thinking is the ability to assume a mental set, to keep simultaneously in mind all of the aspects of a complex situation, to move from feature to feature as indicated by the situation, and to abstract common properties. Complex thinking also concerns the ability to simultaneously consider many different, vague, and subtle aspects of situations; to appreciate differing and contradictory points of view; and to integrate these multiple dimensions to form opinions that are differentiated and nuanced. Normal individuals vary greatly in their abilities to

Telegram: @medical_k

www.konkur.in

engage in abstract thinking—geniuses in mathematics and theoretical physics leave most mortals far behind. Concrete thinking is a disturbance in the ability to form abstract concepts, generally illustrated by literal mindedness and the inability to abstract the commonality of members of a group, for example, the fact that a flea and a tree are similar in that they are both living things. Concrete thinkers seem unable to free themselves from the literal or superficial meanings of words. Concrete thinkers may be more prone to prejudice and stereotypical thinking and more likely to manifest unidimensional or all-or-none reactions to complex situations. Concrete thinking can be seen in individuals with lower intelligence, organic mental disorders, and schizophrenia. Schizophrenic patients may also exhibit highly selective disturbances of abstraction.

Thought Content

The normal content of thought, the buzzing, booming stream of consciousness that constitutes the stuff of everyday life, comprises awareness, concerns, beliefs, preoccupations, wishes, and fantasies occurring with various degrees of clarity, vividness, differentiation, imagination, and strength. Normal thought is often illogic, containing many beliefs and prejudices that may be clearly contradictory but are nevertheless held with passion and conviction.

Belief systems are the scaffolding of thought, chains of impressions, and expectations around which plans and behaviors are organized. Belief systems may be attitudinal, setting general expectations and biases about the world that inform how incoming information is processed; examples are optimism, pessimism, and paranoia. Some beliefs are evanescent, whereas others are pervasive, tenacious, enduring, and influential. The enduring belief systems are associated with behaviors consistent with the belief, at times dominating interpersonal relationships and lifestyles. Some beliefs are unique and private, whereas many are shared by others.

Telegram: @medical_k

www.konkur.in

A 48-year-old man had been deeply pessimistic since childhood. Although he had no vegetative features of depression, he believed and behaved as if the world was an awful place dominated by dishonest and selfish individuals. Having any goals seemed foolish to him, given the nature of the world. He expressed these beliefs regularly to his children, to the dismay of his wife, who did not share his belief system.

Imaginative fantasy is an important component of normal thought. The vivid, eidetic imaginations of young children can produce vivid fantasies in which children become fully immersed, almost as if in hypnotic states. During latency, many children develop imaginary companions as playmates. In later years, imaginative thinking in which previously separate streams of thought playfully interact with one another to produce new ideas may be the essence of the creative reverie. Artists, writers, and creative scientists may retain access to these forms of thinking more readily than others. Meditative states of mind may facilitate the emergence of imaginative insights. Such thinking may also occur in dreams. Intrusive reveries are normal and common components of the usual adult stream of consciousness. During periods of specific deprivation, such as starvation or sexual deprivation, elaborate wish-fulfilling daydreams frequently occur.

Ideas are the contents of the stream of thought. Those that are consistent with one's sense of self, compatible with the individual's self-image, are called ego-syntonic. Other thoughts that conflict with one's central values are called ego-alien or ego-dystonic. An ego-dystonic impulse to kill someone, inconsistent with one's predominant value systems, may generate a counteractive ego-syntonic thought such as "you really don't mean it."

Disturbances in Thought Contents. Abnormal beliefs and convictions form the core of thought content disturbances. Considerations of abnormality regarding beliefs and convictions must take the person's culture into account. Beliefs that may seem

Telegram: @medical_k

www.konkur.in

abnormal in one culture or subculture may be commonly accepted in another. For example, religious hallucinations, attributed to psychological or biologic factors by contemporary Western societies, are routinely attributed to religious and spiritual causes by many other cultures. With regard to intensity of conviction, distorted beliefs range on a continuum from overvalued ideas to the determined, unshakable belief that is characteristic of fixed delusions. Abnormal beliefs and delusions are, in most circumstances, diagnostically nonspecific. Delusions are commonly seen in mania, depression, schizoaffective disorder, delirium, dementia, and substance-related syndromes, as well as in schizophrenia and delusional disorders.

Overvalued ideas are unreasonable and sustained abnormal beliefs that are held beyond the bounds of reason. Patients with overvalued ideas have little or no insight into the fact that their ideas are very unlikely to be valid; however, the ideas themselves are not as patently unbelievable as most delusions. The distorted body images of body dysmorphic disorder exemplify overvalued ideas. Morbid jealousy and preoccupation with a spouse's possible infidelity may constitute an overvalued idea if no real evidence has ever existed to warrant suspicion.

A 42-year-old man who had a brief relationship with a woman was unable to accept the fact that she no longer wanted to see him. He ruminated about every encounter that they had and interpreted small gestures in the past as indicating her undying love for him. His infatuation led him to follow her repeatedly to work and school, and he pursued her relentlessly, to the point that she brought charges against him for stalking.

Ideas of reference are false personalized interpretations of actual events in which individuals believe that occurrences or remarks refer specifically to them when in fact they do not. Ideas of reference may be less firmly held than delusional beliefs.

Telegram: @medical_k

www.konkur.in

A 20-year-old college student was brought to the student health clinic because she was pacing outside her dormitory building in an agitated manner. She stated that she could not sleep for several days because when she heard a cell phone ring, it was a signal that other students were talking about her and laughing at her.

Delusions. Delusions are fixed, false beliefs, strongly held and immutable in the face of refuting evidence, that are not consonant with the person's educational, social, and cultural background. Thus, delusional thoughts can only be understood or evaluated with at least some knowledge of patients' interpersonal worlds, such as their involvements with religious or political groups. One of the mind's functions is to generate beliefs, which may include myths and meaning systems. Shared beliefs provide an individual with a sense of personal and group identity and with ways of understanding reality. They are most noticeable when shared untestable beliefs form the basis for group cohesion, as in religions and cults. Some groups adhere to their cherished beliefs despite the abundance of plausible contrary evidence. Individuals often hold on to their primary beliefs as matters of faith (i.e., alternative, nonrefutable bases for understanding); they may hold these beliefs even in the face of grave personal threat. The strong faith with which religious, political, and nationalistic convictions are held, even at the cost of death, shows the power that these beliefs can have on behavior. Potential mental health advantages of religious beliefs have been demonstrated in epidemiologic studies showing that those with a sense of personal devotion report fewer depressive symptoms.

Subjectively, delusions are indistinguishable from everyday beliefs. Therefore, the subjective experience of a delusion is no different from the subjective experience of believing that the earth is round or that one's spouse is the same person that one married on their wedding day. Because of the identical experience of delusions and other strongly held beliefs, it is generally impossible to argue a

Telegram: @medical_k

www.konkur.in

patient out of a delusional belief. The content of delusions is highly influenced by culture. Centuries ago, delusions of persecution often concerned persecution by the devil and had religious connotations; persecutory delusions today often take on contemporary technologic, political, and social perspectives.

A 25-year-old man diagnosed with schizophrenia adamantly believes that he has discovered a new program that will transform the internet. He explains this transforming discovery is due to his ability to receive messages directly from his computer. He would not elaborate further on the program because of his belief that other people would steal the program from his brain or that his thoughts would be broadcast out loud, destroying his secret discovery.

Although delusions are diagnostically nonspecific, some types of delusions are more prevalent in one disorder than another. For example, although delusions of control and delusional percepts are often seen in schizophrenia, they also occur, albeit less frequently, in psychotic mood disorders. Similarly, classic mood-congruent delusions, with grandiose themes seen in mania or delusions of poverty characteristic of depression, may also be seen in schizophrenia.

Table 8–1 lists some characteristics by which delusions have been classified. Simple delusions contain relatively few elements, whereas complex delusions may contain extensive elaborations of people, spirits, motives, and situations.

Telegram: @medical_k

www.konkur.in

A 32-year-old man is convinced his neighbor is videotaping his movements, monitoring his cell phone activity, and has hacked his WiFi. The patient called the police but later was convinced the police were bought off by his neighbor. Subsequently, the patient installed an elaborate camera system, taped aluminum foil over his windows, and installed a new satellite dish to protect himself against his neighbor's intrusions.

Systematized delusions are usually restricted or circumscribed to well-delineated areas and are ordinarily associated with a clear sensorium and absence of hallucinations. They are often isolated from other aspects of behavior. In contrast, nonsystematized delusions usually extend into many areas of life, and new data—new people and situations—are constantly incorporated to further support the presence of the delusion. The patient usually has concurrent mental confusion, hallucinations, and some affective lability. Whereas the patient with a closed systematized delusional system may go about life relatively unperturbed, the patient with a nonsystematized delusion frequently has poor social functioning and often behaves in response to the delusional beliefs.

Table 8–1.
Characteristics of Delusions

Simple vs. complex
Complete vs. partial
Systematized vs. nonsystematized
Primary (autochthonous) vs. secondary
Persecutory vs. nonpersecutory
How they affect behavior

Complete delusions are those held utterly without doubt. In contrast, partial delusions are those in which the patient entertains doubts about the delusional beliefs. Such doubts may be seen

Telegram: @medical_k

www.konkur.in

during the slow development of a delusion, as the delusion is gradually given up, or intermittently throughout its course.

During an acute schizophrenic episode, a 23-year-old man was completely convinced that the subtle pattern of superficial veins on his legs was evidence of “astral domination” by extraterrestrial beings. After 1 week of antipsychotic medication, he believed the veins were caused by others with special powers but was less sure. Two weeks later, he denied believing that the patterns on his legs were other than superficial veins and dismissed his previous belief with a shrug.

An autochthonous delusion is one that takes form in an instant, without identifiable preceding events, as if full awareness suddenly bursts forth in an unexpected flash of insight like a bolt from the blue. These delusions may be quite elaborate.

After a two-year period of gradual academic and interpersonal decline, a 21-year-old man had the sudden conviction that certain songs played on the radio used his voice in the role of lead singer. He could not explain why this would be so nor why this belief emerged suddenly when it did.

Aside from the autochthonous types, three other types of delusions have been described as primary. Delusional percept refers to the experience of interpreting a normal perception with a delusional meaning, one that has enormous personal significance to the patient. Delusional atmosphere or delusional mood is a state of perplexity, a sense that something uncanny or odd is going on that involves the patient but in unspecified ways. Ordinary events may take on heightened significance, but the delusional interpretations are fleeting, although the uncanny feeling stays. Typically, after a period, full-blown delusions develop, replacing the delusional mood. Delusional memory is the memory of an event that is clearly

Telegram: @medical_k

www.konkur.in

delusional. As an example, a patient “remembered” that his fourth-grade teacher slipped lysergic acid diethylamide (LSD) into his apple juice; this memory served to explain his psychotic disorder. The elaboration of false memories and their subsequent fixed belief may assume delusional proportions.

A young schizophrenic woman attended a “trauma group” with her roommate and gradually came to believe that she had been repeatedly sexually assaulted by her father from the time she was in the crib. What started out as vague dreamlike images gradually coalesced into a series of “sensed” memories that then took on specific visual images of her father’s fingers penetrating her and of his looking down at her in the crib leering. Her parents were horrified by these accusations, and there was not a shred of evidence to corroborate her increasingly venomous accusations.

Patients vary considerably in the extent to which they take action in response to delusional thoughts. Just as patients can experience delusions of their thoughts being controlled (thought passivity), they may similarly experience their feelings, behaviors, and will as controlled by outside forces. These delusions of control (or passivity experiences) occasionally, albeit uncommonly, result in dramatic self-destructive or aggressive behaviors, as illustrated by the murderer who called himself Son of Sam. This psychotic killer murdered a series of people in New York and claimed that he was the powerless agent of a force that required him to commit the acts. To defend themselves and others against delusional anticipated events, some patients may take bold and occasionally destructive actions.

Telegram: @medical_k

www.konkur.in

A 68-year-old patient was brought to the psychiatry emergency center by police after her frightened neighbors heard gunshots coming from her home. The patient stated she was being persecuted by her neighbor's son and had bought a gun to protect herself. She was convinced the neighbor's son switched identities and had "2700 aliases" that he would use to steal from her. The patient observed the son returning home late and night and acknowledged she was shooting at him to protect her life.

Table 8–2 lists some classic types of delusions. Although less common than those involving paranoia, grandiosity, and influence, delusions of misidentification are prominently reported because of their inherently intriguing nature. In Capgras syndrome, the patient believes that someone close to them has been replaced by an exact double. In Frégoli phenomenon, strangers are identified as familiar people in the patient's life. In the delusion of doubles, patients believe that another person has been physically transformed into themselves.

A 23-year-old young woman, recently diagnosed with schizophrenia, was brought to the emergency center by ambulance after she called 911 screaming, "Give me back my mother, I know what you've done." In the hospital, she accused her mother of being a double, in spite of the mother's attempts to show her old family photographs and her birth certificate.

Olfactory delusions that one emanates a foul odor are common in social anxiety syndromes, in which individuals are particularly concerned about potentially embarrassing themselves and others.

Delusions are not only seen in isolated individuals. Shared delusions may occur in couples (folie à deux) and in families (folie à famille). Many psychiatrists consider group delusions to be present in some cults, as well, but exactly where the cutoff points occur

Telegram: @medical_k

www.konkur.in

between delusions and other zealous beliefs held by larger, more traditional and well-organized religious, political, and other groups is arguable.

Table 8–2.
Some Classic Types of Delusions

Delusions of persecution
Delusions of grandeur
Delusions of influence
Delusion of having sinned
Nihilistic delusions
Somatic delusions
Delusion of doubles (doppelganger)
Delusional jealousy (Othello syndrome)
Delusional mood
Delusional perception
Delusional memory
Delusions of erotic attachment (Clérambault syndrome)
Delusions of replacement of significant others (Capgras syndrome)
Delusions of disguise (Frégoli phenomenon)
Shared delusions (folie à deux, folie à trios, folie à famille)

A husband and wife were brought by police for a psychiatric evaluation. They both wore a large colorful talisman made of metal on their head which had a particular significance to them. The reason for the talisman, they concurred, was to ward off cell phone signals which could control their actions and project their thoughts to others. The husband was a dominant personality who had originated this fixed delusion. His wife, a mild-mannered, passive person, seemed to have accepted her husband's interpretation of events without challenging them at all.

www.konkur.in

DISTURBANCES OF JUDGMENT

Judgment involves a complex and diverse group of mental functions that includes analytical thinking, social and ethical action tendencies, and depth of understanding or insight. Analytical thinking includes the capacity to discriminate and to weigh the pros and cons of potential alternative actions. Social and ethical action tendencies are closely related to culture and upbringing. The evidence for genetic factors in antisocial personality disorder (defined primarily by judgments that lead to criminal behaviors) points to the additional role of constitutional factors. Insight may reflect intelligence, learning, cognitive style, and the capacity to integrate intellectual knowledge with emotional awareness.

Impairments of judgment occur in many psychiatric disturbances. Anxiety states, intoxications, fatigue, and even group pressures may cause temporary impairments of judgment in otherwise normal individuals. In mood disorders, judgment may be impaired by either an exaggerated evaluation of risk or failure in depression or, conversely, of inadequate appreciation of risk or danger in mania. Brain damage caused from medical conditions, including persistent substance-related conditions and psychotic disorders, may chronically impair any aspect of judgment in any person, regardless of premorbid character. Poor role models and deviant social backgrounds may lead to social and ethical action tendencies quite different from those of the examiner. Thus, someone raised in a criminal environment may have superb analytical judgment and self-awareness, which are, however, put to illegal use.

Telegram: @medical_k

www.konkur.in

A 48-year-old attorney missed multiple visits with his established psychiatrist and subsequently ran out of his mood stabilizer, in part due to increased travel related to a prominent out of town legal case. His wife of 20 years became increasingly concerned as he erratically began flying first class, spending $40,000 on airfare, and not disclosing his whereabouts. After not communicating with his wife for 2 days, he was found by security at an out-of-town television station claiming he had been hired as their national legal correspondent to provide legal commentary.

Judgment may be impaired in one dimension and spared in others. Individuals may retain sound ethical judgment when their analytical capacities fail or may retain excellent analytical abilities for nonpersonal matters, although lacking insight into personal situations or behaviors.

A 42-year-old chief financial officer of an oil and gas company was admitted for inpatient psychiatric hospitalization. His wife stated that he had been working on a major financial transaction for his company late into the night and not slept for several days. She then found out that he had also been ordering expensive watches and jewelry from the internet, spent $35,000 on these impulsive purchases, and appeared excessively euphoric. During the psychiatric interview and mental status exam, the patient proudly counted backwards very fast during serial 7's and said, "I can give you three things that are similar between an orange and an apple."

Thus, some people who can provide socially appropriate responses to traditional mental status examination questions, such as what one would do in a movie theater if fire broke out, might at the same time be incapable of accurately assessing crucial clinical or more personal matters specifically related to one's capacity to

Telegram: @medical_k

www.konkur.in

provide informed consent, such as the pros and cons of receiving treatment; regarding judgments necessary to provide oneself with food, clothing, and shelter; or insight into one's state of health or illness.

The term insight, usually in the context of self-awareness, has been used in a variety of ways. Basic insight refers to a superficial awareness of one's situation. In evaluating insight into one's psychiatric condition, basic insight allows an individual to acknowledge the presence of an illness. A deeper level of insight is operating when the patient has an intellectual appreciation of what is going on (e.g., "I have hallucinations and delusions, and my doctors have told me that I have schizophrenia and must take medication"). Still deeper levels of insight reflect more complete cognitive and emotional appreciation of a situation (e.g., "I realize that I have schizophrenia, that it impairs my judgment and social function at times, and that I will have to take medications if I am to minimize my symptoms and try to make the most of my life. I feel profoundly disappointed about this affliction because it prevents me from achieving some of the goals I've always wished for. Nevertheless, I have to do my best to get over my disappointment and hurt feelings so that I can get whatever I can out of life.")

Of course, different depths of insight as self-awareness can be evaluated in many other situations, such as physical illness, quality and nature of relationships, an appreciation of strengths and weaknesses in professional situations, and so forth. In formal studies of insight using standardized instruments, lack of insight correlates with poor outcome in schizophrenia and bipolar disorder, medication noncompliance, and suicidality. Improvement of psychosis does not necessarily correlate with improved insight. Impaired insight may be associated with frontal lobe abnormalities. Insight may be as seriously impaired in mania as in schizophrenia and, contrary to earlier beliefs, may be lacking in OCD.

Judgment may be impaired by several factors, including cognitive clouding (as in disturbances of consciousness, for example, intoxication, so that one's usual analytical abilities are impaired), self-deception, and impulsivity.

Telegram: @medical_k

www.konkur.in

Self-deception refers to the almost universal tendency to hide certain issues about the external world or about oneself from various levels of awareness. Self-deception functions as a coping strategy, fostering or maintaining comfortable perspectives about the world and avoiding confrontation with issues and realities that inevitably stir up painful conflicts or the need for difficult actions, thereby preserving emotional calm. In addition, studies suggest that self-deception enables people to act and to be perceived as more convincing in the service of particular goals, as in romantic relationships or business dealings. Therefore, although “kidding ourselves” may sometimes reflect impaired judgment, it may at times also yield certain important strategic advantages.

Impulsive judgment describes a tendency to avoid taking the time and thought to fully understand and integrate all of the facts and levels of awareness required for optimal decision making. Impulsive judgment may occur only with certain issues or situations (such as how one picks investments), signal an impaired state (such as intoxication), or reflect a pervasive character trait.

Rapidly made judgments, and even the so-called snap judgments, may not be maladaptively impulsive, even when they involve very important areas of life. Rapid decisions can be very accurate, highly adaptive, and even lifesaving, especially if made against a background of great experience, wisdom, and forethought concerning the area requiring the decision.

Because, in clinical practice, the terms insight and judgment are often applied to individuals’ awareness and decision making about their psychiatric status, complex motivational states that incorporate insight and judgment related to how one is dealing with one’s problems, the so-called stages of readiness for change, bear mention at this point. Initially described in relation to substance abuse, including alcoholism and smoking, these stages have received considerable attention and form an important aspect of clinical assessment across other diagnostic categories such as eating disorders. Several stages have been described: (1) precontemplation, the person expresses no intention to change (may be in denial); (2) contemplation, the person acknowledges a problem

Telegram: @medical_k

www.konkur.in

and states an intention to change within several months but not right away; (3) preparation, the person intends to do something about changing in the near future and may have already made some false starts; (4) action, the individual has engaged in making sustained behavior changes; (5) maintenance, the individual has been engaged in changed behavior for more than 6 months; and (6) termination, the individual has succeeded in the change and is unlikely to return to the original behavior.

DISTURBANCES OF PERCEPTION

Normal perception first requires that the individual be capable of receiving information as sensations. The data must then be organized to make them meaningful and comprehensible such as distinguishing figure from ground or focusing attention selectively on some part of the sensory field. The organized entities are called percepts. In states of sensory deficit, such as blindness, deafness, and anesthesia, perception is impaired, but perception is still possible because individuals generally perceive information about an object through several sensory modalities concurrently. The intensity of sensation and perception is affected by vigilance and attention. Highly focused attention, as in intense concentration or hypnosis, may result in unusually acute sensation and perception—hyperesthesia, hyperacusis, or extraordinary visual acuity. Focused attention may also result in the inability to sense or perceive: deep anesthesia and negative hallucinations induced by hypnosis are simply induced failures to perceive what exists in the world.

Humans usually operate in an “average expectable environment” in which certain types and levels of sensory input are expected and for which the nervous system is primed. Excessive or inadequate stimulation in any sensory modality, levels of input that are extraordinarily intense, or the presentation of novel stimuli that are entirely different from anything previously experienced by the individual can provoke distorted perceptions in most normal people. For example, total sensory deprivation produced in carefully

Telegram: @medical_k

www.konkur.in

controlled artificial environments may elicit visual and auditory illusions and hallucinations.

Individuals generally exhibit selective perception of the world, depending on what is salient at the moment and on individual memories, emotions, fantasies, and values. Pregnant women are more likely to perceive babies around them than are people who are not as preoccupied with childbearing.

The intensity of perceptions depends on individual sensitivities as well as on mood, anxiety, and substance use. Unmedicated patients with schizophrenia have deficits in olfactory acuity. Depressed patients often describe that colors look faded and that the world looks washed out or gray, even though their capacity to recognize specific colors is unchanged. Similarly, mania is often characterized by heightened perceptions, hyperesthesia. When extreme, these intense perceptions are uncomfortable. Hyperesthesia can also be seen during benzodiazepine withdrawal, hallucinogen use, and, occasionally, as part of an epileptic aura.

The intensity of perception may vary with cognitive style and other psychological and neurologic factors. Some individuals tend to be augmenters and others minimizers of bodily experiences. Chronic pain and some hypochondriacal syndromes may occur more commonly among somatic augmenters.

Selective deficits in the perception of emotions may occur. Emotional aprosodies have been described in which patients with specific neurologic deficits or depression are selectively unable to recognize the expression of facial emotion. These have been linked by positron emission tomography (PET) scan to blunted activity in the right prefrontal cortex and insula.

Illusions

Perceptual distortions in estimating size, shape, and spatial relations are common even in the absence of psychiatric disorders, especially when one is fatigued or excessively aroused. Illusions are misinterpretations of real sensory stimuli, as when a child in a dark bedroom at night sees monsters emanating from shadows on the

Telegram: @medical_k

www.konkur.in

walls. Pareidolia are playful and whimsical voluntary illusions that can be seen when one looks at ambiguously defined or evanescent images such as clouds or flames in a fireplace. The onset and termination of these perceptions is under voluntary control. Trailing, another visual illusion, is the perception that an object moving steadily in space is followed by temporally distinct after-images of itself. The effect is that of a series of stroboscopic photos. This phenomenon may occur with fatigue and is typically seen with marijuana and mescaline intoxication, during withdrawal from SSRIs, or, less commonly, in association with nefazodone.

A 20-year-old male presented to the emergency room after he was brought by police because he was behaving bizarrely in the streets. He denied previous psychiatry history. He reported attending a party with some friends last night where someone gave him some drug. On examination, he reported distortions of objects and persons, stating that “police officers look like giants,” but there were no other significant findings in the mental status examination. These types of illusions are classic examples of visual or optical illusions, which are the most common type of illusions.

Hallucinations

Hallucinations are perceptions that occur in the absence of corresponding sensory stimuli. Phenomenologically, hallucinations are ordinarily subjectively indistinguishable from normal perceptions. Hallucinations are often experienced as being private so that others are not able to see or hear the same perceptions. The patient’s explanation for this is typically delusional. Hallucinations can affect any sensory system and sometimes occur in several concurrently. When perception is altered, combinations of illusions and hallucinations, and often delusions as well, are frequently experienced together. In some studies, 90% of patients with hallucinations also have delusions, and approximately 35% of

Telegram: @medical_k

www.konkur.in

patients with delusions also have hallucinations. Children and early adolescents, however, are more likely to have hallucinations in the absence of delusions. Approximately 20% of patients have mixed sensory hallucinations (mostly auditory and visual) that may accompany functional, as well as organic, conditions. A given external stimulus may evoke very different perceptual distortions in different people.

Three scientists floated in sensory deprivation tanks for long periods. One experienced a few illusions and no hallucinations; the second had many illusions and a few faint auditory and visual hallucinations; and the third had vivid, dramatic, and complex visual and auditory hallucinations.

Hallucinations are experienced by many normal people under unusual conditions. It has been estimated that between 10 and 27% of the general population has experienced memorable hallucinations, most commonly visual hallucinations. The large majority of self-reported hallucinations in community studies, particularly auditory hallucinations, have been associated with depressive and substance use disorders rather than frank psychotic disorders.

A 76-year-old woman reported “hearing and seeing” her deceased husband calling her name, and she wanted to join him in heaven. She had become very depressed after her husband of 51 years passed away 6 months ago. Friends reported that she was more withdrawn, isolated, and stopped going to her place of worship.

Hypnagogic and hypnopompic hallucinations are common, predominantly visual hallucinations that occur during the moments immediately preceding falling asleep and during the transition from sleep to wakefulness, respectively. Hypnagogic and hypnopompic hallucinations both occur in normal people and are also characteristic symptoms of narcolepsy. In acute bereavement, up to 50% of grieving spouses have reported hallucinating the voice or presence of the deceased, and after amputations, phantom limb

Telegram: @medical_k

www.konkur.in

hallucinations are common. Patients who become visually impaired often develop complex hallucinations (i.e., visual hallucinations with preserved insight) with preserved cognitive status, the so-called Charles Bonnet syndrome.

A 77-year-old woman presented to her psychiatrist with mild anxiety symptoms. During the past year she had experienced severe loss in her visual acuity due to age-related macular degeneration. She reported experiencing unexpected vivid hallucinations and described seeing complex shapes of geometric design and animal figures. She had awareness that these “visions” were not real, and her cognitive screen, including the Mini-Mental Status Examination, was normal.

A parallel phenomenon is the emergence of hallucination, including musical hallucinations in individuals with acquired deafness. These observations suggest a “supersensitivity deprivation” hypothesis that, when deprived of important and anticipated perceptual stimuli, the mental apparatus may overinterpret any sensory stimulation as evidence of the presence of the needed objects.

A perceptual release theory suggests that hallucinations emerge from the combined presence of intense states of internal arousal and diminished sensory input (including poor attention and poor capacity to sort out relevant from irrelevant input). Thus, diminished input from the environment (as in sensory deprivation) or reduced capacity to attend to and take in the input (as in delirious states) heightens the likelihood that internal sensations, images, and thoughts are interpreted as originating in the outside environment.

Hallucinations vary according to sensory modality, degree of complexity of the hallucinated experience, the levels of conviction about their reality, the clarity of their contents, the location of their sources of origin, the degree of volitional control over them, and the degree to which the hallucination influences the person’s behavior.

Telegram: @medical_k

www.konkur.in

Auditory hallucinations range in complexity from hearing unstructured sounds, such as whirring noises or muffled whispers, to ongoing multiperson discussions about the patient. The simple auditory hallucinations are more commonly associated with organic psychoses such as delirium, complex partial seizures, and toxic and metabolic encephalopathies. Auditory hallucinations are classically associated with schizophrenia (seen in 60% to 90% of patients) but are also frequently seen in psychotic mood disorders. Twenty percent of manic patients and less than 10% of depressed patients experience auditory hallucinations.

Three types of auditory hallucinations commonly associated with schizophrenia (which, however, are also seen less commonly in patients with psychotic depressions and mania) are (1) audible thoughts described as hallucinated voices that speak aloud what the patient is thinking, (2) voices that give a running commentary on the patient's actions, and (3) hearing two or more voices arguing with each other, often about the patient, who is referred to in the third person.

A 37-year-old man with chronic schizophrenia reported hearing multiple voices, both male and female, commenting on his daily activities. He described the male voice as "critical" and commenting in a negative way about his grooming, clothing, and appearance. The female voice was calming and soothing. At times, he stated he could "block the voices out by putting on loud music." Other times he stated that "they would take over," leading him to feeling despondent and hopeless. He stated during these "terrible times" he considered jumping off a bridge to end the "voices torturing me."

While auditory hallucinations in schizophrenia are frequently mood neutral, hallucinations in patients with mood disorders are characteristically consistent with their mood. In psychotic depression, the voices may be unrelievedly critical and sadistic, whereas in mania the voices often refer to the patient's specialness.

Telegram: @medical_k

www.konkur.in

A 36-year-old woman with bipolar disorder described auditory hallucinations correlating with episodes of severe mania or depression. When she was depressed, she reported hearing voices that were demeaning and called her “fat, ugly, and worthless.” The voices were so unremitting that she became suicidal. However, during an intense euphoric manic episode, she described hearing joyful angels singing and declaring her as the next savior sent to earth by God.

Command hallucinations order patients to do things. Often, the commands are benign reminders about everyday tasks: “Pick up your shoes” or “Clean off the table.” However, the voices may also be frightening or dangerous, commanding acts of violence toward the self or others such as, “Jump off the roof; you’re not worth anything,” or, “Pick up the knife and kill your mother.” These voices vary in insistence and persistence, and patients differ in their capacities to ignore these commands. Patients with marked passivity may be helpless in the face of command hallucinations and may feel impelled to carry out the orders. Even though one study did not find command hallucinations to be associated with a higher risk of harm to the patient or others, the presence of command hallucinations and the patient’s ability to resist must be assessed carefully.

A 46-year-old woman with schizophrenia heard command hallucinations daily for the last 20 years. When her symptoms were relatively quiescent, the voices were benign, and the commands referred to daily behaviors (such as “say thank you”). Under stress, her psychosis exacerbated, and the voices became louder and more insistent and commanded more complex and dangerous behaviors, once precipitating a self-stabbing when the voices demanded it.

Telegram: @medical_k

www.konkur.in

Visual hallucinations occur in a wide variety of neurologic and psychiatric disorders, including toxic disturbances, drug withdrawal syndromes, focal CNS lesions, migraine headaches, blindness, schizophrenia, and psychotic mood disorders. Although visual hallucinations are generally assumed to characteristically reflect organic disorders, they are seen in one-fourth to one-half of schizophrenic patients, often—but not always—in conjunction with auditory hallucinations.

Visual hallucinations range from simple and elemental, in which hallucinations consist of flashes of light or geometrical figures, to elaborate visions such as a flock of angels.

Stimulation of one sensory modality sometimes evokes perceptual distortions in another. Marijuana and mescaline intoxication, for example, have been associated with synesthesia, an experience in which sensory modalities seem fused. This is also a normal experience for many people. Music may be experienced visually, the sound fusing with visual illusions; a tactile sensation may be experienced as a color (e.g., a hot surface may “feel red”).

In certain religious subcultures, visual hallucinations may be experienced as normal. For example, in some fundamentalist Pentecostal churches, worshipers may experience religious visions that they perceive as being from God.

A 62-year-old Native American man was raised on an Indian reservation and was deeply connected to his heritage. He openly acknowledged that the spirit of his elders and ancestors surrounded him. He reported that he could feel and sense their presence around him no matter what he was doing, whether he was working or resting. The presence of these spirits was a guiding force that he felt was calming to him.

Autoscopic hallucinations are hallucinations of one’s own physical self. Such hallucinations may stimulate the delusion that one has a double (doppelganger). Reports of near-death, out-of-body experiences in which individuals see themselves rising to the ceiling

Telegram: @medical_k

www.konkur.in

and looking down at themselves in a hospital bed may be autoscopic hallucinations. In Lilliputian hallucinations, the individual sees figures in very reduced size, such as midgets or dwarfs. They may be related to the perceptual distortions of macropsia and micropsia, respectively, the perceptions of objects as much bigger or smaller than they actually are.

Haptic hallucinations involve touch. Simple haptic hallucinations, such as the feeling that bugs are crawling over one's skin (formication), are common in alcohol withdrawal syndromes and in cocaine intoxication. When unkempt and physically neglectful patients complain of these sensations, they may be due to the presence of real physical stimuli, such as lice. Some tactile hallucinations—having intercourse with God, for example—are highly suggestive of schizophrenia but may also occur in tertiary syphilis and other conditions and may, in fact, be stimulated by local genital irritation. Olfactory and gustatory hallucinations, involving smell and taste, respectively, have most often been associated with organic brain disease, particularly with the uncinate fits of complex partial seizures. Olfactory hallucinations may also be seen in psychotic depression, typically as odors of decay, rotting, or death.

Telegram: @medical_k

www.konkur.in

A 32-year-old woman with schizophrenia described that, over the 15 years of her illness, she had experienced a wide array of hallucinations. She initially noticed celestial voices, auditory hallucinations that included angelic music and comforting words. However, over the years, in conjunction with a pessimistic turn of mind, the voices became more demonic and threatening. At the same time, she began to experience somatic hallucinations consisting of sharp, intermittent electric currents being run through her skin and genitals, which, she was convinced, were the work of evil neighbors who were intent on driving her out of her apartment. With medication, she was partly able to perceive these experiences as hallucinatory; however, most times, particularly when she neglected to take medications, she never doubted their authenticity.

The term pseudohallucination has been used in two ways. First, pseudohallucination refers to perceptions experienced as coming from within the mind (i.e., not at the boundary or outside the mind). Using this definition, loud voices that are alien, ascribed to other beings, but which the patient knows are actually within the mind rather than out in space, are pseudohallucinations. The term has also been used to describe hallucinatory experiences whose validity the patient doubts. A better term for this second phenomenon is partial hallucination, analogous to partial delusion. Functional hallucinations are rare hallucinations that occur only in connection with a specific external perception, for example, in the presence of a sound, such as running water, a color, or a particular place. However, unlike illusions, the hallucinated sounds are not elaborations of the perception but are simply triggered only in that specific context.

Ictal hallucinations, occurring as part of seizure activity, are typically brief, lasting only seconds to minutes, and stereotyped. They may be simple images, such as flashes of light, or elaborate ones, such as visual recollections of past experiences. While the

Telegram: @medical_k

www.konkur.in

hallucinations are being experienced, the patient ordinarily experiences altered consciousness or a twilight sleep.

Migrainous hallucinations are reported by approximately 50% of patients with migraine. Most are simple visual hallucinations of geometrical patterns, but fully formed visual hallucinations, sometimes with micropsia and macropsia, may also occur. This complex has been called the Alice in Wonderland syndrome after Lewis Carroll's descriptions of the world in *Through the Looking Glass,* which mirrored some of his own migrainous experiences. In turn, these phenomena closely resemble visual hallucinations induced by psychedelic drugs such as mescaline.

A flashback is an intense visual re-experience of highly charged past events, which are often replays of hallucinations. They are typically associated with heavy use of hallucinogens, such as LSD and mescaline, and often occur months after the last drug ingestion. The images may be simple or complex geometrical patterns, or they may consist of previously experienced elaborate drug-induced hallucinations. Flashback phenomena may be state dependent. For example, visual hallucinations initially experienced with hallucinogens are more likely to be subsequently experienced as flashbacks when the subject is smoking marijuana. In PTSD, some complex, intrusive flashback-like images may attain a hallucinatory vividness. Images often include horrifying memories of traumatic events that may force themselves repeatedly into consciousness until they are acknowledged and worked through.

Telegram: @medical_k

www.konkur.in

A 33-year-old military combat veteran had left the military with commendation after serving multiple active duty combat tours. He returned home after picking up party supplies for a pool party he was hosting with his new wife at their home. Upon returning from the store and entering the home, he began to loudly scream, “Get down, get down, active shooter, active shooter here.” He was profusely sweating, appeared dazed, and was vividly calling out military commands. Later, his wife found out that her husband smelled the intense smell of ammonia and burned hair when he entered the home, which triggered the flashback memory and vivid re-living of “burning hair and burning bodies.” The wife said she had tried a new home hair permanent treatment which had gone awry.

Hallucinosis is a state of active hallucination occurring in someone who is alert and well oriented. This condition is seen most often in alcoholic withdrawal, but it may also occur during acute intoxications and other drug-mediated states.

A 21-year-old man used LSD daily for 3 days, after which the visual hallucinations that first occurred while under the influence of the drug waxed and waned. He described pareidolias with distracting images of animals when he looked at traffic lights, the sky, or billboards. Trailers were common after he turned his head. Finally, he saw moving colors when he stared at any object for more than a transient time. He assumed that these phenomena represented a lingering effect of the LSD and was not frightened by them. The hallucinations disappeared within 1 week.

Body Image Distortion

Body image includes both perceptual and ideational components and may reflect primarily perceptual distortions or combinations of

Telegram: @medical_k

www.konkur.in

disturbed perception and self-appraisal, or both.

Body image disturbances can occur as normal responses to abrupt changes in the body (e.g., after amputation), in brain disease, and in psychiatric disorders. Phantom limb phenomena are classic body image problems in which an amputated limb is still felt to be present. The sensation may diminish gradually over time; the phantom feels as if it is receding into the stump.

A 34-year-old man presented to his VA hospital mental health clinic appointment for persistent insomnia and anxiety. While on his second tour of active combat duty, he sustained a traumatic injury requiring amputation of his left leg. He reluctantly disclosed that he could feel his amputated leg “going in and out” and thought he was “going crazy.” He described many sensations, sometimes that the area felt warm and tingling, other times, he felt throbbing, itching, and sharp electrical piercing feelings.

Agnosias, lack of awareness of some parts of the body, may accompany brain damage, most often of the nondominant parietal lobe. Patients with obvious motor or sensory deficits may deny that any deficit exists at all (anosognosia), or the denial may be limited to one-half of the body (hemiagnosia), usually the left side. In hemidepersonalization syndromes, a less common disorder (hemiasomatognosia), patients feel that one of their limbs is missing, again usually on the left side. Body image distortions in which a limb feels too heavy (hyperschemazia) or weightless (hyposchemazia) can occur as a consequence of neurologic conditions such as infarction of the parietal lobe. In duplication phenomena, patients feel as if part or all of them has doubled (e.g., they have two heads or two bodies). These rare phenomena may occur in schizophrenia, complex partial seizures, and migraine.

Dysmorphophobia refers to conditions in which patients distortedly perceive and intensely dislike the shape of a particular body part. As such, these symptoms are misnamed because there is no true phobic component such as fear or avoidant behavior. Fine lines exist

Telegram: @medical_k

www.konkur.in

between perceptual distortions and realistic but unhappy appraisals of one's body, given the high social values placed on physical appearance. Dysmorphophobia may occur in the context of some personality disorders or as an isolated disorder called body dysmorphic disorder. In some ways, dysmorphophobia resembles an overvalued idea. Patients may develop dysmorphophobias in relation to any body part; common concerns are hair, breasts, penis size, the shape of the nose, or the shape of the entire body. For some, changing the body part, as in rhinoplasty for those who do not like their nose, seems to effect a lasting positive change in body image, with patients becoming happier with themselves and feeling more attractive for years or lifetimes. In severe dysmorphophobia, patients may undergo multiple plastic surgeries and feel dissatisfied with every result. At times, the condition forms part of a larger and more pervasive syndrome, such as anorexia nervosa.

An attractive 19-year-old woman was preoccupied and perplexed by the fact that she perceived her eyelids as being unequal in size and shape and by the fact that the cleft in her chin was too deep. She spent hours each day in front of the mirror, trying to pose in ways that, from her perspective, did not expose these facial blemishes. She sought consultation from a plastic surgeon, who referred her for psychiatric consultation. After 2 months of treatment with an SSRI, her preoccupations with appearance diminished considerably, and she was able to turn her attention to other issues in her life.

Hypochondriacal complaints also combine perceptual and ideational distortions. Selective hypervigilance to bodily sensations may result in a higher likelihood of perceptions of unpleasant and potentially pathologic body experiences among the "worried well," hypochondriacal populations, patients with somatization disorder (Briquet syndrome), and some patients with panic disorder.

Body image distortions may, at times, be severe or bizarre. Some psychotic patients, either with schizophrenia or depression, develop

Telegram: @medical_k

www.konkur.in

somatic delusions. In depression, this often expresses itself as a delusion that part of or the entire body is rotting or filled with cancer. Some culture-bound syndromes in non-Western cultures express themselves with body image distortions such as koro, in which the man fears that his penis is shrinking into his abdomen.

DISTURBANCES OF CONSCIOUSNESS

Consciousness can be defined as subjective awareness of the self and environment. Biologists increasingly believe that a continuum of consciousness exists, extending from lower animals through *Homo sapiens.* However, consciousness is subject to conflicting definitions and conceptualizations, and exactly where consciousness begins remains unclear. Philosophers agree that it is the subjectivity of experience, the so-called qualia of consciousness, that clearly distinguishes living consciousness from at least this generation's best versions of self-regulating automata, elegant computers, or robots. All current attempts to even approach an understanding of consciousness are very unsatisfying, and consciousness remains unexplained and as yet unexplainable from a scientific point of view. Consciousness has been viewed as an emergent property of complex biologic nervous systems, as a poorly understood general property of an even more mysterious and complex universe, or as a phenomenon to be understood only in religious and spiritual terms. One of the best analyses to date of possible relationships between the construction of a brain and the possibility of consciousness has been set forth by Gerald Edelman, who believes that reflective consciousness cannot occur until complex higher-order brain systems evolve whose major functions are to monitor the experiences, activities, and results of activities of those lower-order brain systems that deal directly with appraising and responding to the external and internal environments. Such higher-order metasystems require the presence of memory so that current and immediate impressions can be checked and compared against past experiences. These metasystems may use a variety of sensor mechanisms to detect and signal their sensations or perceptions of

Telegram: @medical_k

www.konkur.in

various events. Some of these sensors may correspond to feeling states, and some may correspond initially to preverbal thoughtlike mechanisms that contain the capacity to develop and recognize abstract categories and, ultimately, conceptual language-based thought.

Clinically, consciousness can be considered from both qualitative as well as quantitative viewpoints. Qualitatively, consciousness does not seem to be an all-or-none phenomenon. Rather, conscious experiences may gradually and physically shift in focus, intensity, and clarity; altered states of consciousness may occur in which some aspects of consciousness, such as sensation, perception, memory, orientation, and judgment, are enhanced or impaired relative to other aspects. Quantitatively, crude divisions can be made between states depending on the relative presence, impairment, or total absence of consciousness. Even within the single individual, consciousness is not a unitary phenomenon. Multiple streams of thought, operating at multiple levels of preconsciousnesses, appear to exist in all people almost all of the time, with various elements in these coexisting streams constantly shifting into higher or lower levels of conscious awareness. In pathologic states, even more remarkable properties of consciousness are seen, for example, the existence of coconsciousness in humans who have had commissurotomies and of seemingly multiple discrete consciousnesses in patients with dissociative identity disorders.

Experiments involving patients with commissurotomies of the corpus callosum have shown the existence of two virtually separate systems of consciousness that seem to operate side by side. For example, when in the course of an experiment, the picture of a nude woman was flashed only to the right brain (the left visual field) of a commissurotomized patient, the subject verbally denied being aware of anything unusual (i.e., the left brain—the verbal brain—was unaware). But, at the same time, he started to squirm and blush, blurting out, “Oh, you have some machine!” Similarly, when a cup was presented to the right brain (left visual field) only, the patient denied seeing anything (left brain was unaware, and language output of the left brain indicated no awareness), but he was able to

Telegram: @medical_k

www.konkur.in

pick out the cup from an assortment of objects with his left hand (right brain control). That literal splitting of verbal awareness from visual–spatial awareness in the brain produces behavior that is at least superficially similar to that of patients who deny being consciously upset by an event but who react with strong visceral responses. Although this formulation is simplistic, the separate consciousness for logical–verbal and for visual–spatial awareness demonstrated in split brain experiments may be crude analogs for more highly differentiated and discrete types of awareness and modes of information processing. Furthermore, the very fact that there are separate and, to some extent, competing modes of consciousness may increase the likelihood of psychological distress, because the various modes are capable of yielding internally conflicting views of reality.

Psychological and Physiologic Factors

In ordinary states of alert consciousness, individuals are able to deploy adequate amounts of attention to their surroundings and to reflective thought. Normal people vary enormously in their ability to pay careful attention in different settings without being distracted; individual variations may reflect temperamental and cognitive style differences as well as physiologic shifts within the individual. Many functions of attentive consciousness, including attention, planning, and the capacity to appropriately switch between mental tasks, the so-called distractor-resistant memory, have been linked to the activity of specific neurons in area 46 of the prefrontal cortex.

A sense of increased consciousness with heightened alertness, awareness, and sharper thinking may be experienced in states of highly aroused emotional states such as threat, sexual attraction, falling in love, or other high-stakes events such as hunting among primitives, sporting competitions, or performing in front of an important audience. High levels of arousal do not necessarily guarantee effective attention because optimal consciousness depends on optimal arousal. Too little arousal due to illness or fatigue may result in insufficient stimulation and mental lethargy,

Telegram: @medical_k

www.konkur.in

diminishing the sense of alertness and attentiveness, whereas too much arousal may result in hyperintense alertness but distractibility and scattered attention.

Consciousness involves, among other things, the experience of a continuous sense of self and of the environment, existing coherently in time and space. The experience of time and its passage may be altered by shifts in the level of awareness and by emotional states such as boredom, concentration, pain, and discomfort. The experience of time and space may be altered by hypnosis, marijuana, psychoactive and psychedelic drugs, and other events directly affecting brain physiology.

Disturbances of Orientation

Orientation refers to one's awareness of time, place, and person. Accurate orientation requires the integrity of attention, perception, memory, and ideation. Impairments occur primarily in organic mental disorders (i.e., structural and toxic metabolic brain abnormalities) and occasionally in dissociative and psychotic states.

A 75-year-old woman arrived at her primary care physician's clinic. She was recently diagnosed with Alzheimer dementia. The staff recognized her, and she was initially polite and calm with staff. However, the patient soon appeared confused and started getting irritable. She began asking the staff where she was, why she was at the clinic, and was adamant that she didn't have any appointment scheduled for that day.

Normal individuals vary tremendously in their attention to the details of time and in the extent to which their bodies automatically keep time. Some people have reliable built-in clocks by which they can awaken themselves at precise times or accurately gauge the passage of time with uncanny accuracy, even in the absence of external cues—in a psychotherapy session, for example. Others have difficulty making judgments about time and may develop

Telegram: @medical_k

www.konkur.in

pathologic lateness or habitually schedule more activities than could ever be accomplished in the available time. Poor time judgments may be seen in a variety of psychiatric disorders, such as ADHD, or as an independent problem. Benign disorientation to time is common. After a few days in a hospital bed, most people do not know exactly what the day or date is because they are not attending to or receiving their usual cues.

Pathologic time disorientation can be mild or severe, with inaccuracies of estimation ranging from days to years. The dates reported by disoriented individuals may have personal significance such as those of important births, marriages, or deaths.

Because spatial cues are generally more available and obvious than temporal cues, disorientation to place often signifies a greater degree of cognitive impairment than disorientation to time and, therefore, rarely occurs in the absence of time disorientation. Disoriented people may know, more or less, the type of place that they are in without knowing the specific place—patients may recognize that they are in a hospital without being able to name the hospital.

Disorientation to person, a lack of awareness of one's own identity, is typically seen only in advanced dementias such as primary degenerative dementia of the Alzheimer type or in dissociative states. In organically induced postconcussion amnesia, transient global amnesia, and, presumably, psychogenic fugue states, knowledge of one's own identity may disappear, and a person may remain unidentified for an indefinite period until the memory for self-returns.

Disturbances in the Level of Consciousness

Levels of consciousness (i.e., alertness, awareness, and attentiveness) may be pathologically increased or decreased. Such changes are diagnostically nonspecific and can occur in many different disorders. When levels of arousal and alertness are mildly elevated, as in hypomania or with the ingestion of small amounts of psychostimulants, subjective experiences are typically positive. In

Telegram: @medical_k

www.konkur.in

these situations, the person experiences intense alertness, prolonged concentrating ability, and hyperesthesias in which perceptual vividness is heightened: colors are brighter, sounds are sharper, and touch is more intense than usual. With further increases in arousal and consciousness as seen in mania, more severe intoxications with amphetamines and cocaine, and catatonic excitement, attention fragments. Heightened alertness transforms into hypervigilance and paranoia, and hyperesthesias become unpleasant.

Diminished levels of consciousness can be described on a continuum. Clouding of consciousness is marked by diminished awareness of sensory cues and diminished attentiveness to the environment and to the self. Secondary process thinking is most notably compromised, and more primary process thinking emerges into consciousness. In this state, one's ability to appreciate subtleties and to think in a nuanced manner is diminished and is replaced by more dichotomous all-or-none, stereotypical thinking. The level of consciousness may fluctuate rapidly in relation to the internal physiologic state or to the degree of external stimulation. In alterations of consciousness, confusion may occur with disorientation to time, place, or person. The patient is usually highly distractible and unable to pay sustained attention to a single stimulus.

Torpor is a condition in which the patient is drowsy, falls asleep easily, and shows a narrowed range of perception and slowed thinking. Stupor is a state of diminished consciousness in which the patient remains mute and still, although the eyes are open and may follow external objects. In the most extreme impairment of consciousness, coma, there is no evidence of mental activity at all. The patient essentially appears to be functioning on a decorticate or decerebrate level. In akinetic mutism, or coma vigil, patients with profound brainstem lesions appear to be awake with their eyes open, but there is in fact no evidence of consciousness. The commonly used Glasgow Coma Scale incorporates these dimensions.

Delirium, the acute confusional state, is usually characterized by a relatively abrupt onset and short duration of clouded, reduced, and

Telegram: @medical_k

www.konkur.in

fragmented attention; impaired memory and learning; perceptual and cognitive abnormalities, such as hallucinations and delusions; disrupted sleep; and other autonomic dysfunction. The level of consciousness may be consistently diminished or may fluctuate. The electroencephalogram (EEG) usually shows diffuse slowing. Typical motor abnormalities include an increase in general restlessness, fine and course tremors, and myoclonic jerks. Autonomic disturbances commonly include tachycardia, fever, elevated blood pressure, diaphoresis, and pupillary dilation. The causes of delirium are legion, including systemic medical disorders, such as metabolic imbalances or infections, intracranial disorders due to traumatic, structural, and electrical causes, and drug intoxication and withdrawal states.

A 45-year-old secretary was brought by ambulance as she appeared confused at work, trying to grab objects that were not there. Her coworkers reported that she has had problems with anxiety and was taking medications for that reason. In the emergency room, she continued to appear confused and reported that she had run out of alprazolam several days earlier. Review of the controlled substances prescription site confirmed that she had been receiving high doses of alprazolam on regular basis.

A 59-year-old truck driver at work collapsed while complaining of severe chest pain. He was rushed to the hospital, and it was determined that he needed emergency coronary bypass surgery. His surgery was successful, and he was slated for discharge the next morning. That night, the resident physician was urgently called to the floor by the nurse taking care of the patient, who stated that the patient was sweating profusely, confused, agitated, scratching his arms, and shouting that “spiders were crawling all over him.”

Telegram: @medical_k

www.konkur.in

Attentional difficulties are manifested by impairments in the person's ability to deploy, focus, and sustain attention. Some attentional difficulties first appear in early childhood as developmental problems of uncertain cause and are described as attention-deficit disorders (inattentive or hyperactive types). Secondary attention-deficit difficulties may appear de novo in adulthood due to a variety of exogenous agents, psychiatric disorders, and late-life developmental and degenerative factors.

In narcolepsy, characterized by sudden lapses into sleep, one's usual ability to stay alert and maintain consciousness is impaired. At times, the onset of profound sleepiness is gradual, accompanied by hypnagogic phenomena, in which dreamlike images invade consciousness, and at other times the shift in consciousness appears to be almost instantaneous.

A 24-year-old recently engaged woman presented with her fiancé for evaluation. Her fiancé reported that, while shopping for her engagement ring, she was very excited and had an "attack" of being weak in her knees and falling down which lasted almost 1 minute. She reported fully being aware of her surroundings and hearing the clerk and her fiancé calling her name. During the evaluation, she acknowledged significant daytime sleepiness and that her mother suffered from narcolepsy.

1Altered States of Consciousness

Consciousness may also be qualitatively changed, with the production of altered states. Drugs such as scopolamine, with strong central anticholinergic properties, some seizures, and, on occasion, other conditions associated with delirium can induce twilight states, dreamlike states of wakeful consciousness in which attention is poor, an admixture of primary and secondary process thinking appears, and patients fade in and out of alertness. Dreamlike experiences intrude into the stream of conversation. Emotional outbursts or violent acts may occur during twilight states.

Telegram: @medical_k

www.konkur.in

Mystical states of consciousness may occur in normal and pathologic conditions. Intense meditation and peak or epiphanic experiences, reported by more than 10% of normal individuals in community surveys, may produce a sense that the self dissolves or expands, that the self fuses mystically with the cosmos, that time stops, and that universal meaning becomes clear. These perceptions may be accompanied by a sense of rejuvenation and renewed personal identity, ineffability, intense emotionality, and concurrent perceptual changes. Such experiences do not ordinarily last more than a few minutes. Many people have achieved these states through the use of psychedelic agents such as mescaline and LSD. Reports of a white light at the end of a tunnel, described by individuals using psychedelics and in near-death experiences, have been linked to specific neurophysiologic pathways believed to be stimulated under these conditions.

A 43-year-old female accountant with no prior history of spiritual or religious practice sustained a severe head injury in an automobile accident that left her comatose for approximately 6 months. When she awoke, she reported that at some point during her coma, she estimated in the third month, she experienced a profound experience, which included a glorious union with God and knowing that she would only awaken to return to life. After recovery, she became profoundly spiritual, started attending church, reading the Bible, and demonstrated a beatific glow, which she attributed to the experience she had during the coma.

Although hypnosis lacks a consensually accepted definition, its hallmarks are selective attention, suggestibility, and dissociation. Most, but not all, people can be hypnotized to some degree. Up to 90% of people are capable of achieving a light trance, whereas 10% to 20% are capable of entering a deep trance and exhibiting remarkable hypnotic phenomena. Hypnosis occurs when the subject is in a state of heightened, not diminished, attention. EEG studies

Telegram: @medical_k

www.konkur.in

have shown hypnotized subjects to be fully awake and alert. The heightened concentration probably accounts for the unusual levels of sensory and motor performance often seen under hypnosis and self-hypnosis.

Hypnotic phenomena include hypnotically induced hallucinations (including negative hallucinations in which the subject selectively does not perceive sights, sounds, or other stimuli), anesthesia, sustained motor behaviors and acts of strength ordinarily beyond the individual's capacity, and distortions of memory (both hypermnesia and amnesia). Several phenomena that reveal the multiple nature of consciousness, for example, coconsciousness, are also demonstrable. Experiments have shown that even when a subject in deep trance has achieved profound hypnotic anesthesia and can, for example, keep a hand submerged in ice water for longer periods of time than usual, part of the hypnotized subject's consciousness continues to register exactly how painful the experience actually is and can signal the researcher about the pain, by finger movements, without the subject having any conscious awareness or disturbance. This phenomenon, called the hidden observer, has also been seen in postsurgical patients who, under hypnotic trance after surgery, have been able to accurately recall conversations in the operating room that occurred while they were under general anesthesia. Dissociative and psychosomatic phenomena have also been induced with hypnosis. With posthypnotic suggestion, for example, subjects may carry out complex actions without any hint that they are actually doing so because they were previously instructed to act that way under hypnosis. When asked why they are carrying out these activities, such subjects usually make up various reasons, although seemingly unaware of the real reasons for their actions. It has been suggested, not entirely facetiously, that many normal daily activities are conducted in a trancelike posthypnotic state, and although these activities are attributed to conscious intention, they may in fact be carried out due to previous suggestion. Advertisers know this well. Urticaria (hives) can be hypnotically induced and hypnotically made to disappear. Plantar warts have been successfully treated with hypnosis, and, in these conditions, diminished blood supplies to their

Telegram: @medical_k

www.konkur.in

bases have been demonstrated. It has recently been appreciated that yoga masters can exert remarkable control over basic bodily functions through self-hypnosis. As yet, little is known of the full extent to which heightened concentration may influence physiologic regulation.

Suggestibility

Pathologic suggestibility may be seen in several clinical conditions. Automatic obedience has been described in echolalia (the automatic repetition of a sentence or phrase just uttered by another person), echopraxia (the automatic mimicking of a movement performed by another person), and waxy flexibility (maintaining, for a prolonged period of time, a posture in which one is placed), symptoms common in catatonic states. In situations of group delusions, and sometimes in cults, passive individuals adopt the delusional beliefs of stronger ones. In epidemic hysteria, as described among young women at the Salem witch trials in Arthur Miller's *The Crucible,* distorted and even delusional perceptions and beliefs may sweep over a group that has been highly aroused by a charismatic leader.

Autosuggestibility can be seen in the constructions of false memories in which an individual progressively comes to believe that something that never happened in fact occurred. Such false memories may be held with such great conviction that they are indistinguishable from the memories of real events. Because of this, memories recovered during therapy (in which there is often great pressure to "remember" certain events) cannot be taken at face value without corroboration from other sources. Various types and degrees of self-deception may be more common in individuals who are more suggestible.

Dissociative Phenomena

Dissociation refers to the splitting off from one another of what are ordinarily closely connected behaviors, thoughts, or feelings. Dissociative states are those in which there is a disturbance or alteration in the normally integrated functions of identity, memory, or

Telegram: @medical_k

www.konkur.in

consciousness and include trances, fugues, blackouts, multiple personalities (dissociative identity disorder), and dissociative frenzies. Although dissociative states are ordinarily believed to be functional in nature, arising as an adaptive defense in individuals subjected to a great deal of trauma, particularly at early ages, they occur regularly with a variety of neurologic disorders, particularly those with partial complex seizures. In one series, one-third of patients with complex partial seizures had dissociative phenomena, including multiple personality. In these patients, the dissociative phenomena were not related to the seizure activity but to interictal alterations.

As in posthypnotic amnesia, elaborate activities can occur in dissociative states for which the subject has no conscious memory. This amnesia is functional in nature and may be reversed by hypnosis or drug-facilitated disinhibition, for example, with amobarbital (sodium amytal) infusion. In many of the functional dissociative states, amnestic episodes may occur for years or decades before the patient seeks medical or psychiatric attention. Blackouts are periods of amnesia in alcoholism, other intoxications, or after head trauma. An alcoholic blackout period may last for hours to days, after which the person has no recollection of what transpired, although other observers attest to the fact that, during this period, the individual carried out multiple complicated behaviors. Although memory of the blackout is lost to the predominant consciousness, during subsequent re-intoxication, memories of events occurring during the previous blackout may be reawakened. This phenomenon, known as state-dependent memory, occurs in many other conditions as well, signifying that one's ability to retrieve specific memories may be highly influenced by specific physiologic alterations due to external intoxicants or other unusual physiologic states.

Telegram: @medical_k

www.konkur.in

A 43-year-old man with a 20-year history of sustained alcohol abuse was unable, during a period of sobriety, to recall for hospital staff the names, phone numbers, and addresses of his close friends and associates. Several weeks later, when he returned to the emergency department in an intoxicated state, he was able to recall all of those details in a reasonably straightforward manner.

Psychogenic fugue is characterized by prolonged periods in which individuals carry out very complex activities without having any recollection for their previous lives, identities, or even names. They often travel away from customary locales and assume entirely new identities. By definition, psychogenic fugue cannot be due to a neurologic disorder. In comparison, the discontinuity of experience in psychogenic amnesia is typically more circumscribed and does not involve assuming an entirely new identity. The dissociated memories and affects often reveal themselves in disguised form such as nightmares, intrusive visual images, and conversion symptoms. Typically, in psychogenic amnesia, an individual may not be able to recollect what transpired during a specific period, for example, before the age of 9 or 10 years in the context of a traumatic childhood; during catastrophic events, such as traumatic, gruesome combat; or during less momentous events that a person prefers to forget to preserve self-esteem by denying shameful, immoral, or illegal activities.

Telegram: @medical_k

www.konkur.in

A 28-year-old infantryman could not recollect the events of the combat situation in which he had been wounded and several of his comrades killed. Several months afterward, he participated in a series of amobarbital-facilitated interviews, during which the events of combat came back to him. He recalled becoming panicky during the firefight, turning, and running away while several other soldiers in his squad, some of whom were killed, yelled to try to get him to stay in place and fight. After the interviews, he cried inconsolably and blamed himself, somewhat irrationally, for their deaths, wondering if his remaining in place and fighting might have saved their lives.

Dissociative Identity Disorder. Dissociative identity disorder, previously known as multiple personality disorder, is a chronic dissociative state in which two or more separate ongoing identities or personalities alternative in consciousness. It usually occurs in people who, as young children, were severely and repeatedly brutalized. The number of identities is variable, with some cases reporting 25 or more identities. The development of dissociated alter personalities is believed to be a last-ditch, primitive psychological defense against inescapable and unbearable traumatic situations. The personalities may be of different ages and even different sexes. Typically, the presenting identity is dysphoric, anxious, and constricted, may have headaches and periods of blackout or amnesia, and is not aware of the other personalities. A second identity is typically vivacious and uninhibited.

Telegram: @medical_k

www.konkur.in

A 34-year-old female had recently moved to a new city to start a new job. She presented for an intake for chronic depression and anxiety. She was meticulously groomed, seemed shy and soft-spoken, and was wearing very conservative clothing. During the interview, she suddenly became labile, angry, and loudly said, “Stop talking like that.” Then, shortly, she quietly put both her feet on the couch, and started rocking back and forth, speaking in a childlike voice.

Another identity may know all about the other personalities and has a wise perspective on the life events leading to the problems and of possible solutions. A classic case is described in the popular book and film, *The Three Faces of Eve.*

In the so-called channeling, dissociated, complex part personalities are produced in trance states in which fictitious past lives or spirit lives are created.

Ganser Syndrome. In Ganser syndrome, the patient responds to questions by giving approximate or patently ridiculous answers; for example, in response to the question, “What sound does a dog make?” the patient answers, “Moo.” Additional features of the syndrome include alterations in consciousness, hallucinations (or pseudohallucinations), conversion phenomena, and amnesia for the episode during which these symptoms are manifested. This syndrome has most commonly been reported in prisoners and is generally believed to be a dissociative state, although organic features may be contributing factors.

Telegram: @medical_k

www.konkur.in

A 23-year-old man was arrested for auto theft. He had a long history of brushes with the law, including the juvenile justice system, for fire-setting, shoplifting, and physical fights. While in jail, he stated he was confused, could not remember what led to his arrest, appeared distracted at times, pleasant and smiling at other times, and would answer simple questions such as 1 + 1 as equal to 3.

Depersonalization and Derealization. Depersonalization refers to an alteration in one's experience and awareness of the self, leading to feelings of being unreal or detached from one's own body or of feeling like an automaton; it is often accompanied by the complaint that the individual lacks all feelings or sensory experiences. Those experiencing depersonalization frequently fear that they are going crazy. Because of this fear, patients often endure depersonalization experiences for long periods before describing them to a mental health professional. Depersonalization is also characterized by frequent internal nonaudible dialogues between the participating self and the observing self but with full awareness that both parties are the same person (a feature that distinguishes it from hallucinations). Mild sensory distortions—but not hallucinations—are commonly associated with the experience. Depersonalization is seen in a variety of neurologic and psychiatric disorders and is common in complex partial seizures. It may occur in the context of depression, anxiety disorders, or certain personality disorders, or it may occur as an entity by itself. In derealization, individuals feel themselves to be real but feel that the world around them has suddenly become unreal. Derealization often, but not always, accompanies depersonalization. Transient episodes of depersonalization and derealization occur frequently in normal people, particularly during states of fatigue, sleep deprivation, or stressful situations such as bereavement, learning of a terminal diagnosis, or sudden awareness that one is about to be in an inescapable vehicle collision.

Telegram: @medical_k

www.konkur.in

A 42-year-old school bus driver was unable to see a large object in the road in a severe thunderstorm and had an unavoidable collision. Although she was able to swerve the school bus at the last minute, the bus sideswiped a vehicle before coming to a screeching halt. When the police arrived, she could only say that she felt that she was “floating outside her body” and that the “world did not seem real.”

DISTURBANCES OF THE SELF

At the most basic level, the key components of self-awareness are the reality and integrity of the self (that I am one person), the continuity of self (that I am the same person now that I was in the past and that I will be in the future), the boundaries of self (that I can distinguish between myself and the rest of the world as not-self), and activity of self (that it is I who is thinking, doing, and feeling). Additional components of a sense of self include body image and various self-evaluations, including self-esteem and ego-ideal (ideal self). Body image is an individual’s mental representation of their own body. Self-esteem is believed to reflect how one measures up to the desired self-image. To the extent that what one sees in oneself approximates what one would like to be, self-esteem is positive. Ego-ideals are fantasies of the optimum person one could ever wish to be. Any of these qualities may be disturbed in psychiatric disorders.

Within each individual is a group of social selves comprised of the roles and identities that a person assumes and that are evoked in various contexts. The presenting “self” varies depending on the people with whom one interacts, such as parents, romantic partner, child, friend, or employer, and depending on what role one assumes, such as child, parent, colleague, or lover. Accompanying each of these “selves” are various levels of objective and subjective self-awareness and self-understanding.

Telegram: @medical_k

www.konkur.in

Disturbances in Sense of Self

Disturbances of the basic elements of self-awareness may be seen in a variety of disorders. Discontinuity phenomena are characteristic of dissociative states such as psychogenic amnesias and psychogenic fugue. Depersonalization reflects a mild disturbance in the awareness of self as the agent of activity. More severe disturbance is characteristic of the psychotic passivity phenomena seen in schizophrenia. Boundary disturbances may be considered characteristic of all psychotic states regardless of diagnosis.

Disorders of self-integrity are characteristic of both dissociative identity disorders and severe borderline personality disorders in which a person's self-concept and expression of this concept to others is erratic, leading to a sense of unstable identity.

False self describes a persona or a faulty and limited superficial aspect of the personality that an individual builds up as a mechanism for adapting to a hostile world—to please, control, or negotiate with others and with him- or herself. However, the false self does not incorporate, integrate, or validate important fundamental needs, wants, values, and beliefs. Through self-deception and denial, the individual may consciously believe that this "self" constitutes their entire being. However, the false self is a relatively fragile construction that has usually warded off and denied fundamental strivings, which may include needs for autonomy; acting with integrity; expressing certain desires, beliefs, or talents; or other unacknowledged aspects of the self. When these warded-off needs finally break through and demand expression at various points in development, the defective false self may collapse, leading to a period of distress and identity confusion, which individuals sometimes describe as a "nervous breakdown."

Patients with pseudologia fantastica and the impostor syndrome demonstrate extreme examples of inconsistency in the sense of self. In pseudologia fantastica, patients compulsively spin out webs of lies, ordinarily self-aggrandizing ones, and also appear to be trying very hard to deceive themselves into believing that they are true. In the impostor syndrome, such fantasies are acted out by liars and

Telegram: @medical_k

www.konkur.in

impostors who seem to fervently wish that these fantasies were their reality, as if they cannot accept themselves and would be overwhelmingly ashamed to be known for who they actually are. The impostor compulsively adopts the identities of others and may, for example, show up properly attired at diplomatic functions and society galas and interact with the other guests under the assumed identity. Some famous impostors have repeatedly insinuated themselves into inner circles of high society and government.

Transsexualism is a syndrome characterized by the feeling that one was born into a body of the wrong sex and marked by the desire, starting at an early age, to be a person of the opposite sex. Male to female transsexualism is reported most often. Both psychodynamic and biologic theories have been advanced to explain these unusual phenomena. Of note, studies following patients who undergo successful male to female transgender surgery have not revealed higher rates of associated psychopathology than in comparison groups.

Self-esteem is a measure of one's self-appraisal in relation to one's values and ego-ideals. Negative self-esteem is characteristic of depressive disorders, many personality disorders, and situational failures. Superficially inflated self-esteem may be seen in mania (or hypomania) or, in a fluctuating manner, with narcissistic and other personality disorders.

Although some individuals regard their ego-ideals as unattainable and are content to live as imperfect human beings, others strive to approximate their ideals. People who feel driven to achieve unattainable ideal goals or to become unrealistically perfect ideal selves are likely to be chronically dysphoric and have poor self-esteem because their attempts to become their ego-ideals are doomed to failure.

DISTURBANCES OF MEMORY

Memory is not a unitary phenomenon. Capacities to remember vary for the different senses and perceptions. One person may have prodigious musical memory, with the capacity to remember and

Telegram: @medical_k

www.konkur.in

reproduce whole musical pieces after one hearing but be incapable of remembering people's names or telephone numbers. Exceptionally detailed verbal memories have been associated with obsessional cognitive styles. When individuals with extraordinary memories complain of memory loss, ordinary memory tests may be inadequate to detect their deficits, as their relative memory loss may have reduced their capacities to a point within the range of most normal people.

Memory functions have been divided into three stages: registration, retention, and recall. Registration (or acquisition) refers to the capacity to add new material to memory. The material may be sensory, perceptual, or conceptual and may come from the environment or from within the person. For new material to be acquired, the person must attend to the information presented, and it must then be registered through the appropriate sensory channels and then be processed or cortically organized. Retention is the ability to hold memories in storage. Large numbers of neurons are believed to be involved in the storage of a specific memory, and it is believed that reverberating circuits are formed in which memory traces are held by means of changes in proteins or synaptic connectivity, or both. Recall is the capacity to return previously stored memories to consciousness.

Newly registered material is transferred incrementally from immediate to short-term memory to long-term memory. Immediate memory lasts for 15 to 20 seconds, short-term memory (or recent memory) for several minutes up to 2 days (the time involved in new learning and its early consolidation), and long-term (or remote) memory for longer periods. Different physiologic processes mediate each of these stages of memory. Because of this, processes that affect immediate or short-term memory often spare long-term memory. The processes by which memories are transferred from short- to long-term stores are unknown.

Cognitive scientists now refer to short-term memory as working memory, the system that briefly stores and processes information needed for planning and reasoning. Recent studies suggest that the working memory system consists of at least two short-term memory

Telegram: @medical_k

www.konkur.in

buffers, one for verbal and another for visual memories, plus a central executive that manipulates and coordinates information stored in the two buffers for problem solving, planning, and organizing activities. Parallel processing systems involving specific areas of the prefrontal cortex and other brain areas appear to operate separately with respect to various processes concerned with working memory. For example, separate prefrontal areas appear to be involved in working memory functions concerned with object identity and spatial locations.

Other studies suggest that different types of memories are stored and retrieved by different brain systems, so there is at least a dual memory system. The first system, sometimes called a conditioned-emotional system, system for implicit memory, perceptual memory, or nondeclarative memory, is present from birth, operational through life, and addressable by situational, sensory, or affective cues. Past experiences are expressed through images, behaviors, or emotions. These memories need not involve any conscious memories of a past experience. Conditioned fear responses represent examples of memories elicited in this system. The second system, sometimes called narrative–biographical memory, or explicit memory, reflective memory, or declarative memory, emerges during the preschool years and includes information significant to the self. Memories are addressable through intentional retrieval efforts, apart from the original learning conditions. They are identified as representing personally experienced events and compose the individual's life history, approximately equivalent to memory with consciousness or memory with awareness. Clinical studies suggest that, in at least some amnesias, implicit and explicit memory functions may be dissociated.

Disturbances in memory occur through the interruption of registration, retention, or recall.

Disturbances in Registration

Registration and short-term memory retention are usually impaired in disorders that affect vigilance and attention, such as head trauma,

Telegram: @medical_k

www.konkur.in

delirium, intoxication, psychosis, spontaneous or induced seizures, anxiety, depression, and fatigue. A variety of other metabolic and structural brain disturbances can affect short-term memory as well, particularly lesions affecting the mammillary bodies, hippocampus, fornix, and closely associated areas. Patients with impaired attention and concentration who are able to demonstrate immediate recall may not be able to retain or recollect these items from short-term memory. Benzodiazepine use has been associated with working memory difficulties, especially in the older adults. Some short-acting, high-potency benzodiazepines used as sleeping pills may be particularly troublesome in this regard.

Disturbances in Retention

The retention of memories is impaired in posttraumatic amnesia as well as in a number of cognitive disorders, such as dementia of the Alzheimer type and Wernicke–Korsakoff syndrome. The latter, which ordinarily results from chronic thiamine deficiency seen with alcoholism, is associated with pathologic alterations in the mammillary bodies and thalamus.

Disturbances in Recall

Disturbances in recall can occur even when memories have been registered and are in storage. At times, inability to recall may signify that the memory traces themselves have disappeared and are no longer retrievable. However, difficulties in recall can occur separately, as in the everyday event of forgetting the name of a person or object, only to spontaneously remember it hours or days later. In normal forgetting, more remote events are less well remembered than recent ones, and important events are most vividly retained in memory. Some demented patients may lose memories for all events occurring after a specific date or event, as if the slate has been wiped clean, but retain earlier memories. Some individuals may progressively erase memories so that they recall only earlier and earlier events. Specific types of memory functions may be subject to selectively different control mechanisms in the brain. For example,

Telegram: @medical_k

www.konkur.in

recent animal research suggests that endocannabinoids may facilitate the extinction of aversive memories, but not their acquisition or consolidation, through their selective inhibitory effects on local inhibitory networks in the amygdala.

A 21-year-old pregnant woman experiences severe PTSD symptoms related to the trauma of witnessing the father of her baby commit suicide in front of her by shooting himself. She has been self-medicating with two bottles of wine daily, combined with “handlebars” (benzodiazepine bars), which she reports allow her to “forget” and not dwell on the past while getting about her usual day-to-day responsibilities.

Under usual conditions, forgotten events can be recalled with prompting, associative memories, or other forms of stimulation such as hypnosis. As described earlier, state-dependent memories are recall failures, reversed by reinstituting the context in which the memory was originally formed.

Amnesias are syndromes in which short- and long-term memory are impaired within a state of normal consciousness. Thus, memory disturbances in delirium should, strictly speaking, not be considered amnestic syndromes. Anterograde amnesia is the inability to register or learn new information (and therefore to form new memories) from a specific event onward; it typically follows head trauma, states of cerebral physiologic imbalance, or drug effects. Patients who receive electroconvulsive therapy (ECT) frequently have anterograde amnesias during the course of the treatments; the amnesia gradually fades over numbers of weeks. Retrograde amnesia is an impairment in recalling memories that were established before a traumatic event, extending backward in time for variable periods. As memory is regained, the more remote memories usually return first. A patient originally amnestic for the 3-month period before an accident may ultimately be left with amnesia for events only a day or an hour just before the accident. In organically caused retrograde amnesias, remote memories are usually intact, although amnesia may exist for

Telegram: @medical_k

www.konkur.in

more recent events. This contrasts with psychogenic (functional) amnesia, in which the periods of forgotten events may be more spotty or selective.

Hypermnesia, unusually detailed and vivid memory, may occur in gifted people, in association with obsessive-compulsive and paranoid personality traits, and in hypnotic trances. Intrusive memories may occur in PTSD, signaling failure of the mechanisms that usually keep unwanted memories and information out of working memory.

A 28-year-old firefighter and his partner were the first to respond to a five-alarm fire at a popular local business. The firefighters were valiant in their efforts, however, one employee and the firefighter's partner perished. Immediately thereafter, the firefighter reported inability to fall asleep, vivid dreams of the event, sweating, feeling his heart beating fast, smelling smoke, and hearing his partner's voice calling for help.

Although many forgotten memories can be recalled in hypnotic trance, retrospective falsification and distortion may also occur under hypnosis. (Memories recalled under hypnosis usually are not accepted as evidence in court.) Retrospective falsification of memory, the development of false memories, is called paramnesia, also known as *fausse reconnaissance.* Confabulation is another common form of paramnesia in which the patient fills in memory gaps with inaccurate information. The responses given to questions by patients who confabulate may reflect past experiences or bizarre, fantastic stories. Confabulation correlates poorly with memory deficit and is believed to reflect frontal lobe dysfunction and a failure of self-monitoring. Confabulation is prominent in certain alcohol amnestic syndromes, such as Wernicke–Korsakoff syndrome, as well as other disorders of the mammillary bodies, thalamus, or frontal lobes.

Déjà vu is the sense that one has previously seen or experienced what is transpiring for the first time; it is a false impression that the current stream of consciousness has previously been recorded in

Telegram: @medical_k

www.konkur.in

memory. Related phenomena are *déjà entendu,* a sense that one has previously heard what is actually being heard for the first time, and *déjà pensé,* a feeling that one has at an earlier time known or understood what is being thought for the first time. Experiences of *jamais vu, jamais entendu,* and *jamais pensé* involve feelings that one has never seen, heard, or thought (respectively) things that, in fact, one has. These phenomena are all common in everyday life but may increase in states of fatigue or intoxication and in association with complex partial seizures or other psychopathological states.

A 28-year-old music teacher drove 12 hours with minimal breaks in order to attend a music festival for the first time. Upon entering the music hall, he reported suddenly feeling sure that he has been to this music hall before, sat in the same seat, and listened to the same music.

Dementia is a syndrome in which the essential feature is an acquired impairment of short- and long-term memory with associated impairments of abstract thinking, judgment, personality changes, and other cortical disturbances. The symptoms always involve more than one sphere of function. In later stages, demented patients may become helpless, too confused to use a stove, and incapable of remembering the names of close relatives. They may wander into dangerous situations, oblivious of their surroundings. Dementias are caused by a variety of pathogenic processes, some of which are reversible, such as hypothyroidism and subdural hematoma, whereas others are irreversible, such as dementia of the Alzheimer type and multi-infarct dementia. Although the characteristic cognitive disturbances seen in severe major depressive episodes are usually called pseudodementias, many neuropsychiatrists believe that profound cognitive dysfunction meeting criteria for dementia associated with depression should properly be labeled as a reversible dementia syndrome. The presence of pseudodementia, however, is predictive of the development of Alzheimer disease (but not in all cases), indicating that the depression was a prodrome of

Telegram: @medical_k

www.konkur.in

the primary cognitive disorder or that the presence of pseudodementia marks those with an underlying progressive cognitive disorder.

LANGUAGE DISORDERS

Communication difficulties may be due to disorders of thinking as previously described, abnormal speech patterns in mood disturbances and schizophrenia, or primary speech fluency disorders, such as stuttering and stammering, disorders of the articulation and speech apparatus, and CNS disturbances involved in hearing and speech generation (aphasias).

Manic patients typically exhibit pressured speech, in which the speed of the word stream is accelerated. If severe, then the speech may be garbled, imprecise, and difficult to understand. Patients with psychomotor retardation speak slowly and monotonously and have a long speech latency in response to questions. Schizophrenic patients may exhibit a variety of speech abnormalities, including poverty of speech and poverty of content of speech (in which the amount of speaking is normal, but understanding the central message is difficult or impossible). Schizophrenic patients may also be difficult to understand because of the dysarthric effect of antipsychotic medication.

Allusory speech is vague, imprecise, and hard to comprehend because too few cues and details are provided for the listener. Such speech may be heard from some patients with schizophrenia or certain personality disorders, or even normal individuals who wish to convey a sense of mystery by just being suggestive, whose suspiciousness causes them to be reluctant to spell things out clearly, or who believe that the listener is more aware of their private codes, meanings, and allusions than is the case.

Stuttering and stammering (ordinarily synonymous) refer to disturbances in the rhythm and fluency of speech due to blocking, convulsive repetition, or prolongation of sounds. This disorder affects males two to three times as often as females, and there is a high rate of familial transmission.

Telegram: @medical_k

www.konkur.in

Aphasias, impairments of language produced by brain dysfunction, are ordinarily described as being fluent and nonfluent. In fluent aphasias, which generally reflect dysfunction in the left temporal and parietal area, patients have a normal or even elevated verbal output, sometimes with logorrhea, but they ignore the social conventions of conversation. They produce many well-articulated phrases with normal prosody, but there is little informational content. The fluent aphasias are further divided according to the extent of comprehension by the patient and the ability of the patient to repeat what the examiner says. The principal fluent aphasias are Wernicke's aphasia, conduction aphasia, anomic aphasia, and transcortical sensory aphasia.

Nonfluent aphasias are characterized by slow and poor verbal output, difficulty with spontaneous speech, omission of grammatical connecting words, and poor prosody. Patients may produce one-word replies or very short phrases. Brain lesions that cause nonfluent aphasias typically tend to occur in the anterior left hemisphere. The principal nonfluent aphasias are Broca's aphasia, transcortical motor aphasia, global aphasia, and the mixed transcortical aphasias.

In aprosodias, the nonverbal aspects of speech, the melody, pauses, timing, stress, accent, and intonation are impaired. Damage to the right prefrontal region has been associated with expressive aprosodias, and damage to the right temporal region and insula has been associated with receptive aprosodias.

DISORDERS OF THE WILL

Central to the sense of self is the concept of will or volition. Psychologically, will is linked to the concepts of intentionality and of transforming awareness and knowledge into initiating action, as the bridge between desire and action. For individuals to manifest normal will, they must be aware and feel desires—and these desires must arise from within themselves. Concepts related to will that may become the focus of clinical attention when disturbed include motivation and decision making (i.e., the capacity to make choices).

Telegram: @medical_k

www.konkur.in

Pathologically heightened will, seen primarily in manic states, is characterized by excessively intense desires and an overly facile capacity to make decisions, with complex questions being decided on in an instant. With heightened psychological energy, these individuals can start new courses of action with astonishing rapidity. Closer examination of these actions in more extreme cases, however, reveals that they share much in common with decreased will in that the intense desires and quick decisions often reflect impulsiveness, which can be considered an escape from true willing and decision making, rather than enduring desires or thoughtful decision making.

The term abulia has been used to describe the loss, lack, or impairment of the power to will or to execute what is in mind. Abulic individuals show a diminished sense of motive or desire and impairment in making the transition from motive and desire to execution of action. Deficiencies in will may be seen in a variety of psychiatric disorders and at the end of life, when patients have surrendered their will to live and are simply waiting to die. In schizophrenia, a diminished sense of will can be seen in passivity phenomena, as well as in other negative (or deficit) symptoms that may affect thoughts, feelings, and behaviors. These include lack of drive, impersistence at tasks, and a general inner flatness. Depressed patients also describe volitional disturbances in general apathy and anhedonia. Patients who chronically inhale solvents (e.g., glue, gasoline, or toluene), smoke marijuana very heavily, and chronically use hallucinogens have a characteristic amotivational syndrome. The extent to which this lack of motivation results from or contributes to the chronic substance abuse is a matter of debate.

In OCD, both the obsessional thoughts and the compulsive rituals are experienced as ego dystonic and not consonant with the patient's conscious desires and will. Similarly, although patients with anorexia nervosa initially have the conscious experience of willing and controlling their intake of food, during the course of the disorder the sense of willfulness is replaced by one of passivity of being subjugated by obsessional thoughts and compulsive behaviors that assume control of the eating behavior.

Telegram: @medical_k

www.konkur.in

A 28-year-old woman with anorexia nervosa and OCD reports struggling with grocery shopping, which routinely takes her 4 to 5 hours to complete. She reports that she feels compelled to research each item, particularly the fat and sugar content. She has a “calorie calculator” running in her mind, and for each item she purchases, she feels pressure to determine what else she will eat with it so that she does not exceed her calorie limit for each meal. She reports intrusive thoughts that she is fat and needs to keep counting her daily caloric intake. These intrusive thoughts are experienced in parallel to but separate from any other thinking activities in which she happened to be engaged.

Disturbances of volition are among the more common complaints of patients with personality disturbances who request psychotherapy. Individuals with dependent personalities are characterized by difficulties in making decisions by themselves and often engage in courses of action contrary to their own desires. Similarly, individuals with passive–aggressive personalities obscure their own desires by being excessively involved in the demands made on them by others. Their courses of action do not reflect their own decisions so much as the thwarting of others’ desires. People with compulsive personalities use inflexible rules, thereby precluding courses of action based on independent evaluation, individual desires, and decisions. In other situations, they are indecisive, sometimes making impulsive decisions at the last minute when forced to decide. Finally, many individuals seek treatment because of self-designated disturbances of will: they do not know what they want, cannot make choices among several options, or procrastinate excessively. Often, these problems may mask other fears—of wanting, commitment, taking initiative, hard work, success, making a mistake, being criticized, angering others, and all the consequences related to such actions.

DISTURBANCES OF MOOD

Telegram: @medical_k

www.konkur.in

Defining, describing, understanding, and categorizing moods have long been among the most important and difficult tasks in psychiatry. The language of feelings is filled with terms that seem to have mostly idiosyncratic meanings, as patients, phenomenologists, and psychiatrists all struggle both to describe inner emotions and to correlate them with external behavior. Even basic terms, such as mood, affect, emotion, and feelings, lack universal definition. The most common convention, which is used here, defines mood as a sustained or prevailing subjective feeling tone or range of tones. Affect is the moment-to-moment feeling state, sometimes rapidly shifting in response to a variety of thoughts and situations, that the clinician can observe. Emotions have been defined as moods and affects that are connected to specific ideas or to the physical concomitants of moods and affects. Feelings are the most poorly defined of all, leading Karl Jaspers to ultimately describe them as everything for which there is no other name. In common parlance, and often professionally as well, these words are sometimes used interchangeably. The term mood disorders, adopted for the DSM-III-R and DSM-IV-TR, replaced “affective disorders” to describe the same group of psychiatric syndromes, and in DSM-5 it has been sub-divided into bipolar and related disorders and depressive disorders.

Moods, affects, and emotions can be described by a number of important qualities: intensity (shallow to deep), range (broad to narrow [or flat]), stability (rigid to labile), reactivity to external events (none too much), periodicity (periodic to aperiodic), congruence with thought content (congruent [or appropriate] to incongruent), speed of resolution (rapid to slow), and viscosity (evanescent to persistent). The individual’s lifelong predominant mood is one component of temperament. Thus, for example, one may be described as having a calm, buoyant, irritable, depressive, anxious, or sensitive temperament.

Moods, affects, and emotions serve as internal and external signal systems. They signal the state of the individual to others and often elicit necessary help and support from the environment. A baby’s face communicates its state of need, tension, or contentment,

Telegram: @medical_k

www.konkur.in

thereby recruiting appropriate maternal interventions. As adults, much of the most important interpersonal communications are transmitted nonverbally through cues that signal the observer about our moods. Positive words communicated by a scowling or sullen face lead listeners to perceive an angry message regardless of the spoken words. Moods also have an infectious quality and serve as important ways of influencing others. Thus, when people act cheerfully toward others, they, in turn, are more likely to feel cheerful and to reciprocate that cheerfulness.

Internally, moods, affects, and emotions let individuals know how well or how poorly they are doing, allowing them, for instance, to gauge the distance between actual self-appraisal and desired self-expectations. For example, individuals who desire to master important goals and feel that they have a reasonably good chance of doing so ordinarily experience pleasant emotional states in relation to these goals. If something intervenes to prevent them from reaching these goals so that there is an insurmountable gap between their desires and the likelihood of success, then they may feel hopeless. In addition to serving as signal systems, emotional states of nonspecific tension, arousal, or anger usually imply that some action is necessary to secure their discharge or release.

Emotional states and their expression are regulated by biologic, psychological, and cultural influences. For example, emotional or affective lability, characterized by rapidly shifting emotions that seem unattached to the situation, typically occurs premenstrually in some women, with varying periodicity in cyclothymic individuals and in those with cluster B personality disorders, and in relation to need states such as hunger, sleep deprivation, and sexual frustration. Mood shifts have also been described with environment-related physiologic influences such as seasonal changes in light. Psychological regulation of emotions may be related to specific coping mechanisms and the ability to self-soothe, which are developmentally determined. Conscious and preconscious psychological mechanisms, including varieties of self-talk, may help calm or inflame emotions. Cultural factors significantly regulate emotional expression. Although the facial expressions for basic

Telegram: @medical_k

www.konkur.in

emotions are similar in all cultures studied, the range and style of emotional expression permitted in relation to specific contexts varies greatly from culture to culture and from family to family. Some cultures and families are stiff lipped and inhibit the open expression of emotion, whereas others encourage emotional display. Marked differences exist among cultures in the emotional expression of acute grief, fear, pain, and affection.

Depression

The term depression has been used variously to describe an emotional state, a syndrome, and a group of specific disorders. When seen as part of a syndrome or disorder, depression has autonomic, visceral, emotional, perceptual, cognitive, and behavioral manifestations. As a nonpathologic, ubiquitous mood state lasting hours to days, but sometimes longer, feelings of depression are synonymous with feeling sad, blue, down in the dumps, unhappy, and miserable. Depressed mood is common and appropriate after a disappointment or loss. For most people, innate psychological resilience, alternative coping options, and supportive social networks help to alleviate these brief depressive states and prevent them from becoming chronic. Some individuals have a chronically depressed mood, tend to view the world as a difficult place filled with obstacles and burdens, see themselves as victimized, and lack hope for the future. The extent to which constitutional, developmental, and ongoing aversive life events contribute to this pervasive world view is unknown. People who, in early life, were deprived and traumatized may be less resilient and more prone to chronic depressive features than others. Repeated failures and the impact of unrelenting, uncontrollable, and unpredictable negative life events may set the stage for learned helplessness in humans just as they do in animals. A subset of chronically depressed individuals may also have temperamental, biologically driven depression, often seen in conjunction with strong genetic loading for severe mood disorders.

Some depressive states are normal and common reactions to major unwelcome and undesirable life events. Normal bereavement

Telegram: @medical_k

www.konkur.in

best exemplifies this. In bereavement after major losses, such as the death of a parent, spouse, or child, people experience sadness, pining, and yearning but do not ordinarily have the feelings of guilt, unworthiness, and self-reproach that characterize depressive disorders. Feelings of helplessness and hopelessness may be temporarily present in bereavement, but they ordinarily pass with time. In uncomplicated cases, the process of bereavement takes 3 to 6 months in the acute phase and up to 1 year for complete resolution. Bereaved people are more likely to feel physically ill and seek general health care than at other times, and older widowers are more likely to die than age-matched nonbereaved controls. Pathologic or prolonged grief reactions, such as bereavements that last more than 1 year, may be seen when the surviving spouse was excessively dependent on the deceased and is unable to obtain emotional and practical (e.g., financial) support elsewhere or when the survivor is unable to grieve fully because of markedly ambivalent feelings toward the deceased. Distinguishing between pathologic or prolonged grief and grief triggering a depressive episode may not always be possible.

A 33-year-old woman was referred for a psychiatric evaluation by her primary care provider after losing her baby a few hours after birth secondary to anencephaly. The patient reported that she is struggling with low energy, guilt, low appetite, sleep problems, and difficulty concentrating. Her family reports that she has made statements that she wants to join her baby in death as she has no other purpose to live.

Telegram: @medical_k

www.konkur.in

A 52-year-old Hispanic woman was referred to see a psychiatrist by her longstanding family physician who had been treating her for multiple medical problems. Eight months ago, her husband of approximately 25 years passed away after a lengthy illness. She subsequently moved to a different town to live with her daughter and her family. The family became increasingly concerned that she had lost 30 lb, was withdrawn, and was continuously chanting on her rosary beads and “begging to die” in order to join her husband in heaven and take care of him.

The inadequate expression of grief due to incomplete bereavement is believed to be pathogenic in many subsequent psychiatric disorders. For example, impulsive acting out among adolescents who previously lost a parent is often assumed to be due to unresolved grief.

A variety of medical disorders may cause depressive syndromes. Most common among these are endocrine abnormalities, such as hypothyroidism and hyperparathyroidism, and CNS disorders, such as cerebrovascular diseases and Parkinson’s disease. Depressions are more common in strokes affecting left anterior lesions than other locations. Some medications, especially antihypertensive agents affecting adrenergic tone, such as reserpine and possibly β-blockers, may also trigger depressions. The importance of a genetic diathesis in these iatrogenic depressions is not yet known. Depressive syndromes and disorders in general, however, are unquestionably familial and are likely to have genetic contributions, especially in depressions associated with bipolar disorder.

Cognitive features of depression are prominent. Characterizing the exact nature of the memory impairment using standardized tests has been difficult. The cognitive tasks requiring sustained effort and elaborate cognitive processing may be more disrupted in depression than are those tasks that can be accomplished more automatically. The so-called cognitive triad of depression consists of pervasive cognitive schema related to feelings of worthlessness, helplessness,

Telegram: @medical_k

www.konkur.in

and hopelessness—expectations that no one and nothing can, or is likely to, help, either now or in the future; in other words, “I’m not OK, the world is not OK, and it’s never going to get any better.”

Suicidal phenomena are of particular concern. Suicide is common in severe depressive disorders. Depressed patients compose the largest diagnostic group of all completed suicides. However, suicide occurs at high rates in many other conditions as well, notably substance use disorders, schizophrenia, and severe personality disorders. Suicide may occur in these conditions with or without a diagnosable comorbid depressive disorder. Depressed patients with comorbid alcohol use disorder may be at particularly high risk for suicide.

Although consistent, useful, validated predictors of suicide do not exist, certain demographic features are associated with higher risk. These include being white, male, and older and living alone. In the psychiatric history, the single most important factor is that of past suicide attempts. A history of violent behavior may also predict suicide. Murderers have a very high suicide rate, especially those who murder family members during episodes of domestic violence. Among clinical signs, hopelessness, anhedonia, and severe anxiety may predict increased suicide risk. Serious physical illness in association with other risk factors, such as depression, may place a patient at higher risk. A genetic predisposition toward suicidal behavior cuts across diagnostic lines and plays a role in suicide risk. This may reflect a tendency toward impulsive behavior, correlating with low CNS levels of 5-hydroxyindoleacetic acid (5-HIAA), the major metabolite of serotonin.

Suicidal gestures and various acts of self-mutilation are also common among impulsive, dependent, and self-hating depressed people, for whom they serve as tension-releasing behaviors and as cries for help that may enlist desired social support. Because suicidal gestures have been associated with an increased risk for subsequently completed suicide, they should not be taken lightly. Such self-harm behaviors have been shown to persist in patients with borderline personality disorder well into the sixth decade of life. Contrary to earlier thinking, they do not appear to “burn out” with

Telegram: @medical_k

www.konkur.in

age. Subintentional suicide may result when suicidal gestures go awry or when reckless behavior, such as taking unnecessary risks in combat or driving while drunk, prove fatal.

Elated Moods

Elated moods include euphoria, elation, exaltation, and ecstasy. They are marked by feelings of well-being and expansiveness, optimism, capability, pleasure, and grace. Such moods are normally experienced when life is going very well, when long-sought-after goals are achieved, and in states of love, religious fervor, and spiritual transcendence. Peak experiences and experiences of mystic fusion are often accompanied by feelings of exaltation and ecstasy. Sexual pleasure and some chemically mediated states of altered consciousness may also induce these feelings.

Abnormal elated moods are primarily seen as part of manic states and from the effects of certain medications and street drugs. When subtle, as in hypomania, the mood can be ebullient and brimming with self-confidence but with occasional irritability. Other characteristic symptoms of hypomania are increased energy, decreased need for sleep, rapidly flowing thoughts, excessive talking, inflated self-esteem with a demanding nature toward others, and diminished judgment. Mania is a more extreme state in which judgment and sleep are impaired to the point of marked functional disruption. As the mania exacerbates, irritability and anger increase, alternating rapidly with a brittle expansiveness. Cognitions become increasingly disorganized. Psychotic symptoms, usually involving themes of grandiosity or specialness, occur in 50% or more of manic patients. With increasing escalation of the manic state, thinking becomes very fragmented, psychotic symptoms are more prominent, and the syndrome may appear indistinguishable from acute schizophrenia. These three manic states—hypomania, mania, and the psychotic, fragmented manic state—have been referred to as stage I, II, and III mania, respectively. Manic states occur in bipolar disorder, unspecified bipolar disorder, and cyclothymia and as a secondary mania caused by a variety of physical and toxic

Telegram: @medical_k

www.konkur.in

conditions. Such secondary manias may follow specific cerebral insults, accompany systemic disorders, or occur after ingestion of some drugs, including amphetamines, antidepressants, bromocriptine, decongestants, and corticosteroids, among others. Mania is the second most common neuropsychiatric disturbance induced by steroids, occurring in 30% to 35% of patients who develop steroid-induced behavioral disorders. Up to 12% of patients treated with levodopa and bromocriptine for parkinsonism develop mania. Right hemispheric brain lesions are specifically associated with secondary mania.

Hyperthymic personality refers to personality characteristics similar to hypomania, although DSM-5 has no mention of this in its personality section. These include unusual energy, ebullience, confidence, intensity, and so forth but without either the episodic course or the functional impairment of hypomania. Whether hyperthymic personality should be considered a bipolar spectrum disorder or refers simply to high-energy individuals is still unclear.

ANXIETY DISORDERS

Like depression, the term anxiety refers to a number of different entities: a normal transient feeling, often with adaptive functions; a symptom seen in a wide variety of disorders; and a group of disorders in which the symptom of anxiety forms a dominant element. As a transient, disagreeable emotional state, anxiety may be adaptive, signaling anticipated or impending threat and motivating necessary action. In contrast to fear, the emotional state that exists when a source of threat is precise and well known, anxiety occurs when the threat is not well defined.

Patients often find it difficult to describe feelings of anxiety precisely; at its core, however, anxiety is characterized by intense negative affect, associated with an undefined threat to one's physical or psychological self. Patients use terms such as tense, panicky, terrified, jittery, nervous, wound up, apprehensive, and worried to describe their sensations. Anxiety is additionally characterized by somatic, cognitive, behavioral, and perceptual symptoms. The

Telegram: @medical_k

www.konkur.in

somatic symptoms of anxiety are legion and often dominate; a partial list includes twitching, tremors, hot and cold flashes, sweating, palpitations, chest tightness, difficulty swallowing, nausea, diarrhea, dry mouth, and decreased libido. Cognitively, anxiety is characterized by hypervigilance, poor concentration, subjective confusion, fears of losing control or of going crazy, and catastrophic thinking. Behavioral symptoms include fearful expressions, withdrawal, irritability, immobility, and hyperventilation. Perceptual disturbances, including depersonalization, derealization, and hyperesthesia (especially hyperacusis), are also common.

Trait anxiety refers to a lifelong pattern of anxiety as a feature of temperament. Individuals with trait anxiety are skittish, hypersensitive to stimuli, psychophysiologically more reactive than others, and exhibit catastrophic thinking. In contrast, state anxiety refers to episodes of anxiety that are tightly bound to specific situations and do not persist after the provoking situation has abated. Free-floating anxiety is characterized by a persistently anxious mood in which the cause is unknown and in which large numbers of diverse thoughts and events all seem to trigger and compound the anxiety. In contrast, situational anxiety occurs only in relation to specific occasions or external stimuli, as in phobias.

Anxiety symptoms can result from numerous physical conditions as well as from other psychiatric disorders. Many endocrine, autoimmune, metabolic, and toxic disorders, as well as medication side effects, are known to generate anxiety. The psychiatrist must differentiate the response of the patient to an underlying condition (e.g., secondary anxiety) from symptoms generated by the primary disorder itself. In psychiatric populations, anxiety symptoms are prevalent among patients with psychoses, organic mental disorders, depression, and substance use disorders, as well as the specific anxiety disorders. In patients with schizophrenia, anxiety must be differentiated from akathisia, a common and often overlooked syndrome of subjective restlessness, anxiety, and agitation resulting from antipsychotic medication. The coexistence of anxiety symptoms and depression in major depressive disorder is substantial; anxiety symptoms, such as anxious mood and irritability, are seen in the

Telegram: @medical_k

www.konkur.in

majority of depressed patients. In addition, one-half to two-thirds of patients with panic disorder experience a major depressive episode during their lifetime. Medication and drug effects—from acute use, side effects, or as part of withdrawal phenomena—are also common causes of anxiety. Many patients with severe anxiety become dependent on anxiolytic drugs, including benzodiazepines, other sedatives, and alcohol, for symptom relief. During attempts to discontinue these substances, or sometimes during their ongoing use, confusing admixtures of anxiety symptoms, medication effects, and withdrawal symptoms may occur.

A 45-year-old female has been home bound since the start of the COVID pandemic. She is terrified that she will contract COVID-19, so she doesn't leave the house. If family visit, she requires that everyone wear gloves and face shields, and she will not shake hands with or hug her family members when they visit. She even cleans her plates, utensils, and glasses with sanitizer after they leave. She sprays the same alcohol-based sanitizer on her mail and only reads it 3 days after she receives it. When she receives grocery by home delivery, she washes every item with soap and water. If she receives any other packages by mail, she leaves them in her garage for 3 days before opening them.

Although all of the anxiety symptoms caused by drug use are also seen in primary anxiety disorders, perceptual disturbances, such as depersonalization and hyperesthesia, may be more common in sedative-hypnotic withdrawal syndromes than in primary anxiety disorders.

From a psychological point of view, anxiety may signal conflict between opposing desires, wishes, or beliefs on the one hand and major disequilibria generated by negative life events on the other hand. Role strains, conflicts among the major social roles that form a person's identity—spouse, parent, child, wage earner, professional, or community member—are common sources of anxiety. The more important the conflict and the less obvious the resolution, the greater

Telegram: @medical_k

www.konkur.in

the associated anxiety. For example, anxiety symptoms may first emerge when an individual is confronted with an unavoidable, unhappy choice, such as between sustaining a marriage or accepting a career advancement requiring a major move that is unacceptable to the spouse. At times, these conflicts may escape conscious awareness: someone may feel anxious but not know why. Anxiety syndromes frequently result from a combination of several factors. A person in a work conflict facing an important deadline may try to alleviate initial anxiety symptoms by overwork, then ingest caffeine or amphetamines to keep alert, then become exhausted and fatigued, and ultimately use alcohol excessively to calm down, with each of these elements contributing separately to an anxiety state.

Certain developmental life situations are associated with anxiety. Stranger anxiety develops when infants 6 to 8 months of age begin to recognize the difference between mother and others. When children first go to school, mild anxiety symptoms are common; if the anxiety is excessive, then separation anxiety or school phobia may result. During adult life, anxiety often centers around issues of mastery and accomplishment, in both personal and work life. Performance anxiety, or stage fright, is a specific type of pathologic anxiety in which anxiety escalates to panic when public performance is required. In later life, the deterioration of one's body may engender anxiety related to feelings of helplessness and death anxiety.

Panic attack is a circumscribed episode of severe state anxiety lasting minutes to hours, with symptoms escalating in a crescendo pattern. The subjective experience is one of utter terror, with fear that one will die, go crazy, or lose control, accompanied by many of the somatic symptoms of anxiety mentioned above, including severe chest pains, marked shortness of breath, and exhausting fatigue. Individual isolated panic attacks are common, with up to 30% of the general population experiencing at least one attack each year. Panic attacks occur more regularly, and typically more severely, as part of panic disorder or in association with other anxiety disorders. In classic panic disorder, the attacks are spontaneous; that is, they are not triggered by a specific, predictable environment. In contrast, panic attacks associated with other anxiety disorders are triggered

Telegram: @medical_k

www.konkur.in

by specific situations such as in social anxiety disorder by social situations or in specific phobia by confronting the feared object or situation. Patients with other psychiatric disorders may experience limited-symptom panic attacks, with episodes characterized by less intense anxiety and by fewer and milder physical symptoms, such as isolated paresthesias or difficulty breathing. These limited-symptom attacks may represent aborted full-blown panic episodes that are not further exacerbated by secondary psychological reactions to the initial symptoms.

A 32-year-old woman who works as a teacher in an elementary school is having episodes of shortness of breath associated with increased anxiety. She feels as if she is going to die and has to leave her classroom several times during work for that reason. Her primary care provider completed an extensive medical work up that was negative. She began to self-medicate with cannabis, which initially helped to decrease the frequency and intensity of her episodes, but after a few months, they began to recur. Eventually, her concerned husband brought her in for a psychiatric evaluation.

Although American psychiatry has segregated panic attacks from other forms of anxiety, assuming categorical, phenomenologic, and biologic differences, these distinctions are far from universally accepted. Much of European psychiatry views panic as simply an extreme form of anxiety to be understood as part of a continuum of intensity. DSM-5 made it simpler by deleting the association of agoraphobia from panic, and making agoraphobia a separate diagnosis.

Phobias are irrational fears. In an effort to reduce the intense anxiety attached to phobic objects and situations, patients do their best to avoid the feared stimuli. Thus, phobias consist of both the fears and the avoidance components. The fear itself may include all of the symptoms of extreme anxiety, up to and including panic. In specific phobias, persistent, irrational fears are provoked by specific

Telegram: @medical_k

www.konkur.in

stimuli. Table 8–3 lists some illustrative phobias. Common specific phobias include fear of dirt, excreta, snakes, spiders, heights, and blood (also termed blood-injury phobias).

Behavioral, psychodynamic, and biologic theories have all been advanced as causes of phobias. Some well-known phobias, such as fear of animals, may result either from early traumatic events (developing along the paradigm of classic Pavlovian conditioning) or from displacements of early psychodynamic conflicts. Genetic influences may also play a role in the development of phobias. For example, some individuals with blood-injury phobias, which strongly cluster among biologic relatives, may be genetically predisposed by vagal responses to certain stimuli. Animal models also indicate possible biologic vulnerability. Some monkeys that have never previously been exposed to snakes become panicky when placed in the presence of a snake. Because such fear responses obviously have adaptive value, it has been suggested that some human phobic responses also represent exaggerations of adaptive behaviors shaped by evolutionary biology. Complex phobias, more elaborate than specific phobias, involve fears related to a broader range of situations. Agoraphobia, the best known, means fear of the marketplace, symbolizing a fear of open spaces. Agoraphobia can occur in a variety of settings, however, and although it was previously associated with panic disorder, it can occur even in the absence of a panic disorder diagnosis.

www.konkur.in

Table 8–3.
Specific Phobias

Telegram: @medical_k

www.konkur.in

Phobia	Definition
Acrophobia	Fear of heights
Agoraphobia	Fear of open spaces
Alektorophobia	Fear of chickens
Amathophobia	Fear of dust
Amaxophobia	Fear of riding in a car
Apiphobia	Fear of bees
Arachibutyrophobia	Fear of getting peanut butter stuck on the roof of the mouth
Astrapophobia	Fear of lightning
Aviophobia	Fear of flying
Blennophobia	Fear of slime
Claustrophobia	Fear of enclosed spaces
Coronaphobia	Fear of coronavirus
Cynophobia	Fear of dogs
Decidophobia	Fear of making decisions
Didaskaleinophobia	Fear of going to school
Electrophobia	Fear of electricity
Ephebiphobia	Fear of teenagers
Eremophobia	Fear of being alone
Gamophobia	Fear of marriage
Gatophobia	Fear of cats
Gephyrophobia	Fear of crossing bridges
Gynophobia	Fear of women
Hydrophobia	Fear of water
Kakorrhaphiophobia	Fear of failure
Katagelophobia	Fear or ridicule

Telegram: @medical_k

www.konkur.in

Keraunophobia	Fear of thunder
Musophobia	Fear of mice
Nyctophobia	Fear of night
Ochlophobia	Fear of crowds
Odynophobia	Fear of pain
Ophidiophobia	Fear of snakes
Pnigerophobia	Fear of smothering
Pyrophobia	Fear of fire
Scholionophobia	Fear of school
Sciophobia	Fear of shadows
Spheksophobia	Fear of wasps
Technophobia	Fear of technology
Thalassophobia	Fear of the ocean
Triskaidekaphobia	Fear of the number 13
Tropophobia	Fear of moving or making changes

In social anxiety disorder (social phobia), patients become overwhelmingly anxious and fear situations in which they may be observed. In the limited type, only a few specific situations evoke the fear, such as speaking in public or using a public lavatory. In the general type, broad-based fears of social situations globally hamper the person's interpersonal life.

SOMATIC DISTURBANCES IN PSYCHIATRIC ILLNESS

Nearly all psychiatric disorders manifest some change in basic physiologic function. These alterations in somatic function may be quite nonspecific, but the severity of the disruption in normal function may provide clues to the amount of physiologic malfunction seen in the primary underlying psychiatric illness. Although frequently

Telegram: @medical_k

www.konkur.in

nonspecific in nature, the severity of these somatic signs and symptoms provides markers as to the amount of biologic disruption seen in the disorders that cause them. Furthermore, somatic symptoms can also cause exacerbations of some disorders. If untreated, then these processes can create destructive feedback loops in which the disorder causes symptoms, which then exacerbates the disorder, which causes increases in the symptoms, and so on. As examples, the insomnia of manic or hypomanic states, if untreated, causes a marked worsening of the mania; similarly, the weight loss of anorexia nervosa causes starvation effects, such as a preoccupation with food, thus exacerbating one of the hallmark features of the underlying disorder.

Sleep Disturbances

Considering the fact that about one-third of each day's activities are spent sleeping, it is not surprising that psychiatric disturbances are frequently manifested by an alteration in normal sleep. These alterations may be in the timing, the amount, and the quality of sleep as well as the presence of abnormal events occurring while sleeping. In addition, the alterations may be associated with the primary psychiatric disturbance, medications used in psychiatric treatment, or the use of other prescribed agents or substance use.

Insomnia is usually defined by its subjective component as the sensation of not sleeping well or enough. Most, but not all, patients complaining of insomnia demonstrate some sleep abnormality if examined in a sleep laboratory. Insomnia is a common, often chronic, symptom or sign of many different psychiatric disorders, including substance use disorders, depression, generalized anxiety disorder, panic, mania (in which the diminished sleep does not always provoke a complaint), and acute schizophrenia. It may also occur as a consequence of aging or as a symptom or disorder not associated with other psychopathology. Insomnia may also result from the ingestion of substances that alter the normal sleep–wake cycle, including alcohol or stimulants, and by the discontinuation of sedative-hypnotics. Although much attention is often paid to

Telegram: @medical_k

www.konkur.in

distinguishing patterns of insomnia, such as difficulty falling asleep versus middle or terminal insomnia (early morning awakening), or linking specific patterns to a specific disorder (e.g., melancholic depression with terminal insomnia), the clinical usefulness of these distinctions is sometimes unclear.

A 32-year-old computer engineer described herself as a “worry wart.” She reported insomnia “my whole life,” including initial insomnia and multiple awakenings throughout the night. She reported her mind could not relax as she tried to sleep and found herself worrying about “everything that happened during the day.” Inevitably, she would wake up in the middle of the night to “make a list of things I forgot, or review possible mistakes I made at work.”

Hypersomnia, characterized by either excessive nighttime sleep or excessive sleepiness during the day, is less common than insomnia. It, too, however, may reflect a number of different pathologic states. Some depressed patients, especially those with a history of mania or hypomania, may exhibit hypersomnia. Hypersomnia may also be seen during stimulant withdrawal, with excessive use of sedatives or tranquilizers, or in conjunction with a variety of medical disorders. In narcolepsy, the patient has sudden attacks of irresistible sleepiness, a symptom that may be part of a broader syndrome that includes cataplexy (sudden attacks of generalized muscle weakness leading to physical collapse in the presence of alert consciousness), sleep paralysis (waking from sleep with a sensation of being totally paralyzed that may persist for minutes), and hypnagogic hallucinations (vivid visual hallucinations that occur at the point of falling asleep). Narcoleptic attacks are often precipitated by unusual states of arousal (e.g., cataplexy may immediately follow unrestrained laughter or orgasm). Daytime sleepiness may reflect sleep apnea. In this disorder, typically middle-aged patients demonstrate severe snoring—often first reported by their bed partners—and periods when breathing stops. The condition results

Telegram: @medical_k

www.konkur.in

from soft palate abnormalities that cause intermittent airway obstruction throughout the night; patients awake repeatedly to find themselves gasping for air. Associated daytime fatigue is common in sleep apnea. Periodic hypersomnia also occurs in Kleine–Levin syndrome, a condition typically affecting young men in which periods of sleepiness alternative with confusional states, ravenous hunger, and protracted sexual activity. Intervals of days, weeks, or months may pass between these episodes.

Somnambulism, or sleepwalking, and sleep terror disorder (night terror) are two sleep disorders characterized, respectively, by aimless wandering with incomplete arousal and by acute anxiety and physiologic arousal without awakening. Although both disorders typically begin in childhood, sleepwalking may be also initially precipitated by some psychotropic medications.

A 54-year-old man with complex PTSD was treated with a sedative hypnotic by his primary care physician. During this period, his wife noted that he often went to the refrigerator in the middle of the night while sound asleep and ate indiscriminately. When she woke him during these episodes, he appeared dazed and had no awareness of his purposive behaviors. To the best of his recollection, confirmed by his wife, he had no history of somnambulistic phenomena before treatment with the sedative hypnotic agent.

Nightmares are a common complaint, often associated with traumatic events, anxiety disorders, and mood disorders, but not uncommon as an occasional event in otherwise healthy individuals. Vivid dreams and nightmares may also be a medication side effect.

Telegram: @medical_k

www.konkur.in

A 32-year-old woman was treated for a mild depression with an SSRI. Her sleep pattern before treatment had been characterized by hypersomnia, sleeping between 10 and 12 hours nightly. Soon after the initiation of the antidepressant, she noticed that her sleep was not only shorter and more fragmented, but that she had remarkably intense dreams that she remembered vividly. She made clear that these were not nightmares, just dreams with intense colors and clarity, which she rather enjoyed.

Sensory symptoms during sleep, typically described by patients as peculiar feelings in their legs causing an irresistible need to move around, are characteristic of restless legs syndrome. The motor abnormality of repetitive myoclonic jerking of the legs, awakening both patients and their partners, is known as nocturnal myoclonus.

Appetite and Weight Disturbances

A significant change in appetite and weight can be seen in both medical and psychiatric illness. Anorexia may occur in the latter stages of chronic medical illness and is frequently seen in depression, grief, and some anxiety disorders. In addition, anorexia may be secondary to alterations in taste sensation, as a function of psychiatric disturbance or medication side effect. In eating disorders, such as anorexia nervosa, patients may resist hunger to restrict food intake to achieve a physiologically unrealistic low weight. Hyperphagia (increased appetite) occurs in some depressed patients, both with and without a history of mania or hypomania. Binge eating, of up to several thousand calories per episode, may occur as an attempt to self-soothe and emotionally self-regulate during times of increased tension and anxiety and as a key feature of bulimia nervosa or of binge-eating disorder. Increased appetite may be seen as a side effect of many psychotropics or, albeit rarely, in some hypothalamic disorders or in bilateral temporal lobe dysfunction such as Klüver–Bucy syndrome, in which it occurs in

Telegram: @medical_k

www.konkur.in

association with emotional placidity, hypersexuality, hyperorality, and other related symptoms.

A 45-year-old man with schizoaffective disorder had been intermittently erratic with his follow-up visits and had requested several telephone refills over the last several months. He was instructed by his psychiatrist to come in to see him before additional refills could be called in to his pharmacy. Subsequently, he presented for an office visit with his psychiatrist. In the interview it became apparent that the patient had gained a significant amount of weight, approximately 40 lb, in the last several months. He admitted to having a “hunger” for sweets and fatty foods and acknowledged that he had a marked increase in his appetite after he was switched to an atypical antipsychotic.

Energy Disturbances

Normal energy levels vary considerably among people. Some people fatigue easily and are perceived by themselves and others as having “weak constitutions,” whereas others appear to have almost boundless energy and much less need for sleep.

Fatigue is a common nonspecific symptom that occurs in both medical and psychiatric disorders. It is also frequently seen as an unexplained complaint in primary care practices; in one study, 24% of patients complaining of fatigue received no medical or psychiatric diagnosis. Historically, fatigue not due to another disorder, typically in association with “nervousness,” has been described by terms such as asthenia, neurocirculatory asthenia, neurasthenia, and psychasthenia. Consistent with this tradition, many fatigued patients, having been labeled depressed or neurotic by their physicians, are referred to psychiatrists after routine workup has ruled out anemia, hypothyroidism, sleep apnea, and other frequent somatic causes.

Recently, those patients with primary complaints of tiredness have been most commonly diagnosed as having chronic fatigue syndrome

Telegram: @medical_k

www.konkur.in

(CFS), a disorder characterized by fatigue lasting months to years, typically beginning soon after a viral syndrome. In addition to the fatigue, CFS is characterized by myalgias and cognitive changes such as forgetfulness and poor concentration. Although controversy still exists over the extent to which cases of CFS represent discrete post-viral diagnostic syndromes, mislabeled cases of depression, or modern versions of psychasthenia, evidence continues to mount to suggest that these syndromes are discrete postinfectious entities and are not simply variants of or disguised mood or anxiety disorders.

A highly accomplished, energetic 40-year-old woman was referred for psychiatric consultation after her physicians were unable to offer a definitive physiologic diagnosis despite extensive medical workup after the acute onset of profound fatigue occurring in the wake of a mild viral illness. This fatigue caused her to be totally incapacitated and bedridden for many months and left her feeling quite helpless and distraught. It was exacerbated by even small amounts of alcohol. Two independent psychiatric evaluations concluded that the patient had no psychiatric disorder. The patient developed this syndrome after jogging near Lake Tahoe. Some epidemiologic studies found a series of other cases of profound fatigue originating in this particular geographical area after vigorous exercise. Various antidepressants seemed to provide partial relief, but tolerance to their positive effects developed. The fatigue slowly improved over many years; 7 years after the original symptoms, the patient continued to experience waxing and waning fatigue but at a lesser degree than originally.

Disturbances in Sexual Drive

As with energy, variation in the normal range of sexual drives is common. Some individuals are naturally lusty, whereas others have limited sexual desire. Diminished sexual drive with impotence or

Telegram: @medical_k

www.konkur.in

decreased libido is seen in a wide variety of neurologic, metabolic, and other somatic conditions. Among neurologic disorders, complex partial seizures are commonly associated with hyposexuality, occurring in 50% of patients. Psychiatric disorders known for diminished sexual drive include depressive disorders, schizophrenia, and substance use disorders. Diminished libido, erectile dysfunction, and anorgasmia are also common sequelae of many psychotropic agents, especially those with a strong serotonergic action.

A depressed 36-year-old man had an excellent antidepressant response to an SSRI but developed decreased sexual interest and anorgasmia with relative preservation of erectile function. When the sexual side effects did not diminish after 4 weeks, his psychiatrist tried a number of potential remedies. Although sildenafil improved his erections somewhat, his libido and orgasmic function continued to be markedly impaired. He and his psychiatrist agreed to switch to a different antidepressant class that was not associated with sexual side effects.

Increased sexual activity may be seen in some neurologic, psychiatric, and drug-induced disorders. Manic patients frequently exhibit hypersexual interests and behaviors to an unusual degree, compared with their euthymic interests and behaviors. Hypersexuality is occasionally seen in conjunction with epileptic syndromes or in patients who have had diencephalic injuries.

Altered sexuality, including fetishism, sadomasochism, pedophilia, and other paraphilias, may be seen as isolated psychiatric syndromes. In individuals whose previous sexual behaviors were within the bounds of social propriety for their groups, inappropriate sexual behaviors may signal early brain disease or psychosis.

Appearance

Studies show that clinicians often formulate an initial psychiatric diagnosis within 30 seconds of seeing a patient. Although

Telegram: @medical_k

www.konkur.in

approximately one-half of such initial impressions prove to be incorrect, the remainder, however, are validated by psychiatric history and mental status examination, revealing just how much information is communicated by appearance and body language.

Among the physical disorders whose appearances suggest coexistent psychiatric conditions are acromegaly, Cushing syndrome, Down syndrome, systemic lupus erythematosus, fetal alcohol syndrome, Klinefelter syndrome, and Wilson disease, to name a few. The general appearance of the skin may suggest the presence of occult psychiatric problems. The general condition and flush of the skin may reveal hypervascularity and ruddiness suggestive of alcoholism, abscesses indicative of hypodermic needle abuse, weathering and wasting indicative of self-neglect and malnutrition, or even certain tattoos or patterns of tattoos that may have psychological significance to the patient. Healed scars on the wrists and arms may suggest a pattern of self-mutilation. Patchy baldness, especially in conjunction with torn or infected cuticles, indicates trichotillomania, a syndrome of compulsive hair pulling. Psychophysiological symptoms reflecting psychiatric disturbance include urticarial reactions and neurodermatitis, the latter resulting, in part, from self-excoriation, destructive scratching secondary to compulsions, and unrelenting sensations of discomfort.

A 23-year-old woman who had recovered from a severe episode of anorexia nervosa as an adolescent had recurrent depression and persistent personality disturbances characterized by odd and eccentric ideas, shyness, and avoidance. She became enchanted with gothic themes, spent hours on the Internet in chat rooms featuring dark and morbid poetry, and started to have herself tattooed. Within 1 year, she had tattooed every inch of her face, eyelids, lips, earlobes, upper extremities, scalp, and torso with complex, intricate, gothic designs. She acknowledged that tattooing her skin in such an extreme manner served to mark her as deviant and to warn people away from her.

Telegram: @medical_k

www.konkur.in

Examination of the head and neck may reveal exophthalmos or puffy eyelids, suggesting thyroid disease, marked pupillary dilation with anxiety or stimulant abuse, miosis with narcotic use, abnormal pupillary pigments in Wilson disease, salivary gland enlargement in bulimia nervosa, or necrosis of the nasal septum in cocaine use disorders, among other signs. Frequent sighing is a common respiratory sign in depression. Simple sighing must be distinguished from respiratory dyskinesia in psychotic patients who have been treated with neuroleptics. The latter may occur as an acute dyskinesia due to antipsychotic medication, or it may be a late manifestation and component of tardive dyskinesia.

Deviant appearance is quickly perceived by laypeople and professionals and may contribute to the frightened and stigmatizing social withdrawal by strangers, as well as acquaintances, so often experienced by psychiatric patients. Akathisia, dystonic movements, and parkinsonian shuffling gait in patients taking neuroleptics (especially the older, conventional antipsychotics), as well as the dilapidated and unkempt appearance of some psychiatric patients, can immediately signal psychiatric patient status to observers. The term *Diogenes syndrome* has been used to describe old people who have filthy personal appearance and demonstrate severe self-neglect about which they have no shame.

DISTURBANCES OF BEHAVIOR

Aggression, Hostility, Impulsiveness, and Violence

The spectrum of aggressive emotions and behaviors is characterized by heightened vigilance in response to a sense of threat and enhanced readiness to attack. Physiologic tone may be geared for a fight. Assertiveness, the adaptive aspect of these emotions, includes sensing that something needs to be done and feeling willing and competent to take constructive action. The manner and extent to which aggressive emotions can be expressed varies from society to society and from situation to situation. These emotions are among the most carefully regulated because of their potential

Telegram: @medical_k

www.konkur.in

destructiveness. Acts of aggression are on a continuum, beginning with irritability, progressing to verbal threats and intimidation, and extending to physical bullying and assault to homicide, sometimes including acts of calculated violence and sadism.

Irritability is an unpleasant feeling state characterized by inner unease. In contrast to anger, irritability does not lessen after an outburst. Often, others are more aware of an individual's irritability than is the person themself. It is diagnostically nonspecific, seen in a variety of physiologic states—psychotic, anxiety, and mood disorders—and as a lifelong temperamental quality. Hunger, sleepiness, sexual frustration, and pain are among the physiologic triggers commonly associated with irritability.

Individual differences in the tendency toward experiencing and expressing anger and violence are biologic, developmental, and cultural in origin. Some infants are irritable from birth. Subtle early birth injuries and brain anoxia may increase the susceptibility of some people to be violent. Furthermore, studies of EEG patterns in violent people show increased abnormalities, especially in those with repeated violence and violence with little or no obvious motive. Soft neurologic signs are also seen in violent criminals. Biochemically, low cerebrospinal fluid (CSF) 5-HIAA has been associated with a variety of impulsive behaviors, such as violent crimes, recurrent fire setting, and violent suicide attempts.

Consistent with the hypothesis that an inverse relationship exists between central serotonergic system function and impulsive, aggressive behavior, a few double-blind, placebo-controlled studies in patients with cluster B personality disorders have demonstrated that enhancing central serotonergic function by using SSRIs reduces irritability and impulsive aggressive behavior.

Telegram: @medical_k

www.konkur.in

A 32-year-old man came for psychiatric treatment after a breakup with his fiancée of 5 years related to his anger outbursts, in which he would curse, yell, slap, and throw things at her. Once, during a rage attack, he slashed the tires of his fiancée's car. Another time, he impulsively took an overdose of pills that he found at home. He responded to treatment with an SSRI, which improved his mood lability and anger outbursts.

The pathologic childhood triad of bed-wetting past the age of 6 years, setting fires, and torturing animals has been associated with subsequent violent behavior in adults. Interpersonally, studies show that violence-prone individuals require more personal space around their physical person than do others. Violent individuals feel threatened when approached too closely, particularly from the rear.

Psychological and social contributions are also strong. Violence in families breeds violence, and battered children often grow up to be battering adults. Cultural norms for the expression of violence differ considerably. In some socioeconomic and ethnic groups, violent gangs organize the energies of many adolescent youth. For some, violent behavior is an adolescent socialization pattern necessary to prove one's manhood or womanhood. Like other social organizations, violent gangs have detailed rules that inhibit and govern the expression of violence. Some unpredictable and unsocialized violent people are too violent to be contained even in gangs.

Aggressive and violent behavior is diagnostically nonspecific. Violence in schizophrenia may occur as a consequence of paranoid delusions, in response to command auditory hallucinations, or secondary to passivity experiences. Manic patients and those in mixed states may be violent, often in response to minimal provocation. Violent behavior commonly occurs in patients with antisocial and borderline personalities (in the latter often self-directed as well as other-directed). Violent behavior may occur in epilepsy, although rarely during true ictal periods; in frontal lobe syndromes as

Telegram: @medical_k

www.konkur.in

a “release phenomenon;” and in association with abused substances, particularly disinhibiting sedatives, such as alcohol, or stimulants, such as amphetamines and cocaine, which increase irritability, aggressiveness, and paranoia.

Impulsive violence may be provoked by a number of stimuli and situations. Alcohol is perhaps the most common disinhibitor of violence. Intrafamilial violence, the most common setting for homicide, is frequently related to alcohol intoxication. In episodic dyscontrol and intermittent explosive disorder, violent behaviors typically erupt after a person has ingested alcohol, a phenomenon known as pathologic intoxication. In these often ferocious outbursts, the individual may confront or provoke any potential target for violence, including total strangers and police, but significant others, spouses, and parents are frequent victims. Patients with episodic dyscontrol commonly have histories of violent sexual behavior, including rape and, often while intoxicated, speeding and reckless driving, sometimes chasing down, stopping, and attacking other motorists who they believe “get in their way.”

An attractive 40-year-old woman had been highly sought after by rich and powerful men, several of whom she had married and several of whom divorced her because of her uncontrollable rages. She described herself as becoming “insanely jealous” in a flash whenever she saw her husband glancing at other attractive women, and her behavior flared out of control, particularly when she had been drinking alcohol. On one occasion, she bit off one husband’s ear. She attacked another with pots and knives, nearly killing him. She recognized how serious her problems were and sought psychotherapy, medication (SSRIs were helpful), and anger management training to help her control her emotions and behaviors.

Temper Tantrums

Telegram: @medical_k

www.konkur.in

Immature individuals with persistent personality problems may not develop mechanisms to inhibit temper tantrums that they displayed as children. Particularly if childhood tantrums produced the desired result, then learned tantrum behaviors may persist into adult life. Although such individuals may be pleasant and sociable when life is going well, they lack the capacity to tolerate frustration and are easily provoked by threats to self-esteem and self-image and by not having their own way. When frustrated or threatened, they may act like bullies, glare, snarl, yell, shout, intimidate, pout and sulk, and sometimes be physically violent.

Displaced Rage

When circumstances prevent the expression of rage directly against those people or institutions provoking frustration, other outlets for aggression are often found. Acts of violence that are either calculated or wanton may result. Cruelty to animals and fire setting may persist as adult forms of destructive behavior. Rape, an act of control, intimidation, terror, and humiliation, may also displace frustrations that are not expressed more adaptively.

Sadism may occur with or without explicit sexual gratification. Calculated cruelty conducted seemingly without anger or emotional arousal may reflect inadequate development of social morality or individual conscience, as in the conduct of torturers and some cold-blooded murderers. In some societies and under specific circumstances at certain times in history, such activity has been socially sanctioned, suggesting at least that some people lack inborn inhibitions against cruelty or violence.

Telegram: @medical_k

www.konkur.in

A 50-year-old man with antisocial personality disorder was seen in a psychiatric emergency room for violent behavior. During the course of the assessment, he described how he had been emotionally and physically abused by a sadistic father who whipped him repeatedly until he bled and who chained him to a tree in the backyard. This man grew up feeling callous. He enjoyed intimidating and physically hurting others, as he often did in prison. With a laugh and smirk, he reflected on how he turned out to be “just like my old man.”

Self-Mutilation

For a variety of reasons, in many different cultures and in many different disorders, people commit acts of violence against themselves, ranging from body piercing to cutting and burning to autoamputation. Psychotic patients may perform extremely self-destructive acts short of actual suicide that often have symbolic import, such as enucleating their eyes or castrating themselves. Patients with borderline personality disorders or borderline traits may cut themselves repeatedly with broken glass or razor blades or burn themselves with cigarettes on arms, legs, breasts, or other body parts. Patients typically deny that these acts are meant to be suicidal but describe the need to feel external pain to mirror internal suffering, to release tension, or to counteract dissociative-like numbness. Recently, self-cutting has become more common in teenagers, especially girls, as a tension-relieving mechanism.

Telegram: @medical_k

www.konkur.in

A 20-year-old college student was taken to the emergency room by her friends, who were alarmed by the recent transverse cuts on her arms. None of the cuts were deep enough to require sutures, but, even when they had healed, they left obvious small red scars on her skin. In explaining her behavior, the student described that when she was upset, such as after a fight with her boyfriend or a negative telephone call with her parents, she became agitated, and cutting herself consistently relieved the agitation and anxious feelings.

Trichotillomania is a syndrome of compulsive hair pulling, resulting in bald patches. It is often associated with other self-mutilatory behavior, such as picking the face, nails, or cuticles to the point of infection and bleeding. Trichotillomania may sometimes be related to OCD.

Children with Lesch–Nyhan syndrome, a developmental disability syndrome caused by a congenital metabolic abnormality, bite and pick at themselves so compulsively as to do themselves great harm and routinely require restraint. Occasionally, patients with Tourette syndrome demonstrate compulsive self-harming behavior.

Other Disturbances of Feelings

Diminished levels of emotional intensity may be seen in anxiety disorders, mood disorders, and schizophrenia. Mild emotional flattening with blunted ability to feel joy is common in dysthymia. Some patients with narcissistic and borderline personality disorders complain of inner emptiness and pervasive boredom and ennui without demonstrating diminished affect in interviews. Similarly, patients with prominent depersonalization describe numbed emotions. Pathologic levels of blunt or flattened affect, indicating markedly diminished affective expression in relation to specific thought content, may be seen in chronic schizophrenia (as part of the deficit syndrome), some organic mental syndromes, and severe depressions and as a side effect to many medications, including

Telegram: @medical_k

www.konkur.in

SSRI antidepressants, antipsychotic medications, or excessive tranquilizer use. Although the term blunted affect is not classically used to describe the affective flatness of severe depression, it is not always easy to distinguish between schizophrenic and depressive flatness on phenomenologic grounds. Anhedonia, the lack of pleasurable feelings from activities that ordinarily provide pleasure, is also seen as part of severe depressions or schizophrenia. Chronically psychotic patients often exhibit emotional deterioration in which affective experience and expression are entirely unrelated to thought content. Inappropriate affect is the incongruency of affective expression and thought content. The patient may display loud and raucous laughter or giggling in relation to bland or sad thoughts or may show grief without apparent reason. Inappropriate affect sometimes indicates that the thoughts have private meanings for the patients; the emotional expression might make better sense if the private meanings were understood. Inappropriate affect must be distinguished from affective expressions that may actually be appropriate in a given subculture or ethnic group that is unfamiliar to the observer and from defensive affect, such as the nervous laughter used to alleviate tension or ward off crying. Affective (or mood) lability is characterized by rapid emotional shifts, often within seconds to minutes. It is commonly seen during hypomanic states, late luteal phase dysphoric disorder (premenstrual syndrome), postpartum blues, other states of physiologic instability, and in cluster B personality disorders.

A 51-year-old man with lifelong dysthymic disorder was treated with an SSRI. Although he had an excellent antidepressant response, 2 months after beginning treatment, he noted an affective flatness. He described not becoming as easily upset as before treatment (which both he and his wife interpreted positively), but he also believed his sense of joy, in being with his children or in nature, was markedly blunted. He enjoyed positive events but with a marked diminution of affective intensity.

Telegram: @medical_k

www.konkur.in

Alexithymia is difficulty identifying, describing, and differentiating feelings or distinguishing between feelings and physical sensations. Alexithymic individuals often have constricted imaginations and fantasies, are preoccupied with objects and events in the outside world, and have little private, personal internal life. When distressed, the patients are simply aware of not feeling well and usually complain of somatic symptoms, leading to frustrating interactions with their physicians who cannot find physical causes for the presenting physical complaints. Some view alexithymia as a condition in which affect is communicated through somatic language.

With regard to other feeling states that may contribute to pathologic conditions, recent writers have focused on the role of "shame" as a potentially important emotional mediator of specific types of narcissistic injury that may provoke states of depression, rage, PTSD, and suicide, among others.

DISTURBANCES OF INTERPERSONAL RELATIONSHIPS

Normal interpersonal relationships include relationships with parents, children, spouses, siblings, extended family members, friends, colleagues, coworkers, and members of the larger community. These relationships ordinarily help provide for the satisfaction of basic drives, for affiliative needs, and for finding purpose and meaning in life. Through stable and satisfying relationships, human needs are met for intimacy, including love, sex, and affection, to be cared for and nurtured, to provide care, learn, play, relax, dominate, and be productive through mutual effort. Interpersonal relationships are carefully regulated by means of interpersonal signs and signals. The extent to which deviance from these patterns is tolerated in a given relationship varies from behavior to behavior, relationship to relationship, family to family, and culture to culture.

Disturbances in interpersonal relationships may be viewed as characteristics attributable to a single person or as characteristics of an interpersonal system. Individual disturbances are considered to

Telegram: @medical_k

www.konkur.in

be undesirable or maladaptive personality traits. When these traits are present to a significant extent and interfere with social functioning or cause distress, they may compose a personality disorder. Disturbances of interpersonal relationships have also been described at a system level (e.g., as dyadic and family patterns of system disturbance).

Personality Traits and Disorders

Personality, variably defined, is the characteristic pattern of an individual's attitudes, behaviors, beliefs, feelings, thoughts, and values—the sum of a person's emotional, cognitive, and interpersonal attributes. Personality traits are the prominent and characteristic features of an individual's personality and do not imply psychopathology. Aspects of personality are present from early life, and personality traits are relatively stable from adolescence onward, consistent across different environments, and recognizable by friends and acquaintances. The term personality disorder should be reserved for those consistent patterns of thought, feeling, and behavior that are maladaptive. Personality disturbances manifest primarily in interpersonal contexts and in this way may be viewed as interpersonal behavior disorders.

The determinants of personality are multiple and varied—innate and early biologic, developmental, and environmental factors inside and outside the home. Through learning and the environment, temperamental factors (genetic or constitutional) are shaped into character.

The dimensional approach to personality and personality pathology characterizes individuals along a continuum of traits. Five dimensions of temperament have been described that appear to be somewhat independent and to have strong genetic contributions: neuroticism (highly emotional, reactive, and thin skinned, contrasting with emotional stability), extroversion (contrasting with introversion), openness (contrasting with discomfort with novel experiences), agreeableness (contrasting with contrariness), and conscientiousness (contrasting with fickleness). These

Telegram: @medical_k

www.konkur.in

temperamental attributes may have implications for the course of psychotherapies that cut across diagnostic categories.

Another dimension of personality not adequately dealt with in the DSM-IV-TR and now DSM-5 concerns moral behaviors such as honesty and integrity. The extent to which individuals behave honestly and with integrity differs considerably across individuals and in different situations. Deception and lying are common behaviors that occur in benign forms (e.g., in “white lies”) and in pathologic forms, psychiatrically important in antisocial and sociopathic disorders, pathologic liars, and malingerers. Deception and lying may be difficult to assess clinically in the absence of additional informants. Studies of nonhuman primates indicate that, at least among chimpanzees, deception (equivalent to lying and dishonesty) is relatively common and, in some situations, adaptive.

Another personality typology characterizes personality along three dimensions related to temperamental characteristics presumed to be strongly influenced genetically: harm avoidance, novelty seeking, and reward dependence. High scores on the three dimensions characterize inhibition and pessimism, impulsive and exploratory behavior, and dependency and sentimentality, respectively. Different personality types can be described according to patterns of scores on the three dimensions. For example, antisocial personalities are characterized by high novelty seeking, low harm avoidance, and low reward dependence, whereas dependent personalities have low novelty seeking, high harm avoidance, and high reward dependence.

The DSM-IV-TR, by contrast, uses a categorical approach, yet both the large overlap among the DSM-IV-TR personality disorders and the clustering of these personality disorders into three broad groups imply a lack of clear boundaries to the currently defined categories. The three DSM-IV-TR clusters describe odd or eccentric types (cluster A); dramatic, emotional, and erratic types (cluster B); and anxious and fearful types (cluster C). While the DSM-5 task force recommended an alternative model and approach to personality disorders, the APA Board of Trustees decided to keep current nomenclature to preserve continuity. The alternative approach is included as Section III in DSM-5. In this model a greater

Telegram: @medical_k

www.konkur.in

emphasis on personality functioning and trait-based criteria increases the stability and empirical basis of the disorders.

The odd or eccentric group includes paranoid, schizoid, and schizotypal personality disorders. Patients with these personality disorders have the core traits of being interpersonally distant and emotionally constricted. Paranoid personalities are quick to feel slighted and jealous, carry grudges, and expect to be exploited and harmed by others. Schizoid personalities lack friendships or close relationships with others and are indifferent to praise or criticism by others. Schizotypal personalities display odd beliefs, engage in odd and eccentric gestures and practices, and exhibit odd speech.

The dramatic, emotional, and erratic group includes borderline, histrionic, narcissistic, and antisocial personality disorders. Patients with these personality disorders characteristically have chaotic lives, emotions, and relationships. Borderline personalities are impulsive, unpredictable, angry, temperamental, unstable in relationships, compulsively interpersonal, and self-damaging with regard to sex, money, and substance use. Histrionic personalities are attention seeking, exhibitionistic, seductive, self-indulgent, exhibit exaggerated expressions of emotions, and overconcerned with physical appearance. Narcissistic personalities tend to be hypersensitive to criticism, exploitative of others, and egocentric with an inflated sense of self-importance; they feel entitled to special treatment and demand constant attention. Antisocial personalities are described almost exclusively by behavioral rather than affective or relational terms. They are truant, lie, steal, start fights, break rules, unable to sustain work or school, and shirk everyday responsibilities.

The anxious and fearful group includes avoidant, dependent, and obsessive-compulsive personality disorders. Patients with these disorders are characterized by constricting behaviors that serve to limit risks. As examples, avoidant people avoid relationships, dependent personalities avoid being responsible for decisions, and obsessive-compulsive people use rigid rules that preclude new behaviors. Avoidant personalities are hypersensitive to rejection and are reluctant to enter close relationships in spite of strong desires for affection. Dependent personalities show excessive reliance on

Telegram: @medical_k

www.konkur.in

others to make major life decisions, stay trapped in abusive relationships for fear of being alone, have difficulty initiating projects on their own, and constantly seek reassurance and praise. Obsessive-compulsive personalities exhibit restricted expressions of warmth, tenderness, and generosity, and exhibit stubbornness with a need to be right and to control decisions; indecisive at times, they often use overly rigid application of rules and morals to the point of being inflexible.

A characteristic personality disturbance seen with frontal lobe damage is referred to as organic personality disorder in the tenth edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) and personality change due to a general medical condition in the DSM-IV-TR. In DSM-5 it is included as personality change due to another medical condition. Its features include irritability, inappropriate jocularity with euphoria, inappropriate socially disinhibited behavior, and impulsiveness. Other patients with damage to different areas of the frontal lobe, in contrast, exhibit apathy and indifference.

Interpersonal Systems

Couples and families have been studied as systems in their own right, and many qualities of these systems have been identified as being clinically important. A scheme for categorizing relational disorders has been proposed for future editions of the DSM, but, as yet, no single generally accepted typology of family psychopathology or interactional types has been established. However, elements of marital discord and harmony have been operationalized in several standard marital inventories. Characteristics of couples and families that have received the most attention include the rules of communication, such as those governing the directness or indirectness with which disagreement and conflict are addressed; the manner (organized or chaotic) in which communications are conducted; taboo topics and secrets about which no one can openly communicate; the nature and degree of emotional expression, including affection and anger; the cohesiveness, loyalty, and

Telegram: @medical_k

www.konkur.in

compatibility of members; the nature of the members' shared identities on the one hand and their autonomous development and separateness on the other; the extent to which members treat one another respectfully or take one another for granted and use one another; the distribution of power and decision making among members; the maintenance of generational boundaries (e.g., age-appropriate performance of life roles); and the members' orientation toward and concurrence and disagreement about important values involving moral, religious, intellectual, cultural, financial, occupational, and childrearing issues, as well as aspirations, health practices, leisure activities, and other belief systems.

A characteristic family environment, called high expressed emotion, has been identified that defines a relapse-prone family environment in which one individual has schizophrenia, bipolar disorder, anorexia nervosa, or major depressive disorder. This interactional pattern includes demeaning, intense personal criticism ("You are rotten and lazy") and emotional overinvolvement with the identified patient. Aspects of overinvolvement can be measured by quantifying the numbers of hours of face-to-face contact and by the extent to which relatives categorically assert how the patients feel without ever bothering to ask the patients. Despite these descriptive generalizations, the specific elements of high expressed emotion families that make patients vulnerable to relapse are still obscure.

Couple and family system difficulties are most likely to erupt during predictable stressful events in the normal family life cycle, such as during the newlywed period; pregnancy and childbearing; difficult or contentious childrearing; difficulties with parents, in-laws, and other extended family; insurmountable and unanticipated financial or career problems; serious illness or death of a child or relative; the children's adolescence; departure of children from the home; infidelity; and separation.

Interpersonal attachment styles, based on cognitive schemas that have been linked to earlier repeated experiences with caregivers, influence how individuals perceive and act within interpersonal relationships. Specific types that have been described include insecure attachments (several subtypes include preoccupied, fearful,

Telegram: @medical_k

www.konkur.in

and anxious-ambivalent attachment), avoidant attachment (including angry-dismissive and withdrawn attachment), enmeshed attachment, unresolved attachment (in which significant losses have not been dealt with), and secure attachment styles. Specific types and subtypes have now been linked to certain types of health behaviors and clinical outcomes. For example, diabetic patients with dismissive attachment styles, a style found in approximately 25% of the general population and characterized by low trust of others and excessive self-reliance, show a decreased ability to collaborate with providers and have poorer glycemic control than patients with secure attachment styles. In a study at a primary care clinic, patients with insecure attachment styles reported more unaccounted for medical symptoms than others. Among these, patients with preoccupied attachment had the highest primary care costs and usefulness, whereas patients with fearful attachment had the lowest, reflecting their respective tendencies to overuse or underuse medical services.

Interpersonal Disturbances in Illness Behavior

Abnormal illness behavior (dysnosognosia) is a persistently pathologic mode of experiencing, evaluating, and responding to one's own health status despite lucid and accurate appraisal and management options provided by a health professional. These behaviors can be considered as interpersonal disorders between patients and health care professionals. Central to all of these behaviors is the adoption of the sick role by the patient, who then engages in characteristic interactions with health care providers, which typically leave both the provider and the patient dissatisfied. Patients with abnormal illness behavior typically seek repeated medical evaluations from a multitude of physicians, often undergoing a series of expensive laboratory tests. At times, the level of complaints provokes unnecessary invasive laboratory examinations or surgeries, which, in turn, thereby place the patient at genuine medical risk.

Abnormal illness behaviors may be unconscious or conscious. Unconscious abnormal illness behaviors are those in which the

Telegram: @medical_k

www.konkur.in

patient believes the symptoms reflect some genuine illness. These behaviors may occur in somatic symptom disorder, illness anxiety disorder, and conversion disorder (functional neurologic symptom disorder). Abnormal illness behaviors in which patients act sick when they are fully aware that they are not include malingering (in which external incentives—usually financial—are the motivating factors) and factitious disorder with physical or psychological symptoms (Munchausen syndrome). In Munchausen syndrome, patients repeatedly and compulsively present themselves for medical care with feigned or self-induced illness. These self-induced conditions may be so serious as to cause ultimately death: some patients inject themselves with feces to cause systemic infections that then warrant hospitalization and intensive care. When the self-induced nature of the illnesses is discovered, medical staff often become outraged at these patients. The patients rarely accept or cooperate with psychiatric care, so few have been adequately studied. Most do not appear to be psychotic, but there seems to be a disturbance in personality structure. In Munchausen syndrome by proxy, a caregiver, usually a parent, induces illness in a child.

DISTURBANCES IN MOTOR ACTIVITY

Motor behavior is normally finely coordinated, purposeful, and adaptive, and necessary activities are usually carried out efficiently. In psychiatric disturbances, motor abnormalities can involve generalized overactivity or underactivity or manifest in a wide range of specific disorders of movement. Many motor disturbances are seen in psychiatric disorders. Some form part of the core symptoms of the disorders; some occur in disorders that, by their nature, bridge neurology and psychiatry (such as Tourette syndrome); others are acute or chronic medication side effects.

Overactivity

Restlessness and agitation are diffuse increases in body movement, usually noted as fidgeting, rapid and rhythmic leg or hand tapping,

Telegram: @medical_k

www.konkur.in

and jerky start-and-stop movements of the entire body, accompanied by inner tension. Restlessness accompanies psychiatric conditions of high emotional arousal or confusion, such as toxic states, deliria, mania, agitated depressive disorders, and anxiety disorders, as well as many medical disorders such as hyperthyroidism. In some depressive states, agitation is often accompanied by pacing and hand wringing.

Generalized overactivity, in which patients seem to have increased physical energy, is distinguished from agitation by its lack of inner tension and by more purposeful movements. It is commonly seen in mania, hypomania, and anorexia nervosa and as part of ADHD and in response to stimulating drugs and medicines.

A 25-year-old extraordinarily restless man in a psychiatric emergency room, whose glances darted incessantly around the room, paced agitatedly, picked at his skin, shifted constantly on his feet, and jiggled his arms and legs. His speech was rapid, and his mood was irritable. He had been using intravenous (IV) methamphetamine on a “run” for more than 1 week and was brought to the emergency room by relatives who were concerned that he was starting to get paranoid.

In catatonic excitement, much less common now than in the pre-neuroleptic era, patients exhibit disorganized and overactive behaviors, including frantic jumping, thrashing of limbs, and seemingly senseless menacing or attacking behaviors. Such excitement is seen in mania, periodic catatonia, catatonic forms of schizophrenia, and some culture-bound syndromes such as amok. Confusional excitement is a state of restlessness and generalized purposeless activity seen in ictal states, some acute intoxications, and deliria.

Decreased Motor Activity

Telegram: @medical_k

www.konkur.in

Global reductions in motor activity—motor retardation—are seen in a variety of physical disorders, such as hypothyroidism, Addison disease, some infectious and postinfectious conditions, including CFS and post-polio syndrome, and other fatiguing conditions, as well as in some organic mental disorders, intoxications, schizophrenias, and depressive disorders. Poverty of movement (akinesia, or more properly, hypokinesia) may occur in schizophrenia and as a neuroleptic side effect. Changes in the voice frequently accompany the reduced motor activity in schizophrenia and depression, with normal inflection replaced by monotonous tone and prolonged speech latency. In stuporous states, patients remain immobile, although their eyes are open, and they are apparently awake.

Conversion reactions are functional, nonphysiologic, psychogenic impairments in sensory or motor functions. Common motor forms include various paralyses and pareses, including limb paralyses, ataxias, and aphonias. Patients with astasia-abasia have marked unsteadiness of gait. Sensory conversion reactions include blindness, deafness, anesthesia, and analgesia. Some hyperesthesias and pain syndromes may also originate as conversion symptoms.

Telegram: @medical_k

www.konkur.in

An 18-year-old new army recruit from a rural area was brought to the emergency department at an Army post during his period of basic training because his gait had become very unsteady. He was stumbling into walls and seemed unable to maintain an erect posture. He found it necessary to use crutches to ambulate. There was no history of substance use. On examination, the soldier was found to be naïve, tremulous, anxious, and homesick. He had just graduated from high school and had never been away from his family before and missed them deeply. When he was reassured that he would be issued a pass to see his family, his demeanor changed, and his gait instantly improved. To the amazement of his bunkmates and drill sergeant, he was able to leave his crutches at the door. The diagnosis was astasia-abasia.

Catatonic Activity

Catatonia refers to a broad group of movement abnormalities usually associated with schizophrenia but also found in other disorders such as mania, depression, many neurologic disorders (especially those involving the basal ganglia, limbic system, diencephalon, and frontal lobes), systemic metabolic disorders, toxic drug states, and periodic catatonia. Catatonic stupor and excitement have already been noted. Stereotypies are repetitious, bizarre, seemingly non–goal-directed, complex organized gestures or postures that are believed to have private meanings to the patient. Examples include continuously and repeatedly crossing oneself or blessing others in a religious gesture, waving in a stylized manner, and making profane gestures. The stereotypical behaviors commonly seen in autistic children (constant spinning or rocking, often called “stimming”) may provide self-soothing, steady sensory input that helps the patients reduce the degree to which they are disturbed by the ordinarily unpredictable and uncontrollable stimulation coming from the environment. Bizarre posturing may also be seen in catatonia. One chronic schizophrenic patient routinely stood for hours on one leg with his arms in the air

Telegram: @medical_k

www.konkur.in

like a crane. In echopraxia, the patient imitates the examiner's movements and in echolalia imitates speech, as if in mimicry. Some catatonic patients exhibit waxy flexibility, maintaining unusual postures in which they have been posed for prolonged periods of time. Negativism may take the form of refusing to behave in a prescribed manner or resisting passive movement.

Mutism

Mutism may result from a variety of peripheral muscle and CNS conditions and from functional disorders. Mutism may occur in profound depression, catatonic states, and conversion reactions. Elective mutism is occasionally seen in acute adjustment disorders and some personality disturbances.

MOTOR DISTURBANCES AND MOVEMENT DISORDERS

Tremor

Tremors, involuntary oscillating movements of the limbs or head, may occur at rest or with movement. Physiologic tremors, which are minimal at rest and increase with activity, are characterized by small amplitudes and high frequencies. They are characteristic of anxiety, fatigue, and toxic or metabolic disorders, such as caffeinism or hyperthyroidism, and are commonly seen in patients taking a number of different psychiatric medications, including lithium, valproate, and stimulating antidepressants. Coarse tremors, with larger amplitudes and lower frequencies, are seen in Parkinson disease and cerebellar disease. Asterixis is a large-amplitude, flapping tremor of the hands seen in hepatic disease. Parkinsonian symptoms and signs may be seen in psychiatric disorders, particularly in patients taking antipsychotic medications. Symptoms include akinesias with a marked decrease in normally spontaneous fidgeting, stiff gait with diminished arm swing, pill-rolling non-intention tremors (which seem to be less common in drug-induced

Telegram: @medical_k

www.konkur.in

parkinsonism, compared with the idiopathic type), expressionless soft and monotonous speech, micrographical handwriting, and cogwheel rigidity.

Blepharospasm

Blepharospasm is a rapid and violent repetitive, spasmodic movement of the eyelids. These movements are often a side effect of antipsychotic or other medications but are also common in a variety of neurologic disorders, including Meige syndrome and Tourette syndrome.

Tics

Tics are rapid, repetitive, often spasmodic jerking involuntary movements that serve no apparent purpose. The person may try to disguise or hide the tic in a seemingly purposive movement, and the movement may ultimately be shaped into a mannerism. Tics are the central feature of tic disorders, are associated with other disorders, and may occur as a consequence of stimulant use. Tourette disorder is characterized by a chronic shifting array of motor and vocal tics. The tics may include grunts, coughs, clicks, or sniffs, whereas motor symptoms may include eye blinking, tongue protrusions, facial grimacing, hopping, and twitches. Complex tics may merge into complex compulsive behaviors such as squatting, deep knee bends, and retracing steps. Coprolalia, characterized by sudden verbal outbursts of obscenities, occurs in less than one-third of Tourette patients. Mental coprolalia is an associated feature in which obscene words or phrases suddenly intrude into consciousness in an ego-dystonic manner. Obsessive-compulsive symptoms, as well as attention-deficit symptoms, are also common in Tourette syndrome.

Telegram: @medical_k

www.konkur.in

A 21-year-old young man with Tourette syndrome presented to his psychiatrist's office after missing his last two appointments and being off his medications for 1 month. He had recently started a new job delivering pizza. He reported he could no longer control his compulsion to count stairs, tap his fingers, and check his car tire pressure multiple times. During the appointment, while talking, he began blinking his eyes, making guttural noises to clear his throat, followed by a coughing sound, nose picking, and then loudly squealed in a manner that sounded like a cat's meow.

DRUG-INDUCED MOVEMENT DISORDERS

Dystonic Movements

Although dystonic movements are seen in many neurologic disorders, in psychiatric patients, they are almost always secondary to the use of antipsychotic medications. Dystonic reactions consist of intermittent or sustained muscle spasms, typically of the head or neck. Common varieties include tongue spasms causing dysarthria, torticollis (neck spasm), and oculogyric crisis in which there is a forced upward gaze. Opisthotonus (spasms of paraspinal muscles leading to an arched posture) is seen less often. These reactions are most common in young males and typically occur soon after beginning or increasing the dose of a conventional antipsychotic medication.

Akathisia

Akathisia is a syndrome of motor restlessness seen predominantly in the context of antipsychotic and some antidepressant medication use. It has subjective, as well as motor, components. Subjectively, patients experience muscle tension, difficulty finding a comfortable body position, and inability to stop moving; they feel as though they are "jumping out of their skin." Objectively, akathisia classically

Telegram: @medical_k

www.konkur.in

manifests by rocking from foot to foot while standing, frequently crossing and uncrossing the legs when seated, and pacing. Sleep may be disturbed because of physical discomfort. Subjective components of akathisia may be difficult to distinguish from anxiety caused by the primary disorder (typically schizophrenia). Rarely, the restlessness and inner agitation become sufficiently uncomfortable to provoke acts of violence. In pseudoakathisia, objective signs of akathisia are present, but the patient denies feeling restless.

A 45-year-old man with OCD and Tourette syndrome being treated with fluvoxamine, 200 mg per day, inadvertently took 400 mg per day for 3 days. On the third day, he started to feel increasingly agitated, his legs felt restless and jittery, and he started to fidget uncharacteristically. He also noted frequent sighs in his breathing, not his usual respiratory pattern. He recalled feeling these sensations a decade earlier when a previous psychiatrist treated his Tourette syndrome with haloperidol and that his psychiatrist had diagnosed akathisia. After discontinuing the fluvoxamine for 4 days, these symptoms all abated.

Tardive Dyskinesia

Tardive dyskinesia is a movement disorder that occurs only in the context of antipsychotic medication use, occasionally after many months but more commonly after years. The abnormal movements may persist with or without continued medication use or may diminish or disappear over time. The dyskinetic movements occur at rest and can usually be temporarily suppressed volitionally or by purposeful action, distraction, or sleep. The movements are varied. In the most common type, which affects the face, especially the mouth and lips, tongue thrusting, chewing movements, lip smacking, and eye blinking are seen. Another common type is characterized by choreoathetoid movements, such as writhing finger motions. In the less common but more severe truncal dyskinesias, the torso moves in thrusting motions, and respiratory dyskinesia is characterized by

Telegram: @medical_k

www.konkur.in

grunting and irregular breathing patterns. Other tardive (late) syndromes include tardive akathisia and tardive dystonia, in which the abnormal movements emerge late in treatment or upon medication discontinuation.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS), a potentially fatal complication of antipsychotic medication, is characterized by muscle rigidity, fever, diaphoresis, delirium, mutism, and blood pressure abnormalities. Some view NMS as the most severe end of a spectrum that starts with antipsychotic-induced parkinsonism and progresses to extrapyramidal syndrome with fever and then to fulminant NMS.

Rabbit Syndrome

This uncommon drug-induced extrapyramidal syndrome is often misdiagnosed as tardive dyskinesia. It most closely resembles a limited expression of a parkinsonian tremor. Patients make rapid chewing movements similar to those made by rabbits, ordinarily faster and more regular than the orofacial tic of tardive dyskinesia. The tongue is spared.

Serotonin Syndrome

Serotonin syndrome is a disorder caused by excessive serotonergic input in the CNS, probably within the hypothalamus. The most common cause of serotonin syndrome is the combination of two or more medications with serotonin-enhancing properties, usually by different mechanisms. It is characterized by restlessness, myoclonus, hyperreflexia, diaphoresis, shivering, tremor, autonomic changes, including fever, and mental status changes, such as confusion.

MOTOR DISTURBANCES OF SCHIZOPHRENIA

Telegram: @medical_k

www.konkur.in

Many of the abnormal movements ascribed to tardive dyskinesia and other antipsychotic-induced extrapyramidal syndromes have been described in chronically psychotic patients before the introduction of antipsychotic medications. In one series of 100 patients, the large majority of whom were diagnosed as schizophrenic, a review of medical records before 1955 revealed that abnormal purposive movements were found in 83%, mannerisms and tics in 71%, abnormal eye movements in 27%, abnormal postures or facial movements in 42%, and gait abnormalities in 10%. These findings suggest that many patients with schizophrenia have neurologic symptoms not due to medications and that severe psychiatric disorders may have a neurologic component as well.

OTHER MOVEMENT DISTURBANCES

Gait disturbances in patients with psychiatric disorders include a variety of neurogenic gaits consistent with brain disease, intoxications, and medication side effects. These include the festinating gait of parkinsonism, spastic and ataxic gaits of neurologic disease and psychiatric medications, waddling and reeling gaits associated with intoxications, and the nonphysiologic gait disturbances seen in astasia-abasia, a form of conversion disorder. Gait mannerisms include clowning, prancing, and military gaits.

Bruxism, chronic jaw clenching, may occur involuntarily during tension states, as an isolated occurrence during delta sleep, in which it has sometimes been associated with benzodiazepine or alcohol use, or in association with SSRI use. In severe cases, serious damage to dental enamel and temporomandibular joint pain may occur.

Myoclonus, characterized by focal muscle jerking, can be caused in psychiatric patients by certain medications, such as SSRIs or monoamine oxidase inhibitors (MAOIs). Myoclonic jerks may be difficult to distinguish from tics, but the latter often represent larger muscle groups and more highly organized motor patterns.

Telegram: @medical_k

www.konkur.in

Myoclonus may be seen at rest but is more obvious during motor activity.

Seizure-Like Behaviors

In addition to the generalized, petit mal, and complex partial seizures seen in some psychiatric patients, a number of nonepileptic seizure-like behaviors must be distinguished. Breath-holding spells, generally innocuous, impulsive, and tantrum-like phenomena, usually occur in small children who hold their breath during moments of oppositional rage and who may faint as a result. Jerking or twitching motor movements may occur. Temper tantrums in young children may look like seizures, especially to the uninformed observer. The children may lie on the floor, screaming and kicking, and do not respond to the environment. Conversion seizures (hysterical seizures or pseudoseizures) must be differentiated from genuine epileptic seizures. Patients retain consciousness, lack abnormal reflexes, and are not incontinent. However, because so many conversion seizures occur in patients who have genuine epilepsy and who know a good deal about the condition, the differential diagnosis is sometimes difficult.

Compulsive Behaviors

Compulsive behaviors may occur in relation to everyday activities, such as gambling, sexual conquest, shopping, and watching television, or in relation to substances such as alcohol, cocaine, narcotics, and food. Other compulsions involve reckless risk-taking behaviors that provide stimulation and dispel dysphoric moods. Sexual compulsive perversions, such as exhibitionism and sadomasochism, may serve similar purposes. Compulsions are seen in a variety of psychotic and nonpsychotic psychiatric disorders. The cravings that underlie compulsive behaviors are strong motivating forces, and the compulsive behaviors may regulate emotions. Unknown similarities may underlie all compulsive and addictive mechanisms. Current controversies surround the relationships of compulsive, impulsive, and addictive behaviors. Some authorities

Telegram: @medical_k

www.konkur.in

have proposed that all three should be subsumed under the rubric of a so-called reward deficiency syndrome, resulting from various combinations of gene polymorphisms governing dopamine and opioid mechanisms and including serotonin, cannabinoid, and other transmitter systems as well. From this perspective, the compulsive, impulsive, and addictive behaviors all increase the amount of dopamine and potentially other transmitters in specific brain areas. Studies in the past decade have shown that, in various subject groups, the Taq 1 a1 allele of the DRD2 gene is associated with alcoholism, drug abuse, smoking, obesity, compulsive gambling, and several personality traits. Several other candidate genes are also under investigation. Studies have also shown that certain impulse-like behaviors may be associated with very specific genetic polymorphisms. In studies of patients with severe obesity, binge-eating behavior was seen only in those individuals who had specific mutations in genes controlling the expression of melanocortin 4 receptors.

In OCD, the compulsions are ritualized, repetitive behaviors that are performed with the goal of satisfying, neutralizing, and undoing obsessional thoughts. Although intended to decrease anxiety, rituals are never more than transiently successful. The most common compulsions involve checking to make certain that gas jets and faucets have been turned off and that windows and doors are locked, hand washing, repeating certain phrases, counting objects, and placing objects in a prescribed order.

A 47-year-old woman had always been fussy about order and cleanliness but, since the birth of her child 14 years before, had become increasingly obsessed by cleanliness. She spent 3 hours daily ritualistically cleaning the apartment, using three to four rolls of paper towels daily. If a family member left even a fingerprint on a table, she became agitated and spent much time recleaning the surface and admonishing the family member.

www.konkur.in

FUTURE PERSPECTIVES

Particularly in the last decade and in the near future, there is hope that new research and advances in the neurosciences will yield an even greater understanding about psychiatric illness. However, clinical acumen in the practice of psychiatry is still as relevant today as during the origins of psychiatry. A firm conceptual grasp of the clinical descriptors of psychopathology is an important part of a clinician's armamentarium. As yet, nothing has replaced the understanding of psychiatric signs and symptoms integrated in the context of the diagnostic interview and mental status examination in formulating an accurate differential diagnosis and ultimately a comprehensive management plan. Even as psychiatrists move toward further improving and modernizing the categorical diagnostic systems vis-à-vis the DSM-5 diagnostic manual, clinicians will continue to strive to hone and refine their understanding of the clues provided in the clinical manifestations of psychiatric disorders in order to best care for their patients.

9 Classification in Psychiatry

9.1 Present and Future of Classification Systems for Mental Disorders

JAVIER I. ESCOBAR, M.D., M.SC., AND HUMBERTO MARIN, M.D.

This chapter will first discuss the importance of classification systems in the field of medicine, with particular emphasis on mental disorders. It will then provide highlights on the history of psychiatric diagnosis. Next, it will focus on historical, diagnostic, practical, and developmental issues related to current classifications with a particular focus on the Diagnostic and Statistical Manual (DSM) of the American Psychiatric Association (APA), the current classification for mental disorders in North America. Some general information will also be provided on the International Classification of Diseases (ICD) of the World Health Organization (WHO), including a few highlights on the recently released ICD-11.

DSM-5, the latest version of the DSM released in 2013, will be discussed in detail, highlighting major changes from previous editions, its advantages, disadvantages, and shortcomings, as well as practical aspects for its clinical use. Recent updates (from 2014 onward) to the DSM-5 will also be briefly outlined.

Finally, this chapter will present some new developments, particularly the use of dimensional diagnoses, with emphasis on the Research

Telegram: @medical_k

www.konkur.in

Domain Criteria (RDoC) and the potential of these new developments for clinical and research applications.

CLASSIFICATION IN MEDICINE

Classification systems are essential in all sciences. In the case of the medical field, the main functions for a diagnostic classification are communication and prediction. “Diagnosis is prognosis” was the eloquent articulation of two pioneers of psychiatric diagnosis, Donald W. Goodwin and Samuel Guze, both working at Washington University in St. Louis in the early 1970s.

In the field of psychiatry, a critical and perennial problem in developing valid classifications is the fact that for most mental disorders, there are no beacons or reliable markers that would allow the unequivocal identification and systematic separation of disorders. Despite this absence, the functions of psychiatric classifications are still quite relevant, even if they are currently present only as tentative charts or maps, or more descriptively, “blurry lighthouses” that help guide practitioners in the wide, stormy sea of clinical practice. No matter how primitive they may be, these classification systems bring practitioners at least a modicum of security and reassurance for dealing with the complex issues of human behavior, thought processes, cognition, and other subjective phenomena, as the specialty of psychiatry tries to emulate or at best imitate what other medical specialties do in this regard.

In the absence of objective, reliable, measurable markers for specific mental disorders, there are only a few feasible ways for developing classifications of mental illness. The first and most traditional example has been the authority-based method used for classifying mental illness until the mid-20th century. In this tradition, the descriptions of clinical disorders originally made or endorsed by highly visible authorities in the field were gradually accepted until they became common currency.

The strategies that followed the early models added new components, incorporating a consensual, collegiate mechanism, not very different from that of legislative bodies in a democratic state. A key objective of these new efforts was to fill many of the existing gaps in scientific evidence. This process progressively engaged more and more individuals in the discussion. Remarkably, in the end, this strategy got almost everyone on the planet to utilize the same language when discussing mental illness.

Telegram: @medical_k

www.konkur.in

However, as the field of medicine becomes more and more evidence based, a tension has surfaced between the need to adopt the growing body of scientific evidence and the wish to satisfy the needs and interests of a large number of constituent groups, including researchers, clinicians, patients, advocates, public and private health institutions, pharmaceutical companies, data managers, and others. In search of a more thorough inclusion of potential clinical syndromes and seeking additional specificity, the psychiatric specialty has kept building diagnosis after diagnosis, disorder after disorder, hoping perhaps that this would lead to more precise treatment interventions and allow a better prediction of outcomes. However, as it will be seen ahead, the proliferation of disorders supported by rather slim and fragile scientific evidence has become worrisome.

As virtually all of those practicing in the mental health field today were trained as part of the DSM tradition, the system is generally taken for granted, used mechanistically, with little thought about its origins and evolution, benefits, and limitations. Therefore, background information on the origins, evolution, strengths, and weaknesses of the DSM will be provided below.

BRIEF GLOSSARY

First, it is important to define the key terms and concepts to be used herein:

- A *syndrome* is a cluster of symptoms that can result from different disease processes. For example, cough and fever can result from bacterial, fungal, or viral infections, or autoimmunity, all processes implying different interventions and outcomes.
- A *disorder* is something of medical concern in a patient, an abnormality, injury, disability, or aberration. This term is often used instead of the term *disease,* which implies a known pathologic process, used in the case of medical conditions for which the causes are known, and the pathophysiology well established.
- A *diagnosis* is simply the opinion, by someone with expertise in the matter, that a given disorder is present (or absent) in a patient. *Diagnosis* is also used to name the procedure to decide whether or not a certain disease or disorder is present (or absent). A *diagnosis* can be "*categorical*" (the condition is either present or absent) or "*dimensional*" (the condition represents a certain point in a continuum).

Telegram: @medical_k

www.konkur.in

- *Diagnostic classification* is the listing of diagnoses grouped by relatedness. Examples include infectious, autoimmune diseases, cancer, or injuries in medicine, or anxiety, affective or psychotic disorders in psychiatry.
- *Diagnostic criteria* are the rules that need to be followed for making a diagnosis. Once made, a diagnosis is *reliable* if the same conclusion about its existence can be reached by at least two independent observers (inter-rater reliability) or if the patient receives the same diagnosis when examined more than once within a reasonable time period (test–retest reliability). A diagnosis is *valid* if it picks out a "real" entity based on etiology and pathophysiology.
- Diagnostic reliability and validity: It is important to emphasize that *reliability* and *validity* are separate dimensions. In the case of mental disorders, the fact that different observers are able to recognize a set of symptoms when they appear together (reliability) does not necessarily mean that they correspond to a real entity (validity). In fact, the emphasis on diagnostic reliability may have limited the progress in reaching diagnostic validity, especially in the case of disorders with a complex or fluctuating clinical course. Clearly, validity remains elusive for a great majority of psychiatric conditions.

DEFINITION OF MENTAL DISORDER (DSM-5)

As defined in the DSM-5 Manual, "A mental disorder is a syndrome characterized by clinically significant disturbance in an individual's cognition, emotion regulation, or behavior that reflects a dysfunction in the psychological, biological or developmental processes underlying mental functioning. Mental disorders are usually associated with significant distress or disability in social, occupational, or other important activities. An expectable or culturally approved response to a common stressor or loss, such as the death of a loved one, is not a mental disorder. Socially deviant behavior (e.g., political, religious, or sexual) and conflicts that are primarily between the individual and society are not mental disorders unless the deviance or conflict results from a dysfunction in the individual, as described above." The above definition may be difficult to apply to the totality of conditions listed in the manual, and it may be hard to assure or convince practitioners that each disorder included in DSM-5 truly represents a "specific dysfunction in processes underlying mental functioning."

BRIEF HISTORY OF PSYCHIATRIC DIAGNOSIS

While the concept of mental illness dates back at least as far as the Greek civilization or even further back (as suggested by the finding of cranium trepanations in prehistoric times), there has always been significant interest and effort placed on the concept of mental disease or infirmity from ancient times to current day, as healers, physicians, and thinkers from different centuries described mental conditions that are recognizable by today's standards.

Regarding the diagnostic controversy between categories and dimensions, it is interesting to add a historical note to highlight that the Greek philosophers might have started this debate. Indeed, the platonic ideal of classification consisted of an exhaustive, mutually exclusive categorical system, while the Aristotelian approach conceived dimensions, described as overlapping entities, separated from normality by arbitrary thresholds.

Many of the old, historical, or classical designations for mental disorders are still in use today, at least in common parlance, and until very recently, some of them were formally utilized in psychiatric nomenclatures as it was the case with hysteria, hypochondria, mania, and melancholia, the four classic mental syndromes of yesteryear according to Michel Foucault's influential book of the early 1960s.

Systematic, "official" classifications and nomenclatures for mental disorders are rather recent undertakings that convey additional features to the process of naming mental conditions. These systems transform this process into a social enterprise, with implications in many domains of life (e.g., fostering scientific dialogue and progress, public discussion and education, policy decisions, reimbursement for services, data management, treatment, and others).

The introduction, by the middle of the last century, of classification systems for mental disorders that were comprehensive and practical enough to gain wide acceptance was a critical factor contributing to the development of modern psychiatry as a branch of the medical sciences, allowing the specialty to go beyond a simple "humanistic" endeavor. Thus, homage should be paid to the people from multiple disciplines that contributed to the creation, implementation, and, perhaps more importantly, to the reform of older classification systems, in order to make sure that they would remain relevant up to this day and age.

CLASSICAL EUROPEAN PSYCHOPATHOLOGY

In the 19th century and the beginning of the 20th century, key figures of classical European psychopathology were Emil Kraepelin, with his descriptive psychopathologic approach, Carl Wernicke, the main proponent of a biologic approach, and Karl Jaspers, a philosopher who applied his phenomenologic approach to psychiatric assessment and diagnosis. During that same period, North American psychiatry followed the lead of European psychiatry, focusing mainly on the Kraepelinian line. Toward the end of this chapter, these historical approaches will be briefly contrasted with current developments in psychiatric classification, highlighting the need for a richer assessment of psychopathology.

THE U.S. CLASSIFICATION SYSTEMS LEADING TO DSM-5

The intent to record and catalog mental illness in the United States started with the 1840 census, a process that, besides counting people, also incorporated scrutiny of physical illnesses as well as a category for "idiocy/insanity." In the 1880 census, the categories "mania, melancholia, monomania, paresis, dementia, dipsomania, and epilepsy" were added, and these categories were quickly adopted by the "Association of Medical Superintendents of American Institutions for the Insane," a society formed in 1844, which in 1892 changed its name to "American Medico-Psychological Association," and that in 1921 would become the "American Psychiatric Association."

In 1917, together with the National Commission on Mental Hygiene, the society that was the precursor of the APA, developed the "Statistical Manual for the Use of Institutions for the Insane," and also, with support from the New York Academy of Medicine, the same APA precursor developed the "Mental Subsection of the United States General Medical Guide," the "Standard Classified Nomenclature of Disease," known simply as the "Standard." During World War II, U.S. psychiatrists working in the armed forces were involved in the selection and treatment of soldiers, and the Office of the Surgeon General issued a special classification called "Medical 203," which was adopted with modifications by different branches of the armed forces and the Veterans Administration. These different versions of "Medical 203" continued to be used, along with the

Telegram: @medical_k

www.konkur.in

"Standard," and this contributed to the "confusion" highlighted in the foreword to the first edition of the DSM that was introduced in 1952. In a "back to the past" fashion, the controversies related to psychiatric nomenclatures reached a level of "confusion of tongues" in 1948, similar to the one that had plagued the medical nomenclatures in the 1920s. At least three psychiatric nomenclatures were in general use then, the "Standard," and the ones developed by the Armed Forces and the Veterans Administration. All these classification systems were quite disparate and did not fall in line with the International Statistical Classification, so that some of the agencies were in the uncomfortable position of using one nomenclature for clinical use, a second one for disability ratings, and a third one, the international classification, for statistical work. In addition, practically every teaching center in the country had made modifications to the "Standard" for its own use, and assorted modifications of the Armed Forces nomenclature had been introduced into many clinics and hospitals by psychiatrists returning from military duty.

INTERNATIONAL CLASSIFICATION OF DISEASES

The ICD was the descendant of the "Bertillon Classification of Causes of Death," introduced by the French physician Jacques Bertillon in 1893 at the congress of the International Statistical Institute in Chicago. Multiple countries adopted this classification, including those in North America, and in 1900, an international conference revised what was then called the "International Classification of Causes of Death" and agreed to hold revisions of the system every 10 years. In 1948, the then recently created WHO, an agency of the United Nations, assumed responsibility for the ICD. The sixth revision, published in 1949, involved significant changes, as it included morbidity in addition to mortality, so that the title was changed to "International Statistical Classification of Diseases, Injuries, and Causes of Death." It is important to point out that the sixth revision of the ICD was the first one to include a section on mental disorders. The ICD is now in its 11th official edition, and this was released only very recently. Both the DSM and the ICD sections on mental disorders have been working in a collaborative fashion for several decades, and the two systems have become very similar. Therefore, many of the general comments that follow on the DSM would also apply to the mental disorders section of the ICD.

Telegram: @medical_k

www.konkur.in

EVOLUTION OF MODERN PSYCHIATRIC NOSOLOGY IN THE UNITED STATES

In debating the merits and limitations of the DSM (and obviously, the mental disorders section of the ICD system as well), it is important to remember the historical context operating at the time when these systems originated and how the classifications have evolved (or regressed) with the passage of time. The first edition of the DSM was published in 1952, and the first ICD, including a mental nosology, the ICD-6, was published in 1949. This happened long before the emergence of "evidence-based" medicine and psychiatry, at a time when mental nosology in the United States was in a relatively dormant state. Indeed, those were the 1940s and 1950s, the decades of the clinical and theoretical hegemony of both the psychoanalytic theory of Freud and his followers and the biopsychosocial approach of Adolf Meyer. For both of these perspectives, mental illness was a reaction of the mind to outside forces (the family environment for psychoanalysis and the psychological, social, and biologic realms for Meyer and his followers). Thus, in clinical practice, diagnosis made little practical difference as many practitioners would adhere to the theoretical postulates proposed by these dominant systems. Thus, before the middle of the 20th century, mental health clinicians practicing in North America learned their trade and applied it to their clinical practice, with little regard to classifications, research evidence, theories of disease, or potential treatments. A few enclaves in the United States, particularly in the mid-Atlantic area (St. Louis, Baltimore, New York), maintained at least part of the European tradition (again, mainly the Kraepelinian one) and were also influenced by the medical model approach and philosophical realism (positivism, empiricism) more than the phenomenologic model (Jaspers).

It was only in the 1950s that evidence-based psychiatry began to emerge with the development of the first sets of psychotropic drugs backed by systematic research, such as lithium, phenothiazines, tricyclic antidepressants, mono amino oxidase (MAO) inhibitors, and benzodiazepines. Evidence-based psychotherapies such as cognitive behavioral therapy (CBT) would have to wait much longer (until the late 1970s) to be confirmed as "effective" by well-controlled clinical trials.

This was the environment in which the first edition of the DSM (without numeral) was produced, in 1952, by a group of seven people

Telegram: @medical_k

www.konkur.in

commissioned by the APA. The 1952 DSM lists 108 disorders in a descriptive section that takes only 32 small pages of text. However, a significant number of these items correspond to neurologic and other medical disorders that have since then migrated to other specialties. Thus, the actual number of mental disorders in the first DSM was in the two-digit range, a number that has grown to almost 400 in DSM-IV and DSM-5 (Fig. 9.1–1). This explosion in the number and detail of psychiatric disorders that started with the DSM-III will be discussed in more detail ahead in this chapter.

It is important to observe that despite the dominance of the DSM in the United States since the introduction of its first edition in 1952, other methodologies and proposals for psychiatric classifications have been periodically offered, such as the St. Louis criteria and the Research Diagnostic Criteria (RDC). These differ from the DSM in that they placed a major emphasis on available scientific evidence. Some of these proposals have, in turn, influenced the DSM, as will be seen later.

A pivotal U.S./U.K. diagnostic study, demonstrating that training and collaboration across the Atlantic would make compatible the differing diagnostic practices of North American and British psychiatrists, and next, the International Pilot Study of Schizophrenia (IPSS), showing that concordant schizophrenia syndromes could be reliably identified in nine countries of the world, had both an important impact on modern diagnostic developments. The Present State Examination (PSE) developed at Maudsley hospital under the leadership of John Wing, a psychiatrist adhering to Jaspers' phenomenologic approach, provided excellent symptomatic descriptions of the major psychiatric syndromes, and to this date, remains a unique and valuable instrument to assess psychopathology. Its rich descriptions of symptoms and signs make it still ideal for teaching psychiatrists in training about the range of psychopathology.

www.konkur.in

FIGURE 9.1–1. The DSM system. Key issues and number of categories.

MODERN PSYCHIATRIC CLASSIFICATIONS IN NORTH AMERICA

The St. Louis Group

Modern psychiatric classifications in North America were given a "jump-start" in the 1960s, when a group of investigators at Washington University and Renard Hospital in St. Louis, Missouri (one of the "neo-Kraepelinian" enclaves mentioned above), led by Eli Robins and Samuel Guze, started using a process inclusive of successive steps, such as clinical description, laboratory studies, delimitation from other disorders, follow-up studies, and family history, for validating psychiatric syndromes customarily diagnosed in clinical practice. This led to a list of 12 disorders that were deemed "valid" at that time, as they went through the various validation steps listed above. These "valid" entities included hysteria (somatization disorder), panic disorder (anxiety neurosis), obsessive-compulsive disorder (OCD), phobic disorder, affective disorders (depression, mania), schizophrenic disorder, alcoholism, drug dependence, sociopathy (antisocial personality), brain syndrome, anorexia nervosa, and sexual problems. While the parsimonious Eli Robins and Samuel Guze were not rushing to publicize their strategy quite yet, an ambitious psychiatric resident, the late John P. Feighner, convinced his mentors to prepare a paper for publication. The paper, published in the Archives of General Psychiatry in 1972, has become one

Telegram: @medical_k

www.konkur.in

of the most quoted papers in the history of psychiatry. Curiously, Goodwin and Guze never mentioned Feighner's paper in any of the editions of their classical textbook "Psychiatric Diagnosis."

Research Diagnostic Criteria

Next, in the 1970s, came the RDC, an effort led by Robert Spitzer at Columbia University, another U.S. enclave where classical psychopathology had a niche. The "neo-Kraepelinian" RDC, largely based on the St. Louis criteria, set the stage for a "paradigm change" in the official APA classification, as Robert Spitzer was named to lead the APA task force on DSM-III. Spitzer would later state: "With its intellectual roots in St. Louis instead of Vienna, and with its intellectual inspiration drawn from Kraepelin, not Freud, the task force was viewed from the outset as unsympathetic to the interests of those whose theory and practice derived from the psychoanalytic tradition." From that point on, almost everyone practicing today knows the rest of the story. This chapter will return to the more recent iterations on the development of the DSM in the sections ahead.

Heuristic Formulations for Psychiatric Diagnosis

In the late 20th century, in Europe, the "psychological dysfunction" model proposed by the British scientist Sir Aubrey Lewis theorized that constructs such as "phobias," "obsessions," or "thought disorder" were probably linked to biologic mechanisms. Lewis also supported the concept of single depression (rather than the melancholic/reactive dichotomy), as a continuum, with "melancholia" in one extreme and "neurasthenia" in the other. Lewis was a key figure in the ICD-8 classification of mental disorders, the first one containing a glossary. According to Fulford and Sartorius, while the ICD-8 and the glossary were based on a report to the WHO in the early 1960s by British psychiatrist Erwin Stengel (which in turn was based on a logical empiricist analysis of psychiatric classification developed by an American philosopher of science, Carl Hempel), it was Lewis who initiated the key move from the theoretical (etiologic) to the descriptive (symptom-based) classification of mental disorders.

Similarly, DSM-IV-R was significantly influenced by the theories of Jerome Wakefield, another philosopher of science, at the time based at Rutgers University in New Brunswick, New Jersey. Wakefield proposed a "harmful dysfunction analysis" as a theoretical backup for psychiatric

Telegram: @medical_k

www.konkur.in

classifications. According to this theory, there is a subjective element that implies that the condition is “harmful” or “undesirable” to the individual and an objective element that assumes that the condition is due to a “malfunctioning internal mechanism.” Together with Allan V. Horwitz, a social scientist, also at Rutgers, Wakefield published in 2007 a book entitled “The Loss of Sadness: How Psychiatry Transformed Normal Sorrow into Depressive Disorder.” The authors argue in the book that sadness is a normal human emotion that appears in front of losses and misfortunes, and they criticize the almost exclusive biologic focus of psychiatry in interpreting and managing this heterogeneous disorder. To bring into play the contribution of the social sciences, these authors proposed, following the path of DSM-III and IV, the use of bereavement as an exclusionary criterion for depression, adding an additional clause to incorporate and expand relevant contextual factors that would rule out depressive disorder. These would include not only bereavement but also other major life stressors or losses such as marital dissolution, loss of a valued job, and other life events. Little they knew (as will be described ahead under depression) that just a couple of years later, DSM-5 would also strike at the bereavement exclusion.

Dominique Murphy, another philosopher interested in psychiatric diagnosis (who also spent time at Rutgers University), in his book “*Psychiatry in the Scientific Image*,” criticizes the “atheoretical” view of the later editions of the DSM and advocates for a “causal” nosology. While acknowledging the limitations of current theories about causes of mental disorders, Murphy believes it is still possible to move forward even if the theory is not completely worked out. This may become the philosophical or theoretical underpinning for new diagnostic initiatives such as the RDoC to be discussed ahead.

Classifications in Medicine

Despite their pretension of “scientific objectivity,” classification systems in the applied sciences (especially the health sciences) are not created in a social vacuum by completely neutral scientists or practitioners. In the end, these systems represent essentially a consensus or compromise between the needs, beliefs, and expectations of different stakeholders operating at a particular time and place. The complexity of the deliberations is compounded by the fact that the interests and convictions of the various stakeholders may coincide, disagree, or be indifferent to those of the

Telegram: @medical_k

www.konkur.in

others and may also change over time. As mentioned early in this chapter, diagnostic criteria for diseases in other areas of medicine can often be confirmed with objective, verifiable procedures akin to a “gold standard.” However, there are numerous medical conditions, particularly those entities termed “functional” (chronic fatigue, fibromyalgia, irritable bowel, and many others), for which objective, verifiable, and measurable “gold standards” are not available and whose “validity” is as questionable as that of many mental disorders. Several other “physical” conditions, such as asthma, chronic obstructive pulmonary disease (COPD), and diabetes, among others, continue to present significant challenges for their objective assessment and proper management. For example, criteria for diagnosing COPD include first a set of “key indicators” such as “dyspnea,” “chronic cough and sputum production,” “wheezing and chest tightness,” “history of exposure to risk factors,” and “family history.” Some of these indicators (e.g., dyspnea) are quite subjective, may be hard to assess or detect, particularly in the early stages of the disease, and can be shared by a multitude of conditions. “Objective” assessments such as physical examination or chest x-rays convey limited information in early COPD, and results from “the confirmatory test,” spirometry, the true “gold standard,” are often difficult to interpret unambiguously. Even for disorders with clear, measurable markers such as diabetes, diagnostic thresholds change or fluctuate as classifications are updated. For decades, the diagnosis of diabetes has been based on glucose criteria, either the fasting plasma glucose (FPG) or the 75-g oral glucose tolerance test (OGTT). In 1997, the “expert committee on the diagnosis of diabetes” (the equivalent group to the DSM task force) revised the criteria on the basis of retinopathy assessed with new technologies and recommended lowering the cutoff point of FPG from 140 mg/dL to 126 mg/dL. Thus, even in the case of objective, measurable markers, frequent inspection and revision of criteria seem warranted. To further complicate matters, some authors insist that if the “gold standard” for medical diagnosis is defined as the “measure or precise equivalent that is verifiable,” autopsy and biopsy remain the ultimate “gold standards” in the field. This is the main reason why the “consensus of experts” continues to be frequently used as the “gold standard” in medicine, as many medical conditions are not consistently associated with an essential lesion that is universally accepted. Thus, in many instances, quoting from the neurologic textbook

Telegram: @medical_k

www.konkur.in

authored by A. Lerner in 2010, “diagnosis in medicine remains a deductive exercise.”

Of course, the situation of psychiatric diagnosis is much more problematic, as the “symptoms” for most psychiatric syndromes consist of verbal reports and probes obtained directly from the patient, and the “signs” are the observed behaviors, detected through the traditional methods of anamnesis and mental status examination. In most instances, the current method for defining mental disorders involves a “willing suspension of disbelief,” as is accepted, without conclusive proof, that the set of symptoms (“the syndrome”) originate from a common source or that they are at least part of some type of unitary functional unit, as in the case of anxiety, depression, mania, psychoses, or dementia.

Advantages of the DSM System

The scientific/collegiate/consensus mechanism adopted by the APA (especially for the more recent versions of the DSM) was based on focused discussion by groups of experts under the umbrella of the organization. Since the APA, in general, has had good social and scientific standing, this mechanism has been a good practical solution throughout the years, both from the scientific and political points of view. The initial impact of clearly and succinctly defining key syndromes such as schizophrenia, panic anxiety, melancholic depression, manic-depressive illness, or dementia, backed by solid historical descriptions in the scientific literature, observations on heritability, and other features, supported the unitary character of the key syndromes. These were the clinical entities acknowledged by the St. Louis Group in the 1960s, whose existence and validity received a powerful confirmation with the therapeutic advances of the 1950s and 1960s, showing that there were pharmacologic agents that specifically targeted each of these syndromes and that apparently, “treatment-response” to a certain agent was a “marker” for a certain clinical condition. This was, of course, an illusion that gradually dissipated with the passage of time, following the accrual of evidence from randomized clinical trials and cumulative clinical experience.

Shortcomings of the DSM System

The most important intrinsic weaknesses attributed to the DSM include the following:

Telegram: @medical_k

www.konkur.in

- The proliferation of new disorders in each new version of the DSM classification with only limited support in scientific evidence
- The problem of the arbitrary thresholds, for example, number of symptoms or duration in time required for a diagnosis
- The frequent need to use nonspecific diagnostic codes such as the “not otherwise specified” (NOS).
- The problem of comorbidity, as a significant number of patients qualify for a high number of DSM diagnoses simultaneously.

All these problems are intimately related and will be briefly discussed below.

As mentioned before, only a handful of diagnoses listed in the first two versions of the DSM have survived in recent editions, while the total number of diagnoses approaches 400 in DSM-5.

The main reasons for this explosion in the number of psychiatric diagnoses include the following:

- Breaking down or fragmenting well-accepted diagnostic entities, such as for example, “anxiety,” into large numbers of “subtypes” of decreasing validity. In order to create these new disorders, the detail of each diagnostic definition keeps growing, incorporating complex and arbitrary thresholds. With the increase in detail and restrictiveness, the clinical representativeness of each definition tends to diminish, and trivial disorders may be reified.
- The persistence and the creation in each DSM edition of “mental disorders” defined on the basis of their discordance with culturally sanctioned rules of behavior (such as personality disorders and a number of sexual disorders).
- The proliferation, in the absence of scientific evidence, of disorders defined by circumstances external to the individual, such as the addictive disorders, separated according to individual substances, behavioral addictions, or phobic disorders.
- The need felt by clinical practitioners to use vague, ambiguous codes, such as the NOS categories in DSM-IV, may arise to a large extent from the conflict between the increasing detail and restrictiveness of the DSM classification and the heterogeneity of clinical populations regarding number and assortment of symptoms, their duration or severity, and sequencing or fluctuation over time. Thus, the more “precise” and restrictive the definition of a mental disorder becomes, the lower the proportion of clinical patients that would meet the criteria

Telegram: @medical_k

www.konkur.in

for that specific disorder and the larger the number of patients that may have to be allocated into nonspecific categories.

- Unfortunately, this increased detail of the definitions on paper is generally interpreted by administrators and data managers as equivalent to improved diagnostic ability in clinical practice, which is clearly not the case. An emerging reality is that insurers and data managers may end up rejecting nonspecific categories and demand the formulation of precise diagnoses at the risk of losing reimbursement. Moreover, arbitrary thresholds such as the 6-month duration rule may exclude many cases that would go on later to develop full-blown syndromes.

Increasing Complexity of the DSM Process

The first DSM was prepared by the "Committee on Nomenclature and Statistics of the American Psychiatric Association" and published in 1952. This first DSM listed 7 people as members of the "APA Committee on Nomenclature and Statistics" that produced the manual, and this remained unchanged for DSM-II (10 people, including 2 who were "consultants" and 1 "representing the council"). However, the explosion in the size and complexity of the DSM system starts with DSM-III. The number, functions, and size of committees increased exponentially, and the decision-making process was organized in various layers. The DSM-III included a "Task Force on Nomenclature and Statistics" with 19 members, 12 Advisory Committees (each targeting specific types of disorders) with up to 18 people each, as well as other committees such as the "Multiaxial Diagnosis Committee," the "Glossary of Technical Terms Committee," the "Assembly Liaison Task Force," and the "Board of Trustees Ad Hoc Committee" plus numerous consultants. DSM-III, with its operational structure and descriptive criteria presented in a "Chinese menu" format, quickly became the predominant paradigm at a time of limited treatment resources, insufficient research, and scarce evidence about causality. An enhancement of communication was the paramount initial consideration at the time, and DSM-III seemed quite successful in accomplishing this goal, as attested by its worldwide use. Responding to the publication of DSM-III in 1984, Gerald Klerman, an influential psychiatrist, also a "neo-Kraepelinian," stated categorically, "the problem of diagnostic reliability has been solved."

Telegram: @medical_k

www.konkur.in

The ensuing DSM-III-R simply broadened the criteria, and DSM-IV added a requirement for “Clinical Significant Distress or Impairment.”

DSM-5

The DSM-5 task force was officially convened in August 2007. It originally consisted of 26 members, 20 of them U.S. academic psychiatrists with high visibility in different areas of the specialty, one representative for psychiatry residents, one representative for patients, two psychiatrists representing APA governance (board and assembly), and one psychiatrist representing the World Psychiatric Association. As in the case of DSM-III and IV, the DSM-5 task force was the steering body for the whole process. The first step was to name several workgroups with responsibility for specific diagnostic areas, each led by a member of the task force. Each of these workgroups had, on average, about 10 members, as well as long lists of consultants. For the ensuing 5-year period (2008 to 2013), the task force and workgroups frequently met both in person and via teleconference, reviewing the evidence base related to current diagnoses, as well as that for potential new ones. The initial goal was to come up with a new system that capitalized on the gains of the “decade of the brain” with the tremendous progress made in basic neuroscience and the enthusiasm generated by the sequencing of the human genome. Because the risk for key disorders such as schizophrenia, bipolar, and major depressive disorder has a major familial component, it was hoped that by the time of the new DSM edition, specific genetic markers such as polymorphisms or structural abnormalities would have been identified, which would “tag” certain disorders and help to dissect them into meaningful phenotypes. Another expectation was that the increased research using objective tools such as structural and functional neuroimaging would yield reliable “markers” for several psychiatric disorders. Also, the initial hope was that DSM-5 would become a second “paradigm shift” for psychiatric diagnosis (DSM-III has been viewed as the first) by incorporating a dimensional approach as an alternative to a categorical one, considering new models of classifying psychiatric syndromes (e.g., brain “circuitry”), and hopefully decreasing rather than increasing the number of diagnostic categories in the manual. Upon gathering the task force and the workgroups and reviewing the available evidence, the unbridled enthusiasm on finding “markers” from neuroimaging or genetic studies and the possible use of novel strategies

Telegram: @medical_k

www.konkur.in

such as “brain circuitry” to classify mental disorders quickly dissipated and “reality” would soon set on the horizon. It thus became clear that the main task of DSM-5 should be an effort to enhance the current descriptive, operational approach by eliminating dubious syndromes, improving wordings and definitions, examining the evidence for new diagnostic entities, and the practical utility of a dimensional approach. As part of this process, the task force carefully examined previous versions of the DSM, particularly DSM-IV, to identify key areas in need of revision or elimination. There was awareness on the fact that in defining mental disorders, previous versions of DSM had not described or mapped natural phenomena accurately, implying—using the traditional analogy of carving a turkey—that the diagnostic system “did not carve nature at the joints.” It became clear that the multiple categories with doubtful boundaries forced clinical practitioners (at least the most scrupulous ones) to overutilize the “NOS” or “NOS” diagnoses. This was confirmed by a survey of general use, showing that the most common diagnosis made by psychiatrists in North America was “Depressive Disorder NOS.” The discussions also acknowledged that while DSM-III (and also DSM-IV) responded to a strong desire for inter-rater reliability by developing operational criteria, they arbitrarily treated every disorder as a category that was discontinuous from “normal” and from other disorders, thus avoiding dimensional approaches for descriptions of disorders. It was also felt that when applied rigidly, DSM-IV criteria appeared to limit research and therapeutic developments. Also, important components of key syndromes, such as cognitive problems in schizophrenia, were not emphasized in the previous DSM criteria and were largely ignored until National Institute of Mental Health (NIMH) took the initiative with the MATRICS project.

At about the same time as DSM-5 developments, the revision of extant categories of mental disorders was also being proposed for the ICD by leading psychiatrists from outside the United States. For example, the British psychiatrist David Goldberg highlighted that the three main problems of DSM-IV and ICD-10 classifications were the high rates of “comorbidity” produced by current rules, the increased use of nonspecific (NOS or NEC) diagnoses by practicing clinicians, and the fact that each edition was longer and more complex than the one preceding it.

The Process of Approving/Disapproving Changes or New Diagnoses in DSM-5

Telegram: @medical_k

www.konkur.in

In contrast with the simple structure of the first DSM, in which one committee made all the decisions, DSM-5 had to deal with several levels or layers for clearance and approval of the new proposals. The first premise was that any changes to DSM-IV or proposals for new diagnoses had to be evidence based. Thus, on top of the already complex structure of the DSM-III and DSM-IV, a consulting body charged with veto power was added. Instead of going directly to the task force, committee recommendations went to an “independent” body called the “Scientific Advisory Committee” (SAC), created by APA leadership as an important step to review the scientific justification for proposed changes and assure the rigor and consistency of the DSM review process. This committee functioned outside the DSM organizational structure and reported, in an advisory role, to the APA President and Board of Trustees overseeing the DSM process. A second committee, called the “Clinical Public Health Committee” or CPHC, also named by APA leadership outside DSM’s organizational structure, reviewed proposals keeping in mind potential practical or public-health implications of proposed changes and new diagnoses and also made specific recommendations. The CPHC used a large list of advisors from academia and clinical practice as “peer reviewers.” The SAC and CPHC recommendations then went to the full task force for final debate and a decision on whether or not new diagnoses and significant changes in existing diagnoses should be implemented. These final recommendations were then forwarded to the APA Board of Trustees for their review. The Board had the final say about changes, revisions, and new diagnoses that were printed in the DSM-5 manual. The number of people involved in the DSM-5 process was far higher than that of previous editions. More importantly, about 30% of workgroup members were international colleagues from countries outside the United States.

DSM-5 Field Trials

These trials specifically examined the reliability of DSM-5 diagnostic changes (e.g., depression, post-traumatic stress disorder [PTSD], schizophrenia) and new diagnoses (e.g., hoarding disorder, somatic symptom disorder). The trials were rigorously designed and controlled. People with specific disorders were matched to people without the disorders and examined independently by two clinicians who did not know the patient or their diagnosis on two separate occasions. These trials took

Telegram: @medical_k

www.konkur.in

place at several academic centers in the United States and included both children and adult populations. As the major purpose of these trials was to assess reliability, a set of expectations was formed based on revisions of the literature on current reliability estimates in the medical field. The key measure of reliability was the intraclass kappa coefficient, a measure of how well a first diagnosis predicts a second independent one. A literature review by Helena Chmura Kramer, PhD and collaborators in 2002 had noted that κ > 0.8 would be an "extraordinary" result; κ 0.6 to 0.8, an "excellent" result; κ 0.4 to 0.6, a "good" result; κ 0.2 to 0.4, an "acceptable" result, and κ < 0.2 or lower, an "unacceptable" result. This review found "excellent" to "good" reliabilities with such procedures as coronary arteriography, x-rays, inspection of conjunctives for anemia, and liver scans. Clinical assessments such as the "Lasègue sign" and estimations of reliability to judge "quality of medical care" tended to have only an "acceptable" level of reliability, while procedures such as pelvic examinations in the emergency room (ER) had "unacceptable" levels of reliability.

Table 9.1–1.
Reliability of Major DSM-5 Diagnoses

Disorders	Kappa
PTSD	0.67
Neurocognitive disorder	0.78
Somatic symptom disorder	0.61
Hoarding disorder	0.59
Bipolar	0.56
Schizophrenia	0.46
Major depression	0.27
Mixed anxiety depression	−0.004

PTSD, Post-traumatic Stress Disorder.

Results of the DSM-5 field trials showed "excellent" agreement for major neurocognitive disorder, PTSD, somatic symptom disorders, autism spectrum disorder (ASD), and most of the self-rated "cross-cutting" symptom-based measures. Schizophrenia and bipolar disorder showed

Telegram: @medical_k

www.konkur.in

"good" reliability. Major depression had a disappointingly low level of reliability, and subtypes such as "anxious depression" were completely unreliable. These field trials were much more rigorous than those of DSM-III and DSM-IV and gave confidence in the robustness of most of the changes and the few proposed new diagnoses that were tested (Tables 9.1–1 and 9.1–2).

Key Changes in DSM-5

The DSM-5 Manual. The Official Manual of the fifth edition of the DSM has 947 pages. The manual is divided into three main sections.

Table 9.1–2.
Reliability of Dimensional Diagnoses and Crosscutting Symptom Measures

	Kappa
Dimensional Measures	
Autism spectrum disorder	0.69
New (alternate) personality disorders	0.41
Crosscutting Symptom Measures	
Psychosis	0.80
Depression	0.79
Anxiety	0.75
Somatic symptoms	0.73

Section I includes "the DSM-5 basics" such as introduction, use of the manual, and a cautionary statement about forensic use of the manual.

Section II, the key section of the manual, includes all the diagnostic criteria and codes for the officially approved diagnoses.

Section III includes new diagnoses not ready for "prime time," an alternate category of personality disorders, instrumental tools for dimensional measurements, as well as an instrument for assessing functional disability (WHODAS).

There is also an "Appendix" that includes highlights of changes from DSM-IV to DSM-5, a glossary of technical terms, cultural concepts of

Telegram: @medical_k

www.konkur.in

distress, and an alphabetical listing of DSM-5 diagnoses and ICD 9-CM and ICD-10 codes.

Deletion of the Multiaxial System. The five-axis frame of DSM-III and IV was eliminated in DSM-5. This makes DSM-5 closer to the structure of the ICD diagnostic system that has traditionally used a single axis. However, regarding the number of diagnoses or their quality, this reduction in the number of axes may have been inconsequential, as the personality disorders, one of the most questioned diagnostic groups, which had their own axis, Axis II, in DSM-IV, was kept unchanged and became one of the disorders listed in the main section (section II) of the Manual.

Dimensional Approach. In the introduction to DSM-5, it was stated that on the basis of early DSM-5/ICD-11 collaborations in diagnostic developments, clustering of disorders into “externalizing” versus “internalizing” perspectives represented an empirically supported framework. While strongly insinuated early in the process, a true dimensional perspective did not actually surface in DSM-5. Perhaps, the only noncategorical approach in DSM-5 is the “crosscutting” symptom dimensions (depression, anxiety, somatic symptoms, and others) that tend to be distributed across many diagnoses. These are based on self-rated measures, and a majority are taken from the Patient-Reported Outcome Measurement Information System (PROMIS), developed under the sponsorship of NIH. These are dynamic tools used to measure health outcomes from the patient’s perspective. They include symptom dimensions for pain, fatigue, physical functions, depression, anxiety, social function, etc., and are available for children and adults. These symptom dimensions are included in section III of the manual, with the hope that clinicians may include them in the clinical assessments.

Structure and Grouping of Disorders. Major changes in DSM-5 included the removal of PTSD and acute stress disorders from the anxiety disorders category in DSM-IV and their placement in a new stand-alone chapter called Trauma and Stress-Related Disorders (TSRD). OCD was also moved out of the anxiety disorders chapter and also placed in a new chapter called Obsessive-Compulsive and Related Disorders. This group also includes “body dysmorphic disorder,” “trichotillomania” (hair-pulling

Telegram: @medical_k

www.konkur.in

disorder), a new diagnosis “hoarding disorder,” as well as excoriation or “skin-picking” disorder.

New Disorders. Key new disorders that were included in the main section (section II) of DSM-5 were “Autism Spectrum Disorder,” “Somatic Symptom Disorders,” “Hoarding Disorder” (a diagnosis of major public health significance, as every department of health in the country has had to deal with the hoarding issue, either of animals or things), “Skin-Picking Disorder,” “Intellectual Developmental Disorder” (formerly Mental Retardation), “Disruptive Mood Dysregulation Disorder,” “Mild Cognitive Impairment,” “Insomnia Disorder,” “Nightmare Disorder,” and “Suicide Disorder.” New Disorders, judged not to be ready for “prime time,” were included in section III of DSM-5. These include the Alternate Category of Personality Disorders, Persistent Complex Bereavement Disorder, Caffeine Use Disorder, Internet Gaming Disorder, Neurobehavioral Disorder Associated with Prenatal Alcohol Exposure, Suicidal Behavior Disorder, and Nonsuicidal Self-Injury.

Neurodevelopmental Disorders. Mental Retardation was renamed Intellectual Disability (Intellectual Developmental Disorder). ASD replaces Autism, Asperger Syndrome, and Pervasive Developmental Disorder NOS in DSM-IV.

Neurocognitive Disorders. These disorders were previously referred to in DSM-IV as “dementia, delirium, amnestic, and other cognitive disorders.” In DSM-5, they are headed by “delirium.” A new category in DSM-5 is “mild neurocognitive disorder,” added as a lesser form of cognitive deficit, to contrast it with “major cognitive disorder” and the “major–minor” dichotomy is used for the remaining disorders in this category, including “major or minor neurocognitive disorder due to Alzheimer disease,” “major or mild frontotemporal neurocognitive disorder,” “major or mild neurocognitive disorder with Lewy bodies.”

Schizophrenia Spectrum and Other Psychotic Disorders. Included under this heading are “schizotypal personality disorder,” “delusional disorder,” “schizophreniform disorder,” “schizophrenia,” “schizoaffective disorder,” “substance/medication-induced psychotic disorder,” “psychotic disorder due to another medical condition,” and “catatonia,” including several subtypes. In the case of DSM-5 schizophrenia, all subtypes were

Telegram: @medical_k

www.konkur.in

eliminated, and criteria for the disorders were slightly modified. This included removal of special consideration for “bizarre” delusions and “special” hallucinations under criterion A (characteristic symptoms). Rewording of negative symptoms in efforts to provide more clarity (“affective flattening” was changed to “restricted affect”; “alogia or avolition” was changed to “avolition/asociality”). Also, in order to meet criterion A for the disorder, at least one of two required symptoms must be delusions, hallucinations, or disorganized speech.

Bipolar and Related Disorders. This group includes “bipolar I disorder,” “bipolar II disorder,” “cyclothymic disorder,” “substance/medication-induced bipolar and related disorders,” “bipolar and related disorder due to another medical condition,” “other specified bipolar and related disorders,” and “unspecified bipolar and related disorder.” In the case of bipolar disorder, the inclusion of “increased energy/activity” as a criterion is a symptom of mania/hypomania. Also, the addition of “mixed features” specifiers for mania, hypomania, and depression (see below). The complete list of “specifiers” for bipolar and related disorders include “anxious distress,” “manic or hypomanic episode with mixed features,” “depressive episode with mixed features,” “with rapid cycling,” “with melancholic features,” “with atypical features,” “with psychotic features,” “with catatonia,” and “with seasonal pattern.”

Depressive Disorders. Included here is “Disruptive Mood Dysregulation Disorder,” a new disorder intended to decrease the “excess” of diagnoses of bipolar disorder observed in children and adolescents. “Major Depressive Disorder” remains virtually identical to the DSM-IV category, except for the elimination of the bereavement exclusion (this was done, despite the statement under the definition of mental disorder in the introduction to DSM-5—see our discussion regarding the definition for a mental disorder earlier in this chapter). “Persistent Depressive Disorder (Dysthymia)”; “Premenstrual Dysphoric Disorder”; “Substance/Medication-Induced Depressive Disorder”; “Depressive Disorder Due to Another Medical Condition”; “Other Specified Depressive Disorder”; and “Unspecified Depressive Disorder.” Also, there is a list of “specifiers,” including a new one, “with anxious distress,” in addition to “with mixed features,” “with melancholic features,” and “with atypical features.”

Telegram: @medical_k

www.konkur.in

Anxiety Disorders. With the transfer of PTSD and OCDto stand-alone groupings, the disorders remaining in this category are “separation anxiety disorder,” “selective mutism,” “specific phobia” (with several subtypes), “social anxiety disorder,” “panic disorder,” “agoraphobia,” “generalized anxiety disorder,” “anxiety disorder due to another medical condition,” “other specified anxiety disorder,” and “unspecified anxiety disorder.”

Trauma and Stressor-Related Disorders. “Post-traumatic Stress Disorder (PTSD)” and “Acute Stress Disorder” were moved out of the anxiety disorders group (where they were in DSM-IV) to this new, stand-alone category. The criteria for PTSD were carefully revised. In DSM-IV, PTSD included three clusters of symptoms: (1) reexperiencing fear memories (intrusive memories), (2) avoidance of trauma reminders (amnesia, withdrawal, avoidance of situational reminders), and (3) hyperarousal symptoms (sleep disturbance, heightened arousal response). In DSM-5, the definition of a “traumatic event” was clarified. One extra criterion, D3, was added (persistent negative emotional state). Criteria C now focuses on “avoidance,” while criteria D focuses on negative cognitions and mood. Language and descriptions were enhanced for precision. Basically, DSM-5 has expanded the definition of PTSD beyond the “fear” construct, adding another cluster of symptoms to acknowledge negative alterations in cognition and mood (pervasive negative emotional states, negative appraisals about oneself or the world, and excessive blame). In total, DSM-5 increased PTSD symptoms to 20, up from 17 in DSM-IV. Potential combinations of symptoms got increased more than 10-fold. According to some experts, this makes the disorder more heterogeneous and may complicate the research agenda. “Adjustment Disorders” are also listed under TSRD together with “Reactive Attachment Disorder” and a new condition, “Disinhibited Social Engagement Disorder.” The latter emphasizes the recognition of symptoms associated with neglect during childhood. Regarding the effects of these changes in clinical practice, experts have stated, “there is potential for improved assessment of stressor-related conditions in children.”

Substance Use Disorders. Substance abuse and substance dependence were consolidated into a single disorder called “substance use disorder.” A continuum or dimension was created that includes “mild,” “moderate,” or “severe” substance use. One of the DSM-IV abuse criteria

Telegram: @medical_k

www.konkur.in

was removed ("legal consequences such as multiple arrests"), and a new criterion, "craving," was added.

Somatic Symptom and Related Disorders. This new category replaced the somatoform disorders category from DSM-IV. All diagnoses that had been subsumed under the somatoform disorders category in DSM-IV were merged into a common category, significantly revised, or placed in another section of the diagnostic manual. The DSM-IV requirement for symptoms to be "medically unexplained" was removed from DSM-5. Somatization Disorder, Pain Disorder, and Undifferentiated Somatoform Disorder were all merged into a new diagnosis called "Somatic Symptom Disorder." Hypochondriasis became "Illness Anxiety Disorder." "Conversion Disorder" was significantly revised, and the term "Functional Neurological Symptom Syndrome" was added to the title of this disorder in parentheses. "Psychological Factors Affecting Other Medical Conditions," "Factitious Disorder," "Other Specified Somatic Symptom and Related Disorder," and "Unspecified Somatic Symptom and Related Disorders" were the new disorders adopted in the new category of somatic symptom disorders. "Body Dysmorphic Disorder" was moved to the new obsessive-compulsive and related disorders group. In terms of specific criteria, Somatic Symptom Disorder requires one or more somatic symptoms to be present, but unlike DSM-III and IV, in DSM-5, the emphasis is placed on the behavioral and psychological elements of the syndrome, such as preoccupation and concern with the physical symptoms. It is also possible for Somatic Symptom Disorder to have special features (e.g., predominantly pain symptoms) or different severity dimensions, depending on the number of A and B criteria present beyond the threshold for diagnosis.

Childhood Disorders. A single spectrum diagnosis, ASD, replaces "Autistic Disorder," "Asperger Disorder," and "Pervasive Developmental Disorder not otherwise specified." ASD is now differentiated from social communication disorder by the presence of the restrictive and repetitive behavior criterion. Addition of "specifiers" for all neurodevelopmental disorders "associated with known medical or genetic condition or environmental factors." As stated by Michael Rutter, a leading expert in this area, "it was necessary to abandon the DSM-IV classification because it had been ignored or was sidestepped by clinicians and researchers."

Telegram: @medical_k

www.konkur.in

Personality Disorders. These remained unchanged in DSM-5, as the original DSM-IV personality disorders were all retained in section II of the DSM-5. However, an “alternate” category of Personality Disorders has been included in section III. This consists of a trait-based diagnostic approach that separates functional impairment (A criteria) and the expression of characteristic traits (B criteria) for the six personality disorders that were tested in the field trials. A more flexible trait-specified profile can now be used for patient presentations that do not fit well the six subtypes. A similar strategy was adopted in ICD-11.

Sleep–Wake Disorders. This group includes a large number of categories and subcategories, starting with Insomnia Disorder, Hypersomnolence Disorder, Narcolepsy (various subtypes), as way as a long list of “Breathing-Related Sleep Disorders” (Obstructive Sleep Apnea–Hypopnea, Central Sleep Apnea, Idiopathic Central Sleep Apnea, Cheyne–Stokes Breathing, and other subtypes) and “Parasomnias” (including nonrapid eye movement sleep arousal disorders, Nightmare Disorder, Rapid Eye Movement Sleep Behavior Disorder, Restless Leg Syndrome, and other subtypes).

Other Conditions that May Be a Focus of Clinical Attention. This includes a long list of headings and subheadings, a majority tagged with “V” codes. The main headings are “Relational Problems,” “Abuse and Neglect,” “Child Physical Abuse,” “Child Sexual Abuse,” “Child neglect,” “Child Psychological Abuse,” “Adult Maltreatment and Neglect Problems,” “Educational and Occupational Problems,” and several others adding to a total of 133 separate codes, making up about one-third of the total categories in DSM-5.

Specific Areas of Concern in DSM-5

Proliferation of Mental Disorders. The most common public criticism of later editions of the DSM manual has to do with the growth in both the number of mental disorders and the scope of their definitions. The expressed or tacit implication of this is that it implies a growing and unjustified medicalization of multiple areas of daily life. As mentioned above, the number of disorders included in the first edition of the manual (DSM-I) has been multiplied at least fourfold in the subsequent editions. Reviewing the various editions of the DSM, it is obvious the growth in the

Telegram: @medical_k

www.konkur.in

number of disorders does not reflect the inclusion of many new disorders, but that it is due mainly to the subdivision or “splitting” of traditional disorders such as anxiety, affective, addictive, and psychotic disorders into countless subtypes (Table 9.1–3). The numbers speak eloquently: DSM-5 lists 438 diagnostic codes, while DSM-IV had 361, and DSM-III 265. However, the number of specific categories in DSM-5 is smaller than those in DSM-IV.

Telegram: @medical_k

www.konkur.in

Table 9.1–3.
The Increase in the Number of Diagnoses between the 1952 DSM I and DSM-5: The Case of Anxiety Disorders

Telegram: @medical_k

www.konkur.in

DSM I 1952	Includes anxiety reaction and six related “reactions,” dissociative, conversion, phobic, obsessive-compulsive, depressive, and psychoneurotic. **(Total = 6 Disorders)**
DSM-II	Eliminates the qualification of “reaction” and includes all of the anxiety-related diagnoses from DSM I, and some related new ones, such as hypochondriacal, neurasthenia, or depersonalization, in the general category of “neuroses.” **(Total = 8 Disorders)**
DSM-III	The category anxiety disorders appears for the first time, including a total of 10 disorders in four groups: ▸ Phobic disorders (including agoraphobia with panic attacks, agoraphobia without panic attacks, social phobia, simple phobia) ▸ Anxiety states (including panic disorder, generalized anxiety disorder, obsessive-compulsive disorder) ▸ Post-traumatic stress disorder (PTSD; including acute PTSD, chronic PTSD) ▸ Atypical anxiety disorder To the above disorders, two categories should be added as they were included in DSM-II among the anxiety neuroses. They are: ▸ Somatoform disorders (including somatization, conversion, psychogenic pain, hypochondriasis, and atypical) ▸ Dissociative disorders (including psychogenic amnesia, psychogenic fugue, multiple personality, depersonalization, and atypical dissociative) In addition, several ambiguously defined “adjustment disorders” either expressly or implicitly are merged into the anxiety disorders category. **(Total = 21 Disorders)**
DSM-IV-R	The category anxiety disorders includes, besides generalized anxiety disorder, eight specific anxiety disorders, and two unspecific anxiety disorders; to these, the following added: five specific and two unspecific somatoform disorders, and

Telegram: @medical_k

www.konkur.in

	four specific and one unspecific dissociative disorders and again, the adjustment disorders **(Total = 23 Disorders)**
DSM-5	Anxiety disorders include 10 specific and 2 unspecific disorders (the first 2 were previously accepted only for children): ▸ Separation anxiety disorder ▸ Selective mutism ▸ Specific phobia ▸ Social anxiety disorder (social phobia) ▸ Panic disorder ▸ Panic attack specifier ▸ Agoraphobia ▸ Generalized anxiety disorder ▸ Substance/medication-induced anxiety disorder ▸ Anxiety disorder due to another medical condition ▸ Other specified anxiety disorder ▸ Unspecified anxiety disorder Obsessive-compulsive gets its own group with seven specific disorders and two unspecific categories. Trauma gets its own group (trauma- and stressor-related disorders) which includes reactive attachment disorder and disinhibited social engagement disorder (previously used only in children), PTSD, acute stress disorder, adjustment disorders (including five specific and one unspecific disorders), and two unspecific categories. Somatic symptom and related disorders loses pain disorder and body dysmorphic disorder (which migrates to obsessive-compulsive) but still lists five specific disorders and two unspecific categories. Dissociative includes three specific disorders and two unspecific categories. **(Total = More than 45 disorders)**

Personality Disorders. From the perspective of medicine, the concept of “personality” has always been a rather vague sociocultural construct, hard to define even in psychological terms, and thus quite alien to the medical sciences. Indeed, most of the “personality disorders” are value judgments regarding eccentricities, peculiarities, or extremes in the

Telegram: @medical_k

www.konkur.in

behavior of an individual when they are compared with culturally predominant norms. The personality disorders that remain in DSM-IV and DSM-5 (there were no changes in the latest edition) largely represent such “value judgments,” often designated using critical, condemnatory, or pejorative language. Since DSM-III, personality disorders have remained virtually untouched except for the elimination of the multiaxial system in DSM-5 and the proposal for an “alternate category” with dimensional rather than categorical overtones that was relegated to section III of the DSM-5. This alternative category is being evaluated and shows promise.

Sexual Disorders. In parallel with the personality disorders, the inclusion of certain “sexual disorders” in a section originally headed by homosexuality has also been a point of contention within the DSM. “Sexual deviations” were included among the personality disorders in the first DSM and remained there in DSM-II. From DSM-III on, sexual disorders were listed under a separate group and have continued to proliferate in each new edition of the manual. Thus, DSM-5 added several new disorders, a number of them among the paraphilias, a particularly problematic set of disorders whose definition may even conflict with the definition of a mental disorder as included in section I of the DSM-5.

The Media Storm Surrounding DSM-5. Neither the task force and workgroups nor the APA, in general, did presage the avalanche of criticisms, complaints, passions, and lobbying unleashed during the DSM-5 process, starting soon upon release of the initial plans to revamp DSM-IV and continuing until the release of the printed manual. Nothing like this had happened (at least not to this extent) in the case of DSM-III, DSM-IV, or even ICD-10. A notable observation was the broad news media coverage that went far beyond the United States and Canadian boundaries, a clear proof of the national and international interest generated by the DSM classification and psychiatric diagnosis in general.

Global Issues Related to Diagnosis

Although the DSM system is primarily designed for use in North America, it is also used in many other countries of the world, particularly for research purposes. Starting with DSM-5, international input was actively sought, both in the preparatory phase and also as part of the workgroups. Critiques related to DSM psychiatric diagnoses include their

Telegram: @medical_k

www.konkur.in

"globalization." For example, attention deficit hyperactivity disorder (ADHD), a disorder first recognized in the United States in the 1960s, spread to the United Kingdom, Germany, France, Italy, and Brazil, possibly influenced by the transnational pharmaceutical industry, the role of the internet, and activism of advocacy groups. A relevant example is the one provided by Professor Sing Lin from Hong Kong, a member of the somatic disorders work group in DSM-5. It relates to what has happened with the diagnosis of Anorexia Nervosa in Hong Kong. In the 1980s and early 1990s, the disorder was very rarely diagnosed, as patients only had somatic complaints ("bloated stomachs"). In 1994, a teenage anorexic girl collapsed and died in a busy downtown street in Hong Kong. This quickly caught the attention of the media, who become aware of the U.S. diagnostic manuals, and reported that anorexia nervosa in Hong Kong was the same disorder as that in the United States and Europe. Obviously, the disorder began to appear with increasing frequency, the major complaints of sufferers shifting from somatic complaints to "fat phobia."

Dealing with Conflict of Interest

A most salient public criticism of DSM-IV and DSM-5 has been the potential "conflict of interest" of those involved in the process of revising and preparing the diagnostic manuals. While having ties with the pharmaceutical industry is the most frequently mentioned conflict of interest, there are several other potential conflicts, such as ties to patient advocacy groups, health insurers, organizational memberships, and other groups that may have a vested interest in the definition of mental disorders. These latter conflicts are rarely addressed. The inclusion or elimination of a mental disorder or a change toward a more restrictive or comprehensive definition of a disorder, all affect the size of the population covered (most commonly, increases it), and with it, the work opportunities for professionals, the potential income for drug companies, and the potential profit for public or private health insurers all grow larger. Also, given the financial benefits accorded by several diagnoses such as the coverage/subsidies for educating autistic children in several states, the worker compensation laws, and the veterans administration service-connected disabilities, it is not surprising that the redefinition of disorders such as autism in DSM-5 led to a heated debate not only in mental health journals but also in the press and mass media, with organizations like

Telegram: @medical_k

www.konkur.in

"Autism Speaks" publishing the names and affiliations of members of the work force so that they could be lobbied. Another vested interest implicit in the DSM diagnostic process is obviously that of the APA, the owner of the copyrights for DSM. The APA has a large stake in the commercial success of a manual that has gradually become one of its main sources of income. Creating expert committees completely devoid of conflicts of interest seems quite unrealistic, and it may be an impossible task. However, at a minimum, a "transparency policy" for full disclosure of all possible conflicts of interest should be ensured, and fortunately, it has become the standard.

Changes in Medical Practice

Another factor that may play a role in the proliferation of disorders is the increased access of populations to health information in the age of the internet, resulting in a growing medicalization of daily life. The increased access to treatment occurs all across medicine, and the tendency of people to look for treatment for conditions that were previously nondiagnosable or viewed as mild or even trivial is now a worldwide phenomenon. The thresholds for treatment for elevated cholesterol, blood glucose, or blood pressure seem to be continuously getting lower (e.g., the uniform 100 threshold rule). A growing number of individuals seek the genetic or pharmacologic answers for obesity, a condition that some years ago was not even considered to be a disease. In addition, many individuals currently seek treatment not because of any defect or illness, but for cosmetic or hedonic reasons, not restricted to cosmetic surgery, such as the growing number of males with normal sexual function who ask for prescriptions of phosphodiesterase inhibitors in order to have more frequent sex (the so-called "recreational use"), or patients with no attention disorders who ask for prescriptions of stimulants to gain an edge at school or work.

Alternatives to Traditional Classifications

The DSM-5 task force discussed a number of alternatives to the DSM-IV classification. One initial model was that proposed by Dennis Charney, a biologically oriented psychiatrist, then at NIMH, that suggested a multiaxial futuristic diagnosis, in which Axis I represented Genotype, Axis II, Neurobiologic Phenotype, Axis III, Behavioral Phenotype, Axis IV, Environmental Modifiers or Precipitants, and Axis V, Treatment Targets

Telegram: @medical_k

www.konkur.in

and Therapeutic Response. While this model appeared quite promising and scholarly, the scientific evidence and the needed “markers” remain elusive.

Brain Circuitry. Progress in basic neuroscience during the decade of the brain has been unraveling, with good precision, brain circuits related to specific behaviors or emotions. Emerging techniques such as optogenetics nurture the “circuit dynamics of psychiatric disease,” receiving ample coverage in medical journals (JAMA) and the news media (The New Yorker). While most of this basic research is in the preclinical phase (animal models), the circuit-level perspective makes it possible to generate hypotheses on how the effect of multiple genes may lead to specific psychiatric syndromes. Some of the main circuits now under scrutiny include the following:

1. A “frontothalamic-striatal circuitry” that may be involved in cognitive control of behavior and thought to be of relevance to schizophrenia, ADHD, addictions, and impulse control disorders.
2. A “fear circuitry,” with neuronal connections based on the amygdala, involved in conditioned fear, of possible relevance to anxiety and depressive disorders.
3. A “reward circuitry” consisting of mesotelencephalic dopaminergic projections that may be relevant to addictions, impulse control disorders, schizophrenia, as well as the hedonic component of mood disorders.
4. A “regulation of mood states” circuitry involving the medial prefrontal cortex, amygdala, and hypothalamus, and possibly relevant to depression, mania, and mood disorders in general.

A key question posed during the development of DSM-5 was whether or not at that time, the specialty (psychiatry) and practicing clinicians (psychiatrists, psychologists, social workers, and others) were ready for classifications based on hypothetical pathophysiology, lacking solid, consistent “markers” and the quick answer was “not quite yet.”

NIMH Research Domain Criteria. The RDoC, launched in 2009, was created in response to the growing awareness of challenges arising from the use of categorical diagnostic systems in research on mental illnesses. The main purpose was to create an alternative system for investigating

Telegram: @medical_k

www.konkur.in

mental disorders by focusing on disruptions in normal adaptive functions rather than traditional symptom-based diagnoses. The development of the initial version of the RDoC framework was the collaborative effort of over 200 leading scientists and was influenced by decades of behavioral and neuroscience data.

The RDoC matrix was conceived as a tool for use by researchers to help them structure their study designs around behavioral or cognitive concepts.

The current version of RDoC contains six overarching systems or domains that influence human functioning. These are:

- Negative Valence Systems
- Positive Valence Systems
- Cognitive Systems
- Social Processes
- Arousal and Regulatory Systems
- Sensorimotor domain

BRIEF HISTORY OF RDOC. This alternative diagnostic approach was developed by Bruce Cuthbert and Thomas Insel at NIMH, and curiously, it first came into play in the NIMH Director's blog, coinciding with the final release of DSM-5 in 2013. It quickly spread to the news media that "NIMH had disapproved DSM-5," at the same time that it (NIMH) urged (or mandated?) as a condition for future funding, the use of RDoC, their alternative and complex strategy for classification that at the time appeared quite incipient indeed. As described in the NIMH website, RDoC is conceived as a dimensional system (reflecting, brain circuit-level measurements, behavioral activity, etc.) spanning the range from normal to abnormal. As it happens with dimensions in medicine such as hypertension or levels of cholesterol in plasma, this approach has to define cutoff points for the definition and extent of psychopathology (e.g., mild, moderate, and severe). It is of interest to observe that the NIMH document acknowledges that "to the extent that DSM-5 introduces dimensions in addition to classes, the crosswalks to RDoC dimensions may be enhanced."

However, RDoC does not adhere to current DSM categories, as its intent is "to generate classifications stemming from basic behavioral neuroscience." Rather than starting with an illness definition and seeking

Telegram: @medical_k

www.konkur.in

its neurobiologic underpinnings, RDoC begins with brain–behavior–brain relationships and links them to clinical phenomena based on several units of analysis such as neuroimaging, physiologic activity, behavior, and self-reports of symptoms. One of the key goals stated for RDoC is to allow researchers to choose independent variables from among several different units of analysis. The RDoC framework is explicitly agnostic with respect to current definitions of disorders. For instance, depression as a clinical syndrome has been related to abnormal activity in the amygdala, anterior cingulate cortex, nucleus accumbens, and multiple monoamine systems, while also strongly comorbid with multiple anxiety disorders, eating disorders, etc. The idea is that studying the individual mechanisms may lead to a better understanding of current disorders, or perhaps new and novel definitions of disorders, but in either case, improved information about treatment choices.

The RDoC research framework is described as a matrix whose rows correspond to specified dimensions of function, called “constructs,” that represent the fundamental unit of analysis in this system. The hope is that these functional behavioral dimensions and related genes and circuits would be continually refined as science advances. The expectation is that most research studies will focus on a single “construct” or compare two separate “constructs” on relevant measures. “Constructs” are grouped into “domains of functioning.” These include “negative and positive valence systems,” “cognitive systems,” “systems for social processes,” and “arousal/regulatory systems.” The various columns in the matrix represent different classes of variables (or units of analysis) used to study the domains/constructs. These variables include genes, molecules, cells, neural circuits, physiologic elements (e.g., cortisol, heart rate, startle reflex), behaviors, and patient self-reports. Neuronal or brain circuits represent the core of these variables. The inclusion of a “construct” in this system depends on the specification that a particular brain circuit or brain area implements that dimension of behavior. It is also acknowledged in the document that given the complexity of the brain and behavior, there can be various degrees of ambiguity in this regard.

“Constructs” included in the matrix are based on current literature reviews that have provided a neurobehavioral research base for each of the entries. The document also emphasizes that “these particular domains and constructs are simply starting points that are not definitive or set in concrete. It is expected that these will change, dynamically, with input

Telegram: @medical_k

www.konkur.in

from the field, and as future research is conducted." A major aim of RDoC is to create a framework for grouping participants in research studies in order to create foundational research literature that informs future versions of nosologies based upon genetics and behavioral neuroscience. RDoC is not intended for clinical diagnosis at the current time. In the future, research supported by RDoC could inform diagnostic approaches using new laboratory procedures, behavioral assessments, and novel instruments to provide enhanced treatment and prevention interventions. It is also hoped that RDoC will support the enhanced development of new pharmacologic and psychosocial interventions based upon neurobiologic and behavioral mechanisms. The intent of the RDoC is to accelerate the pace of new discoveries by fostering research that translates findings from basic science into new treatments addressing fundamental mechanisms that cut across current diagnostic categories.

In a release, following the DSM-5/RDoC controversy, NIMH Director Thomas Insel argued that the RDoC project is a move forward in "precision medicine." He stated that "it is possible that specific mutations in relevant brain circuits can be found that explain some cases of schizophrenia, bipolar disorder, or autism, just as mutations in the tumor explain cancer, but that precision medicine for mental disorders will not come from a single genomic glitch. Rather, like many other areas of medicine, many genes each contribute only a small amount of vulnerability as part of an overall risk profile that includes life experiences, neurodevelopment, and social and cultural factors. RDoC assumes that many kinds of data are needed to reach precision, a situation akin to triangulating in order to find your position on a map. These data will draw from many sources, including symptoms, genotype, physiology, cognitive assessment, family dynamics, environmental exposures, and cultural background."

However, to be clear, this dimensional approach represents a dramatic shift in the classification of psychiatric disorders. It theorizes those behavioral consequences of brain functioning, such as for example, working memory or reactivity of the amygdala, as measured during tests such as functional magnetic resonance imaging (fMRI), would define clinical characteristics that reflect with greater precision the biology of the illness, possibly leading to more specific therapeutic targets compared to the broad overlapping categories of the DSM.

Telegram: @medical_k

www.konkur.in

Despite the authority backing it, the initial reception of this new system was mixed among leading researchers, many remaining skeptical about the RDoC approach. According to some of the experts, the existing evidence makes the RDoC approach questionable. Two well-known psychiatry researchers argued that “patients with ADHD and patients with psychosis may show similar abnormalities in frontal brain function just as patients with PTSD and patients with psychosis may show similar overactivation of the amygdala in fMRI images, but the underlying reasons for these superficial similarities are different, and so are the treatments. The treatment of frontal lobe dysfunction in ADHD (e.g., stimulants) will make psychosis worse, just as the treatment for amygdala overactivation in psychosis (antidopaminergic drugs) is likely to have adverse effects in patients with PTSD.”

The DSM-5/RDoC controversy was at least temporarily settled after the NIMH director and the President of the APA produced a joint statement stating that “all medical disciplines advance through research progress in characterizing diseases and disorders. DSM-5 and RDoC represent complementary, not competing, frameworks for this goal.” That statement also highlighted that “for practicing clinicians, DSM-5 represents the best available evidence at this time.”

RDOC RECENT UPDATES. RDoC continues to be used in research sponsored by NIMH, and the institute has recently released some updates to its RDoC framework. The first of these updates, taking place in mid-2018, reorganized the positive valence domain. Since the time of its creation, RDoC was envisioned as a dynamic and continually developing framework. Now, the RDoC unit has unveiled changes to the RDoC framework—a reorganization of content within the positive valence domain. This domain includes systems primarily responsible for responses to positive motivational situations or contexts, such as reward seeking, consummatory behavior, and reward or habit learning. The revisions were spearheaded by the RDoC Matrix (CMAT) Workgroup—a group made up of members of the Nationally Advisory Mental Health Council, scientific experts, and NIMH staff. The main alterations in the positive valence domain include changing some of the constructs listed in the original version to subconstructs in the new version (e.g., Initial Responsiveness to Reward) and the addition of new constructs (e.g., Probabilistic and Reinforcement Learning). The reorganization is intended

Telegram: @medical_k

www.konkur.in

to make the constructs more straightforward and to align them more closely with computational and animal model perspectives, as well as data from human neuroimaging studies. The updates to the Positive Valence domain are the newest example of RDoC as a dynamic research framework—one that evolves to incorporate the latest findings from the research community and provide exemplars for future research.

A second update, dated January 2019, involved the addition of a sensorimotor domain to the RDoC Framework. The aim of this new sensorimotor domain is to help foster earlier and more precise identification of the role of motor systems disruptions in psychopathology and aid in the development of more effective treatments for people who are affected by these disruptions.

The new sensorimotor domain consists of four constructs (Motor Action, Agency and Ownership, Habit, and Innate Motor Patterns), the first of which includes five subconstructs. Detailed definitions of these domains and constructs can be found on the RDoC page of the NIMH website.

This change to the framework was again spearheaded by the CMAT Workgroup. The addition of the new domain is intended to encourage a systematic approach to the study of motor function in psychopathology, which will hopefully lead to better identification of, and treatment for these disruptions.

The addition of the sensorimotor domain is touted as the latest example of RDoC as a dynamic research framework—one that evolves to incorporate the latest findings from the research community and provide exemplars for future research.

The RDoC group has also provided details on specific constructs/subconstructs under each domain and listed well-referenced specific tasks (or tests) to assess each of them. This should be very helpful for researchers using the RDoC. For example, for assessing the "acute threat" construct of the negative valence system, a number of potential tasks have been detailed (Trier Social Stress Test, Behavioral Approach Test, Cold Pressor Test, CO2 challenge, Stranger Tests and Fear Conditioning Tasks).

A brief example of domains, constructs/subconstructs, and recommended tasks is presented in Tables 9.1–4 and 9.1–5.

ICD-11 and Dimensional Classification. The recently published ICD-11 criteria for mental disorders is also considering a move toward a

Telegram: @medical_k

www.konkur.in

dimensional classification. ICD-11's workgroup argues, as also did DSM-5, that mental disorders can be best conceptualized as representing several interacting and underlying dimensions and not as discrete categories. They add that dimensional classification places a stronger focus on current clinical presentations and is more compatible with an approach to prognosis or recovery rather than viewing a given diagnosis as representative of a type of person or being stable over time.

ICD 11 has proposed a dimensional category for psychotic disorders, replacing ICD 10 subtypes of schizophrenia (paranoid, hebephrenic, catatonic) with a set of symptom ratings that correspond to the person's current functioning on several dimensions. These dimensional ratings summarize specific problems that may be the target of specific interventions, and that can improve or remit over time.

ICD 11 has outlined a dimensional classification of personality disorders very similar to what DSM-5 initially proposed for the main body of the manual and which unfortunately ended up relegated to section III of the DSM-5 manual as "Alternative DSM-5 Model for Personality Disorders." This section of the manual includes "emerging measures and models" as well as "conditions for further study."

DSM-5, ICD-11, and Dimensional Diagnoses in Clinical Practice. A key objective in publishing DSM-5 was to improve upon previous versions of the manual by revising categories and rigorously assessing (and proving) their reliability. A secondary goal of DSM-5 was to incorporate new strategies (dimensional approach) and provide potential new disorders in need of further evaluation and testing. The idea was to create an open, "living" system that could be easily updated as new evidence accrued. DSM-5 is unlikely to change clinical practice, and many practicing psychiatrists largely remain unaffected or indifferent in front of debates, as recently highlighted by psychiatrist-correspondent Sally Satel in a leading editorial. Satel adds, however, that DSM-5 diagnoses will "become passports to insurance coverage, keys to special education services, and tickets to disability benefits." Thus, it seems quite relevant for practicing clinicians to get to know and use DSM-5 criteria properly. Despite the shortcomings detailed above, the DSM-5 manual provides an excellent description of most of the key syndromes encountered in clinical practice.

Therefore, while psychiatrists wait for future diagnostic developments, the proper, "informed" use of DSM-5 will guide clinical practitioners in assessing, understanding, and cataloging complex mental health phenomena. The expectation—assuming the manual is truly a "living document"—is that experiences accruing from its clinical use may lead to the reinforcement, revision, or even the elimination of some diagnostic labels.

Brief Updates on DSM-5 Manual and Diagnoses. The original idea behind DSM-5 was to make it a "living document" that could be updated as needed, based on available clinical and scientific evidence.

In 2017, the APA published a supplement titled "DSM-5 Update, Supplement to the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition" that included coding changes related to ICD-10 as well as specific updates on DSM-5 criteria and text, including changes and amendments for several disorders.

The updates to criteria and text included in the supplement include the following disorders:

Telegram: @medical_k

www.konkur.in

- Brief psychotic disorder (change to specifiers)
- Bipolar I and II disorders (change in criteria for manic and hypomanic episodes; change in text for severity specifiers and seasonal pattern)
- Specifiers for bipolar and related disorders
- Adjustment disorders (change to specifiers)
- ASD (change to criterion A)
- Delusional disorder (change in subtypes section of text)
- Persistent depressive disorder (change to differential diagnosis section of the text)
- Specifiers for depressive disorders (changes in text definitions; change to the definition of “with mixed features”)
- Disruptive mood dysregulation disorder (change to the text of section on development and course)
- Generalized anxiety disorder (change to differential diagnosis section)
- Acute stress disorders (change to differential diagnosis section)
- Somatic symptom disorder (change to differential diagnosis section of text)
- Alternative model for personality disorders (AMPD) (change to criterion B1 for OCD)
- Depressive episodes with short-duration hypomania (change in criterion A)

Next, another update titled “Supplement to the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition” was published in October 2018.

It included minor new changes in the following disorders (it also reiterated the changes proposed in the updates for 2015 and 2016):

- Psychotic Disorder (Coding Note)
- Bipolar Disorders: “With Psychotic Features” Specifiers
- Substance/Medication-Induced Bipolar and Related Disorder (Coding Note)
- Specifiers for Bipolar and Related Disorders: (“With Psychotic Features” Specifiers)
- Substance/Medication-Induced Depressive Disorder: (Coding Note)
- Other Specified Depressive Disorder; Unspecified Depressive Disorder
- Substance/Medication-Induced Anxiety Disorder: (Coding Note)
- Other Specified Anxiety Disorder; Unspecified Anxiety Disorder

Telegram: @medical_k

www.konkur.in

- Substance/Medication-Induced Obsessive-Compulsive and Related Disorder: (Coding Note)
- Acute Stress Disorder: (Criterion A)
- Substance/Medication-Induced Sleep Disorder: (Coding Note)
- Substance/Medication-Induced Sexual Dysfunction: (Coding Note)
- Substance/Medication-Induced Major or Mild Neurocognitive Disorder: (Coding Note)
- Diagnoses associated with substance class: adjustment to neurocognitive disorders column
- No Diagnosis or Condition

In February 2020, the most recent update entitled "Supplement to Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition Avoidant/Restrictive Food Intake Disorder Diagnostic Criteria F50.82" was issued. This supplement highlights minor changes in the text of criterion "A" for Avoidant/Restrictive Food Intake Disorder.

Finally, in March 2022, the APA published the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Text Revision (DSM-5 TR). This revision updated all diagnostic criteria and ICD-10-CM codes since DSM-5's publication in 2013. Key new elements are the addition of Prolonged Grief Disorder (PGD) to Section II, considerations on the impact of racism/discrimination on mental disorders and new codes to flag and monitor suicidal behavior.

As can be inferred from these updates, most of the action has taken place 1 or 2 years after the official publication of DSM-5 (2014 and 2015), possibly reflecting a transient "post-DSM-5 enthusiasm" in refining criteria. Since that time, there have been relatively minor changes, and updates and these have mainly concerned ICD-10 codes, as well as a few minor changes and "tweaks" in the criteria and text for a handful of disorders.

Current Research on DSM-5 Diagnostic Categories. That current research is actively testing and probing DSM-5 diagnoses can be briefly illustrated through the brief presentation of a couple of recent papers, one focused on the AMPD, the other on PTSD criteria.

The first paper focusing on AMPD provides a brief overview of the dimensionally oriented AMPD that was included in section III of DSM-5. This paper highlights the fact that since its publication in 2013, the AMPD has inspired a substantial number of studies, underlining AMPD's generative influence on the field. These studies illustrate the reliability and

Telegram: @medical_k

www.konkur.in

validity of the constructs delineated in the AMPD and underline the empirical challenges to the conceptual clarity of the AMPD, such as evidence of substantial correlations between indices of personality functioning (criterion A in the AMPD) and maladaptive personality traits (criterion B in the AMPD). The key future directions pointed by the researchers would include first a practical component, linking the AMPD research efforts to improving the lives of persons who suffer from PDs, and then surmounting the various challenges germane to the evolution of the DSM itself.

The second paper focusing on PTSD aims at answering the question of how well PTSD can be assessed and compared, spanning the transition between DSM-IV and DSM-5, using different PTSD Checklist (PCL) instruments. This diagnostic study included 1,921 individuals and showed substantial to excellent agreement when individual items, "probable PTSD" and "sum scores" were compared between the previous PCL version and that of *DSM-5*. Thus, the two PCL instruments showed nearly identical associations with comorbid conditions. These results provide support for the transition from the PCL-C to the PCL-5 without losing the ability to monitor trends and associated comorbidities.

We certainly hope that more systematic research on updating/improving current diagnostic systems continues to be implemented in the near future and that it leads to additional improvements in the extant classifications.

Closing Reflection: DSM-5, ICD-11, and RDoC: What Can We Learn from the History of Psychiatric Diagnosis? Karl Wernicke believed that all mental disorders were brain disorders. This belief appears to be the main context for new diagnostic approaches such as the RDoC.

Emile Kraepelin's main premise was that "all psychiatric disorders should follow the medical model of disease." As it has been articulated above in this chapter, starting with DSM-III, American nosology became uniquely "Kraepelinian," with an emphasis on descriptive psychopathology, following the medical model approach.

Karl Jaspers, who published his "Allgemeine Psychopathologie" (General Psychopathology) in 1913, maintained that "psychiatry is a hybrid discipline that must combine the methods of the natural and the social sciences." This "middle ground" approach that incorporates a "social context" had great influence in the psychiatric traditions of the United Kingdom but not in the United States.

Telegram: @medical_k

www.konkur.in

A leading proponent of this middle-ground approach was Professor John Wing, at Maudsley Hospital in London, following the path of Sir Aubrey Lewis and other pioneers. Wing developed the PSE, a semistructured instrument rich in clinical phenomenology that provides detailed symptomatic and syndromic descriptions with elaborate probes, thus requiring significant training and clinical expertise. Previous editions of the PSE were successfully used in two pivotal international studies on psychiatric diagnosis in the 1960s and 1970s, the “United States/United Kingdom Diagnostic Project” (U.S./U.K. study) and the “International Pilot Study of Schizophrenia (IPSS),” both coordinated by the WHO. The U.S./U.K. study demonstrated the extent to which a diagnosis of “schizophrenia” in the United States was broader and less definable compared to its use in England and demonstrated that through training and the use of a structured instrument (the PSE in this instance), wide differences in diagnoses of schizophrenia across the Atlantic would virtually disappear. The IPSS showed that a “concordant” group of patients with schizophrenia could be identified in all countries by trained clinicians using the same diagnostic strategy (PSE). Incidentally, a new version of the PSE, the Structured Clinical Assessment in Neuropsychiatry–Present State Examination (SCAN-PSE), continues to be used by a few teams of investigators around the globe, including a few sites in the United States. This approach emphasizes the need to gather rich clinical data (clinical phenomenology) that takes into account social and environmental influences in addition to biology. The assumption is that biologic systems interact closely with the environment and that social influences can generate or amplify biologic impairments. Unfortunately, this “middle ground” approach to psychiatric diagnosis has been abandoned by modern classifications. Moreover, clinical and epidemiologic studies incorporate questionnaires that are often administered by lay interviewers and contain only brief or abridged instruments to gauge psychopathology. This leads to rather dry, impoverished clinical assessments.

The next paradigm change for psychiatric classification (and it is doubtful for now that RDoC truly represents such a breakthrough) will necessarily have to wait for a much clearer understanding of the matrix of brain structures, such as neuronal circuits, the “omics” repertoire (genomics, proteomics, metabolomics), and a more profound understanding on how social experiences affect and influence such

Telegram: @medical_k

www.konkur.in

systems. In the interim, perhaps a return to Jasper's phenomenologic approach, with its rich and meaningful analysis of symptom presentations, should be welcomed by many scholars, practicing clinicians, and researchers, as a valuable step in this process. This may help the careful delineation of various pathophysiologic hypotheses that would enhance diagnostic validity by providing etiologic knowledge, a promising alternative to the "reliable" but imprecise classifications based on symptoms and subjective reports.

9.2 The Classification of Mental Disorders in the International Classification of Diseases (ICD-11)

Javier I. Escobar, M.D., M.Sc., and Carlos López-Jaramillo, M.D., Ph.D.

The International Classification of Diseases (ICD) of the World Health Organization (WHO) is the classification system utilized across the world for clinical, epidemiologic, and administrative purposes. It names and classifies conditions in the areas of health and disease and contributes to the implementation of health policies. The ICD is used by physicians, nurses, and other health professionals, as well as administrators,

Telegram: @medical_k

www.konkur.in

scientists, researchers, and health insurance companies, among others. The systematic use of this classification allows the examination of the incidence and prevalence of diseases and other health problems worldwide. The proper and systematic use of ICD diagnostic codes allows the creation of reliable registries, which provide a solid base for assessing morbidity and mortality statistics globally. It, therefore, makes it possible to have a global perspective on health and health-related issues.

To American psychiatrists, ICD is of utmost importance as ICD-10 is currently the official system for coding and billing purposes in the United States. Fortunately, the DSM-5 developers took this into account, and in the fifth revision published in 2013, each DSM-5 diagnosis has corresponding ICD-10 Clinical Modification (CM) codes. In the 1970s, the U.S. government decided that ICD-9 codes were not specific enough for clinical use in the United States and developed the CM version. In DSM-5, ICD-10 codes are headed by the letter F. For example, the corresponding ICD-10 codes for anorexia nervosa are F50.01 for the restrictive type and F50.02 for the binge-eating/purging type. The fact that ICD-10 codes are embedded in DSM-5 facilitates the task of shifting from ICD-9 to ICD-10. However, as will be seen ahead, this does not necessarily mean that there is a perfect diagnostic correspondence between DSM-5 and ICD-10 or now ICD-11.

The WHO recently released the 11th version of the ICD classification (ICD-11) for mental disorders. While the official release of this classification was expected for 2015, the process was delayed. Because of this, the information related to ICD-11 is quite fresh, and the broad use of the system is yet to be fully realized. WHO has been conducting training programs worldwide to familiarize people with this latest version of the international classification.

The goal of this chapter is to focus primarily on the recently released ICD-11 classification for mental disorders. The chapter will first provide a brief outline of the history and development of the ICD system leading to ICD-10. Next, it will describe the process of revising ICD-10 and developing ICD-11. It will briefly discuss the main goals set forward, the obstacles faced, and the mechanisms utilized to sort these out. The main body of the chapter will be a detailed description of the categories for mental disorders included in ICD-11, based on the review of authoritative references and other WHO sources, including international lectures and

Telegram: @medical_k

www.konkur.in

courses focusing on key diagnostic areas of this new classification of mental disorders.

Acknowledging the international input on DSM-5 and the ongoing consultation between the American Psychiatric Association (APA) and WHO, a general expectation was that ICD-11 would resemble DSM-5 to a larger extent than ICD-10 resembled DSM-IV. However, as will be seen ahead, significant differences remain between the DSM-5 and ICD-11 systems. The controversies surrounding the new section on mental disorders of the ICD-11, the similarities and differences with DSM-5, and the complex task of harmonizing these classifications will be analyzed in more detail ahead.

Excellent, detailed descriptions of the ICD and the whole WHO Family of International Classifications (WHO-FIC) can be found elsewhere. Our intent here is to provide only a brief description of the ICD classification as well as a brief outline of the relevant WHO-FIC categories. This brief introduction is intended to highlight the most salient features of the ICD classification to serve as a general background to frame discussions on the ICD system.

THE INTERNATIONAL CLASSIFICATION OF DISEASES

The ICD is the evolving core of a set (or a “family” as it has been called) of disease and health-related classifications. It was the product of a commendable international effort intended to improve the analyses, first of mortality statistics and later those of morbidity, for public health purposes. With time, the actuarial and epidemiologic focus of ICD classification would be extended, allowing its use as an instrument to aid diagnostic and assessment processes in medicine in efforts to improve clinical practice, contribute to research, and facilitate administrative tasks.

The ICD within the WHO Family of International Classifications

The WHO-FIC is a set of classifications that are used to describe and produce information about different aspects of health, disease, and health systems around the world. The strong endorsement that WHO-FIC has received from the United Nations reflects its alignment with the core values of this international organism. The core function of the WHO-FIC is to aid the production of reliable statistical information and assist statistical

Telegram: @medical_k

www.konkur.in

systems at local, national, and international levels. These statistics would, in turn, be employed in various ways by different kinds of stakeholders to provide input for actions intended to improve the health status and health care of populations around the world. In order to achieve these goals, the WHO-FIC uses a standardized language with the main goal of improving communication between groups and individuals working in the field of health across the world.

The WHO-FIC has been subdivided into *reference*, *derived*, and *related* classifications.

Reference classifications: These deal with basic parameters of health such as death, disease, functioning, disability, health, and health interventions. They can be used at both individual and population levels. The reference classifications of the WHO-FIC include the following:

- The ICD
- The International Classification of Functioning, Disability, and Health (ICF 2) classifies functioning and disability
- The International Classification of Health Interventions (ICHI)

Derived classifications: As the name suggests, these are systems derived from reference classifications developed for more specialized purposes. They are usually created by picking up and rearranging various elements from reference classifications that are complemented by adding up new items (concepts, descriptions, etc.) to the original structure.

The most recently developed *derived classifications* in the WHO-FIC include the following:

- The ICD-11 for Mental, Behavioral, or Neurodevelopmental Disorders
- The ICD-11 for Mental and Behavioral Disorders, Clinical Descriptions and Diagnostic Guidelines
- International Classification of Diseases for Oncology, Third Edition (ICD-O-3)
- Application of the International Classification of Diseases to Neurology (ICD-10-NA)
- Application of the International Classification of Diseases to Dentistry and Stomatology, Third Edition (ICD-DA)

Related classifications: These contain descriptions of other aspects of the health experience and the health system that are deemed relevant for the purposes of health care. They may come from other sectors and/or

Telegram: @medical_k

www.konkur.in

working groups of the WHO (e.g., Classification of External Causes of Injury or ICECI, the Anatomical Therapeutic Chemical Classification System with Defined Daily Doses or ATC/DDD). Also, these can come from other international organizations (e.g., the International Classification of Primary Care, Second edition, or ICPC-2, the International Classification for Nursing Practice, or ICNP, etc.).

Table 9.2–1.
Types of Classifications of WHO Family International Classification

1. Reference Classifications
International Classification of Diseases (ICD)
International Classification of Functioning, Disability and Health (ICF)
International Classification of Health Interventions (ICHI)
2. Derived Classifications
International Classification of Diseases for Oncology, Third Edition (ICD-O-3)
The ICD-11 for Mental, Behavioral or Neurodevelopmental Disorders
The ICD-11 for Mental and Behavioral Disorders Diagnostic Criteria for Research
Application of the International Classification of Diseases to Neurology (ICD-10-NA)
Application of the International Classification of Diseases to Dentistry and Stomatology, Third Edition (ICD-DA)
3. Related Classifications
International Classification of Primary Care, Second Edition (ICPC-2)
International Classification of External Causes of Injury (ICECI)
Technical aids for persons with disabilities—Classification and terminology (ISO9999)
The Anatomical Therapeutic Chemical Classification System with Defined Daily Doses (ATC/DDD)
International Classification for Nursing Practice (ICNP)
Verbal autopsy standards: ascertaining and attributing causes of death

Table 9.2–1 shows the general structure of the types of classifications used by the WHO-FIC.

Telegram: @medical_k

www.konkur.in

Development of the International Classification of Diseases

To classify is to cluster and allocate a set of objects (in this case, disorders) according to logical rules that guide the clustering activity. These rules specify what type of criteria would determine that a given disorder belongs to a particular category (e.g., the presence or absence of delusions and/or hallucinations; a longer duration vs. a brief duration of symptoms, etc.). Also, the relationships between the members of a category must be specified. Usually, an important purpose of the classification of diseases is to bring information to the users about the health problems included within its categories. The information conveyed by the classification will then be used according to the needs of the user (e.g., diagnosis, research, policy, etc.). Thus, classifications are crucial for generating certain types of information that will be stored and then used for comparison purposes, exchanges, analyses, disease monitoring, and of course, policy decisions about health, disease, and health care.

This practical aim of classifications has led to the assertions that classifications are not *true* or *false*, but only *useful* or *not useful,* depending on their purpose. Thus, a classification of diseases can be very useful for clinical diagnosis if it contains diagnostic features. Then it can be used in epidemiologic research on a particular health problem if the diagnosis of the disease (the purpose of the classification) is accurate enough to permit the measuring of prevalence or incidence of the disorder in populations, and so on. However, a diagnostic classification can be less helpful or even useless when utilized for other purposes. The pre-eminence of practical utility over other features of classification such as truthfulness, ease of use, heuristic value, methodologic and/or scientific rigor, social consequences, etc., have been debated for a long time.

As mentioned before, one of the most important uses of disease classifications is to improve communication across a heterogeneous group of users, including clinicians, researchers, or statisticians, but also between organizations and institutions that manage international or global information on diseases and health-related matters. If communication is understood as being an exchange of information between users, it presupposes a common language. The organized collection of certain terms and meanings and a clear description of the rules for their use are the functional characteristics of contemporary international classifications.

Developers of classifications must make decisions about which terms, concepts, and descriptions are to be included or excluded. They must

Telegram: @medical_k

www.konkur.in

outweigh the pros and cons of these selections. They have to justify a certain degree of standardization of language (and thinking) in efforts to improve communication at the expense of suppressing the natural variability inherent to human experiences of health and disease. Although some of these decisions are supported by empirical research, often, developers and reviewers of nosologies have to resort to nonempirical solutions (e.g., practical reasons).

It must also be remembered that users can come from different disciplines, pertain to different organizations, and thus have different knowledge backgrounds, goals, and interests. The heterogeneity of users is not a trivial matter. One of the main challenges for a multipurpose classification (i.e., a classification that will be used to provide epidemiologic information to public health authorities but at the same time must help clinicians to make accurate diagnoses) is to offer to an ample variety of users the information they need without modifying the basic structure of their practices. Otherwise, a classification should be created and tailored for each group of users, something that is not deemed practically feasible and could lead to communication problems.

A Chronology of ICD Development. It can be said that classifying diseases according to a set of specific principles (e.g., symptoms) has been the rule since the beginning of medicine. The objects, principles, types, methods, and purposes of classification have been changing according to the historical period, and change has been driven by diverse factors such as scientific, philosophical, practical, cultural, political, economic, and legal issues. The mid-19th century, more specifically the year 1853, is generally identified as the one when interest arose to start cataloging the causes of death that could be used in “all countries” as part of the first International Statistical Congress. Two years later, William Farr presented a five-group classification of diseases: epidemic diseases, constitutional diseases, local diseases (arranged according to their anatomical site), developmental diseases, and diseases that are a direct consequence of violence. Revisions using Farr’s principles were made in 1865, 1874, 1880, and 1886. Principles of classification were changed in 1893, when Alphonse Bertillon, a French biometrics researcher, submitted to the newly created International Statistical Institute (ISI) a comprehensive classification of causes of death based on a synthesis of English, German, and Swiss classifications. Causes of death were divided

Telegram: @medical_k

www.konkur.in

into two main groups: those due to generalized diseases and those localized to a particular organ or anatomical site. Bertillon's classification proved successful and was adopted by several countries, and the ISI officially recommended that this classification (the International List of Causes of Death [ILCD]) should be adopted by all those offices that were not yet using it. Later in 1929 and 1938, the revisions of the ILCD were made by commissions composed of representatives of both the ISI and the Health Organization of the League of Nations. In 1946, the aim of the international efforts on classification was expanded beyond death causes, and the WHO was commissioned to create an International List of Causes of Morbidity. After a meeting in 1948, the work on the revision of the classification was from then on carried out by the WHO with the support of national committees on vital and health statistics. The constitution of the WHO includes the development of the classification as one of its functions. The 7th revision conference was held in Paris; the 8th, 9th, and 10th revision conferences were held in Geneva in 1965, 1975, and 1989.

It seems clear that the most distinctive characteristic of the history of the ICD enterprise has been to foster international participation in efforts to create a classification of causes of death and disease that would be both useful and used by countries all around the world.

The ICD-9

The ninth revision (1975) deserves at least a brief mention here because important changes at different levels of the classification process were implemented during this revision. This marked the beginning of the ICD "family," as several additional documents were introduced, including "the classification of procedures in medicine" and the "classification of impairments and handicaps."

Also, the ICD was adapted to the needs of primary care as well as certain medical specialties (e.g., oncology).

Recommendations and norms were issued about such matters as lay reporting of disease, mortality coding rules, and the selection of a single cause for death statistics. Also, the well-known convention of using a dagger (†) to mark the underlying disease and an asterisk (*) to mark its manifestations was issued during this process. Perhaps one of the most important single events for classification in psychiatry was ICD-9's inclusion of a glossary and brief descriptions of the categories included in the fifth chapter (mental disorders), a procedure that was not part of the

Telegram: @medical_k

www.konkur.in

other chapters. The intent of the glossary and the clinical descriptions was to assist clinicians in making the diagnosis.

The 10th Revision of the International Classification of Diseases

Mental disorders were included in Chapter V of ICD-10 as “Mental and Behavioral Disorders.”

Approved in 1992, the ICD-10 was divided into three volumes. In volume 1, “the tabular list,” all medical conditions included in ICD-10 were listed. The listing was organized alphanumerically, ranging from A00 to Z99. In this 10th version of the ICD, diagnostic codes do not go beyond the fourth character (e.g., F31.0). Each character corresponds to the hierarchical level of the classification. For example, in the code F321, the “F” corresponded to Mental and Behavioral Disorders; “F3” corresponded to Mood (Affective) Disorders, the “F32” to Depressive Episode, and “F32.1” to Moderate Depressive Episode.

Table 9.2–2 shows the list of chapters of ICD-11.

The ICD-10 Version for Use in Primary Care (ICD-10 PHC). An important side product of ICD-10 was the PHC version that focused on mental disorders commonly seen in primary care. The development of this version involved significant communications and exchanges of information between general practitioners and psychiatrists. It included a list of criteria and guidelines for 28 mental disorders commonly seen in primary care.

The Research Version of ICD-10. Consistent with the idea of a multipurpose classification for multiple kinds of users, the ICD-FIC included a version for research called “Diagnostic Criteria for Research” (ICD-10 DCR). Compared to previous versions, this one was less descriptive but included more precise wording, more restrictive definitions, a description of inclusion and exclusion criteria, and definitions of fixed symptom thresholds.

COMPARING ICD AND DSM CLASSIFICATIONS

The existence of two main systems of classification that have widespread international use requires an understanding of their differences and similarities. Comparisons between the two systems have proven difficult, as they represent different conceptualizations of purposes and methods for classifying mental disorders. It is often forgotten that the specific aims that developers of each particular classification system had in mind will heavily influence the methods for its development and the final written

Telegram: @medical_k

www.konkur.in

product. Therefore, it is not surprising to find out that the ICD and DSM classifications have several differences, some more substantial than others. These differences do not imply that one of the classifications is better than the other. Choosing one over the other is essentially a value judgment, and henceforth relative. For example, a classification X can be considered better than classification Y if clinical utility is the point of reference for judgment. However, classification Y could be considered better than X if it is decided that research utility is the main criterion for judging superiority.

The most important differences between ICD and DSM stem from the goals of the umbrella organizations that created them. Thus, as an international tool, ICD's key aim is to provide clinically useful descriptions for users pertaining to different national and cultural backgrounds across the world without negatively affecting other important features like reliability, validity, and clinical utility. As a national classification in the United States, DSM is built to make diagnostic recommendations of interest primarily to members of a national professional organization (the APA). The ICD is a system for illness reporting, whose use is mandatory in the countries that agreed to use it. National classifications (DSM) do not require governmental approval but are under the authority of the professional associations (in this case, the APA) that regulate their construction, revision, and release.

ICD has to undergo a series of steps prior to submission and approval. The approval comes first from reference centers, and then it is submitted to the health ministers of the countries members of the WHO that will discuss its acceptance. This international process involves a high level of consultation and negotiation, in which the views of different countries (and their health traditions) have to be understood, respected, and taken into account. The international character and orientation of ICD is a different process from the international dissemination and acceptance of the DSM system. ICD is primarily concerned with incorporating conceptual and guiding principles for clinical practice globally, while DSM has other priorities such as the use of the classification for research purposes. Making different versions available for different needs and users means that the ICD has to offer clinical descriptions that are useful and practical for users from different professional backgrounds (not only psychiatrists or physicians) without negatively affecting other important features like its international character and reliability. Consequently, different versions of

Telegram: @medical_k

www.konkur.in

the ICD have been made available for psychiatrists, primary care practitioners, and researchers. National classifications like the DSM tend to be “prescriptive” in the sense that they regulate what terms can or cannot be used to report diagnoses. More recently, the DSM system also developed a version for use in primary care. International classifications take a different approach, and therefore, rather than dictating or prescribing, they aim at providing useful, practical categories that health professionals can use in their daily clinical work.

A frequent example of the practical advantages of the ICD system over the DSM is the use of a particular approach to facilitate sorting out the frequent presentation of both anxiety and depressive symptoms in a given patient when there is not a clear predominance of either clinical presentation. For this type of situation, the ICD has provided, for some time, a category called “mixed anxiety and depression,” mainly because practicing clinicians view this as an important issue and have insisted on having it available as part of the classification.

The DSM system, on the contrary, has not accepted such a category, although it has been acknowledged that it merits further study. This difference in strategy between ICD and DSM has been framed as the “bottom-up” versus the “top-to-bottom” approaches to classification.

The use of clinical descriptors instead of diagnostic (“operational”) criteria is undoubtedly one of the most important differences between ICD and DSM, reflecting concepts and values underlying the ICD enterprise. ICD developers decided to include brief clinical descriptions—a narrative account of the main features of the disorders—to help diagnosticians. DSM developers took the approach of articulating a list of criteria accompanied by instructions about the number and the combinations of criteria needed to make a diagnosis. Both approaches have strengths and limitations, mostly related to the specific purposes for using the classification (e.g., clinical work vs. research).

If one accepts that both classifications have their strengths and limitations, then some categories may be better portrayed in DSM and some in ICD. Since both systems have been created with different aims in mind, the acceptability and satisfaction of users is an important additional factor to consider when comparing these two diagnostic traditions.

Telegram: @medical_k

www.konkur.in

Table 9.2–3.
Summary of Major Differences between DSM and ICD

DSM	ICD
▶ National classification of the United States	▶ Official world classification
▶ Focus on psychiatrists and psychologists	▶ Designed to be used by and useful for the different health professionals
▶ Developed to fulfill the particular information needs of the U.S. health system	▶ Created with the idea of being useful for different health systems around the world
▶ Operational criteria	▶ Clinical descriptions
▶ Property of the APA	▶ Free of charge and open access
▶ U.S. Anglophone perspective	▶ Multilingual and multicultural
▶ Advantages for research	▶ Advantages for clinical use
▶ Different formats, one version	▶ Multiple versions and formats for multiple users

In general, practicing clinicians consider ICD to be clinically useful and many scholars and clinicians, many of them practicing in the United States, view it as more appealing than the DSM system for clinical use.

In the United States, DSM is most frequently used by psychiatrists, less so by psychologists, a trend that might be changing. Surveys of international clinicians indicate that they tend to use DSM more than ICD, possibly because DSM is what they were primarily taught during their psychiatric/psychological training. Moreover, researchers and other international scholars appear to have adopted DSM as their preferred diagnostic system. Researchers seem to feel more comfortable with DSM because of the "operational" criteria, which allows for a more distinct recording and sorting out the clinical features of the disorders.

Table 9.2–3 shows a summary of the differences between DSM and ICD.

Specific Differences between ICD and DSM

Empirical Comparisons: ICD-11 versus DSM-5. Although there is a general impression that ICD-11 and DSM-5 have more similarities than

Telegram: @medical_k

www.konkur.in

differences, empirical data suggests that concordance between the two systems is not as good as expected.

In an important comparison published in 2009, Michael First reported that out of the 176 criteria sets he examined, only one disorder (transient tic disorder) had identical DSM-5 and ICD-11 definitions. Twenty-two percent of the nonidentical sets had definitional differences that were conceptually based, while the other 78% had nonconceptual-based differences. Several other studies have also reported significant differences between DSM-5 and ICD-11.

MENTAL DISORDERS IN ICD-11

In Chapter 6 of ICD-11, mental disorders were renamed as "Mental, Behavioral or Neurodevelopmental Disorders." The term "neurodevelopmental" has a long history but was not included in previous editions of the ICD or the DSM. The term is used to describe disorders of early onset that affect cognitive and social functions, display important sex differences, and have a chronic course leading to impairment and lasting into adulthood.

Main issues highlighted herein:

1. A general overview of mental disorders in ICD-11.
2. Changes in specific mental disorders between ICD-10 and ICD-11.
3. General issues and problems encountered in the process of updating ICD-10, and a brief discussion of how these were sorted out.
4. The process of "harmonizing" ICD-11 and DSM-5.

The Process of Developing ICD-11 from ICD-10

Several key features deemed essential for developing solid, useful, and practical classifications were incorporated as "conceptual signposts" in the development of ICD-11.

These included the following:

- The system originates and expands from a set of basic points and agreements between mental health professionals.
- It requires simplicity and understandability to allow its easy use by those dealing with common mental disorders.
- It should be attractive to users as a tool of information exchange.

Telegram: @medical_k

www.konkur.in

- It must be easily translatable into any already established national classifications.
- It should be conservative and theoretically familiar in order to be acceptable to diverse users with different levels of knowledge, disciplinary backgrounds, and interests.
- Changes should be implemented only when there is sufficient knowledge available to justify innovations.
- Because of its international character, the languages in which it will be translated must be kept in mind.
- Successive revisions must retain continuity with the previous versions.

Why Change ICD-10? No extant classification is considered "good enough," either from a taxonomic point of view or from the perspective of yielding reliable, practical diagnoses for clinical work and/or research.

Some of these difficulties have been linked to irregularities in terms, concepts, and descriptions leading to limitations in the diagnostic information contained in the descriptions of disorders.

The environmental components and the context in which classifications are used undergo profound changes with the passage of time. Therefore, major reasons for reviewing ICD-10 included efforts to improve the consistency and uniformity of the diagnostic information provided by the clinical descriptions and to adapt to new demands from users and conditions of use. It is important in this context to generate new research data about mental disorders that is backed up by scientific developments (evidence based) and that satisfies new demands from clinical users about utility and ease of use in various political, social, and economic environments. It must also be user-friendly, adapt to new technologic environments, and be amenable to frequent updates.

Improving Classification Systems without Losing What Has Been Gained. A revision process needs to keep a balance between conservatism and innovation. In other words, it should improve the classification as much as possible without losing any of the good elements present in it. The process of revising ICD-10 has been compared to the release of new "software." Besides offering new features, it also has to be compatible with previous versions. Similar to what was proposed for DSM-5 ("living document"), ICD-11 was expected to experience transformations if and when new scientific information became available.

Telegram: @medical_k

www.konkur.in

Maintaining the Basic Purposes While Increasing the Diversity of Stakeholders. The three basic purposes of the classification (clinical, public health, and research use) have to be maintained. The main stakeholders of ICD-11 include the governments of the WHO member countries, health care professionals (not only mental health professionals or psychiatrists), and researchers. However, patients and "users" of mental health services have also been included among the stakeholders, although the mechanisms for their participation have not been yet clearly articulated. Other important stakeholders are legal systems, health policymakers, and payers of health care services.

Clinical Utility: The Core Principle Guiding the 11th Revision of ICD. As stated before, clinical utility backed up by research evidence was the guiding principle for ICD-11. Michael First and collaborators noted that "clinical utility deserved to be an organizing priority for the revision so long as it did not sacrifice validity as established by the best available science." However, owing to the scarcity of data coming from "best available science" that can be used to inform classification, utility, reliability, and some equivalents of validity became the core guiding principles of ICD-11.

The development and refinement of classifications in psychiatry is a reminder that the discourse on science, scientific rigor, objectivity, and so on must be approached cautiously because very often, the practical needs and social pressures are the drivers of diagnostic decisions. This is not a negative issue per se. What is undesirable is the "reification effect" of classifications in the absence of acceptable reliability and validity.

WHO TAG-MND, GSPN, and CDDG. The WHO's Topic Advisory Group (TAG-MND), originally created in 2007, had the main objective of drafting proposals for the classification of mental disorders in ICD-11.

The TAG-MND, in turn, created several subgroups (e.g., epidemiologic group, groups working on harmonization ICD-11/DSM-5, mental disorders in primary care, health problems related to substance misuse, childhood mental disorders, intellectual disability (ID), and personality disorders).

The WHO also created a coordinating group to establish the Global Scientific Partnership Network (GSPN), involving experts representing different disciplines and traditions in psychiatry. Its role is to help in the gathering and analysis of research data relevant to classification, the design of field trials, and the assessment of the translation process, among its principal tasks.

Telegram: @medical_k

www.konkur.in

Active consultation (with individuals, institutions, and governments) and a thorough literature review relevant to the classification of mental disorders were also implemented as part of this process. Technical preparation and final ICD-11 products were assigned to a WHO special unit.

These complex tasks turned into a long and tortuous process marked by delays and postponement of deadlines.

For mental health professionals, the "Clinical Descriptions and Diagnostic Guidelines (CDDG) for ICD-11 Mental and Behavioral Disorders" were prepared. Informally known as the "blue book" during the tenure of ICD-10, CDDG was intended primarily for clinical, educational, and service use.

A particularly important feature of the ICD-11 CDDG is the description of the essential features of each disorder (those that clinicians would reasonably expect to find in all cases of the disorder). This highlights essential features that may resemble diagnostic criteria but generally avoid cutoffs or other precise requirements (such as symptom counts, duration of symptoms, etc.).

This approach was intended to conform to the way clinicians actually make diagnoses, flexibly exercising clinical judgment, and enhancing clinical utility by considering and encouraging descriptions of cultural variations in clinical presentations and other contextual and health system–related factors relevant to clinical practice. This approach was consistent with expectations of clinicians elicited early in the process and was confirmed by field studies.

A lifespan approach was also adopted in ICD-11, thus ending the separation of disorders by the age of onset.

Cultural Issues in ICD-11. An important new feature in ICD-11 is the inclusion of relevant information related to cultural background. This was based on expert advice and systematic reviews of the literature. Each diagnostic area in ICD-11 includes a description of possible cultural issues operating in each instance.

A good example to illustrate this new dimension is the cultural outline for assessing panic disorder as included in the ICD-11 manual.

CULTURE-RELATED FEATURES

Telegram: @medical_k

www.konkur.in

- The symptom presentation of panic attacks may vary across cultures, influenced by cultural attributions about their etiology. For example, individuals of Cambodian origin may emphasize panic symptoms attributed to dysregulation of *khyâl*, a wind-like substance in traditional Cambodian ethnophysiology (e.g., dizziness, tinnitus, neck soreness).
- There are several notable cultural concepts of distress related to panic disorder, which link panic, fear, or anxiety to etiologic attributions regarding specific social and environmental influences. Examples include attributions related to interpersonal conflict (e.g., *ataque de nervios* among Latin American people), exertion or orthostasis (*khyâl cap* among Cambodians), and atmospheric wind (*trúng gió* among Vietnamese individuals). These cultural labels may be applied to symptom presentations other than panic (e.g., anger paroxysms, in the case of *ataque de nervios*), but they often constitute panic episodes or presentations with partial phenomenologic overlap with panic attacks.
- Clarifying cultural attributions and the context of the experience of symptoms can inform whether panic attacks should be considered unexpected, as must be the case in panic disorder. For example, panic attacks may involve specific foci of apprehension that are better accounted for by another disorder (e.g., social situations in social anxiety disorder). Moreover, the cultural linkage of the apprehension focus with specific exposures (e.g., wind or cold and *trúng gió* panic attacks) may suggest that acute anxiety is expected when considered within the individual's cultural framework.

Definition of Mental Disorders in ICD-11

ICD-11 defines mental, behavioral, and neurodevelopmental disorders as "syndromes characterized by clinically significant disturbance in an individual's cognition, emotional regulation, or behavior that reflects a dysfunction in the psychological, biological, or developmental processes that underlie mental and behavioral functioning. These disturbances are usually associated with distress or impairment in personal, family, social, educational, occupational, or other important areas of functioning."

ICD-11's Prototypes, Criteria, and Clinical Descriptors. The question of which is the best approach to portray symptoms and other clinical features of mental disorders in such a way that they are easy to identify and can be readily used by clinicians was carefully considered during the process of revising.

Telegram: @medical_k

www.konkur.in

Thus, as part of the ICD-11 approach, clinicians provided input on whether or not the diagnostic features outlined in the clinical description matched those of “real” patients. The process emphasized the relevance of clinical and phenomenologic information about the disorders, including essential, typical, or pathognomonic features, differential diagnosis, the boundary with normality, typical course, as well as developmental and cultural-specific features.

The procedure called “prototype matching” consists of clinicians estimating to what extent the patient’s clinical presentation matches a paragraph-length description of the disorder. The clinician has to estimate the extent of matching using a 5-point scale, from 1 (“little or no match”) to 5 (“very good match”). The expected result will consist both of a dimensional diagnosis (capturing the extent to which the patient has the disorder) and a categorical one because higher ratings (4 and 5) correspond to the presence of the disorder. A rating of 3 indicates “subthreshold” or “clinically significant features.” Despite its limitations, the “prototype matching” procedure was considered an important development, and there was consensus to keep refining this approach in the near future.

Dimensions and Categories in ICD-11. The use of the term “dimensional” has become fashionable in psychiatry in recent times, following the debate and controversies between DSM-5 proponents and those advocating “pure” dimensional models such as the Research Domain Criteria (RDoC) proposed by the NIMH. The potential complexity of this approach and the focus on assessing specific constructs is illustrated in Tables 9.2–4 and 9.2–5.

DSM-5 considered dimensions, at least in the initial phases of its development, and provided potential dimensions that were included in section III of the DSM-5 manual. Dimensional approaches are viewed as novel, as they may free psychiatric classifications from the conceptual, empirical, and practical restraints of operational categories.

While its emphasis is placed on categories, ICD-11 also considers dimensions for use in a number of clinical scenarios where these may be feasible and also potentially helpful.

Dimensional Perspectives in ICD-11. The dimensional potential of the ICD-11 is most clearly realized in the classification of personality disorders.

In nonspecialist settings, the dimensional rating of severity for ICD-11 personality disorders offered greater simplicity and increased clinical utility compared to the ICD-10 classification of specific personality disorder categories. It allows improved differentiation of patients who need more complex interventions as compared to those requiring simpler treatments. It also facilitates tracking clinical changes over time.

Telegram: @medical_k

www.konkur.in

The dimensional perspective eliminates both the excessive comorbidity of personality disorders and the unspecified personality disorder diagnoses. It also provides a base for doing research on the various dimensions and potential interventions for the various manifestations of these disorders.

A set of dimensional qualifiers has been introduced to describe the symptomatic manifestations of schizophrenia and other primary psychotic disorders. Rather than focusing on diagnostic subtypes, the dimensional classification focuses on relevant aspects of the current clinical presentation in ways that are much more consistent with recovery-based psychiatric rehabilitation approaches.

These dimensional approaches to personality disorders and symptomatic manifestations of primary psychotic disorders are described in more detail under the respective sections ahead in this paper.

"Specifiers" and "Qualifiers" in ICD-11. ICD does not use coded "specifiers" because of the limits of the coding system. Therefore, in instances where certain features of a disorder are deemed important and need to be highlighted, noncoded "qualifiers" can be added (see, e.g., schizophrenia below).

Chapter 6 in ICD-11: Mental and Behavioral Disorders

The ICD-11 chapter on mental disorders is Chapter 6, thus being located in a different section as it was the case with ICD-10.

Table 9.2–6 shows a list of blocks of Chapter 6, Mental and Behavioral Disorders of ICD-11.

Telegram: @medical_k

- 6E8Z Mental, behavioral or neurodevelopmental disorders, unspecified

General Structure of the Diagnostic Categories and Clinical Descriptions in ICD-11

Telegram: @medical_k

www.konkur.in

In order to improve uniformity in the ICD-11 descriptions, the working groups used a template known as the "content form." This template standardized the general structure of the information included for each disorder. The variability and unevenness of content and format in ICD-10 are thought to reflect the work of different groups of experts who work independently, generally with little overall coordination and without adequate standardization of the different sections.

For ICD-11, the "content form" includes items arranged in a special manner and guided by rules of application that yield technical, clinical, and administrative information. Also, a standard format for clinical descriptions and diagnostic guidelines is prepared.

Indeed, a number of experts have insisted for some time that diagnostic guidelines should become more realistic from a cognitive perspective, that is, using a structure that truly represents the way clinicians think, practice, and use their clinical judgment.

Table 9.2–7 illustrates the standard format for ICD-11 Clinical Descriptions and Diagnostic Guidelines.

ICD-11 Field Trials

A series of field trials, both clinic based and internet based, are conducted, focusing on clinical utility and reliability. The web-based field studies use standardized case materials in order to test whether or not the clinical guidelines for ICD-11 diagnoses produce more consistent diagnostic behavior than ICD-10. The methodologic rigor and predictive power of the vignette's methodology is a key strength in this process. Vignettes are designed to produce a behavioral response (diagnosis) by clinicians, which in turn help assess the usefulness of the classification. The Global Clinical Practice Network (GCPN) was established to allow mental health and primary care professionals from all over the world to participate directly in the development of the ICD-11 CDDG through internet-based field studies.

Telegram: @medical_k

www.konkur.in

Table 9.2–7.
Standard Format for ICD-11 Clinical Descriptions and Diagnostic Guidelines

Category Name
Brief Definition: containing a summary statement (100–125 words) of the common essential features of the disorder
Inclusion Terms
Exclusion Terms
Essential (Required) Features: relatively explicit guidance regarding features needed to confidently make the diagnosis
Boundary with Normality (Threshold): specifying those aspects of the disorder that are indicative of its pathologic character
Boundary with Other Disorders (Differential Diagnosis): this section provides guidance to the clinician about how to make this differentiation
Coded Qualifiers/Subtypes
Course Features: information on temporal patterns like age of onset, persistence, duration, likely progression over time, etc.
Associated Clinical Presentations: information about features that are important and help to recognize variations in presentation but also highlights areas where clinical intervention might be important
Culture-Related feature: brief information regarding cultural considerations for diagnosis
Developmental Presentations
Gender-Related Features

The GCPN includes about 15,000 clinicians from 155 countries. Most members are physicians, predominantly psychiatrists, and 30% are psychologists.

All WHO global regions are represented in proportions that largely correspond to the number of mental health professionals in each region, with the largest proportions coming from Asia, Europe, and the Americas (approximately equally divided between the United States and Canada on the one hand and Latin America on the other). The ICD-11 field studies program also represents an area of major innovation. This program of work includes novel methodologies for studying the clinical utility of the draft diagnostic guidelines, including their accuracy and consistency of

Telegram: @medical_k

www.konkur.in

application by clinicians as compared to ICD-10, as well as the specific elements responsible for any observed discrepancies. A key strength of the research program is that most studies are conducted in a given time frame, allowing results to provide a basis for revision of the guidelines in efforts to address any observed weaknesses. Global participation is a defining characteristic of the ICD-11 CDDG field studies program (World Psychiatry 18: 1-February 2019).

Several GCPN studies have been completed to date, most focusing on comparisons of the proposed ICD-11 diagnostic guidelines with ICD-10 guidelines in terms of accuracy and consistency of clinicians' diagnostic formulations, using evaluations of standardized case material to test key differences. Other studies have examined gradients for diagnostic qualifiers and how clinicians actually use classifications. GCPN studies have been conducted in Chinese, English, French, Japanese, Russian, and Spanish and have included an examination of results by region and language to identify potential difficulties in global or cultural applicability as well as problems in translation.

Clinic-based studies have also been conducted through a network of international field study centers to evaluate the clinical utility and practical value of the proposed ICD-11 diagnostic guidelines in natural conditions in the settings in which they intend to be used. These studies also evaluate the reliability of diagnoses that account for the greatest proportion of disease burden and mental health services utilization. International field studies are located in 14 countries across all WHO global regions, and patient interviews for the studies are conducted in the local language of each country.

The ICD-11-Primary Health Care (ICD-11-PHC)

Similar to what was done in the case of ICD-10, the 11th edition of ICD also has revised the classification for use in primary care settings, the ICD-11-Primary Health Care (ICD-11-PHC). The working group had anticipated that although many of the disorders included in the ICD-10-PHC would be retained, some more "radical" proposals were made, pending field test results.

These proposals included recommendations such as:

- Abandon the distinction between anxiety and mood disorders and create a category called "dysphoric disorders." This will allow clinicians

Telegram: @medical_k

www.konkur.in

to diagnose depression, anxiety, or the combination of both as "anxious depression."

- Anxiety disorder would be largely equivalent to generalized anxiety disorder (GAD), but without the longitudinal criteria duration, to facilitate detection and intervention by general health professionals.
- A new category of "bodily distress disorders" will include bodily distress syndrome (formerly unexplained somatic complaints), health preoccupation, and conversion disorder.

Specific Disorders in ICD-11

Schizophrenia or Other Primary Psychotic Disorders. This grouping includes the following disorders:

6A20 Schizophrenia
6A21 Schizoaffective disorder
6A22 Schizotypal disorder
6A23 Acute and transient psychotic disorder (ATPD)
6A24 Delusional disorder
6A2Y Other specified primary psychotic disorder

Note that the name of the category was changed from "schizophrenia, schizotypal and delusional disorders" in ICD-10 to "schizophrenia or other primary psychotic disorders" in ICD-11.

Symptomatic profile and duration of illness were the main basis for categorization.

Schizophrenia, schizoaffective disorder, and ATPD were the categories that underwent the most significant changes.

SCHIZOPHRENIA. The specificity and diagnostic value of "first-rank symptoms" has been challenged and thus, it was "de-emphasized" in ICD-11. The diagnosis of schizophrenia requires the presence of two out of eight possible symptoms, one of which must be a "core symptom" (delusions, thought insertion/withdrawal, hallucinations, and thought disorder). The duration requirement is the same as it was in ICD-10 (i.e., 4 weeks). If a patient presents with the required symptomatic profile but does not fulfill the duration criteria, the disorder would be classified as "unspecified primary psychotic disorder."

Telegram: @medical_k

www.konkur.in

As in DSM-5, traditional clinical subtypes (paranoid, catatonic, and others) were dropped because of their lack of longitudinal stability and prognostic value. Also, research shows that these subtypes are seldom used in clinical practice.

In general, the ICD-11 category of schizophrenia looks quite similar and compatible with the DSM-5 category except for the issue of "functional impairment." The ICD's general position of not including functional impairment as part of the definition of a disease or a disorder will be continued in ICD-11. Consequently, it will not be part of the diagnostic guidelines for schizophrenia, although for ICD, generally, "functional impairment" is still an important clinical "qualifier." In DSM-5, "functional impairment" is a key criterion of clinical significance and is thus necessary to diagnose the disorder.

"Qualifiers" in ICD-11 are equivalent to "specifiers" in DSM-5. They constitute an important resource in the process of defining and characterizing the clinical conditions of patients with schizophrenia and schizoaffective disorder. This seems particularly useful for treatment formulation, planning, and implementation. There are "qualifiers" for symptoms, course of illness, cognitive function, and functional impairment.

- Symptom qualifiers: These include the presence of positive, negative, depressive, manic, or psychomotor symptoms.
- Course qualifiers: First/only episode versus multiple episodes, acute versus chronic, full remission versus partial remission, acute versus insidious onset.
- Cognitive qualifiers: These qualifiers help to focus attention on cognitive impairment for therapeutic and rehabilitation purposes.
- Functional impairment qualifier: This is consistent with the WHO's International Classification of Functioning, Disability, and Health (ICF).

SCHIZOAFFECTIVE DISORDER. Schizoaffective disorder continues to pose difficulties in the new nomenclatures because it is not clear how diagnostic characterizations can improve the validity and reliability of this problematic construct for clinical and/or research purposes. In ICD-11, this diagnosis is only made when a patient fulfills criteria for both schizophrenia and a mood disorder of at least moderate/severe degree of severity. The total duration of both components should be of 4 weeks. Apparently, the issue about the need and/or utility of longitudinal criteria for diagnosis has not yet been resolved.

Telegram: @medical_k

www.konkur.in

SCHIZOTYPAL DISORDER. Schizotypal disorder is established as a functioning pattern for at least 2 years. Patients are characterized by eccentricities in behavior, appearance, speech, cognitive and perceptual distortions, and reduced ability to establish interpersonal relationships. In ICD-11, this diagnosis is made when the unusual behavior does not meet requirements or does not have sufficient intensity or duration to be diagnosed as schizophrenia.

ACUTE AND TRANSIENT PSYCHOTIC DISORDER. The European perspective on ATPD is different from that of DSM-5, and the former perspective has always been the main influence for the ICD classification of these disorders. In DSM-5, these disorders tend to be viewed more pragmatically as being clinically similar to schizophrenia except for duration. The European tradition views these disorders as a heterogeneous group of psychoses that are different from schizophrenia, both in terms of clinical presentation and pathophysiology. The main clinical features include sudden onset, brief duration, and, most importantly, a polymorphic clinical presentation. Focusing on simplicity and ease of use, it is likely that the “acute polymorphic psychotic disorder without symptoms of schizophrenia” (F23.0) in ICD-10 will be the clinical template for ATPD in ICD-11. Duration up to 3 months will be allowed, as 2 to 4 months is the modal duration for ATPD and other psychoses of sudden onset. When an “acute polymorphic disorder with features of schizophrenia” lasts less than 4 weeks, the diagnosis will be of “unspecified primary psychotic disorder.” If the duration is more than 4 weeks, then a diagnosis of schizophrenia must be made. “Schizophreniform disorder” will not be introduced as a category in ICD-11.

Mood Disorders. Mood Episode Descriptions:

Depressive episode
Manic episode
Mixed episode
Hypomanic episode
Mood disorder descriptions

Bipolar and Related Disorders:

Telegram: @medical_k

www.konkur.in

6A60 Bipolar type I disorder
6A61 Bipolar type II disorder
6A62 Cyclothymic disorder
6A6Y Other specified bipolar or related disorders

Depressive Disorders:

6A70 Single episode depressive disorder
6A71 Recurrent depressive disorder
6A72 Dysthymic disorder
6A73 Mixed depressive and anxiety disorder
GA34.41 6AZY 6A8Y
Premenstrual dysphoric disorder
Other specified depressive disorders
Other specified mood disorders

In the last few decades, the field of mood disorders has been the scenario of profound changes in conceptualization, and there were many discussions related to their classification and diagnosis in ICD-11. How to improve the detection of bipolar disorders, specifically, how to diminish delayed diagnosis, underdiagnosis, and overdiagnosis, was at the center of active work in this area. Also, there have been attempts to approach the difficult question of how to detect bipolar disorder in front of a first “unipolar” depressive episode. Hypomania has also been at the center of discussions due to the inherent problems of deciding on its presence or absence and the difficulties for retrospective detection. The bipolar distinction between types I and II (and other possible subtypes) was part of many debates. Finally, there was the major issue of what to do (nosologically speaking) with those clinical presentations that include both manic and depressive features (formerly called mixed states in DSM) and which were dropped from DSM-5 and conceptualized as “specifiers.” However, the presence of a symptomatic mix in the case of unipolar depression created a problem, as it permitted the “intrusion” of a bipolar presentation as part of a unipolar mood disorder. Passionate debates on this topic have been fueled by the concern that the use of antidepressants in patients with bipolar disorder worsens the clinical course of these patients. There were several articles and editorials in the literature devoted to what “ICD-11 should do” with various mood disorders.

Telegram: @medical_k

www.konkur.in

Some of the key ideas from these debates included the following:

- Although the intention is to achieve a higher rapprochement between ICD-11 and DSM-5, there are several important points in which divergence can be expected.
- The general structure of the category appearing in the ICD-11 offers a single diagnostic category, “mood disorders,” subdivided into bipolar disorders and depressive disorders.
- The adoption of dimensional measurements and/or modeling of mood disorders seems to be out of consideration for the future.
- Insofar as the decisions made for ICD-11, some of the consultants involved in the review process appeared to question the scientific validity of the concept of “spectrum” and rejected its inclusion in the classification.
- There were proposals directed toward changes in syndromes such as melancholia, psychotic and catatonic depression, cyclothymia, dysthymia, rapid cycling, etc. However, at present, these proposals were not incorporated into the written document.
- The controversial category “mixed depression and anxiety disorder” is retained because of its clinical utility, which has been reinforced through clinicians’ surveys and field trials.
- Key concepts that were carefully considered by ICD-11 workgroups include bereavement and the diagnosis of major depression, the nosologic status of mixed states, and the presence of hypomanic symptoms in major depression.

THE ISSUE OF BEREAVEMENT AS EXCLUSION CRITERIA. An important debate followed the removal of bereavement as an exclusion criterion for diagnosing a major depressive episode in DSM-5. The position of the ICD-11 developers is that bereavement should continue to be an exclusion criterion for the diagnosis of depression. For example, a key leader of WPA has stated that this change in DSM-5 “is likely to be perceived by the general public as a further step in psychiatry’s attempt to pathologize normal human processes.” In several articles on the subject, some of the authors involved in the ICD-10 revision process declared that “this could be one of the points of disagreement that make it difficult to harmonize the two classifications” and have argued that there is no scientific evidence at present to justify the removal of grief. Indeed, this

Telegram: @medical_k

www.konkur.in

opinion is also shared by a number of U.S. experts such as Alan A. Horwitz and Jerome C. Wakefield in their book “The Loss of Sadness.”

COURSE SPECIFIERS AND MIXED STATES. One of the most-commented novelties in the mood disorders category in DSM-5 refers to the disappearance of the category of “mixed episode” in bipolar disorders and its new conception as a “specifier.” The ICD workgroup members questioned the diagnostic usefulness of this change and have recommended keeping the criteria for a mixed episode unchanged in ICD-11. There was also little support for the inclusion of “depression with hypomanic symptoms” in ICD-11.

Anxiety or Fear-Related Disorders

6B00 Generalized anxiety disorder
6B01 Panic disorder
6B02 Agoraphobia
6B03 Specific phobia
6B04 Social anxiety disorder
6B05 Separation anxiety disorder
6B06 Selective mutism
6B0Y Other specified anxiety or fear-related disorders

GENERALIZED ANXIETY DISORDER. GAD is one of the diagnostic categories with significant reliability/validity problems, and it is considered a residual category because it is very frequently found along with other disorders. In spite of this, GAD retains clinical relevance and is thought to have a significant impact on health and quality of life. Recommendations for the new GAD diagnosis in ICD-11 included the following:

- A need to find better ways to emphasize “worry about everyday matters” as a core feature of GAD. “Apprehensive expectation,” a concept related to worry, but having several unique features, was also recommended as a core feature for the disorder.
- It was also thought that the presence of “excessive worry” (a construct difficult to operationalize and not always recognized by patients) and its frequency or duration should help define the boundaries between “excessive” and “normal” worrying.

Telegram: @medical_k

www.konkur.in

Restlessness, tension, and gastrointestinal symptoms were emphasized as the most frequent and most important somatic complaints in patients with GAD.

- The status of GAD as a “residual category” is being addressed by allowing the diagnosis to be made in the presence of other disorders in which worrying is not the central feature.

PANIC DISORDER AND AGORAPHOBIA. The main changes in ICD-11 included the separation of panic disorder from agoraphobia, as DSM-5 had also done. While this may increase the level of comorbidity, the separation of these two disorders is consistent with the results of research and field studies. An important issue about anxiety disorders is the importance of contextual and culturally mediated influences on clinical presentations such as the contents of worry, the importance attached to worrying in certain cultures, the places, and situations where agoraphobia can occur, the fear of offending others versus being criticized by others and other issues.

SPECIFIC PHOBIAS AND SOCIAL PHOBIA. The subtyping of specific and social phobias in DSM is an important difference with ICD. ICD workgroup members argue that naming specific phobias has no clear clinical utility.

Obsessive-Compulsive or Related Disorders

6B20 Obsessive-compulsive disorder (OCD)
6B21 Body dysmorphic disorder
6B22 Olfactory reference disorder
6B23 Hypochondriasis (health anxiety disorder)
6B24 Hoarding disorder
6B25 Body-focused repetitive behavior disorders
6B25.0 Trichotillomania (hair pulling disorder)
6B25.1 Excoriation (skin picking) disorder

6B2Y Other specified obsessive-compulsive or related disorders

While ICD-11 was being developed, the main issue with respect to OCD was whether or not ICD-11 would follow DSM-5 in creating a separate category for OCD and related disorders. In the end, this was the outcome, with the creation of a separate category grouping obsessive-compulsive

Telegram: @medical_k

www.konkur.in

and related disorders. The distinction between “urge” and “impulse” was also debated, in particular its cross-cultural aspects. ICD-11 has a qualifier for insight, separating it into “fair to good” or “poor to absent,” although the clinical utility in identifying a broad spectrum of insight was questioned, as clinicians may be unable to reliably distinguish “poor” insight from “good/fair” or “delusional” insight. ICD-11 did not include a tic specifier as done by DSM-5.

Disorders Specifically Associated with Stress

6B40 Post-traumatic stress disorder (PTSD)
6B41 Complex post-traumatic stress disorder
6B42 Prolonged grief disorder
6B43 Adjustment disorder
6B44 Reactive attachment disorder
6B45 Disinhibited social engagement disorder
6B4Y Other specified disorders specifically associated with stress

QE84 Acute stress reaction

Post-Traumatic Stress Disorder. Changes in the description and classification of PTSD in ICD-11 include the following:

- The creation of a separate diagnostic category for stress-related disorders.
- The discussions about the quality of the traumatic/distressing event related to PTSD and other clinical problems in this new category.
- Increased attention to the distinction between PTSD and normal “adaptive fear reactions” to ongoing trauma (e.g., continuing conflict, forced migration, and natural disasters).
- Inclusion of “complex PTSD.”
- Identifying acute stress reaction as a normal reaction to an abnormal event.
- Emphasizing the advantages of ICD-11 over DSM-5 due to its simplicity, clinical utility, and feasibility in “low-resource and humanitarian settings.”

Intellectual Disability/Mental Retardation. The working group on mental retardation (MR) published several papers on the rationale and

Telegram: @medical_k

www.konkur.in

process for replacing the ICD-10 conceptualization of MR with the concept of intellectual developmental disorders (IDD) in ICD-11.

For the last two decades, there have been very important discussions on how to properly name, define, and assess IDD. In general, the term “intellectual disability” (ID) has widely replaced MR for policy, administrative, and legislative purposes in many industrialized countries and in an increasing number of low- and middle-income countries. However, the question as to whether IDD represents a disability or a health condition remains unanswered. There was a consensus in the working group about the need to reorganize IDD as part of the larger grouping of neurodevelopmental disorders. The term “intellectual” was favored because, in most countries, it is widely used and is broadly acceptable in many contexts. The term “developmental” refers to the period during which the brain and its functions are developing and thus can be impaired. The term “developmental” also implies a process and a lifespan perspective and emphasizes the dynamic nature of IDD. The proposed definition of IDD is “a group of developmental conditions characterized by significant impairment of cognitive functions, which are associated with limitations of learning, adaptive behavior, and skills.” The main descriptors of IDD include the following:

- Marked impairment of core cognitive functions that can have different patterns. This impairment affects the development of knowledge, reasoning, and symbolic representation, according to the level expected for age peers and the cultural and community environment.
- Problems with verbal comprehension, perceptual reasoning, working memory, and processing speed.
- The cognitive impairment is associated with difficulties in learning, academic, and practical knowledge.
- Problems with adaptive behavior with limitations in relevant conceptual, social, and practical skills.
- Difficulties in managing behavior, emotions, interpersonal relationships, and motivation.
- IDD is a life span condition requiring consideration of developmental stages and life transitions.

It is important to signal that this approach distinguishes between IDD (a clinical meta-syndrome) and ID (the functioning/disability counterpart), conditions that have different scientific, social, and policy applications.

Telegram: @medical_k

www.konkur.in

Alcohol-Related Disorders. ICD-11 includes the following alcohol-related disorders: acute alcohol intoxication, harmful use, dependence syndrome, withdrawal, mental disorders, and alcohol-induced disorders arising from the use of alcohol. The new coding for alcohol intoxication defines it as a transient state following alcohol consumption resulting in disturbances in the level of consciousness, cognition, perception, affect, behavior, or other psychophysiologic functions and responses. Typical symptoms include mood instability, false judgment, impaired social or professional functioning, and improper sexual or aggressive behavior. Harmful use of alcohol is defined as a pattern of alcohol use that is causing damage to health following repetitive episodes of intoxication, regular intake of large quantities of alcohol, or harmful use of alcohol. The damage may be physical or mental, including violence and self-harmful acts of bodily damage requiring medical intervention. Alcohol dependence core features would include the following:

- Difficulties in controlling substance-taking behavior are often in combination with a strong desire or sense of compulsion to take alcohol.
- Alcohol use plays a dominant role in the individual's life.
- Physiologic symptoms: tolerance and characteristic physical withdrawal state or syndrome (not just hangover).

Personality Disorders and Related Traits

6D10 Personality disorder (general diagnostic requirements)
6D10.0 Mild personality disorder
6D10.1 Moderate personality disorder
6D10.2 Severe personality disorder

QE50.7 Personality difficulty
Trait Domain Qualifiers:

6D11.0 Negative affectivity

6D31.1 Detachment

The conceptualization and classification of personality disorders in psychiatry and by psychiatrists is one of the areas of persistent debate among mental health clinicians and researchers. In general, there is a

Telegram: @medical_k

www.konkur.in

profound dissatisfaction with the psychiatric approach to this problem. Tyrer (2015) summarizes what ICD-11 did in this regard:

- Abolish type-specific categories of personality disorder, apart from the presence of personality disorder itself.
- Define different degrees of severity as a helpful tool to decide on the individual's personality functioning at the time of the assessment.
- Five domains are used as qualifiers: (1) negative affective features (tendency to manifest a broad range of distressing emotions); (2) dissocial features (disregard for social obligations, conventions, and the rights and feelings of others); (3) features of disinhibition (persistent tendency to act impulsively); (4) anankastic features (narrow focus on the control of one's own and others' behavior to ensure that it conforms to the "individual particularistic ideal"); and (5) features of detachment (emotional and interpersonal distance).

Table 9.2–8 shows the category names and essential features of personality disorders in ICD-11.

Feeding and Eating Disorders

6B80 Anorexia nervosa
6B81 Bulimia nervosa
6B82 Binge eating disorder
6B83 Avoidant-restrictive food intake disorder
6B84 Pica
6B85 Rumination–regurgitation disorder

6B8Y Other specified feeding or eating disorders

This is another area of controversy and dissatisfaction for clinicians and researchers. In efforts to improve the state of affairs, a number of proposals have been made as summarized below:

- Feeding and eating disorders were merged into a single grouping.
- In the case of anorexia nervosa, dropping some requirements (e.g., amenorrhea) and broadening the category by expanding other criteria (including developmentally and culturally relevant presentations). A severity qualifier "with dangerously low body weight" was included to distinguish the most severe cases of anorexia nervosa.
- Bulimia nervosa was expanded to include subjective binge eating.

Telegram: @medical_k

www.konkur.in

- Binge-eating disorder was included as a specific category. Its definition includes subjective/objective binge eating without regular compensatory behaviors.

Impulse Control Disorders

6C70 Pyromania
6C71 Kleptomania
6C72 Compulsive sexual behavior disorder
6C73 Intermittent explosive disorder
6C7Y Other specified impulse control disorders

Disorders due to Addictive Behaviors

6C50 Gambling disorder
6C51 Gaming disorder
6C5Y Other specified disorders due to addictive behaviors

GAMING DISORDER. Gaming disorder establishes a new behavior pattern leading to the persistence of online or offline gaming. In ICD-11, this diagnosis is made when a patient has impaired control over gaming behavior, and this takes priority over other interests in life and daily activities. This behavior must be manifested for a prolonged period of at least 12 months.

ICD-11 AND DSM-5: SOME CONTROVERSIES

Psychiatric classification is undoubtedly one of the most polemic issues surrounding psychiatry as a medical specialty. The controversies about classification across the two systems can be summarized as follows:

- Epistemologic, for example, what kind of knowledge is gained from classifications, and what are their knowledge limits?
- Metaphysical and ontologic, for example, what is a mental disorder? Are mental disorders natural kinds or constructs?
- Ethical, for example, what are the consequences of using a classification system in terms of the good that can be achieved for patients, society, and psychiatry?

Telegram: @medical_k

www.konkur.in

- Practical (usefulness). The usual debate is if classification systems serve the purposes for which they were created, that is, improving communication among clinicians, helping clinical practice, research, and administrative/legal issues.
- Methodologic. What is the best way to classify mental disorders, and how this way can be carried out?
- Sociologic, for example, what are the politics behind classification of mental disorders? How do clinical and political uses of classifications relate to each other? What relationships exist between the classification of mental disorders and vested interests like those of pharmaceutical companies? What is the sociology of the groups developing classifications?
- Legal, for example, how do classifications influence the legal system? How do the needs of legal systems influence psychiatric classification?
- Social, for example, do classification systems promote (or defuse) stigma?
- Personal, for example, do classifications create self-stigma in the patients receiving aid from legal or governmental systems based on a psychiatric diagnosis?

Table 9.2–8.
Category Names and Essential Features of the Proposal for Personality Disorders in ICD-11

Telegram: @medical_k

www.konkur.in

Panel 2: Proposed category names and essential features of personality disorders in International Classification of Diseases (ICD)-11

Personality disorder

- A pervasive disturbance in how an individual experiences and thinks about the self, others, and the world, manifested in maladaptive patterns of cognition, emotional experience, emotional expression, and behaviour.
- The maladaptive patterns are relatively inflexible and are associated with significant problems in psychosocial functioning that are particularly evident in interpersonal relationships.
- The disturbance is manifest across a range of personal and social situations (ie, is not limited to specific relationships or situations).
- The disturbance is relatively stable over time and is of long duration. Most commonly, personality disorder has its first manifestations in childhood and is clearly evident in adolescence.

Late onset qualifier

- If the disturbance has its origin in adulthood, the qualifier for “late onset” may be added. The “late onset” qualifier should be used for cases in which, by history, there is no evidence of personality disorder or its early manifestations prior to age 25 years.

Mild personality disorder

- There are notable problems in many interpersonal relationships and the performance of expected occupational and social roles, but some relationships are maintained and/or some roles carried out.
- Examples: Able to maintain, and has some interest in maintaining, a few friends. Intermittent or frequent, minor conflicts with peers, co-workers and/or supervisors or, alternatively, exhibits withdrawn, isolative behaviour but, in either case, is capable of sustaining and willing to sustain employment, given appropriate employment opportunities. Has meaningful relationships with some family members but typically avoids or has conflict with others. Mild personality disorder is typically not associated with substantial harm to self or others.

Moderate personality disorder

Telegram: @medical_k

www.konkur.in

- There are marked problems in most interpersonal relationships and in the performance of expected occupational and social roles across a wide range of situations that are sufficiently extensive that most are compromised to some degree.
- Examples: Able to maintain very few friends or has little interest in maintaining friendships. Regular conflict with peers, coworkers and/or supervisors or marked withdrawal and isolative behaviour that interferes with the ability to function constructively at work or with others. May exhibit little interest in and/or efforts toward sustained employment when appropriate employment opportunities are available. May have a history of frequently changing employment as a result. Has conflicted, or a marked absence of, relationships with many family members. Moderate personality disorder often is associated with a past history and future expectation of harm to self or others, but not to a degree that causes long-term damage or has endangered life.
- Examples: Recurrent suicidal ideation or suicide attempts without clear expectation of death, recurrent episodes of self-harm without clear lethality, recurrent hostile and confrontational behaviour, or occasional violent episodes that involve only minor destruction of property (eg, breaking things) or interpersonal aggression such as pushing, shoving, or slapping that is not sufficient to cause lasting injury to others.

Severe personality disorder

- There are severe problems in interpersonal functioning affecting all areas of life. The individual's general social dysfunction is profound and the ability and/or willingness to perform expected occupational and social roles is absent or severely compromised.
- Examples: Has no friends but may have some associates. Unwilling or unable to sustain regular work due to lack of interest or effort, interpersonal difficulties, or inappropriate behaviour (eg, irresponsibility, fits of temper, insubordination), even when appropriate employment opportunities are available. Conflict with or withdrawal from peers and coworkers. Family relationships are absent (despite having living relatives) or marred by significant conflict. Severe personality disorder usually is associated with a past history and future expectation of severe harm to self or others that has caused long-term damage or has endangered life.

Telegram: @medical_k

www.konkur.in

- Examples: Suicide attempts with a clear expectation of death, episodes of self-harm that permanently injure, disfigure or deform the individual, episodes of serious property destruction such as burning down someone's house in anger, or episodes of violence sufficient to cause lasting injury to others.

Reprinted from Tyrer P, Reed GM, Crawford MJ. Classification, assessment, prevalence, and effect of personality disorder. *The Lancet.* 2015;385(9969):717–726. Copyright © 2015 World Health Organization, with permission of Elsevier. doi: 10.1016/S0140-6736(14)61995-4.

The existence of two main classification systems that have important similarities but equally important differences adds up to these complex controversies. The launching of the DSM-5 has revitalized several discussions both at theoretical and practical levels, one of the most important being the issue of how much ICD and DSM should resemble each other in terms of a theory of mental disorders, aims, scope, methodology, and content, among others. This section will focus on the debates about the issue of harmonization because some think that both classifications must resemble each other as much as possible, but at the same time, both are needed, while others, on the contrary, maintain that there must be a certain distance and/or independency between both, and finally, there are authors who think that at the end one of them should replace the other.

Harmonization

The issue of how much DSM and ICD should resemble each other has recently been discussed under the label of "harmonization." Despite the aesthetic and rhetorical appeal that this term conveys, the concept needs to be carefully defined and articulated. The Oxford Advanced Learner's Dictionary defines "harmonize" as follows:

- "To harmonize with something" = "if two or more things harmonize with each other or one thing harmonizes with the other, the things go well together and produce an attractive result."
- "Harmonize" = "something to make systems or rules similar in different countries or organizations."

Therefore, at least from the perspective of the current English language, harmonization of the two systems is not simply to combine them but to

Telegram: @medical_k

www.konkur.in

make them similar and/or equivalent. Because of the international and multicultural character of ICD, the meaning of harmonization was also checked in leading Spanish, French, Italian, and German dictionaries. This reveals semantic differences that should be kept in mind for the harmonization enterprise. In Spanish, for example, emphasis is made on the fact that the parts or objects to be harmonized should not reject each other. In French, the definition emphasizes agreement between elements and the importance of the goal to be achieved. Thus, in all of these languages, harmonization does not simply mean unification but some sort of “shared understanding” and complementarity. However, harmonization is also a technical term used for the main goal of reaching a high degree of similarity between international systems of rules, laws, definitions, or specific criteria.

The Direction of ICD-DSM Harmonization

One of the most sensitive issues about this harmonization project is whether ICD should resemble DSM or DSM resemble ICD. Probably, in some instances, the harmonization should go in one direction (e.g., DSM to ICD), while in others, the opposite would be the case (e.g., from DSM to ICD). The necessary comparison between both systems and the decision that one would prevail over the other adds sensitivity to the process. For example, if it is decided that anxiety disorders are better approached by ICD than DSM, DSM should make an effort to resemble ICD in regard to this group of disorders. Conversely, if the criteria for mood disorders in DSM are deemed better, thus, ICD should adopt them. No matter how logical this sounds, problems and debates will arise among proponents or detractors of either system.

Based on the above considerations, criteria for deciding the direction of harmonization should take into account:

- Methodologic issues: Which of the two systems can ensure that its rationale and criteria are fewer subjects to undesirable and avoidable biases?
- Empirical support: Which of the two systems has been tested by means of well-designed studies (including field trials) whose results support the usefulness, validity, or reliability of the diagnostic categories?
- Ease of use: Which system is easier for clinical use and well liked by busy clinicians?

Telegram: @medical_k

www.konkur.in

- Participation of different stakeholders: Which system has duly incorporated the opinions and/or feedback of patients, families, clinicians, and health providers?
- Transnational sensitivity and precision: Which classification is better suited for use across different countries, cultures, and languages?
- Cross-cultural sensitivity and precision: Which classification can be better adapted to different cultural environments?
- Development and advance potential: Which classification has a structure that allows rapid incorporation of changes or scientific advances, especially now that both aspire to be “living documents”?

Clearly, these matters cannot be resolved using only empirical data, and in the end, harmonization becomes a political issue. Here, negotiation and the ability to reach agreements are at the core of the harmonization projects. Thus, both empirical and nonempirical issues have to be addressed in the process of harmonization.

“Harmonization” in the Psychiatric Literature

To gain some insight on this issue, the authors reviewed papers addressing directly (in their title, abstract, and/or keywords) the issue of “harmonization” of the two diagnostic systems. Most of the articles merely state the general importance of “harmonization” but do not provide additional details or recommendations. The emphasis on harmonizing clearly stems from the perceived differences across the two systems that may interfere with communication among clinicians and international research efforts. Clinicians, researchers, and developers of both classifications have all called for harmonization. For most of these parties, harmonization entails diminishing and, if possible, eliminating significant differences between ICD and DSM. Also, there is a general consensus on the importance of harmonization, even in the case of authors who are critical about DSM and/or ICD.

The WHO addressed this issue directly by creating a “DSM-ICD Harmonization Coordinating Group” that also included members of the DSM-5 Task Force and the International Advisory Group revising ICD-11. The charge for this group was “to facilitate the achievement of the highest possible extent of uniformity and harmonization between ICD-11 mental and behavioral disorders and DSM-5 psychiatric disorders and their diagnostic criteria.” Also, it was recommended that “The WHO and APA

Telegram: @medical_k

www.konkur.in

should make all attempts to ensure that in their core versions, the category names, glossary descriptions, and criteria are identical (author's emphasis) for ICD and DSM."

The major tasks of this group were as follows:

- To identify effective mechanisms to share information on the developmental processes of the two diagnostic systems.
- To find strategies to narrow the differences between the two diagnostic systems.
- To coordinate efforts toward harmonization of the two diagnostic systems by making specific recommendations to the respective decision-making bodies.

To provide a forum in which difficult issues around harmonization can be discussed and common approaches identified.

As articulated before, harmonization and unification are different goals, although they could be part of a sequence, starting with harmonization, and once empirical data is available and conceptual agreements and political consensus reached, unification could follow. Clearly, there are system differences that are more difficult to harmonize, for example, conceptual and ideologic issues, but others, for example, operational ones, can be approached in a straightforward fashion. The process should start by listing and describing the main differences between both classification systems. A second step would entail a detailed analysis of the nature of these differences, for example, which of them are operational, which of them are terminologic, and which of them are conceptual. A third step would be to tackle first terminologic and operational differences and later on focus on the conceptual ones.

Michael First, a North American psychiatrist who has been engaged in the ICD process, proposed three basic harmonization strategies:

- To select one of the two systems as the starting point for a future single and unified classification.
- To create a new common set of DSM-5 and ICD-11 criteria by selecting the best elements from each system in terms of reliability, validity, and clinical utility.
- A third strategy would be to pick the definitions and criteria for a disorder from either one of the two systems and identify it as the "harmonized" DSM-5 and ICD-11 definition for each disorder. For a particular disorder, the decision to choose either the harmonized DSM-

Telegram: @medical_k

www.konkur.in

IV or ICD-10 criteria set could be based on several mutually agreed steps, including empirical evidence of superior validity, reliability, or clinical utility.

Harmonization is an important task but remains a very difficult one, especially because of the differences in the origins, purposes, scope, concepts, and ideology underlying both classifications.

SUMMARY AND CONCLUSIONS

- The new ICD-11 section on mental disorders is finally out.
- The ICD-11 appears to remain faithful to the original principles and purposes underlying this international classification.
- It seems clear that changes included in the ICD-11 were mostly driven by clinical utility.
- Harmonization between ICD and DSM was one of the original goals articulated by the developers and potential users of each of these systems. However, significant differences across the two systems still remain.
- Due to the recency of the release of ICD-11, more time will be needed to analyze the impact that this system may have on clinical practice.

10 Neurocognitive Disorders

10.1 Cognitive Disorders: Introduction

IQBAL AHMED, M.D., F.R.C.PSYCH.

Cognitive domains include complex attention, learning, memory, language, perceptual-motor function, executive function, and social cognition as defined in DSM-5. These domains are interdependent in their effects on each other and impact personal, occupational, and social functioning. Disorders that primarily affect one or more of these domains are considered cognitive disorders in DSM-5. While these disorders are mostly associated with older adults, they are not uncommon in younger adults as well, especially those that are related to traumatic brain injury, infections, etc. These disorders may have complex presentations, often with the prominence of other psychiatric symptoms such as mood, anxiety, psychotic and behavioral symptoms, multiple etiologies of the cognitive disorders, presence of other premorbid psychiatric disorders, and medical comorbidity. This can lead to diagnostic and treatment challenges.

Delirium is particularly problematic in this regard. Delirium is often superimposed on an existing, although often unrecognized,

Telegram: @medical_k

www.konkur.in

dementia and possible multiple risk factors such as multiple neurologic and medical comorbidities and the use of deliriogenic medications. Drs Solai, Sujata, Gebara, and Fabian review the burden generated by delirium in medical settings. Delirium is ubiquitous in acute medical settings, making the older adults and, in particular, those with other cognitive disorders vulnerable. Nevertheless, early recognition and correct differential diagnosis of delirium remain a challenge due to the variable and fluctuating nature of the presenting signs and symptoms. This can be a particular challenge with hypoactive delirium, which sometimes gets misdiagnosed as depression. Screening for delirium, including the use of standardized instruments, is therefore critical, especially in patients with dementia, medically ill hospitalized older adults, and all patients in critical care settings for early diagnosis and intervention. The development of effective interventions for delirium has been slow to emerge, perhaps because of its multifactorial nature. Recent work, which indicates the effectiveness of multicomponent behavioral and supportive interventions in the prevention of delirium, provides some hope and a model for reengineering acute hospital care for at-risk patients. Research also suggests that antipsychotic drugs, which for a long time have been used extensively in the treatment of delirium, do not seem to contribute to any beneficial outcomes, except possibly for the treatment of severe agitation and aggression. Certain dementias, such as dementia with Lewy bodies or late stages of Alzheimer disease, may have chronic clinical presentations virtually indistinguishable from delirium except for temporal onset and the lack of an identifiable acute source.

Julie Graziane and Iqbal Ahmed review recent advances in the current understanding of the neurodegenerative dementias. In addition to the advances in imaging and genetics, great strides have been made in understanding Alzheimer disease, for example, identifying the mechanisms by which accumulation of amyloid beta protein can interfere with cognitive function, even prior to the emergence of the defining neuropathologic lesions, plaques, and tangles. This elaboration of the “amyloid hypothesis” of Alzheimer disease has led to efforts to develop a number of antiamyloid

Telegram: @medical_k

www.konkur.in

therapies. However, trials to treat patients with dementia due to Alzheimer disease with these agents shown limited efficacy. However the Food and Drug Admininstration (FDA) granted expedited approval to two anti-amyloid agents aducanumab and lecanemab. With an increased understanding of the mechanisms of dementia, the clinical imperative has been to develop approaches for early case identification. Currently, there are efforts to study the role of risk factors for the development of Alzheimer dementia, such as traumatic brain injury, vascular risk factors such as diabetes and hypertension, and inflammation. Research, predominantly epidemiologic, has focused on preventive measures such as physical and cognitive exercises, diets such as the Mediterranean-DASH (dietary approaches to stop hypertension) Intervention for Neurodegenerative Delay diet and the Mediterranean diet, increased social engagement, and improved mood and sleep, among others.

The boundaries between types of dementia can be diffuse. The most common neuropathologic presentations associated with dementia reveal mixtures of Alzheimer disease and vascular and Lewy body pathologies. Pure syndromes are relatively less common, although often the dementia is ascribed to one of the coexisting pathologies, most often Alzheimer disease. Strategies regarding how to understand or reconcile the potential contributions of multiple pathologies to disease onset and progression in the clinic are needed. Some of these are now emerging as the result of the approval of several agents for in vivo imaging of amyloid and tau protein deposits in relation to the evolving symptoms of Alzheimer disease. Tau pathology, while present in Alzheimer disease, also extends to define another set of neurodegenerative dementias that include different forms of frontotemporal dementia (FTD), corticobasal degeneration, and progressive supranuclear palsy. Non-tau, ubiquitin-positive inclusions in the brain are the other major pathologic forms of FTD.

Finally, advances in the genetics of FTD have been quite rapid. Twenty percent of FTD is due to a genetic mutation, and 40% of FTD cases have a family history of dementia, psychiatric disease, or motor symptoms with no clear pattern of inheritance. The three most

Telegram: @medical_k

www.konkur.in

common mutations are in microtubule-associated protein tau (MAPT), progranulin (GRN), and Chromosome 9 Open Reading Frame 72 (C9orf72). Not surprisingly, given the frequent initial presentation of progressive alterations in behavior, psychiatric syndromes are often initially suspected in individuals with FTDs, with up to 50% of individuals with the behavioral variant of FTD first being diagnosed with a primary psychiatric disorder. The Neuropsychiatric International Consortium for Frontotemporal Dementia (NIC-FTD) developed guidelines to assist with distinguishing FTD from primary psychiatric disorders.

Limbic predominant age-related transactive response DNA-binding protein 43 (TDP-43) encephalopathy, referred to as LATE, is a TDP-43 proteinopathy with or without hippocampal sclerosis pathology is a newly described dementia that typically occurs in patients over the age of 80 as a progressive amnestic syndrome, similar to dementia of the Alzheimer type but with a more gradual decline in cognition.

The course of nearly all subjects developing progressive dementia is complicated by the onset of one or more distinct behavioral syndromes, including anxiety, depression, sleep problems, psychosis, and aggression. These symptoms can be as distressing and disabling as the primary cognitive disorder and are a prominent reason for institutional care. Unfortunately, given the prevalence of these behavioral changes, efforts at the development of new treatments targeting behavioral disruption in dementia have been very limited but are now emerging as a new focus for investigation. So far, pharmacologic interventions have shown to have limited effectiveness and carry significant risk of morbidity and mortality. However, behavioral treatments such as the describe, investigate, create, and evaluate (DICE) method have shown promise. By incorporating the emergence of psychotic symptoms in older adults, even in advance of the development of dementia, into an epidemiologic and neurobiologic framework, new approaches for the diagnosis and treatment of psychosis and agitation are being developed.

Daniel Varon and Carmen Andreescu review the increasing knowledge about mild cognitive impairment, a clinical presentation

Telegram: @medical_k

www.konkur.in

that often indicates the presence of a neurodegenerative disorder. When MCI presents as an isolated amnestic symptom in late life, it appears to predict the subsequent onset of Alzheimer disease. The main differentiation between MCI and a major neurocognitive disorder due to Alzheimer disease resides in the lack of functional impairment in MCI. Although other conditions, including other neurodegenerative syndromes, focal brain lesions, metabolic disturbances, and alcohol use, may lead to isolated amnestic disorders, in practice, MCI due to underlying Alzheimer disease is more common. Recognition that neurodegeneration may precede clinical symptoms by 10 years or more has further led to the proposal of stages for preclinical Alzheimer disease, characterized by the presence of biomarkers of amyloid and tau accumulation and neurodegeneration in the absence of overt cognitive and behavioral symptoms.

The recognition of a long, preclinical stage of neurodegeneration also indicates that in some older adults who have neurodegenerative pathology and cognitive impairments, the cognitive symptoms might actually result from a comorbid condition independent of or additive with the degenerative lesions. One of the possible treatable conditions leading to an amnestic syndrome is thiamine deficiency presenting as delirium and other symptoms (Wernicke syndrome), secondary to nutritional deficiency in alcohol use disorders, malignancies, malnutrition, and hyperemesis. Treatment with high-dose intravenous thiamine may prevent the development of an irreversible amnestic disorder (Korsakoff syndrome).

Robert Boland and Iqbal Ahmed in the chapter on Cognitive Disorders due to Another Medical Condition or Substance discuss additional medical and substance-induced causes of dementia and amnestic disorders that form the differential diagnoses for many of the conditions reviewed in the earlier chapters. These include neurologic disorders such as traumatic brain injury, strokes, demyelinating disorders and tumors, infectious disorders such as HIV and syphilis, endocrine disorders such as thyroid disorders, nutritional disorders such as thiamine and vitamin B12 deficiencies, and autoimmune disorders such as anti-N-methyl-D-aspartate

Telegram: @medical_k

www.konkur.in

(NMDA) encephalitis among others. Substances implicated in the development of cognitive symptoms include prescribed drugs, such as drugs with anticholinergic properties, anxiolytics, sedative-hypnotic agents, and opiates, as well as abused drugs, such as inhalants and stimulants. Optimum care for disorders described in this section requires close collaboration with other medical, neurologic, and rehabilitation specialists.

10.2 Delirium

Telegram: @medical_k

www.konkur.in

Mandayam Sujata, M.D., Marie Anne Gebara, M.D., Tanya Fabian, Pharm.D., Ph.D., and Lalithkumar Solai, M.D.

Delirium is a not-so-uncommon clinical syndrome seen in older adults, particularly with increasing age. Delirium, as defined by the Diagnostic and Statistical Manual of Mental Disorders (DSM)-5-Text revision (TR), is characterized by an acute decline in both the level of awareness and cognition with impairment in attention. The challenge with delirium is that it can mimic other clinical syndromes by presenting as perceptual disturbance, abnormal psychomotor activity, mania and sleep cycle impairment. Due to this and its poor recognition, delirium can significantly complicate patient outcomes.

It is reported that less than 2% of community-dwelling older adults suffer from delirium. But it increases significantly on admission to hospitals ranging in rates between 14% and 24%, which further increases during hospitalization to anywhere between 6% and 56% depending on the medical issue leading to the hospitalization. Unfortunately, despite being such a common occurrence in hospitals, delirium is often underrecognized/unrecognized by medical professionals. It has been estimated that 40% to 60% of the patients (depending on the treatment setting) are misdiagnosed. In most cases, the development of delirium is multifactorial, including stress or trauma to the central nervous system (CNS), drug toxicity or withdrawal, and metabolic disorders arising from organ failure. Despite the numerous etiologies that have been noted, the underlying pathophysiology of delirium is still not clearly understood.

DEFINITION

The term delirium originates from the Latin verb *deliro*—to be crazy, which is taken from de + lira, a furrow (i.e., to go out of the furrow or veer off the track). The core symptoms of delirium include a *disturbance of attention and awareness* (changed from the word consciousness in DSM-IV-TR) that develops rapidly, usually hours to days and tends to fluctuate during the day. It is a common clinical

Telegram: @medical_k

www.konkur.in

syndrome that typically heralds an increase in morbidity and mortality. Based on a good review of symptoms, there is usually a common cause (but not always) that could explain the change observed in the cognition. When a specific general medical condition has been identified as the cause of the delirium, it is diagnosed as delirium due to a general medical condition, such as delirium due to pneumonia. At times the symptoms of delirium could be secondary to drug intoxication (e.g., cocaine or alcohol) or due to drug withdrawal (e.g., alcohol or benzodiazepine). But most delirious episodes happen in the context of multiple factors, such as dehydration, pneumonia, and pain in a patient who is abusing alcohol. These deliriums are defined as delirium secondary to multiple etiologies. International Classification of Diseases (ICD-10) classifies delirium as either due to (1) alcohol or other psychoactive substances or (2) not induced by alcohol or other psychoactive substances. For consistency reasons, this chapter will not focus on delirium induced by alcohol or other psychoactive substances as it will be covered elsewhere. ICD-10 describes delirium (like DSM-5) as an etiologically nonspecific organic cerebral syndrome with features *impairing consciousness and attention, perception, thinking, and memory*. But it also includes other signs and symptoms as part of the diagnostic criteria for delirium. These include (but are not limited to) the following: psychomotor disturbance, disturbance of the sleep–wake cycle, and emotional disturbance (such as irritability).

Typically, due to the misdiagnosis, patients with delirium tend to remain in the hospital longer and are more commonly discharged to long-term care facilities. Behavioral manifestations of delirium may interfere with treatment compliance and are often precipitants for psychiatric consultation. A consultant psychiatrist should provide and/or advocate for the appropriate treatment beyond simple medical expedience, including prevention of future episodes.

HISTORY

The earliest known references to delirium in medical literature are found in the writings of Hippocrates.

Telegram: @medical_k

www.konkur.in

Some 2,400 years ago, in his Book of Epidemics, Hippocrates described the following case:

Erasinus, who lived near the Canal of Bootes, was seized with fever after supper; passed the night in an agitated state. During the first day, he was quiet, but in pain at night. On the second day, symptoms all exacerbated; at night (mad). On the third day, he was in a painful condition; great incoherence. On the fourth day, he was in a most uncomfortable state; had no sound sleep at night but dreaming and talking; then all the appearances worse, of a formidable and alarming character; fear, impatience. On the morning of the fifth day, he was composed, and quite coherent, but long before noon was furiously mad, so that he could not constrain himself; extremities cold, and somewhat livid; urine without sediment; died about sunset.

Even before the term “delirium” was coined, Hippocrates observed many of the syndrome’s essential features. Tradition holds that the word delirium was first used in the formal medical context by Celsus in the first century AD. However, Celsus used the term delirium to describe a spectrum of mental disorders ranging from general insanity to acute transient states of mental disturbance, including phrenitis, lethargus, hysteria, melancholia, and mania.

Aretaeus of Cappadocia, a contemporary of Celsus, was perhaps the first to classify mental disorders into acute and chronic categories. Aretaeus identified both phrenitis and lethargus as acute manifestations of the disease. The ancient Greek terms phrenitis and lethargus have given rise to the modern English words frenzy and lethargy, respectively. This observation is significant as it introduces the concept that delirium is both an acute syndrome and that it consists of different variants or subtypes. This distinction by Aretaeus may represent the first recorded description of both the hyper- and hypoactive motor elements of delirium.

Several centuries later, Philip Barrough advanced and further clarified the concept of delirium in his 1583 textbook *The Method of*

Telegram: @medical_k

www.konkur.in

Physick. Barrough proposed that delirium constituted a derangement of some combination of three main internal senses: imagination, cognition, and memory. This concept of deranged senses was elaborated by Thomas Willis in his 1672 treatise De Anima Brutorum, which established that delirium was, in fact, a syndrome with a specific set of symptoms and not a disease.

In the 18th century, Erasmus Darwin and John Hunter made significant contributions to the evolving theory of delirium. Darwin was the first to compare delirium with the dream state, noting that both states constituted an interruption of “voluntary power” and a suspension of the ability to attend to one’s external environment. Darwin’s notion of the interrelation of delirium and dreams was expanded even further by John Hunter, who defined delirium as “a cessation of consciousness” of one’s own existence.

Later in the same century, James Sims was the first to argue that delirium was distinctly different from general insanity and that it constituted an “alienation of the mind.” Sims also distinguished two variants of delirium, which he referred to as low or raving, that correspond almost perfectly with the modern concepts of hypo- and hyperactive motor subtypes of delirium.

The 19th century saw critical advances in the development of the concept of delirium. A medical dictionary published by Rees in 1818 argued strongly for clarification and unification of the concept of delirium within the medical community. He even went so far as to scold other medical writers who persisted in using the term delirium in an ambiguous sense. Rees built on the work of his predecessor Sims, insisting that delirium be recognized as a distinct condition with two specific variants and a unique etiology that was localized to the brain.

This is the sense in which delirium is commonly understood: but by some writers, delirium is the term employed to denote the whole class of mental derangements, including the different forms of mania, melancholy, and febrile delirium.

Arguably, the most important contribution to the development of the concept of delirium took place in the 20th century when George Engel and John Romano demonstrated that delirium was due to a

Telegram: @medical_k

www.konkur.in

reduction in the metabolic activity of the brain. Through the use of electroencephalograms (EEGs), Engel and Romano illustrated that decreased background activity corresponded proportionately with a decrease in cognition, memory, and attention. Interestingly, these findings of reduced metabolic activity were observed in all subtypes of delirium, regardless of the level of psychomotor activity.

In introducing a reliable diagnostic tool and demonstrating the underlying mechanism of this mental disorder, Engel and Romano finally confirmed the observations of countless astute clinicians. The history of delirium stretches back over two millennia, yet it is only in the latter part of the past century that psychiatrists have managed to unify its concept and elucidate its mechanisms.

COMPARATIVE NOSOLOGY

Since delirium is usually due to multifactorial causes, there are many synonyms for delirium that have been introduced and adopted by medical practitioners. Various specialties have used different terms, such as encephalopathy and acute brain syndrome. Unfortunately, these multiple terms falsely suggest an element of variation that further complicates the recognition and management of delirium within and across medical specialties. In psychiatry, the term acute confusional state has been used as an equivalent designation for delirium, despite the ambiguity this additional term creates.

In general medicine and many of the medical subspecialties, the terms encephalitis and encephalopathy prevail in both the medical literature and clinical practice. Encephalitis refers to an inflammation of the brain parenchyma, as distinct from the meninges, which is usually associated with an infectious state. The term encephalopathy is less specific and refers to any disorder of the brain parenchyma yet is most often associated with organ failure and metabolic disorders. These examples illustrate the diversity of terms that are employed to identify delirium, and many other examples abound.

Although many of the aforementioned terms accurately describe individual elements of delirium, they fail to present a comprehensive summary of the patient. To be accurately diagnosed and managed,

Telegram: @medical_k

www.konkur.in

all aspects of the delirium, from etiology to resultant symptoms, must be included in the assessment. This comprehensive evaluation requires a consistent nosologic system. Great strides have been made in the establishment of such a system since the American Psychiatric Association's first attempts to clarify the concept of delirium in the third edition of the DSM. The 10th edition of the ICD classification of delirium (F05) now has many similarities with DSM-5.

The confusion surrounding the use and definition of the term delirium is further compounded by the existence of clinical subtypes referred to as the hyperactive, hypoactive, and mixed states of psychomotor activity. It should be noted that these designations are strictly clinical and may represent different manifestations of the same pathophysiologic state, or one type or another may be more commonly seen depending on the underlying etiology. Misconceptions regarding all these terms are a significant concern as they may result in a failure to correctly diagnose and manage the delirious patient.

ETIOLOGIES

Delirium in older adults is often multifactorial and can occur in a multitude of settings. Up to half of hospitalized older adults develop delirium. There are different causes of delirium that can affect older adults, including the emergence of delirium (from anesthesia) postoperatively, intensive care unit (ICU) delirium, delirium at the end of life, as well as delirium superimposed on dementia.

The multifactorial model for delirium has been widely accepted. It highlights the complex relationship between predisposing and precipitating factors. Predisposing factors are baseline vulnerability factors, and precipitating factors initiate or lead to the development of delirium. Individuals with less predisposing factors require more stressors to induce delirium, while highly vulnerable patients require much less noxious insults to develop delirium. Current management approaches to delirium focus primarily on the precipitating factors. Managing predisposing factors of delirium becomes essential in

Telegram: @medical_k

www.konkur.in

preventing delirium and decreasing the risk of future episodes of delirium and the morbidity/mortality associated with it.

Baseline or predisposing factors that increase the risk of developing delirium include age and dementia. Reduced functional reserve, whether physical or cognitive, results in a poorer response to stress. It is postulated that age results in physiologic brain changes leading to diminished cognitive reserve. Cognitive impairment and dementia are significant risk factors for the development of delirium postoperatively. In fact, there is a bidirectional relationship between delirium and cognitive decline. Other predisposing risk factors include a history of delirium, functional impairment, vision and hearing impairment, depression, and alcohol abuse.

In hospitalized patients, precipitating factors include physical restraints, malnutrition, the addition of more than three medications, use of bladder catheters, and iatrogenic events such as hospital-acquired infections or medication-related complications and electrolyte abnormalities. Medications that can precipitate delirium include sedative–hypnotics such as benzodiazepines, propofol and barbiturates, anticholinergic agents, analgesics (such as opioids), histaminic agents, steroids, and dopamine agonists. Disruption of circadian rhythms and insomnia predispose the development of postoperative delirium. Pain is considered a stressor and directly increases the risk of postoperative delirium in older adults.

End-of-Life Delirium

End-of-life delirium is also known as terminal restlessness/delirium. End-of-life delirium makes treatment of terminally ill patients particularly challenging. It will most often manifest in the last 24 to 48 hours of life but can develop weeks before death. The prevalence of delirium in palliative care inpatient units can be as high as 88% in patients with advanced cancer. This is likely due to the accumulation of multiple contributing factors (such as multiorgan failure, opioid use, dehydration, etc.). Delirium can be reversible in almost half of these episodes when precipitating factors include dehydration or

Telegram: @medical_k

www.konkur.in

psychoactive medication use. However, in cases of refractory or irreversible delirium, palliative sedation is indicated at the end of life. End-of-life delirium can be particularly distressing to patients and, more so, their families. As such, it is a common reason for admission to inpatient hospice. The precipitating factors for terminally ill patients are similar to other factors in other populations, including anticholinergic medications, anxiolytics, opioids, steroids, infection such as pneumonia or urinary tract infection (UTI), electrolyte or fluid imbalance, as well as poor pain management and constipation.

ICU Delirium

The ICU setting has some of the highest rates of delirium across all health care settings, particularly in patients on mechanical ventilation. The predisposing and precipitating factors for ICU delirium are similar to delirium in other settings, with the addition of mechanical ventilation. The predisposing factors such as age, cognitive disorder, frailty, alcohol or drug use, and severe underlying disease are all significant factors. Precipitating factors include metabolic disorder, in addition to sepsis, hypotension, inadequate pain management, sleep disorders, and complicated surgery. Similar to other settings, drugs that can precipitate delirium include benzodiazepines, opioids, anticholinergic drugs, and steroids. In addition, deep sedation (compared to light or interrupted sedation) is a risk factor. Morphine and meperidine have long half-lives and tend to accumulate, making short-acting opioids a preferred choice. The ABCDE bundle approach has been recommended for ICU delirium. It consists of assessing pain, daily trials of spontaneous awakening and spontaneous breathing trials, choosing shallow sedation if possible, monitoring delirium, early mobility and exercise, and family engagement and empowerment. Hypoactive delirium appears to be more common in the ICU than hyperactive or mixed delirium.

Postoperative Delirium

Postoperative delirium most often occurs within the first 2 days and can occur in up to half of all older adults following a hip fracture or

Telegram: @medical_k

www.konkur.in

cardiac surgery. Delirium that develops later is often associated with postoperative complications or withdrawal from alcohol or other medications. Looking back at the multifactorial model for delirium, anesthesia and surgical procedures are significant precipitating factors.

Coronary Artery Bypass Graft

The incidence of delirium after coronary artery bypass graft (CABG) procedure has ranged from 3% to 35%. Several factors play a role in the development of delirium in patients with post-CABG. A systematic review that examined data across 97 studies and pooled 60,479 patients who underwent CABG identified several nonmodifiable risk factors for delirium. Significant risk factors include (1) preoperative cognitive impairment, depression, stroke history, and higher European System for Cardiac Operative Risk Evaluation (EuroSCORE) score, (2) intraoperative increase in intubation time, and (3) postoperative presence of arrhythmia and increased days in the ICU. On the other hand, higher preoperative cognitive performance was protective for delirium.

Hip Replacement

Delirium is a common adverse event in patients undergoing hip replacement, with estimates in the range of 15% to 60%. Several studies have indicated that post–hip replacement delirium has been associated with increased morbidity and mortality. A systematic review that pooled 5,364 patients with hip fracture showed a 24% incidence rate of delirium after hip fracture repair. The risk factors for developing delirium included preoperative cognitive impairment (odds ratio [OR] 3.21, 95% confidence interval [CI] 2.26–4.56), advanced age (standardized mean difference 0.50, 95% CI 0.33–0.67), living in an institution (OR 2.94; 95% CI 1.65–5.23), heart failure (OR 2.46; 95% CI 1.72–3.53), total hip arthroplasty (OR 2.21; 95% CI 1.16–4.22), multiple comorbidities (OR 1.37; 95% CI 1.12–1.68), and morphine usage (OR 3.01; 95% CI 1.30–6.94). Female

Telegram: @medical_k

www.konkur.in

patients were less likely to develop delirium after hip surgery (OR 0.83; 95% CI 0.70–0.98).

Substance Intoxication

Substance intoxication and substance use withdrawal can both present with delirium. These will be covered in detail elsewhere. However, since the number of older adults in the United States with substance use disorder has been projected to almost double in the next 20 years, they will be briefly covered here.

The diagnosis of substance-induced delirium is made when a medication or other chemical agent is thought to be etiologically related to the condition. The responsible substance may be determined from clinical history, physical examination, and laboratory tests, such as a toxicology screen. The goal of treatment is to remove the offending agent. Familiarity with the common toxicologic syndromes (also known as toxidromes) is useful, as it may guide the investigation to include screening for additional agents. Awareness of the local prevalence of various drugs of abuse can also give some indication of the etiology of the syndrome. Clinicians need to keep current with drugs of abuse, newly approved drugs, herbal preparations, and teas as potential causes of delirium.

Intoxication with a variety of drugs of abuse is known to cause delirium. Examples include cocaine, PCP, heroin, alcohol, nitrous oxide, amphetamine and its derivatives (e.g., speed and ecstasy), 3,4-methylenedioxymethamphetamine (MDMA), and marijuana. Flunitrazepam (Rohypnol) and γ-hydroxybutyrate (GHB) are other common choices of recreational drug users with the potential for delirium.

Substance Withdrawal–Induced Delirium. In addition to substance intoxication, acute change in mental status can herald a substance withdrawal delirium. The diagnosis may be supported by autonomic changes or the detection of a substance or its metabolite in the urine or serum. When reviewing the history and chart of a patient presenting with delirium, a thorough review of medications

Telegram: @medical_k

www.konkur.in

and substances should be conducted to include medications that are prescribed and over the counter as well as the use of illicit substances and any recent changes. This is especially true when a patient is admitted emergently into the hospital and is unable to give a reliable history.

Alcohol Withdrawal. Alcohol withdrawal is associated with the classic agitated withdrawal delirium, also known as delirium tremens. This syndrome, synonymous with severe alcohol withdrawal, presents with delirium, autonomic hyperactivity, and frequent visual and tactile hallucinations and carries a significant risk of seizures and death if untreated. Patients admitted to the hospital may present several days into admission with alcohol withdrawal and may be at risk of delirium tremens. Histories of complicated alcohol withdrawal, medical comorbidity, and elevated blood pressure are associated with an increased risk of delirium tremens. In addition, benzodiazepine withdrawal may appear similar to alcohol withdrawal and may also be accompanied by seizures. The onset of symptoms is dependent on the half-life of the particular benzodiazepine.

Opiate Withdrawal. Opiate withdrawal presents with severe flu-like syndromes, gastrointestinal (GI) cramping, diarrhea, diaphoresis, autonomic hyperactivity, and craving. Delirium may also occur with opioid withdrawal and has been reported when patients are switched from transdermal fentanyl (Duragesic) to morphine (Duramorph). The presentation may occur because of unknown prior use of opiates in the context of abuse or prescription or methadone (Dolophine) maintenance.

DIAGNOSIS

Delirium, despite its common presentation in older adults, is frequently missed in various clinical settings. Fluctuation over hours in the presentation of symptoms further complicates the identification of delirium. Some studies have indicated that up to two-thirds of delirium cases have been missed by clinicians. Obtaining a good

Telegram: @medical_k

www.konkur.in

history from the patient's caretaker is an essential step in diagnosing delirium. In fact, neglecting this step is the leading reason for missing the diagnosis of delirium. If no history can be obtained, the patient should be assumed to be delirious until proven otherwise. Older patients should be aroused during rounds and evaluated daily for the hypoactive form of delirium, which is subtler and often overlooked.

Approaches to Diagnosis

When clinicians search for the underlying cause of delirium, they need to be aware of the possibility of occult or atypical presentations of many diseases in the older adults, including myocardial infarction, infection, and respiratory failure, like delirium, which is often the sole manifestation of serious underlying disease. During the current COVID pandemic, reports indicate that delirium may be a symptom of COVID in older patients. All preadmission and current medications, including longstanding ones should be reviewed for indication and risk/benefit. These can contribute to delirium and should be reevaluated. If changes in long-term medications are appropriate, the hospital represents a safe and ideal venue for making these changes. A complete medical history must be meticulously obtained to detect occult alcohol or benzodiazepine use, which can contribute to delirium.

Rating Scales in Delirium

Delirium is a diagnosis that is detected through a good review of signs and symptoms and bedside cognitive assessment. But certain instruments can help or assist in standardizing the approach to the diagnosis. Every older hospitalized patient should undergo brief but formal cognitive testing with the use of instruments such as the Mini-Mental State Examination (MMSE) and the Confusion Assessment Method (CAM). CAM primarily focuses on four major clinical features of delirium, including acute onset, inattention with fluctuations, disorganized thinking, and altered level of consciousness. The full CAM also looks for evidence of disorientation, memory impairment, psychomotor changes, altered sleep–wake cycle changes, and

Telegram: @medical_k

www.konkur.in

perceptual disturbances. CAM has been validated in a number of settings, such as inpatient units, emergency rooms, and the ICUs. In mechanically ventilated older patients, the instrument evidenced high rates of validity when compared to expert clinicians using DSM-IV-TR criteria with 95% sensitivity and 88% specificity. The administration time is usually about 2 minutes.

PATHOLOGY AND LABORATORY EXAMINATION

The utility of extensive routine laboratory testing in delirium has not been demonstrated. In many instances, the cause of delirium is obvious and often predictable, particularly when a good review of systems is conducted with the patient and or caregiver. In most patients, only testing what is necessary to confirm the diagnosis might be performed. In other situations, delirium may be the initial manifestation (or the only sign) of an underlying illness. The clinician must decide whether the known acute illness (such as pneumonia or hyponatremia) is sufficient to cause delirium, often a difficult decision. Some investigators recommend extensive enough lab or radiographic testing to exclude the common causes of delirium. A chest roentgenogram should be considered because pneumonia is one of the most common causes of delirium in older patients, and typical symptoms may be absent. In the current pandemic, testing for COVID is seen as a standard of care in such patients. An electrocardiogram (ECG) may be helpful in detecting cardiac ischemia. If hypoxia is suspected, pulse oximetry could be done, especially in postoperative patients. Arterial blood gases are most useful in patients with suspected acid–base disturbances, hypercapnia, and severe hypoxia.

Blood Chemistry, Urinalysis, and Cerebrospinal Fluid Examination

When routine testing is considered, then it should be individualized and limited initially to basic blood chemistry studies that assess for electrolyte, glucose, calcium, renal, and hepatic abnormalities and

Telegram: @medical_k

www.konkur.in

complete blood cell counts that assess for anemia or leukocytosis (indications of possible infection). Additional tests should be considered as directed by findings from the history and physical examination or if the cause remains elusive after the initial assessment.

Results of urinalysis that suggest the presence of infection should be followed with cultures and sensitivity studies. Caution should be used when ordering urinalysis in a nursing home setting patients as there is a big initiative for antibiotic stewardship and proper identification of true UTI with fever, burning or pain during micturition, increased WBCs with neutrophils. This has to be balanced with the knowledge that these patients may have compromised immunity and may not evidence all the classic signs and symptoms of UTI except for the sudden onset of mental status change or delirium. Determination of drug levels and toxicology screens may be necessary for selected patients.

Most hospitalized older patients with fever and delirium, however, have primary causes outside the CNS and do not require routine cerebrospinal fluid (CSF) studies. A CSF examination is important in the patient with delirium and fever in whom encephalitis or meningitis is suspected. Infection, dehydration, and metabolic disturbances accounted for 97.5% of cases of fever and delirium in one study, which found only one case each of bacterial meningitis and aseptic meningitis. One other important piece of information to remember while investigating the causes of delirium is that many times there may be multiple causes of delirium than just one factor.

Electroencephalography and Neuroimaging

Again, delirium is purely a clinical diagnosis. When that is in doubt, an EEG may be useful to clarify the diagnostic issues; however, caution must be used as EEG has a false-negative rate of 17% and a false-positive rate of 22%. Most patients with delirium will demonstrate diffuse slow-wave or low-voltage activity. The EEG may be useful in differentiating delirium from psychiatric disorders and identifying certain diagnoses, including hepatic encephalopathy,

Telegram: @medical_k

www.konkur.in

uremia, CNS infections, and seizures. In some patients, the EEG findings may indicate a focal rather than a global impairment and may thus suggest a localized cerebral event.

Neuroimaging as a routine test in delirium has a very low yield. When it is used, it is preferable to go with computed tomography (CT) head before considering magnetic resonance imaging (MRI) or functional studies. Neuroimaging studies should be reserved for patients with new focal neurologic signs, those with (a) history or signs of head trauma, (b) fever and acute changes in mental status in whom encephalitis is suspected, or (c) no other identifiable cause of the delirium. Neuroimaging may also be considered when the history cannot be obtained or the neurologic examination cannot be completed (e.g., when the patient is combative) so as not to miss uncommon conditions that are life-threatening but treatable such as subarachnoid hemorrhage and encephalitis. In older patients with a history of falling, neuroimaging such as CT head may be important for ruling out subdural hematoma (even if a head injury was not reported). If signs of focal neurologic impairment are present, CT or MRI of the head is indicated. Functional imaging studies such as blood flow, single-photon emission computerized tomography (SPECT), or positron emission tomography (PET) have yielded important findings on the pathophysiologic features of delirium; however, their role in the evaluation of delirium is unclear.

DIFFERENTIAL DIAGNOSIS

As mentioned earlier in this section, a good clinical history, physical examination, and laboratory studies are helpful in distinguishing delirium from other causes of global cognitive impairment, such as dementia, depression, and functional psychosis. Dementia (covered elsewhere within this section) has a gradual onset, persists for more than 1 month, is usually progressive, and is not associated with reduced alertness until terminal stages. Dementia, however, predisposes to delirium. Clinicians have to be very alert in picking up on delirium through the sudden deterioration of cognitive or functional ability in a patient with dementia. A delirium that is

Telegram: @medical_k

www.konkur.in

superimposed on a dementia process seen for the first time may be difficult to distinguish from a natural progression of the cognitive impairment or an atypical dementia. Considerable overlap exists between the two conditions, and the diagnosis of dementia should be deferred until the delirium clears and an appropriate evaluation has been done after several months have passed.

Hypoactive delirium can easily be mistaken for depression. Social withdrawal, limited speech, apathy, and poor attention with impaired cognitive testing could occur in both clinical situations. But typically, in depression, there is no change in the consciousness level, and there is a lack of fluctuation of the clinical presentation as seen in delirium. Acute psychosis can mimic a hyperactive delirium, but hallucinations tend to be typically auditory, delusions are more systematic and well formed, and the symptom fluctuation so characteristic of delirium is not noted. EEG findings are usually normal in subjects with psychosis or depression in comparison with the diffuse slow-wave activity seen in patients with delirium. Similarly, anxiety, a state of profound apprehension with increased motor activity and autonomic arousal, can resemble hyperactive delirium. Once again, there is a lack of change in the level of consciousness, and there is limited fluctuation in the presentation. Anxiety is common among hospitalized patients, particularly postoperatively and in ICUs, where fears of pain, disability, and death can be exacerbated by sensory impairment, sleep deprivation, current pain, and medications. It is imperative to clarify the diagnosis of anxiety versus delirium as treatment of one may adversely affect the other. For example, an agitated patient with hepatic encephalopathy can experience worsening if treated incorrectly for anxiety with benzodiazepines.

Diagnosing Delirium in Special Populations

Delirium in Patients with Dementia. Dementia is the biggest risk factor for delirium, and it has been reported that close to two-thirds of the cases of delirium occur in patients with dementia. There is a strong relationship between dementia and delirium that is not yet

Telegram: @medical_k

www.konkur.in

fully understood. The underlying vulnerability of the brain in patients with dementia may predispose them to the development of delirium as a result of insults related to acute medical illnesses, medications, or environmental perturbations. Some Studies suggest that delirium could persist for months or even years in some patients. The presence of such types of persistent delirium blurs the boundaries between delirium and dementia further. Some argue that delirium and dementia may not be independent disorders but could represent points along the continuum of cognitive disorders. This is substantiated by similar changes seen in cerebral metabolism (decrease), cholinergic deficiency, and certain inflammatory changes between these two disorders.

The presence of baseline dementia in a patient makes it challenging to detect delirium. Studies have shown that the severity of dementia can also influence the prevalence of delirium, meaning the more severe dementia, the higher the prevalence of delirium.

One important question that always comes up when treating an older patient with delirium is “Does delirium contribute to dementia”? The simple answer is that delirium does not cause the changes seen in dementia but does contribute to the worsening of the overall status of a patient with dementia. In the past, it was thought that if the underlying causes of delirium were treated well, then the subject’s premorbid cognitive and functional status could be restored. Several recent findings, such as long-term cognitive decline in patients with delirium seen in an epidemiologic study and some of the irreversible causes of delirium that result in neuronal damage indicate otherwise lately.

Families typically note that patients never return to baseline after an episode of delirium. This has been well noted in older patients with dementia. Delirium tends to worsen the trajectory of cognitive decline in dementia patients, leading to an increased rate of hospitalizations, institutionalization, and also increases the mortality risk by at least twofold in one study.

Delirium in Patients with Serious Mental Illness. Since delirium can present with psychosis and disturbance of sleep issues, it can

Telegram: @medical_k

www.konkur.in

confound the diagnosis when it presents in patients with schizophrenia and bipolar disorder. Only 48% of delirious patients were actually recognized as having delirium at the time it occurred. Patients with these disorders are at higher risk for delirium due to their comorbid medical issues and medications (many anticholinergic). In one study on the prevalence of delirium in psychiatric inpatients, the overall incidence of delirium was 14.6%. Delirium was most common among patients with schizophrenia and bipolar disorder; patients with bipolar disorder had the highest incidence (35.5%). Older age was the only significant demographic risk variable. The hospital stays of patients with delirium were 62.1% longer than those of patients without delirium.

Delirium in Patients with Terminal Illness. Delirium can complicate the clinical presentation in terminally ill patients. As the goals of care change in these patients, there is an urgency to better manage pain with the use of pain medications, treating infections, and avoiding hospitalizations. In one study, 228 participants (49.9%) among 457 terminally ill inpatients were screened. The prevalence of delirium was 46.9% (n = 107). Of these, the most common subtype was hypoactive (68.2%). The mortality rate of inpatients with delirium (77.6%) was higher than those without delirium (50.9%). The overall detection rate by any member of the palliative care team was 44.9%. The detection rate of the hypoactive subtype was only 20.5%, which was significantly lower than that of the hyperactive/mixed subtypes. Therapy for delirium was prescribed in 42.1%, with haloperidol being the most common medication. It has been estimated that approximately 50% of cases of delirium occurring in patients receiving specialist palliative care are potentially reversible.

Delirium in Children. The clinical features of delirium are not well known in children as in adults. One study in more than 100 consecutive psychiatric consultations over 4 years showed 84 patients aged 6 months to 18 years were identified with delirium. These patients had a longer length of stay and higher mortality (20%). Overall, the presentation and course of delirium were similar

Telegram: @medical_k

www.konkur.in

in adults (except for psychosis and disorientation), and the DSM criteria were found applicable in the pediatric population.

In another study, children had more sleep–wake disturbance, fluctuating symptoms, impaired attention, irritability, agitation, affective lability, and confusion as compared to adults. Adults had more impaired memory, depressed mood, speech disturbance, delusions, and paranoia. Impaired alertness, apathy, anxiety, disorientation, and hallucination occurrence were similar between both groups. These may represent true differences in the presentation of delirium across the life cycle or may be attributable to inconsistent methodologies. Prospective studies are needed to resolve these questions.

The classic onset of delirium is rapid—over a few hours or days—and the symptoms can be highly variable and intermittent. Various team members and families may witness completely different behaviors within a brief time span. A patient can go from being drowsy to being wakeful to then being hypervigilant within a few hours. Delirious patients can present with manic-like symptoms (poor sleep, pressured speech, high energy, agitation), depression-like symptoms (withdrawn, isolative, poor motivation, low energy), anxiety-like symptoms (anxious, poor sleep, restlessness, agitation), sleep disorder–like symptoms (reversed sleep–wake cycle, insomnia, hypersomnolence), and schizophrenic-like symptoms (hallucinations, delusions, paranoia, thought disorganization). As a result, the early detection diagnosis of delirium may be overlooked. Alternatively, caregivers might recognize that the patient is confused but fail to appreciate the significance of this change in condition, particularly when they seem to be less confused at times. Consequently, the problem may not be addressed until further deterioration ensues.

A cardinal feature of delirium is reduced alertness, manifested by difficulty maintaining or shifting attention. The delirious patient cannot ignore irrelevant stimuli and is easily distractible. Since many of the cognitive functions depend on attention, they tend to perform poorly in many cognitive tasks. The impaired memory seen in delirium usually represents an inability to register recent information

Telegram: @medical_k

www.konkur.in

because of inattentiveness, but retrieval of older information can also be disturbed. Higher integrative functions are similarly affected; the result is a reduced ability to plan, solve problems, or guide actions. Due to this, a typical new-onset delirious patient could be much worse cognitively than a patient suffering from dementia for a few years. These disturbances in attention often increase toward evening, a characteristic known as sundowning, which may result from fatigue and reduced sensory input. The confused patient cannot plan cognitive functions appropriately. Consequently, subjects demonstrate incoherent speech and a diminished ability to sequence actions properly (e.g., rising from a bed or walking), which can lead to injury. Typically, sleep becomes brief and fragmented, and fatigue tends to aggravate the symptoms of delirium. Subjects often demonstrate a reversal of sleep patterns, with daytime napping and nocturnal wakefulness.

Several clinical subtypes of delirium have been described. Commonly, delirium is classified on the basis of the level of psychomotor activity. Although certain types of delirium may frequently occur in patients with particular disease states, they are neither exclusive to nor diagnostic of specific underlying medical conditions. Similarly, the manifestation of delirium cannot be fully predicted by the presence of a particular etiologic toxin or illness. The hyperactive (increased psychomotor activity) variant of delirium is most commonly recognized and tends to be readily apparent even to the casual observer. It is often associated with the adverse effects of anticholinergic drugs, drug intoxication and withdrawal states. Characteristically, patients may exhibit agitation, psychosis, and mood lability and may refuse to cooperate with medical care, may demonstrate disruptive behaviors (such as shouting or resisting), or may sustain injuries from falling, combativeness, or pulling out catheters and intravascular lines.

The hypoactive (decreased psychomotor activity) variant of delirium is more common than hyperactive delirium in older patients, but it is less frequently recognized. Often it may be misattributed to depression or dismissed as a transient, insignificant problem. Metabolic conditions such as hepatic or renal encephalopathy are

Telegram: @medical_k

www.konkur.in

frequently associated with hypoactive delirium, but other causes are also common. Patients with hypoactive delirium may appear sluggish and lethargic as well as confused. The absence of disruptive, bizarre, and injurious behaviors contributes to the lack of recognition. In some studies, it has been noted that up to two-thirds of the patients with delirium could be unrecognized or underrecognized. This quiet state of withdrawal, apathy, and clouded inattention differs from the drowsiness seen in persons dozing or sleeping in that these latter subjects can be quickly aroused to (and remain in) normal consciousness by mild stimuli. In hypoactive delirium, however, strong stimuli (e.g., vigorous shaking or shouting) are often needed for arousal, which is incomplete and transient at best.

Because of the multiple etiologic factors, the fluctuating course, and the individual medical comorbidities, many patients who experience delirium have a mixture of both hypo- and hyperactive variants. Such patients are thought by some researchers to be at the highest risk of substantial morbidity and mortality. In one recent study conducted on critically ill patients, mixed type was most common (54.9%), followed by hypoactive delirium (43.5%) and purely hyperactive delirium (1.6%). In a post–hip surgery population, 47% were the hyperactive type of delirium, and both hypoactive and mixed types were each seen in 26% of the group. Similar rates were reported in a patient group admitted to an inpatient geriatric ward.

Hallucinations, misperceptions, illusions, and delusions are reported to occur in at least 40% of cases of delirium and can accompany both hypo- and hyperactive subtypes. Hallucinations are usually visual, ranging from dream-like experiences to terrifying visions, and may, in fact, represent “sleep without muscle atonia.” Auditory hallucinations, as well as those involving taste and smell, also occur, although much less frequently. Delusions are often paranoid or persecutory (e.g., suspicion of poisoned food or fear of intended harm by nursing staff).

Although these are some of the most distressing symptoms, the presence or absence of perceptual disturbances is not helpful in determining the cause or level of severity of delirium. Their presence, however, does confirm the diagnosis of an acute delirious

Telegram: @medical_k

www.konkur.in

state. Of importance, these sensory features tend to be less common in older than in young patients. Rather, somatic features such as urinary incontinence, gait impairment, tremor, and language disorders (including receptive and expressive aphasias) tend to predominate.

COURSE AND PROGNOSIS

Symptoms of delirium usually last about 7 days in most patients, but there is much variability, with slow resolution of symptoms contributing to persistent symptoms of delirium at 6 to 8 weeks for severely ill patients. In one study, it was reported that 80% of all delirious patients recovered by 7 to 10 days, but 5% of them do end up having the episode beyond 1 month. Symptom resolution is frequently incomplete by hospital discharge, with as many as 15% of patients remaining symptomatic of delirium at 6 months. There have been numerous methodologic limitations of some studies examining long-term follow-up. The presence of dementia and the level of medical comorbidity were not always controlled for, and the sample sizes were frequently small. In general, studies suggest that the increased mortality risk associated with delirium was maintained at 12, 24, and 36 months, with a risk ratio of at least 2 at all time points. In addition, at 24 months, the increased risk of cognitive and functional impairment remained. One study followed older patients discharged from an emergency room who were delirious. The mortality outcome at 6 months postdischarge for delirious patients not identified by the emergency room treating team was three times higher than the delirious patients who were identified and treated in the emergency room. The mortality rate was similar for the treated delirious patients as the nondelirious patients.

Early recognition of delirium is hypothesized to improve prognosis by allowing clinicians to address underlying medical conditions and substances earlier in the course. Surprisingly, preventive measures to improve prognosis have demonstrated mixed results. This may be due to insufficient exposure to staff, poor retention of the information presented, or other patient and clinician factors. The outcome

Telegram: @medical_k

www.konkur.in

measure used in these trials included time to delirium resolution, increase in independence in activities of daily living, decreased length of stay, and increased rate of discharge to the community rather than institutional settings. For example, one positive study demonstrated that the presence of a liaison psychiatrist in an orthopedic unit reduced the frequency of delirium and decreased the length of stay for the patients in the intervention group. Another study, which looked at whether a geriatric consultation followed by the involvement of a liaison nurse with the consultant and primary team, failed to demonstrate that the intervention had any benefit. An educational intervention to physicians and nurses by means of distribution of guidelines for recognizing delirium and formal educational in-services about the guidelines failed to improve outcomes in acute care hospitals in England.

Recent reports of multidisciplinary educational interventions have shown some benefit in decreasing the new onset of delirium and the length of stay in delirious patients in medical units. In another report, in an academic medical center in the United States, a multicomponent interventional strategy failed to reduce the rate of delirium, placement into nursing homes, need for home care visitation, readmission rates into the hospital, and self-rated health measures, and failed to improve functional status. Adherence to nonpharmacologic interventions for delirium was directly related to patient outcomes in this multicomponent intervention in the United States.

PREVENTION

Preventing delirium is the most effective strategy for reducing its frequency and complications. Successful prevention strategies include recognition of predisposing factors and early intervention to address or remove precipitating factors. The Hospital Elder Life Program (HELP), a model of care designed by S.K. Inouye provides a comprehensive patient-centered approach to early identification of delirium risk factors and targeted interventions to address cognitive impairment, sleep deprivation, immobility, dehydration, and vision or

Telegram: @medical_k

www.konkur.in

hearing impairment. HELP has been implemented in over 200 hospitals worldwide and has shown to be both effective and cost-effective in reducing delirium and improving outcomes for hospitalized elders. Similarly, the Yale Delirium Prevention Trial demonstrated the effectiveness of nonpharmacologic interventions to reduce the risk of developing delirium, including orientation and therapeutic activities for cognitive impairment, methods to improve communication, use of eyeglasses and hearing aids to reduce vision and hearing impairment, and employment of nonpharmacologic interventions to prevent sleep deprivation, volume depletion, and immobility while minimizing the use of psychoactive drugs.

While current evidence does not support the routine use of medications to prevent delirium, efforts to minimize or avoid the use of potentially inappropriate medications in older adults are an effective prevention strategy. Medications that have the potential for inducing or worsening delirium include anticholinergic agents, antipsychotics, sedative–hypnotics including benzodiazepines and nonbenzodiazepine "Z drugs," corticosteroids, H2-receptor antagonists, and opioid analgesics.

TREATMENT

Nonpharmacologic Treatment

Early identification and treatment of underlying medical conditions and/or contributing medications remain the first line in the management of delirium along with multimodal nonpharmacologic approaches. These may include modifying the patient's surroundings to maximize the safety and calmness of the environment and providing reassurance to decrease fear and agitation associated with delirium. Environmental considerations may enhance the patient's ability to appropriately interpret their surroundings; for example, rooms with a window view will provide orientation, and patients with eyeglasses and hearing aids should have access to these devices when appropriate. Paper and pencil should be provided to improve communication when the patient cannot respond verbally because of

Telegram: @medical_k

www.konkur.in

intubation. Furthermore, avoid extremes of sensory input such as stimulus overload in a loud and busy hospital unit or placing two affected patients in the same hospital room. Placing patients near a nursing station to facilitate close observation and maintenance of patient comfort and adequate pain control are also important in managing delirium. However, determining the appropriate level of analgesia in a patient with delirium can be challenging, and the use of certain medications can worsen delirium. Physical activity should be initiated as soon as possible in order to minimize the adverse effects of immobility (e.g., pressure sores), avoid deconditioning, and enhance orientation. Normal sleep–wake cycles can be promoted by the use of environmental cues such as windows and clocks. Adequate nutrition is important for recovery from delirium and the underlying illness, as well as for providing useful orientation. Interruptions of sleep should be minimized when possible, and brief, judicious use of sedative agents may be appropriate in some cases.

Psychosocial support can be provided by family and staff. Family members and staff can provide reassurance and reorientation to reduce anxiety and agitation. Familiar items from home may be useful for some patients. The availability of staff or family members to provide constant observation can minimize the need for physical restraints. When possible, continuity in staff can help decrease patient fears and paranoia because of unfamiliar faces. Conversations within earshot of a patient with delirium can be misinterpreted and produce a worsening of the patient's symptoms. Therefore, education of family and staff and modification of behavior can be helpful.

Pharmacologic Treatment

At present, there are no U.S. Food and Drug Administration (FDA)-approved medications for the treatment of delirium. Few controlled trials have been conducted to determine which agents are most beneficial in managing the symptoms of delirium; however, two general classes of medications—antipsychotics and benzodiazepines—are most frequently utilized in clinical practice,

Telegram: @medical_k

www.konkur.in

depending on the etiology of delirium. The use of certain psychoactive medications can worsen delirium and, therefore, should be reserved for the management of behaviors associated with delirium that pose a safety risk for the patient and others.

Antipsychotics. Despite a lack of evidence demonstrating the efficacy of antipsychotics in the treatment of delirium or positive impact on clinical outcomes, low-dose antipsychotics may be used off-label when agitation or psychotic symptoms are refractory to nonpharmacologic approaches and impact the safety of the patient and staff, as well as proper care of the patient. Given safety concerns associated with antipsychotics in older patients, antipsychotics should be given at the lowest effective dose and only when the benefit outweighs the risk. Furthermore, these agents should be tapered and discontinued upon symptom resolution.

Haloperidol is commonly used off-label to treat delirium despite weak evidence to support its efficacy or impact on the duration of delirium. This potent agent may be preferred over other antipsychotics because it has fewer anticholinergic and hypotensive side effects. However, the increased potency of haloperidol is associated with an increased frequency of extrapyramidal side effects, including dystonic reactions, akathisia, tardive dyskinesia, malignant catatonia, and cardiovascular effects. Therefore, the patient should be monitored closely not only for effectiveness but also for adverse events.

Haloperidol is commonly administered orally and intramuscularly in various clinical settings. The use of intravenous haloperidol (which is also not FDA approved for the treatment of delirium or any other indication) is most commonly seen in critical care settings and is associated with an increased risk of QTc prolongation. ECG monitoring is recommended when haloperidol is administered via the intravenous route. Clinical observations have noted a possible decrease in the serious side effects in comparison with the oral and intramuscular routes. Other older antipsychotic drugs, including thioridazine, droperidol, and chlorpromazine, have been found to be equally effective; however, because of a higher incidence of

Telegram: @medical_k

www.konkur.in

anticholinergic side effects (which may worsen delirium), haloperidol is preferred.

Several recent studies have evaluated the use of atypical antipsychotics in the management of delirium and have shown some promise in terms of both efficacy and safety, particularly in postoperative patients. Similar to low-dose haloperidol, evidence supports the use of low-dose risperidone, olanzapine, and quetiapine in controlling the aggression associated with delirium. Although atypical antipsychotics are relatively less likely to cause extrapyramidal side effects, they are not without adverse effects. The FDA has issued a safety class warning regarding the use of all antipsychotics in patients with dementia as they are associated with a higher incidence of mortality.

Benzodiazepines. Benzodiazepines have been used historically in the management of delirium primarily to sedate agitated patients with hyperactive delirium. Current evidence suggests that benzodiazepines can increase both the risk and duration of delirium, particularly in older adults. Therefore, the use of benzodiazepines should be reserved for the management of agitation associated with sedative–hypnotic withdrawal (e.g., alcohol, benzodiazepines, barbiturates, meprobamate, and carisoprodol) and the treatment of delirium tremens. In addition, patients experiencing alcohol withdrawal with suspected Wernicke encephalopathy should be given high-dose thiamine via the intramuscular or intravenous route as oral absorption is very poor to prevent progression to Korsakoff syndrome.

Melatonin and Ramelteon. A 2014 study got a lot of attention as it showed significant prevention of delirium in acute care patients receiving 8 mg of ramelteon (3% vs. 32% in the placebo group) at night. Studies since then have looked at melatonin and ramelteon in delirium prevention and treatment. Four of the five trials studying the effect of melatonin analogs in preventing delirium reported a beneficial effect, but study heterogeneity limited any broad recommendations. Further studies are necessary to assess the

Telegram: @medical_k

www.konkur.in

benefits of melatonin and ramelteon in both the prevention and treatment of delirium.

Finally, limited evidence suggests that dexmedetomidine may be effective in the management of delirium in the ICU setting; however, results have been mixed. Larger, well-designed trials are warranted to more clearly define the place in therapy for these agents.

Electroconvulsive Therapy. Electroconvulsive therapy (ECT) is reserved as a treatment of last resort for patients with delirium and severe agitation who are not responsive to pharmacotherapy. ECT is usually given en bloc or daily for several days, sometimes with multiple treatments per day. ECT use in delirium should be monitored closely as ECT can cause delirium on its own.

Treatment of Specific Etiologies of Delirium

Anticholinergic Intoxication. As previously stated, psychoactive medications can contribute to an increased risk of developing delirium, especially those medications with high anticholinergic properties like benzodiazepines, sedative–hypnotics, antipsychotics, and opioid analgesics in addition to many over-the-counter medications. It is important to note that there can be a cumulative effect of the anticholinergic load from multiple medications. Therefore, the preferred course of action is rapid identification and removal of the offending agent.

Anticholinergic poisoning almost always results in delirium and is often accompanied by physical agitation and visual hallucinations. Physical signs resulting from antimuscarinic action include widely dilated, poorly reactive pupils; warm, dry skin; dry mouth; fever; tachycardia; elevated blood pressure; constipation; and urinary retention. The use of cholinesterase inhibitors, such as physostigmine, has been shown to reduce the severity of delirium but requires repeated dosing because of a short half-life. In a comparison study of physostigmine and benzodiazepines for anticholinergic poisoning, physostigmine was effective, whereas the benzodiazepine was ineffective and was associated with a higher

Telegram: @medical_k

www.konkur.in

complication rate. Cholinesterase inhibitors approved by the FDA for Alzheimer disease (donepezil, rivastigmine, and galantamine) have not been well studied in the treatment of delirium and are not without safety concerns. Thus, these agents are not recommended as a therapeutic modality in the management of delirium.

Substance Intoxication. Substance cessation is the first essential step in the management of substance-induced delirium. The primary focus in managing a patient with substance intoxication is supportive, ensuring that the patient does not have significant respiratory depression or cardiovascular abnormalities. For benzodiazepine ingestions, the benzodiazepine receptor antagonist flumazenil may be helpful; however, repeated administrations might be required. In mixed ingestions that include benzodiazepines and tricyclic antidepressants or carbamazepine, flumazenil may precipitate cardiac dysrhythmias or seizures. Opioid intoxication may cause respiratory depression in addition to delirium. Reversal with naloxone or naltrexone may be considered with adequate support and monitoring of the cardiovascular and respiratory status. Naloxone acts through competitive binding at opioid receptors and results in the reversal of receptor-mediated actions of opioids and, therefore, can precipitate acute withdrawal. Naloxone may be administered intramuscularly, intravenously, or intranasally. This agent has a short half-life and may require repeated administration depending on the half-life of the ingested opioid. There are many other agents that are used in the context of emergency care as antidotes to substances ingested.

Substance Withdrawal. Benzodiazepines are used widely for the treatment of alcohol withdrawal, with the goals of reducing the severity of withdrawal, preventing delirium, and reducing the incidence of seizures. A systematic review identified 57 relevant randomized controlled trials with a total of 4,275 participants. The quality of the included studies, many of which date from the 1970s and 1980s, was fair, and most were small. Only 9 studies clearly concealed the allocation of patients to treatment or control groups,

Telegram: @medical_k

www.konkur.in

and only 21 adequately described the randomization procedures, although all but 3 were double blinded.

The evidence-based guideline from the American Society of Addiction Medicine was recently updated and still recommends benzodiazepines as a first-line agent for the treatment of alcohol withdrawal. The guideline notes that although agents with a longer duration of action may provide fewer breakthrough symptoms, those with a shorter duration of action, such as lorazepam (Ativan), may be preferred when there is concern about prolonged sedation (e.g., in patients with significant comorbidities or liver disease).

End-of-Life Delirium. Not all causes of delirium are reversible, and realistic treatment expectations should be set after a discussion with the patient and caregivers. When delirium occurs in the context of a terminal illness, issues about advanced directives and the existence of a health care proxy become more significant. This scenario emphasizes the importance of early development of advance directives for health care decision making while a person has the capacity to communicate the wishes regarding the extent of aggressive diagnostic tests at life's end. The focus may change from an aggressive search for the etiology of the delirium to one of palliation, comfort, and assistance with dying.

10.3 Major Neurocognitive Disorders (Dementia)

JULIE GRAZIANE, M.D., AND IQBAL AHMED, M.D., F.R.C.PSYCH.

This chapter will provide an overview of the clinical concept of major neurocognitive disorders that are caused by neurodegenerative disorders and review the common features of these major neurocognitive disorders. The most common subtypes of the major neurocognitive disorders will then be presented, and specific features will be discussed in detail. This chapter will discuss neurodegenerative neurocognitive disorders not caused by general medical conditions or substances: Alzheimer disease, frontotemporal dementia (FTD), dementia with Lewy bodies (DLB), dementia due to Parkinson disease (PDD), corticobasal degeneration (CBD), progressive supranuclear palsy (PSP), dementia due to Huntington disease, the prion diseases, and limbic predominant age-related TDP-43 encephalopathy (LATE). Please refer to the relevant chapters in this section for a discussion of vascular dementia, dementia in human immunodeficiency virus (HIV), and substance-induced dementia.

DEFINITION

Dementia refers to a disease process marked by progressive cognitive impairment in clear consciousness. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) describes dementia, now subsumed under the term major neurocognitive disorder, as significant cognitive impairment in one or more of the domains of complex attention, executive function, learning and memory, language, perceptual-motor ability, and social cognition. These deficits represent a decline from a previous level of functioning, so dementia does not refer to low intellectual functioning or intellectual disability which are developmental and static conditions. This decline is often noted by the individual affected, a family member or other caretaker, or the clinician, and should be demonstrated on standardized neuropsychological testing, and if that is not possible,

Telegram: @medical_k

www.konkur.in

another measurable clinical assessment. These cognitive deficits interfere with independent functioning in daily activities and cannot occur exclusively in the context of a delirium or be better explained by another mental disorder. In DSM-5, major neurocognitive disorder is distinguished from mild neurocognitive disorder by the amount of cognitive decline. Mild neurocognitive disorder requires modest cognitive decline, as well as a lack of interference in activities required for independent living, although greater effort or compensatory mechanisms may be necessary to maintain this independence. The etiologies of major neurocognitive disorders are diverse and include degenerative diseases, general medical illnesses and infection, those that are substance-induced, and combinations of the above.

HISTORY

The word dementia derives from the Latin word *dementatus*, meaning out of one's mind, and, as such, was potentially applicable to any state of psychopathology. Celsus probably first used the term *dementia* in the first-century CE, although one of the first attempts to describe an etiology beyond old age was in the 4th-century CE by Oribasius, physician to Emperor Julian. Oribasius wrote of a disease of cerebral atrophy that caused loss of intellectual capacity and weakness of movement. It was not until the 19th century that the distinction between cognitive impairment due to dementia was separated from that caused by mental illness by Jean Etienne Dominique Esquirol, as described in his classic work *Mental Maladies: A Treatise on Insanity.* Esquirol identified three varieties of dementia: Acute, chronic, and senile. Senile dementia was defined as a "cerebral affection . . . characterized by a weakening of the sensibility, understanding, and will" and also by marked impairments in memory, reasoning, and attention. Esquirol also described hallucinations, delusions, aggressive behavior, and motor impairments in patients with dementia.

In 1845, Wilhelm Griesinger was the first to describe senile dementia as a disease of the cerebral arteries. However, it was one of Griesinger's students, Emil Kraepelin, who later narrowed the scope of dementia by differentiating senile dementia from psychoses with cerebral arteriosclerosis, which later came to be known as dementia praecox and, finally, as schizophrenia. Also, in the late 19th century, reports of plaques

Telegram: @medical_k

www.konkur.in

and atrophy in the brains of patients with memory deficits and mental confusion began to emerge. In 1907, Alois Alzheimer was the first to identify specific histopathologic changes associated with progressive degenerative dementia. He described two cases of dementia (in 1907 and 1911) characterized by symptoms of aphasia, apraxia, agnosia, and the histopathologic finding of neurofibrillary tangles and milar foci (plaques) that distinguished it from dementia associated with cerebral arteriosclerosis. Today, efforts continue to focus on elucidating the etiology of dementia and to further delineate the associated pathologic and physiologic abnormalities observed across the range of clinical presentations with specific emphasis on genetics, prevention, and treatment.

COMPARATIVE NOSOLOGY

The conceptualization of dementia has evolved through successive editions of the DSM. In DSM-III, dementia was categorized as a syndrome and as a disorder. Organic brain syndrome included dementia and distinguished dementia from cognitive impairment syndromes caused by general medical conditions or substances. Dementias were also listed separately as specific disorders and included primary degenerative dementia of the Alzheimer type, multi-infarct dementia, dementia due to alcoholism, and dementia not otherwise specified. In DSM-IV, specific criteria for dementia due to Alzheimer disease, vascular disease, specific medical conditions, and substance-induced conditions were presented. The DSM-IV-TR further divided dementia into two more categories, adding dementia due to multiple etiologies, where each individual etiology is listed separately, and dementia not otherwise specified, which encompassed dementia that did not fall into one of these categories or where the etiology had not been established.

The DSM-5 utilizes the terms major neurocognitive disorder and mild neurocognitive disorder, which broadly correspond with the commonly used terms dementia and mild cognitive impairment (MCI), respectively. The term neurocognitive disorder is broader than “dementia”; it extends beyond late-life to include neurocognitive impairments at all ages, including, for example, those caused by traumatic brain injury (TBI) or HIV infection. The addition of mild neurocognitive disorder is a change from DSM-IV. Another change is that the diagnosis of major neurocognitive

Telegram: @medical_k

www.konkur.in

disorder can, rarely, be based on substantial impairment in even a single cognitive domain, if sufficient to interfere with independence in everyday activities (e.g., profound isolated memory or language deficit caused by a strategically located stroke or head trauma). Major and mild neurocognitive disorders are the basic clinical syndromes, with a major neurocognitive disorder requiring significant cognitive decline in one or more neurocognitive domains. DSM-5 provides definitions and examples for the different cognitive domains, which include complex attention, executive function, learning and memory, language, perceptual-motor, and social cognition. With DSM-5, significant impairment in any of these six domains can qualify for a diagnosis of a major neurocognitive disorder, as opposed to earlier versions of the DSM when memory impairment was a required criterion for a diagnosis of dementia. Assessment of these domains and related functional activities are essential in the conceptualization of an individual's dementia process and related impairments in the daily life of the individual. DSM-5 provides further diagnostic criteria for the etiologic subtyping of the syndromes, for example, with criteria for neurocognitive disorders due to Alzheimer disease (where memory is typically impaired) and frontotemporal lobar degeneration (where speech, behavior, and executive function are typically impaired), with further criteria provided in accordance with current expert criteria for those diseases. Specifiers exist for the presence of behavioral symptoms, as well as for the level of severity in major neurocognitive disorder, with mild severity indicating difficulties in instrumental activities of daily living, moderate severity indicating difficulties with activities of daily living, and severe for those who are fully dependent.

The etiology-specific criteria within the DSM-5 are fairly compatible with the criteria set forth by many of the major expert workgroups and consensus guidelines, including the National Institute on Aging-Alzheimer Association Workgroup Criteria for Alzheimer disease, the International Work Group on Frontotemporal Dementia, and Pick Disease criteria for Frontotemporal Dementia, the Consortium on Dementia with Lewy Bodies International Workshop Criteria for DLB, the Movement Disorder Society Task Force criteria for Dementia Associated with Parkinson Disease, the Movement Disorder Society Criteria for PSP, and an International Consortium's Criteria for Corticobasal Degeneration. Since the publication of DSM-5, a consensus working group has also formed to describe the

Telegram: @medical_k

www.konkur.in

clinical entity and neuropathologic criteria for the diagnosis of LATE, which will be further described later in this chapter. As more clinical data and biomarkers for specific neurocognitive disorders are identified, these guidelines are updated. Since DSM-5 was published, there have been updated expert workgroups and consensus guidelines for the diagnosis of Alzheimer disease, DLB, and PSP. As a result, the DSM-5 criteria may be slightly different from that of a more recently updated expert workgroups.

Another classification system for dementias is offered in the *International Statistical Classification of Diseases and Related Health Problems*, 10th revision (ICD-10). This still uses a syndromic approach and offers criteria for general dementia and specifically for four types, Alzheimer disease, vascular dementia, dementia in other diseases classified elsewhere, and unspecified dementia. These criteria require a decline in activities of daily living.

EPIDEMIOLOGY

Worldwide, it is estimated that about 50 million individuals have dementia. With the aging of the population, this number is projected to increase to 152 million by the year 2050. A significantly higher number of women worldwide have dementia compared to men, with an estimated 27 million women versus 16.8 million men. While women do have a longer life span than men, this discrepancy is not based solely on this, as the age-standardized global prevalence of dementia in women is about 1.17 times that of men.

In the United States, an estimated 6.2 million individuals age 65 years or older were living with Alzheimer dementia in the year 2021. Prevalence rates of Alzheimer dementia increase with age, and range from an estimated 5.3% of individuals age 65 to 74, to 13.8% of individuals between ages 75 to 84, to 34.6% of individuals older than the age of 85. The prevalence of all dementias in individuals over the age of 65 in the United States is estimated to be about 11%. In the United States, the prevalence of dementia in individuals older than 65 is highest in African American individuals (13.8%), followed by Hispanic individuals (12.2%), non-Hispanic white individuals (10.3%), American Indian and Alaska Natives (9.1%), and lowest in Asian and Pacific Islanders (8.4%).

The prevalence differs depending on the population. The prevalence rates reported above apply to the general population. However, in a

Telegram: @medical_k

www.konkur.in

primary care population, the prevalence rates are higher and higher still in the general hospital setting. In the skilled nursing facility population, rates are closer to 50% to 60%.

Prevalence rates and anticipated changes in these are variable depending on the world region being studied. About 60% of individuals with dementia live in low or middle-income countries. A 2013 systematic review and meta-analysis estimates slightly higher prevalence rates for those over the age of 60 in Latin America (8.48%) and the Caribbean (8.12%) and lower rates for the four sub-Sahara African regions (2.07% to 4%). Latin America, North Africa, and the Middle East, as well as China, India, South Asia, and the Western Pacific, are expected to have a rapid increase in the prevalence of dementia. The lower rates of dementia, as well as a smaller expected rise in prevalence in the sub-Sahara regions, may be due to the differing projections of aging there, secondary to that region's higher rates of child mortality and HIV. A 2017 review of 14 population-based studies across Western Europe, the United States, Japan, and Nigeria showed declining or stable prevalence and incidence of dementia, particularly in Western countries. The Global Burden of Disease Study 2016 estimated age-standardized prevalence of dementia to be highest in Turkey, followed by Brazil.

Risk and Protective Factors

The leading risk factor for dementia is older age.

Beyond age, there are a number of modifiable risk factors of dementia, some of which can begin to be addressed in early life, and others in mid- and then others in later life. The 2020 report of the *Lancet* Commission estimates that these modifiable risk factors may contribute to about 40% of dementias worldwide. Addressing these risk factors as early as possible allows for the potential enhancement and then maintenance of cognitive reserve as well as the reduction of neuropathologic change.

The level of education an individual achieves is the first of these modifiable risk factors. The brain has its greatest neuroplasticity in adolescence, and so emphasis should be placed on advocacy for strong primary and secondary education. Less education, as well as illiteracy, have been associated with a higher risk of dementia. More years of formal education may subsequently confer some protection against dementia, with some studies showing that every additional year of education decreases dementia risk. Education after adolescence may be more

Telegram: @medical_k

www.konkur.in

helpful in maintaining cognitive functioning and in the promotion of cognitively stimulating activities, which may aid in the maintenance of cognitive reserve.

Vascular risk factors increase the risk not only for vascular dementia but also for Alzheimer disease and dementia in general. Hypertension, particularly long-term hypertension starting in midlife, increases the risk for dementia, with this risk increasing if this persists into late life. Midlife hypertension has been associated with reductions in brain volume and increased white matter intensities. It is recommended that individuals maintain a systolic blood pressure of 130 mm Hg or less in midlife. It should be noted that the U.S. and Puerto Rico Systolic Blood Pressure Intervention Trial (SPRINT) showed fewer dementia diagnoses, MCI diagnoses, and combined MCI or dementia diagnoses in individuals in the intensive treatment arm (systolic blood pressure of <120) versus those in standard treatment (<140). Lower blood pressure in late life, however, may actually be a sign of illness. High cholesterol is also a risk factor for dementia. Cardiovascular disease, particularly when combined with peripheral vascular disease, also confers greater risk. Cerebrovascular disease is also a risk, not just for vascular dementia but also for Alzheimer disease. Congestive heart failure and atrial fibrillation are also risk factors.

Diabetes has been associated with an increased risk of dementia. This risk increases with the severity and duration of diabetes. Evidence is mixed as to whether treatment for diabetes mitigates this risk or not. Obesity is also associated with increased dementia risk and is another modifiable risk factor that should be addressed as early as possible.

Early-life depression has been associated with an increased risk of Alzheimer disease, and the long-term depressive burden has also been shown to be associated with an increased risk of cognitive decline, dementia, and MCI. The relationship between late-life depression and dementia is more nuanced. Late-life depression is associated with increased dementia, but at least some of this risk is due to late-life depressive symptoms occurring as part of the prodrome or early signs of dementia. It remains unclear whether antidepressant use helps to mitigate the risk of depression.

Sleep disturbance has been associated with an increased risk of dementia. A 2018 meta-analysis showed associations between insomnia and a heightened risk of Alzheimer disease, and sleep-disordered

Telegram: @medical_k

www.konkur.in

breathing was associated with increased risk of all-cause dementia, Alzheimer disease, and vascular dementia.

There is an increased risk of dementia, and more specifically, Alzheimer disease in individuals with TBI. This risk further increases when the TBI is associated with loss of consciousness and with more severe injury.

Excessive alcohol consumption is associated with dementia, while mild to moderate alcohol intake may actually be protective. There is also an association between alcohol use disorders and early-onset dementia. Individuals should avoid drinking more than 21 units of alcohol per week. Individuals who smoke are also at higher risk of developing dementia than nonsmokers. While there is an inverse relationship between smoking and the development of Parkinson disease, given the numerous other health consequences of smoking, individuals should be encouraged to quit smoking whenever possible.

Anticholinergic medications, particularly those used for depression (mainly amitriptyline, dosulepin, and paroxetine), antiparkinsonism, and urologic reasons (mainly oxybutynin and tolterodine), have been associated with an increased incidence of dementia. This association is present even for these medications prescribed 15 to 20 years prior to the diagnosis of dementia. Gastrointestinal medications with a high anticholinergic burden have not been associated with a dementia diagnosis. Selective serotonin reuptake inhibitors (SSRIs) with a lesser anticholinergic burden have been associated with a higher dementia incidence, but this association has only been seen for prescriptions that were closer to the time of diagnosis, suggesting a possible reverse causation effect.

The relationship between physical activity and the risk of development of dementia is complex, particularly given physical activity's role in the management of diabetes, hypertension, and obesity, but evidence suggests that physical inactivity increases the risk of dementia. Individuals, particularly those who are overweight, who engage in more leisure-time physical activity in midlife as well as increased leisure-time physical activity from mid- to late-life have been shown to have lower dementia risk. More long-term trials are needed, particularly in regard to the specific types of exercise and the duration needed to mitigate this risk.

Exposure to air pollution, particularly high nitrogen dioxide and fine ambient particulate matter from traffic exhaust and residential wood burning are associated with a heightened risk of dementia. This

Telegram: @medical_k

www.konkur.in

environmental risk may affect those from more socioeconomically disadvantaged groups.

Reduction in social isolation in later life has also been shown to provide some protection against the development of dementia. This may help in the maintenance of cognitive reserve.

Hearing impairment has been associated with increased temporal lobe volume loss, including in the hippocampus and entorhinal cortex, and has also been associated with a heightened risk of dementia. Notably, the use of hearing aids helps to mitigate this risk. As such, the use of sensory assistive devices when needed, as well as promoting protection from excessive noise exposure earlier in life, are important in the reduction of this risk.

There is increasing evidence that higher adherence to a Mediterranean diet is associated with less cognitive decline and a reduced risk of developing Alzheimer disease.

While there has been some research looking at protective factors in the development of dementia, clinical trials of putative protective factors including vitamin E, folate, vitamin B_6, and vitamin B_{12} to decrease the incidence of dementia have been negative. There has also been mixed epidemiologic evidence regarding statins decreasing the risk of developing dementia; however, a 2009 Cochrane review found no effect from the use of statins in late life on the prevention of Alzheimer disease or dementia.

Many of the risk factors described above are considered to be modifiable, providing opportunities to be addressed years and sometimes decades before the typical onset of dementia. The Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability provided older individuals at risk for dementia multimodal interventions including management of vascular and metabolic risk factors, nutrition recommendations, physical exercise, cognitive training, and social activities; these interventions were associated with a reduction in the risk of cognitive decline, as well as improved executive functioning and processing speed. In addition, a retrospective cohort study of 196,000 individuals showed a healthier lifestyle, which was defined as no smoking, regular physical activity, a healthy diet, and moderate alcohol consumption was associated with a lower risk of development of dementia in individuals with high genetic risk compared to those with unfavorable lifestyle factors.

ETIOLOGY

There are many different etiologies for major neurocognitive disorders. Neurodegenerative disorders account for the vast majority of dementia cases. The most common is Alzheimer disease, which primarily involves neurodegeneration of the cholinergic system, among others. Alzheimer disease, alone or in combination with other etiologies, accounts for about 70% to 80% of dementias. On neuropathologic examination of individuals with dementia, the majority of diagnoses are of mixed pathology, with Alzheimer disease comorbid with vascular infarcts or cortical Lewy body disease. In one neuropathology study of individuals diagnosed with probable Alzheimer disease, on autopsy, only 42.4% were found to have pure Alzheimer disease pathology, and more than 45% of individuals were found to have mixed pathology. DLB is characterized by the same neuropathologic changes as Alzheimer disease, with neurofibrillary tangles and plaques, plus Lewy bodies in cortical and brain stem regions, and accounts for about 15% to 35% of dementias. Vascular disease, both small vessel and large vessel disease affecting cortical or subcortical regions accounts for about 5% to 20% of dementias. Cognitive deficits depend on which brain regions are affected or disconnected. The FTDs involve neurodegeneration and neuropathologic changes in frontal lobe and temporal lobe regions. In early-onset dementias (those occurring before the age of 65), frontotemporal lobe degeneration or vascular disease is the second most common etiology, following Alzheimer disease. Other neurodegenerative disorders affecting primarily the basal ganglia also cause dementia, specifically Parkinson disease, CBD, PSP, and Huntington disease. These account for a smaller proportion of dementia cases. Finally, prion diseases (e.g., Creutzfeldt–Jakob disease [CJD], Gerstmann–Sträussler-Scheinker disease [GSS]) include both spontaneous and transmissible forms and can cause rapidly progressive dementias.

Other neurologic disorders that can cause impairment in multiple cognitive domains include multiple sclerosis, brain tumors, normal-pressure hydrocephalus, subdural hematoma, and TBI. Other medical conditions can also cause dementia, such as endocrinopathies (e.g., hypothyroidism), vitamin B_{12} deficiency, uremia, autoimmune disease (systemic lupus erythematosus), and others. Infectious diseases such as

Telegram: @medical_k

www.konkur.in

HIV and syphilis can cause dementia; HIV infection will be discussed in another chapter. See Table 10.3–1 for a list of etiologies of dementia.

DIAGNOSIS AND CLINICAL FEATURES

Clinical Features

The hallmark feature of dementia is cognitive impairment. Patients must demonstrate impairment in one or more cognitive domains (see Table 10.3–2 for DSM-5 criteria). The onset, duration, course, presentation, and associated symptoms vary depending on the type of dementia. A general overview is provided here, while a more detailed discussion of the clinical features of each type of dementia will be presented in each individual section.

Table 10.3–2.
DSM-5 Criteria for Major Neurocognitive Disorder

A. Significant cognitive decline from a previous level of functioning in one or more cognitive domains, as evidenced by:
   1. Concern from the individual, the clinician or another knowledgeable informant that there has been significant cognitive decline
   2. Substantial impairment in cognitive performance, ideally seen on standardized neuropsychological testing, or if that is not available, another clinical assessment
B. Cognitive deficits interfere in independence in daily activities
C. The deficits do not occur exclusively during the course of a delirium
D. The deficits cannot be explained by another mental disorder

Cognitive Impairment. Memory impairment refers to the inability to learn new information or to recall previously learned information. In general, short-term memory is impaired before long-term memory. Short-term memory impairment is often manifest as forgetting recent events and

Telegram: @medical_k

www.konkur.in

conversations, repetitive questions, the repetitive retelling of stories, forgetting the date, forgetting appointments, misplacing objects, losing valuables, and forgetting that food is cooking on the stove. Patients are unable to learn new information or new skills and may become overwhelmed, disoriented, or confused in new environments (i.e., traveling or moving). Later in the illness progression, long-term memory will become impaired, and patients will no longer recall their personal past history and will forget previously highly learned material. Procedural memory for previously learned skills may be retained longer.

Language impairment can manifest as difficulties in receptive or expressive language. Aphasia may be evident as word-finding difficulties resulting in reduced fluency of productive speech, word substitutions, or mispronouncing words. Patients may have difficulty remembering the names of distant family members or friends, or acquaintances they see infrequently. As language impairment progresses, patients may forget the names of close family and friends. They often have difficulty maintaining conversations or may use generalized, vague terms to try to maintain the conversation; eventually, they stop initiating conversation. Individuals may appear more withdrawn and disengaged as their ability to engage with others through conversation becomes more impaired. They may develop paraphasic errors and have poverty of content with empty speech. Eventually, speech may become incomprehensible and unintelligible.

Perceptual-motor impairments include difficulties in visual perception and visuoconstruction, as well as apraxia and agnosia. There may be difficulties in navigating in familiar environments, and individuals may have more trouble during times of dusk, when lighting changes may affect perception. Apraxia, or impaired ability to carry out motor activities despite intact motor function, may manifest in the earlier stages as difficulty using familiar tools or machines (i.e., microwave oven, washing machine, lawn mower, drill) or trouble performing previously acquired skills (i.e., knitting, woodworking). In later stages, there may be dressing, bathing, or feeding apraxias that contribute to impairment in the ability to perform activities of daily living. Agnosia, or failure to recognize or identify objects despite intact sensory function, may be reflected in the inability to recognize familiar objects, familiar faces, or in later stages, one’s own reflection in the mirror. It also manifests as a lack of insight into one’s own impairment and unrealistic assessment of one’s abilities.

Telegram: @medical_k

www.konkur.in

Individuals with impairments in complex attention typically have difficulty when there are competing stimuli, such as multiple conversations or ambient sound from the television or radio. They are easily distracted and have trouble registering new information; thinking may also appear to take longer.

Impairment in executive functioning refers to disturbances in planning, organizing, sequencing, and abstracting. Impairment in this area is reflected in difficulty performing complex tasks or problem-solving. This may manifest as trouble preparing a meal, managing medications, or managing finances. Judgment is often impaired, and bad decisions are made because of deficits in executive functioning combined with a lack of recognition of difficulties.

Social cognition includes the ability to recognize emotions and the ability to consider another individual's mental state. Impairments in social cognition may initially be manifested as difficulty recognizing social cues or emotions in others, apathy, disinhibition, and changes in levels of extraversion or introversion. Family members of the individual may describe a change in personality. As these impairments progress, behavioral changes become more overt, with individuals making sexually or politically inappropriate comments and showing disinhibited and intrusive behaviors that lack awareness of another's personal space.

Functional Impairment. According to DSM-5, each of the cognitive deficits must result in a significant impairment in functioning that represents a decline from a previous level of functioning. If patients are still working, there must be difficulties with job performance. Difficulties in managing finances or medications may also be evident. Initially, there may be difficulty performing instrumental activities of daily living and eventually basic activities of daily living (see Table 10.3–3 for a description of these). There may also be difficulties in social functioning. This may manifest as disengagement from usual activities and interests or trouble maintaining social relationships and social roles.

Screening

The role of dementia screening is dependent on the medical setting and the history presented by the patient or concerned family members. The U.S. Preventative Services Task Force does not recommend for or against screening for dementia in the primary care setting. However, in 2011 the Center for Medicare and Medicaid Services began to require screening for cognitive impairment during the Annual Wellness Visit. Given the high prevalence of dementia, especially with advancing age, screening for dementia in high-risk groups may offer great clinical benefit. Dementia is associated with higher rates of delirium, adverse drug reactions, and falls so recognizing dementia earlier in its course might raise awareness and target prevention efforts to try to avoid these potential complications. In the psychiatric setting, screening for cognitive impairment in older adults is essential given dementia's relationship to depression. Also, some of the earliest signs of certain dementias may be behavioral or personality changes that may lead individuals to initially present for psychiatric evaluation and treatment. Early recognition would also allow for initiating potentially disease-modifying agents, when they become available, earlier in the course of illness that may potentially delay progression to more advanced stages.

Evaluation

A complete evaluation for dementia begins with a thorough history from both the subject and a reliable informant. Given the nature of memory loss in dementia, an accurate history cannot be expected to be obtained from the patient alone. Relevant aspects of the history include the onset of cognitive impairment (insidious or sudden), course (gradual or step-wise,

Telegram: @medical_k

www.konkur.in

progressive or episodic, or fluctuating), and duration of the impairment. An assessment of each cognitive domain is critical. For memory, enquire about short-term, long-term, and remote memory. For language, enquire about word-finding difficulties and remembering names of family members and friends. For complex attention, enquire about difficulties maintaining attention when there are competing stimuli; for example, an individual may have difficulty following conversation in large groups of people or when the television or radio is also on. For perceptual-motor abilities and praxis, enquire about difficulties in navigating previously familiar environments, use of familiar tools or machines, maintenance of previously acquired skills, and dressing or feeding apraxias. For agnosia, enquire about recognition of familiar objects and insight into their condition and limitations. Enquiring into executive function involves assessing one's ability to perform complex tasks or solve problems, such as the ability to manage finances or medications. For social cognition, changes in behavior or personality may be subtle or more overt, depending on the severity of the dementia.

Evaluation of Cognitive Domains

The degree of functional impairment should be ascertained. Assessment of executive functioning can be helpful in evaluating functional status (see Table 10.3–4). Asking about driving, management of finances, medication management, and activity planning can provide some information as to an individual's day-to-day functioning level. If there is suspicion of greater levels of impairment, enquiring about the ability to perform basic and instrumental activities of daily living is important (see Table 10.3–3). In some settings, evaluation with a structured measure, such as the Kohlman Evaluation of Living Skills (KELS) test, may be available to assist in gauging an individual's safety in the home.

In addition to the cognitive symptoms and related decline in functioning, patients should be evaluated for the behavioral and neuropsychiatric manifestations of dementia; these are described in more detail below. The Neuropsychiatric Inventory (NPI) is a useful tool that was developed to assess psychopathology in dementia patients and evaluates 12 neuropsychiatric disturbances: delusions, hallucinations, agitation, dysphoria, anxiety, apathy, irritability, euphoria, disinhibition, aberrant motor behavior, night-time behavior disturbance, and appetite and eating abnormalities.

Telegram: @medical_k

www.konkur.in

Medical and neurologic history is relevant, especially any changes that may have a temporal relationship to the onset or worsening of cognitive dysfunction. Cerebrovascular events can coincide with the onset or worsening of vascular dementia or dementia of any etiology. Certain medical illnesses can contribute to the onset of dementia, and these may even be reversible causes of dementia that, when treated, can result in improvement in cognitive symptoms and functioning. Vascular risk factors, history of head trauma, and HIV risk factors may be relevant.

Psychiatric history is also relevant as certain psychiatric conditions may overlap with or predispose to dementia. Depression can cause cognitive impairment that may mimic dementia and may be associated with an increased risk for Alzheimer disease. Patients with Down syndrome will develop Alzheimer disease at an early age. Alcohol and substance abuse history should be ascertained. Family history of dementia, early-onset dementia, Huntington disease, or other neurologic diseases is important.

Several aspects of the social history are particularly relevant. Education level is important as higher education may be a protective factor, and level of education is relevant in interpreting findings on cognitive testing as normative values are dependent on age and education. Exposure to certain chemical agents may also be relevant as some chemical exposures may be associated with particular types of dementia.

cognition	change?
	Does the individual appear to be less empathic or more disinhibited in their speech or behavior?
	Is the individual making sexually, politically, or religiously inappropriate comments?
	Does the individual show a lack of awareness of another's interpersonal space?

Data from Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (Copyright © 2013). American Psychiatric Association.

A complete physical and neurologic examination is necessary. The physical examination is targeted toward medical conditions that may cause dementia. The neurologic examination is necessary to identify focal neurologic signs that may point to specific brain lesions or pathology.

The mental status examination is useful to assess not only the pattern of cognitive impairment, which may help with the diagnosis of the type of dementia, but also self-care abilities (appearance and grooming), behavior (degree of engagement in the interview, demeanor, inappropriate behavior), affect (apathy, depression, anxiety), speech (language function, fluency, comprehension), perception (hallucinations, paranoia, delusions), and insight and judgment.

Bedside cognitive testing is performed to characterize the pattern and extent of cognitive impairment. Two of the more commonly known bedside cognitive exams, the mini-mental status exam and the Montreal cognitive assessment (MoCA), are no longer in the public domain and have been monetized by their authors. Publically available tests include the mini-cog, the St. Louis mental status exam (SLUMS), the Kokmen short test of mental status (STMS), and the Rowland Universal dementia assessment scale (RUDAS). Addenbrooke cognitive examination (ACE), now in its third version, is another screening test that also examines attention, memory, language, orientation, and visual perceptual and visuospatial skills. There is a shorter version of this scale, known as the M-ACE, which has been developed and validated; this exam is scored out of 30 points and can be given in under 5 minutes. While bedside cognitive evaluation can be helpful when a clinician is suspicious of a mild or major neurocognitive disorder, consideration should be given for referral to a neuropsychologist for detailed cognitive testing on one of several standardized test batteries used commonly in the older adults with

Telegram: @medical_k

www.konkur.in

dementia. These more detailed tests may be beneficial in more clearly delineating areas of impaired function and in providing a baseline against which illness progression can be measured.

Severity Measures. There are several widely employed scales to assess the severity of dementia in terms of the level of cognitive and functional impairment. The Clinical dementia rating scale (CDR) measures several domains of function, including memory, orientation, judgment and problem-solving, community affairs, home and hobbies, and personal care. Another staging scale is the functional assessment staging (FAST) which has been developed to track the course of Alzheimer disease and is also useful for other dementias. Staging is based on the ability to perform certain skills or functions and is dependent on baseline skills, acquired deficits, and the social environment. Therefore, if a patient is not performing a certain skill because they never did or because their current environment does not demand it, it is not counted as a deficit. Patients with a CDR score of 0.5 or a FAST stage 2 to 3 have mild deficits in memory and sometimes other areas but have only mild or questionable functional difficulties. This generally corresponds with a diagnosis of MCI or mild dementia. Patients with a CDR score of 1 and a FAST stage 4 have some difficulty with instrumental activities of daily living, but they can still remain fairly independent with some assistance and prompting which corresponds to “mild” dementia. Patients with a CDR score of 2 and FAST stage 5 or 6 have impairment with more basic aspects of maintaining a home and themselves and will require some assistance with instrumental activities of daily living. Patients with a CDR score of 3 or FAST stage 6 or 7 have “severe” dementia and require considerable to total assistance with personal care and activities of daily living. In the terminal phase, patients develop contractures and are bed-bound, and require total care.

Neuropsychiatric Manifestations

Neither the DSM-5 nor ICD-10 requires neuropsychiatric or behavioral symptoms for the diagnosis of dementia. However, these symptoms commonly co-occur with dementia and are often the cause of the greatest caregiver distress.

Neuropsychiatric symptoms or behavioral disturbance are common in many types of dementia, although prevalence rates vary widely depending on the population and dementia subtype studied. It is estimated that

Telegram: @medical_k

www.konkur.in

almost 90% of patients with Alzheimer disease will have some type of neuropsychiatric symptoms during the course of the disease. The prevalence of behavioral disturbance increases with advancing dementia. Behavioral disturbances include mood changes, anxiety, personality changes, psychosis, sleep disturbances, agitation/aggression, and other behaviors, each of which is described below.

Mood Changes. Depressive symptoms are the most common neuropsychiatric symptom in dementia, followed closely by apathy and anxiety. Major depression is common early in the course of dementia, and prevalence rates are estimated at about 10%. Depressive symptoms are even more common, occurring in about half of patients with Alzheimer disease, and may be an early manifestation of the disease. These may be a consequence of aspects of neurodegeneration, and depressive symptoms correlate with greater temporal lobe and cingulate gyrus hypometabolism. In addition, depressive symptoms, emotional lability, and irritability may be related to psychological reactions to the awareness of losing one's memory and anticipation of increasing functional impairment. Suicidal ideation and behavior may also occur through the course of dementia but are especially concerning in mildly impaired individuals who have insight into their deficits and still have the executive capacity to formulate and carry out a plan. Depression tends to decrease in prevalence with advanced dementia, so treatment for early depression may be withdrawn as the illness progresses. Elation and even a frank manic episode can also occur in the context of dementia but is rare.

Anxiety. Anxiety is fairly common throughout the course of dementia and is estimated to occur in about 60% of patients. Anxiety is often manifest as fear of being alone, and patients will search for their caregivers so as not to be alone. Some patients exhibit "catastrophic reactions" when confronted with their cognitive limitations or when facing changes in routine or environment.

Personality Changes. A range of personality changes may be evident. FTD often presents with disinhibition and impulsivity, which often predate obvious cognitive deficits. Examples include making inappropriate jokes, being overly familiar with strangers, disregarding social norms, inappropriate sexual remarks or behaviors, impulsive buying, or succumbing to salespeople or exploitative schemes. Alternatively, an

Telegram: @medical_k

www.konkur.in

apathy syndrome with amotivation and withdrawal may also be associated with various types of dementia, including Alzheimer disease and vascular dementia. In some cases, pre-existing personality traits may become stronger or exaggerated during the course of a dementing illness.

Psychosis. Psychotic symptoms in dementia generally occur in the middle stages of illness and often co-occur with behavioral disturbance. A common early psychotic symptom is paranoia and the belief that belongings have been stolen. This may develop as a result of poor short-term memory and misplacing objects. The inability to find a lost or misplaced object is interpreted in a paranoid way with the conviction that the object must have been stolen. This paranoia can become more pervasive as the illness progresses. In later stages, patients may have hallucinations in any modality, but most commonly, visual hallucinations. They may see deceased relatives. The hallucinations are often congruent with delusions of the same theme. People often believe they are still working or engaging in previous activities. Psychotic symptoms can sometimes lead to agitation, aggression, and behavioral disturbance as patients act out on their hallucinations, paranoia, or delusional thinking.

Sleep Disturbance. With advancing dementia, altered sleep–wake cycles can result in disrupted and fragmented sleep in about half of patients. Patients may have phase-shifted sleep, going to bed late, and sleeping late in the morning. They may also take frequent naps, which may be more prevalent in less stimulating environments where there is less to keep them engaged and awake. Sleep disturbance has been linked to activation of the inflammatory response and β-amyloid deposition.

Agitation and Aggression. Agitation and aggression become more prominent with increasing levels of dementia severity. There is a significant spectrum of behaviors that fall under the label of “agitation.” These behaviors are not always aggressive or directed toward a target. Agitation may also include nondirected behaviors such as continually pacing back and forth or purposeless hyperactivity such as continuously rummaging through drawers. Agitation and aggression can come in both physical and verbal forms, with some individuals hitting or striking out, while others may swear, make threats, or have persistent disruptive but nonthreatening vocalizations. The behaviors can be environmentally or

Telegram: @medical_k

www.konkur.in

task-dependent, such as with personal care, or may be more generalized. These behaviors often lead to acute hospitalization, placement in higher levels of care, cause significant caregiver burden, and even cause disability in caregivers due to injury.

Other Behavioral Disturbances. As cognitive impairment progresses, some individuals become at risk of wandering. This can be particularly dangerous in situations of inclement weather and for those individuals with altered sleep–wake cycles who still reside at home with a caregiver, as wandering may occur at nighttime. Disinhibited social behavior may also be seen, with individuals making inappropriate comments or gestures in public places.

LABORATORY EXAMINATION AND PATHOLOGY

The following are descriptions of the different studies available to aid in the diagnosis of dementia. The decision to order these to aid in the identification of a specific etiology of dementia is guided by the history and clinical examination, as well as the differential diagnosis.

Laboratory Studies

The purpose of obtaining routine laboratory studies in the evaluation of dementia is to rule out other general medical causes of dementia, including potentially reversible causes (see Table 10.3–5). These include complete chemistry panel, complete blood count, hepatic function, thyroid-stimulating hormone, vitamin B_{12}, and folate. Other laboratory studies that may be indicated depending on the history might include venereal disease research laboratory (VDRL) for syphilis, erythrocyte sedimentation rate, and HIV.

Structural Neuroimaging

Structural neuroimaging studies are obtained to rule out abnormalities in the brain that can cause or contribute to dementia, including normal pressure hydrocephalus, subdural hematoma, brain tumor or metastases, or cerebrovascular events. In general, a computed tomography (CT) scan is sufficient. However, magnetic resonance imaging (MRI) is preferred if looking for small or deep brain infarcts, as this imaging modality is better for visualizing vascular changes. Atrophy may be seen in patterns

Telegram: @medical_k

www.konkur.in

suggestive of specific dementia causes (see the review of individual causes of dementia, in the section on Major Neurocognitive Disorder Subtypes, below). An MRI with gadolinium contrast is useful if there is a high index of suspicion for a tumor.

Table 10.3–5.
Laboratory Evaluation of Dementia

Assessments	Rationale
Labs: Complete blood count, serum electrolytes, renal and hepatic function, glucose, albumin and protein, vitamin B_{12} and folate, rapid plasma reagin (syphilis), thyroid-stimulating hormone, urinalysis	Rule out correctable or contributory causes of dementia
Structural imaging: Computed tomography or magnetic resonance imaging	Rule out infarcts, mass lesions, tumors, and hydrocephalus
Molecular and functional imaging: PET-amyloid imaging, tau-PET imaging, Dopamine transporter (DaT) scan, SPECT, fluorodeoxyglucose-PET	Identifies certain pathologic biomarkers (Aβ or tau accumulation) or patterns of cerebral blood flow and/or metabolism that may be characteristic of specific neurodegenerative disorders
Cerebrospinal fluid	Detect altered levels of amyloid-beta and tau protein in Alzheimer disease, or elevated 14-3-3 protein and neuron-specific enolase in Creutzfeldt–Jakob disease

Molecular Neuroimaging

In an effort to identify biomarkers of the differing dementia processes, much work has gone into the development of molecular and functional imaging. During the progression of a particular neurodegenerative

Telegram: @medical_k

www.konkur.in

process, these markers may have differing utility. Positron emission tomography (PET) amyloid imaging can be used to identify beta-amyloid (Aβ) accumulation. The absence of amyloid deposits indicates the dementia is not likely to be due to Alzheimer disease. Tau-specific PET imaging allows for the in vivo detection of hyperphosphorylated tau aggregates. These aggregates can be seen in Alzheimer disease, PSP, CBD, frontotemporal lobar degeneration, and chronic traumatic encephalopathy. The main tracer currently available, flortaucipir, shows the greatest affinity for the hyperphosphorylated tau seen in Alzheimer disease. In addition, the degree of tau accumulation seen on PET imaging appears to correlate better with the degree of cognitive impairment compared to amyloid accumulation. Single-photon emission computed tomography (SPECT) or fluorodeoxyglucose (FDG)-PET can be used to demonstrate blood flow or metabolic rate in various brain regions to try to elucidate the etiology of dementia. For example, in Alzheimer disease, there is a characteristic pattern of decreased uptake in the posterior cingulate, temporal, and parietal cortex. In vascular dementia, there will be patchy areas of decreased uptake correlating to areas of hypoperfusion or infarct. In FTD, there will be a pattern of diminished uptake in primarily frontal as well as anterior temporal lobe regions, and in DLB, there may be a pattern of occipital hypoperfusion. Dopamine transporter imaging uses ligands specific for the dopamine transporter to examine the nigrostriatal dopamine system and is abnormal in Parkinson disease, DLB, multisystem atrophy, and PSP.

CSF Studies

CSF biomarkers are reflective of rates of production coupled with clearance of specific proteins at a specific point in time. These studies may be used to measure beta-amyloid protein, tau protein, and phospho-tau, all of which may be altered in Alzheimer disease. In Alzheimer disease, there is a characteristic pattern of decreased beta-amyloid with increased phosphorylated and total tau. Phosphorylated-tau is only elevated in Alzheimer disease, whereas increases in total tau are more reflective of more generalized neuronal damage at a specific point in time, such as after a TBI or a stroke. CSF studies in sporadic CJD may show elevations in 14-3-3, total tau, or neuron-specific enolase.

Electroencephalogram

Telegram: @medical_k

www.konkur.in

Electroencephalograms (EEGs) may have a role in dementia evaluation if there is a concern about a seizure disorder or delirium. In CJD, EEG can show periodic sharp wave complexes. However, EEG is not necessary for the routine evaluation of dementia.

Neuropsychological Testing

Neuropsychological testing may be useful in elucidating the pattern of cognitive deficits in cases where the presentation is not typical of any one type of dementia. In Alzheimer disease, there is a pattern of early short-term memory and language impairment followed by the development of executive dysfunction and then visuospatial dysfunction. LATE presents with an amnestic syndrome similar to that seen in Alzheimer disease. In FTD, memory is relatively spared, while either language impairments or executive dysfunction predominate. In vascular dementia, there is a pattern of patchy deficits depending on where vascular lesions have occurred in the brain. Neuropsychological testing may also be helpful in identifying when cognitive impairment is due to depression or a factitious disorder.

Neuropathology

In individuals whose dementia does not arise from a previously characterized familial autosomal dominant mutation, a definitive diagnosis of dementia type can only be made with a neuropathologic investigation of the brain through either brain biopsy or autopsy. There is usually not a clinical indication for brain biopsy, so postmortem evaluation of the brain is the only way to provide a definitive diagnosis of dementia type.

DIFFERENTIAL DIAGNOSIS

In the evaluation of cognitive impairment, the psychiatrist must first determine that this is not occurring in the sole presence of a delirium and that the cognitive impairment is not the result of a mild neurocognitive disorder. Medical conditions that can cause cognitive impairment and medication-induced impairment should be ruled out. Other mental disorders, such as a schizophrenia spectrum or psychotic disorder, a depressive disorder, a substance-related disorder, and a factitious disorder, must be ruled out as well. Once these causes have been ruled out, the focus switches to identifying the diagnosis of the specific

Telegram: @medical_k

www.konkur.in

underlying neurodegenerative disorders. These are described briefly below.

Delirium

Delirium can be differentiated from dementia by the presence of an altered level of consciousness with the cognitive impairment, whereas dementia by definition is in clear consciousness. In delirium, the onset is generally sudden and acute and represents a significant change from baseline. There is typically a fluctuating level of alertness. Attention is the hallmark cognitive domain that is impaired. Delirium can occur in patients with dementia, and in fact, dementia is a risk factor for the development of delirium. Dementia accounts for the baseline cognitive decline that is punctuated by an acute worsening related to the delirium. Delirium is usually precipitated by one or more, and usually a combination of, medical factors or medications, or substances.

Mild Neurocognitive Disorder

Mild neurocognitive disorder, more commonly known as MCI, is impaired cognition in one or more domains, but to a lesser degree than in dementia. There may be mild impairments in the more complex aspects of daily functioning, or an individual may need to rely on more compensatory strategies; however, there is no significant impairment on activities of daily living. Because the pathophysiologic process of neurodegenerative dementias begins years before there is evidence of cognitive or functional impairment, MCI may represent a prodromal state of these disorders. However, not all individuals with MCI will go on to develop dementia. Research to recognize and quantify biomarkers to identify those both with and without MCI who will go on to develop dementia is underway.

Medical Conditions

General medical conditions that can cause or exacerbate cognitive impairment must be ruled out. Treatable factors that can cause or contribute to dementia include hypothyroidism, hypercalcemia, hypoglycemia, vitamin B_{12}, thiamine or niacin deficiency, renal or hepatic impairment, or autoimmune disease (i.e., lupus erythematosus, vasculitis, neurosarcoidosis, Hashimoto encephalopathy; see Table 10.3–1).

Telegram: @medical_k

www.konkur.in

Medications

Many medications, alone or in combination, can cause cognitive impairment that may mimic dementia. Medications with anticholinergic properties are major culprits (see Table 10.3–1).

Schizophrenia Spectrum and Other Psychotic Disorders

Schizophrenia is associated with multiple cognitive deficits. These cognitive deficits may emerge prior to the onset of the psychotic syndrome in young adulthood and often progress during the early years of subsequent illness but are relatively constant thereafter. Some individuals with schizophrenia will develop a progressive deterioration of cognitive functions beginning in late life, which may represent a superimposed neurodegenerative process.

Depressive Disorders

Cognitive impairment frequently co-occurs with depressive episodes in late life. The impairment is substantial (though less so than in dementia) and is present in about 50% of depressed older adults, which is more frequent than in younger patients. Cognitive impairment in the context of depression was formerly termed “pseudodementia.” In the past, it was widely believed that cognitive impairment mimicked the symptoms of dementia but reversed upon resolution of the depressive episode. Numerous studies have now shown that when cognitive impairment co-occurs with depression in late life, it generally persists into depression remission, particularly in the memory and executive function domains. Thus, in many cases, both depression and cognitive impairment in the older adults likely have shared neurobiologic underpinnings. Moreover, depression seems to increase the risk for future dementia (both Alzheimer disease and vascular dementia), although it is not known whether depressed mood represents prodromal dementia or is etiologically related to future progressive decline. The varied findings in depression suggest that there are likely multiple phenotypes and pathways with different long-term trajectories and cognitive outcomes.

Alcohol Use Disorder

Substance use disorders, particulary alcohol use disorder, can cause neurocognitive disorders. Cognitive impairment is usually worse when

Telegram: @medical_k

www.konkur.in

patients are still actively using alcohol or other substances, and there may be some improvement with abstinence.

Factitious Disorder

Malingering or factitious disorder may present with dementia-type symptoms. The cognitive deficits are inconsistent over time and generally uncharacteristic of the pattern and course of dementia. There is some secondary gain from appearing cognitively impaired.

Neurodegenerative Disorders

Once the diagnosis of dementia, or major neurocognitive disorder, is identified and the above etiologies have been ruled out, the differential diagnosis shifts to identify the most probable specific etiology of the neurodegenerative process. Information and data obtained from the history, examination, neuropsychological testing, and imaging studies aid in the identification of the specific etiology and are summarized for each disorder in the individual sections below. It is also possible for an individual to have more than one neurodegenerative process occurring at the same time (e.g., both Alzheimer disease and Lewy body disease); this can blur the diagnostic picture, and unfortunately, a definitive diagnosis cannot be made until autopsy.

COURSE AND PROGNOSIS

The course and prognosis of dementia are variable depending on the etiology.

In general, onset is insidious, although abrupt onset due to a cerebrovascular or traumatic event is possible. Duration is generally years, although it may vary from 6 months in the case of CJD to 15 years with Alzheimer disease. In neurodegenerative dementias, there is a progressive cognitive decline and progressive functional impairment that may be of variable rate and pattern depending on the etiology and type. Dementia eventually leads to death unless another disease process supersedes it.

Identifying the correctable causes of cognitive impairment such as vitamin B_{12} deficiency, hypothyroidism, or normal-pressure hydrocephalus can result in some improvement in symptoms. Also, modifying vascular

Telegram: @medical_k

www.konkur.in

risk factors can ameliorate the course of dementia, even of nonvascular etiologies.

Gradual functional decline renders patients increasingly more dependent over the course of the illness. They slowly lose the ability to function independently. They lose the ability to perform instrumental activities of daily living such as shopping, meal preparation, managing finances, and managing medications. Then they have difficulty bathing and maintaining hygiene and dressing and feeding themselves. They require more and more prompting and then assistance with these tasks as the disease progresses, and they will eventually require total care.

Dementia increases the risk for complications from intercurrent medical illness, including delirium. Any medical illness can precipitate a rapid decline in cognition and functioning and markedly increase the level of care required. Dementia is also associated with an increased risk of falls and adverse reactions to medications.

MANAGEMENT

Management of dementia requires an individualized, multimodal approach not only targeting cognitive deficits but also addressing neuropsychiatric symptoms and overall level of functioning as well as caregiver issues, legal issues, safety, community support, and levels of care. Treatment modalities and strategies will vary with the stage and type of dementia and must evolve over time to address changing issues. Educating patients and their families about the course of illness and providing individualized treatment plans that ensure safety and adequate levels of care are essential.

General principles of dementia management will be provided here. The American Psychiatric Association Treatment Guidelines recommend that patients with neuropsychiatric symptoms of dementia be assessed for the type, frequency, severity, pattern, and timing of symptoms, as well as for potentially modifiable contributing factors, such as pain. For those patients with agitation or psychosis, it is recommended that response to treatment be assessed with a quantitative measure, such as the Brief Psychiatric Rating Scale or the NPI Questionnaire. The evidence and rationale for specific treatments for each specific type of dementia will be discussed in that section.

Telegram: @medical_k

www.konkur.in

Nonpharmacologic Management

Psychological, behavioral, and psychosocial interventions which are specifically tailored to the individual with dementia are an important component of the management of the patient with dementia of any type. Educating patients and families about dementia and the course and what to expect at each stage is important for general treatment and anticipatory planning. Maintaining safety, ensuring adequate supervision and support, connecting patients and their families with community supports and resources, providing support for caregivers, and encouraging legal and financial planning all play an important role in the management of the patient with dementia.

Psychotherapeutic Approaches. Psychosocial interventions are an important component of the management of a patient with dementia of any type. While these interventions are important, there is no conclusive data on what type of patient or disease process to best use them for. Evidence supporting many of these therapies is limited as few have been subjected to randomized, double-blind, controlled trials, and many of the reported studies are often limited by small sample size, poorly characterized patient populations, incompletely described interventions, poorly defined outcomes, or short duration of follow-up.

Psychotherapy. Psychotherapy may be useful in earlier stages of dementia before short-term memory is too impaired. A 2014 Cochrane review of six studies looking at the effects of therapy on depression and anxiety in individuals with dementia and MCI demonstrated a reduction of depressive symptoms; however, there was no effect on self-rated or caregiver-rated anxiety. The psychotherapeutic approaches in these studies ranged from therapeutic counseling to cognitive behavioral therapy to brief interpersonal psychodynamic therapy. In the latter, emphasis was placed on improving interpersonal relationships and included the caregiver for a brief portion of each session.

Reminiscence therapy has also been studied in dementia. This therapy allows patients to recall and relive past life events, stimulating memory and mood within the context of their life history. This therapy has resulted in modest short-term gains in mood, behavior, and cognition in “confused” older adults.

Telegram: @medical_k

www.konkur.in

Behavioral Management. Behavioral management has an important role in the management of dementia. Behavioral treatments that identify antecedents and consequences of problem behaviors and then effect changes in the environment to alter the behaviors have been shown to be beneficial in reducing disruptive behaviors in small trials and case studies and are widely employed in clinical practice. For example, scheduled toileting can reduce the frequency of urinary incontinence. Behavior management training programs for caregivers in the community or in residential or nursing homes have shown modest reductions in problem behaviors and, in some studies, improvement in mood, cognition, and physical role function. Limited follow-up data suggest that the benefits do not persist beyond the intervention.

Cognitive Training. Cognitive training places a focus on the guided practice of tasks, with the goal of improving orientation, memory, attention, and problem-solving. A 2019 Cochrane review examining 33 studies found cognitive training to be associated with small to moderate positive effects on global cognition and verbal semantic fluency when compared to a control intervention, but not to alternative treatments, such as occupational therapy, mindfulness, or reminiscence therapy. Future trials are needed to establish whether these effects are retained in the long term.

Stimulation-Oriented Therapies. Stimulation-oriented therapies aimed at enhancing pleasurable activities have some support from clinical trials. Examples include recreational therapy (i.e., crafts, games), art therapies, pet therapy, multisensory stimulation, simulated presence, aromatherapy, and exercise. Results with most of these modalities are mixed, with some studies demonstrating improvements in mood and behavior and reductions in agitation and problem behaviors and others showing no significant benefit. Despite the lack of convincing evidence for these modalities, their inclusion in a multimodal treatment plan for patients with dementia is humane and makes sense.

Psychoeducation. Providing education to patients and their families about dementia, its course, consequences, and treatment is important in helping them to plan for future disability. While anticipating the upcoming stages can be difficult, it affords patients the opportunity to make arrangements while they are still able to be involved in the decision-

Telegram: @medical_k

www.konkur.in

making process. There are many excellent resources, including books and community agencies, available to help guide families through the caregiving process.

Safety Awareness and Management

HOME SAFETY. Another important aspect of dementia management is maintaining safety in the community and at home. Patients with dementia are at greater risk for accidents. Forgetting to turn off the stove while cooking can lead to fires. Individuals may have more difficulty preparing meals, so assistance for this from family or supplemental meal programs may be helpful. Forgetting to lock doors can increase the risk of burglary or home invasion. As dementia becomes more severe, patients are at higher risk of wandering, so door alarms or identification bracelets may be necessary. Dementia patients are more vulnerable to predatory scams through door-to-door, phone, or mail solicitation. Assessing gait and risk of falls as well as a patient's insight into what to do during an emergency is also important. Addressing threats to patients' safety is necessary to protect patients from inadvertently harming themselves or others.

MEDICATION MANAGEMENT. As patients have more difficulty with memory and executive functioning, it may be more difficult for them to manage their own medications, particularly if they are required to take multiple medications or medications multiple times a day. The assistance of a family member is often necessary, and at times may be needed during the MCI stage.

DRIVING. Driving safety is an important issue. Dementia patients are at greater risk for motor vehicle accidents. Patients should be advised to limit their driving in the mild stages of dementia and to stop driving at the first signs of impaired driving ability or accidents or when they have reached the moderate stage of illness. Referral for driving evaluations is recommended to assess driving skills when in doubt or to confirm to patients their limitations. Many states have mandatory reporting laws. Driving restrictions can be very difficult for patients to accept due to the loss of independence. Families often need to get involved in enforcing these restrictions, removing keys, or disabling or removing vehicles.

Telegram: @medical_k

www.konkur.in

Legal and Financial Planning. Patients and their families should be encouraged to pursue legal planning such as living wills, power of attorney, and guardianship for when they no longer have the capacity to make decisions for themselves. Careful financial planning for in-home or facility-based care is often needed and is best accomplished in advance.

Caregiver Support. Caregiver burden associated with caring for a loved one with dementia is great. About two-thirds of dementia caregivers are women, and almost a third are age 65 or older. Over half of caregivers are caring for a parent or in-law with dementia, and about 10% are caring for a spouse with dementia. In 2020, caregivers provided an estimated 15.3 billion hours of unpaid help or 26.3 hours of care per caregiver per week. As individuals with dementia decline, they become more dependent and require help with more activities of daily living. Caregiving is physically as well as emotionally demanding because the patient has less ability to communicate, eventually may not recognize the caregiver, and frequently exhibits inappropriate and difficult behaviors. Fifty-nine percent of caregivers report high to very high emotional stress from caregiving. Caregivers are at risk of physical injury by the patient during periods of providing direct assistance with activities of daily living or due to agitation or acting on delusional beliefs. Behavioral disturbance in patients is a major source of caregiver burden and also increases the risk for caregiver depression. Finally, caregivers also frequently become isolated from their social supports as patients can no longer engage in their usual social functions. The lack of social support is another risk factor for developing depression.

Caregiver stress and depression can also impair the caregiver's ability to provide adequate and appropriate care and is a risk factor for abuse and neglect of the demented patient. Therefore, treatment of the demented patient must also include addressing the needs of, and when appropriate, treating the caregiver. Interventions shown to reduce caregiver burden include psychoeducation about dementia and comprehensive support, including individual and family counseling and support groups. Problem-solving therapy for caregivers of individuals with dementia and MCI has recently been shown to be effective in reducing depression and anxiety. Multidisciplinary and individualized approaches particularly aimed at managing problem symptoms and behaviors may be especially beneficial.

Telegram: @medical_k

www.konkur.in

Abuse and Neglect. Patients with dementia are at greater risk for elder abuse and neglect. The strains of caregiving are a risk factor for caregivers to abuse those in their care. In addition, due to poor memory and inability to recall or solve problems, the individual with dementia may be less likely to report abuse, or the veracity of their reports may be questioned.

There are several instruments used to screen for elder mistreatment, but none has been widely accepted. In situations where abuse or neglect of the demented patient is suspected, further evaluation is indicated. Reporting is mandated in some states when elder mistreatment is suspected so that a complete investigation can be conducted and interventions performed when necessary.

End-of-Life Issues. Dementia is a terminal illness. Alzheimer disease is listed as the sixth leading cause of death in the United States and as the fifth leading cause of death worldwide.

While patients often die of intercurrent illnesses before the end stage of dementia, many patients succumb in the end stage of dementia, often due to pneumonia or other infections. Complications of end-stage dementia include loss of appetite, inability to feed oneself, and swallowing difficulties, making it difficult to ensure adequate nutrition. When dementia progresses to this stage, families will be faced with decisions regarding many life-prolonging interventions, including placement of feeding tubes and treatment of emergent infections. Ideally, these issues will have been addressed with the patient while in early illness stages or via a preexisting advance directive, so the patient's wishes can be used to guide the decision-making process.

Palliative care, and eventually hospice, are important treatment aspects to consider, as it allows the focus of treatment to be on the relief of symptoms, and in doing so help to prevent both under treatment of symptoms such as pain, as well as overtreatment of other symptoms with possibly aggressive means. Symptoms palliative care can help focus on include pain, eating and drinking problems, and breathlessness. The incorporation of palliative care may also be helpful in the reduction of caregiver burden.

A main challenge in the integration of palliative care and hospice services in the treatment of dementia is identifying the appropriate timing, particularly as dementia is often not acknowledged as a terminal illness.

Telegram: @medical_k

www.konkur.in

The National Hospice and Palliative Care Organization notes that a patient is likely to die within six months if their FAST is at stage 7 and there are one or more listed medical or nutritional complications; stage 7 is defined as dependence in all activities of daily living, occasional incontinence of bowel and bladder, and speech limited to five words. The advanced dementia prognostic tool (ADEPT) was developed with the goal of estimating 6-month survival in nursing home residents with advanced dementia and appears to be more useful as a continuous measure. This index weighs the following factors in determining a risk score: length of stay in the nursing home, age, male sex, shortness of breath, presence of at least one pressure ulcer at stage 2 or higher, activities of daily living, length of time spent in bed, poor oral intake, bowel incontinence, BMI of less than 18.5, recent weight loss, and congestive heart failure.

Pharmacologic Treatments

Pharmacologic treatments available for dementia are limited to symptomatic relief. To date, with the exception of interventions to reduce the risk of recurrent stroke in vascular dementia, there are no treatments available that can alter the disease course or produce substantial or long-lived improvements in symptomatology.

Treatment of Neuropsychiatric Manifestations

Treating the neuropsychiatric manifestations is an important part of the management of the patient with dementia. The neuropsychiatric manifestations, particularly agitation, behavioral disturbances, and psychosis, contribute substantially to caregiver stress and often prompt transitions to higher levels of care. These neuropsychiatric symptoms can occur with all etiologies of dementia. It is estimated that 97% of individuals with dementia will experience a noncognitive neuropsychiatric symptom as part of their dementia. Adequate control of these symptoms can markedly improve the quality of life of the patient and caregiver alike.

Psychosis and Behavioral Disturbance. Psychotic symptoms in dementia include hallucinations, delusions, and paranoia which are often associated with agitation or aggression. The term agitation as it relates to individuals with cognitive impairment or dementia covers a broad array of behaviors and has been defined by the International Psychogeriatric Association as behavior consistent with emotional distress, manifesting

Telegram: @medical_k

www.konkur.in

itself as excessive motor activity, verbal aggression, or physical aggression, which causes excess disability and is not solely attributable to another cause. Motor activity may include pacing, rocking, gesturing, pointing fingers, restlessness, or performing repetitious mannerisms. Verbal aggression can include yelling, screaming, shouting, or the use of profanity. Physical aggression can be directed toward a target or not and may include behaviors like grabbing, shoving, hitting, pushing, kicking, scratching, biting, or destroying property. Agitation can occur both with and without aggression. Agitation is present in many outpatients with dementia and maybe even more common in those residing in nursing facilities.

NONPHARMACOLOGIC MANAGEMENT. Nonpharmacologic treatments of neuropsychiatric symptoms are first-line, with the goals of nonpharmacologic management being prevention of the problematic behavior, symptom relief, and reduction of caregiver stress. The DICE approach has been identified as a nonpharmacologic approach to the management of these symptoms and involves the provider, the caregiver, and the individual with dementia if possible. The first step is to *describe* the problematic behavior in the context of its occurrence. The second step requires the provider to *investigate* potential underlying and modifiable causes of the behavior, such as problematic medications, pain, infection, change in routine, etc. The third step in this approach is to then *create* and implement a treatment plan for the behavior; this step often requires collaboration between the different parties involved and should take into account the patient, the caregiver, and the environment. Finally, the last step of this approach is to *evaluate* whether the treatment plan was instituted and the effectiveness of this.

The creation of a treatment plan often involves caregiver education, enhancing communication between the caregiver and the individual with dementia, and helping the caregiver to identify simplified yet meaningful tasks and routines for the individual with dementia. When a target behavior is associated with a particular activity, either modifying the activity or avoiding it if possible, can eliminate the behavior. Simplifying activities or modifying expectations to the cognitive and skill level of the patient can eliminate frustration. Modifying the environment to compensate for the patient's deficits can eliminate triggers for problem

Telegram: @medical_k

www.konkur.in

behaviors. Ensuring adequate sleep, nutrition, and stimulating activities can also help reduce agitation.

When the behavior poses a threat to the patient's or caregiver's safety, more restrictive measures must be considered. In a nursing home or hospital setting, one-on-one supervision may be required. The use of physical restraints should be avoided if possible as they may increase the risk of falls and mortality.

When nonpharmacologic measures are ineffective, or safety is an issue, pharmacologic approaches should be considered; however, risks associated with these medications may outweigh the potential benefit. As such, it is essential that a discussion between the clinician and the patient's surrogate decision-maker occur when pharmacologic treatments are being considered.

PHARMACOLOGIC TREATMENTS

Selective Serotonin Reuptake Inhibitors. There have been several studies of SSRIs in the management of behavioral disturbance. As the tolerability of these medications may be greater than that of the antipsychotics, they may help in the management of agitation, especially in patients in whom the risk-benefit ratio for the use of antipsychotic medication is not favorable. A 2011 Cochrane review of nine trials examining the effects of antidepressants and trazodone on agitation found there to be limited evidence to support their use. The Citalopram for Agitation in Alzheimer disease study found that patients who were treated with citalopram compared to placebo were less likely to show delusions, anxiety, irritability, or lability, and caregiver distress was also decreased. However, treatment was also associated with a worsening of cognition and prolongation of the QTc interval.

Antipsychotics. The second-generation antipsychotics risperidone (Risperdal), olanzapine (Zyprexa), quetiapine (Seroquel), and aripiprazole (Abilify) have been studied in placebo and active comparator-controlled trials of psychosis and agitation in dementia in both nursing home and community outpatient settings. Studies of risperidone, olanzapine, and aripiprazole have shown modest but clinically significant improvements in measures of agitation, aggression, psychosis, and behavioral disturbances. These agents are indicated as first-line treatments in patients with dementia when agitated, aggressive, or psychotic behaviors

Telegram: @medical_k

www.konkur.in

are present and either the patient's function is impaired, or they are endangering themselves or others.

A meta-analysis of these studies demonstrates greater benefit for symptoms of agitation than psychosis. There is also a significant placebo response rate in these studies suggesting the importance of nonpharmacologic measures in the treatment of agitation and psychosis. The largest comparison study of three different second-generation antipsychotics—risperidone, quetiapine, and olanzapine—in patients with Alzheimer disease and psychosis or agitation treated for up to 36 weeks, the CATIE-AD trial, demonstrated no differences between any of the treatment groups and placebo in the primary outcome measure, time to discontinuation of treatment for any reason. However, time to discontinuation for lack of efficacy favored olanzapine and risperidone, while time to discontinuation due to adverse events or intolerability favored quetiapine and placebo.

First-generation antipsychotics have also been extensively studied for the treatment of psychosis and agitation in dementia. Two meta-analyses of these trials showed clinically significant improvement with several first-generation antipsychotics of 59% and 64% compared to 41% and 38% with placebo, respectively. There were no significant differences between agents. However, adverse effects were common, and drop-out rates were high.

Clozapine (Clozaril) has been shown to be useful in controlling psychotic symptoms in patients with Parkinson disease and DLB due to the absence of extrapyramidal side effects. There is no currently available data to support the efficacy of ziprasidone (Geodon), iloperidone (Fanapt), lurasidone (Latuda), asenapine (Saphris), and paliperidone (Invega) in treating behavioral disturbances in dementia. In 2023, the FDA approved brexpiprazole (Rexulti) specifically for the treatment of agitation associated with dementia due to Alzheimer disease; this is the first treatment to be approved for this indication.

Antipsychotic medications are associated with serious side effects and morbidity, particularly in the older adults. The first-generation antipsychotics, particularly the high potency agents such as haloperidol, are associated with a higher risk of tardive dyskinesia, neuroleptic malignant syndrome, akathisia, and parkinsonism. The low-potency agents, such as chlorpromazine, are associated with central and peripheral anticholinergic effects, sedation, and postural hypotension.

Telegram: @medical_k

www.konkur.in

Second-generation antipsychotics are associated with an increased risk for metabolic syndrome, including weight gain, diabetes mellitus, and hyperlipidemia, but can also cause sedation, fatigue, and extrapyramidal side effects as well.

Both first- and second-generation antipsychotics have been associated with increased risk of cerebrovascular events and mortality, with first-generation medications having a slightly higher risk. In discussing the risks and benefits of these medications, it is important to recognize the above risks, as well as the risks of untreated or undertreated psychosis and agitation, which could lead to inadvertent harm to self or others, restraint use, poor quality of life, and placement in a higher level of care. Therefore, the use of antipsychotic medications for the treatment of psychosis and agitation must be carefully considered after nonpharmacologic measures have been implemented, weighing the evidence for the potential benefit for target symptoms, against the risks of the medications themselves and the risks of alternative approaches to maintaining safety.

After 4 weeks of treatment with antipsychotic medications, if there is no clinical improvement, then the medication should be tapered and withdrawn. If an antipsychotic trial is beneficial, there should be a discussion with the patient and surrogate decision-maker about the benefits of the medication, potential harm, and previous attempts at a taper, with consideration being given to the recommendation to taper and withdraw the medication within four months of initiation. The patient should then be assessed at least monthly for the reemergence of symptoms for at least 4 months after discontinuation. Long-acting antipsychotic injectable medications should not be utilized unless it is also indicated for a co-occurring chronic psychotic disorder.

Benzodiazepines. Benzodiazepines have been compared to placebo as well as to antipsychotics for the treatment of behavioral disturbances. In general, they are more effective than placebo but less effective than antipsychotics in controlling behavior symptoms. However, they may be associated with paradoxical effects, disinhibition, worsening cognition, and falls. Cumulative toxicity tends to be greatest with long half-life agents, which should be avoided. At present, the use of benzodiazepines is largely limited to short-term control of acute agitated behavior with short-acting agents such as lorazepam (Ativan) or oxazepam (Serax).

Telegram: @medical_k

www.konkur.in

Anticonvulsants. Data on the use of carbamazepine (Tegretol) is favorable. It has been shown to have modest benefits for agitation in short-term trials; however, its risk of side effects and drug-drug interactions are limiting. Oxcarbazepine and valproate (Depakene) have not been shown to be efficacious in randomized controlled trials. A 2019 review of 15 case series and reports suggest a possible benefit of gabapentin and pregabalin for the treatment of behavioral symptoms, but no randomized controlled trials have been performed. The newer anticonvulsants have not been studied for behavioral disturbances in dementia.

Others. There is some evidence to suggest that trazodone may be helpful in decreasing irritability, anxiety and restlessness, and affective disturbance, especially in patients with FTD. Acetylcholinesterase inhibitors and memantine have been shown to have little benefit in the treatment of agitation and psychosis. Pimavanserin, which is a selective 5-HT_{2A} receptor inverse agonist and antagonist, demonstrated potential efficacy in the treatment of psychotic symptoms in Alzheimer dementia in a randomized placebo-controlled study, with there being a larger treatment effect shown in patients with more severe psychotic symptoms at baseline. The benefit of treatment compared to placebo was significant at 6 weeks but not at 12 weeks. A Cochrane review showed potential benefits of methylphenidate in the improvement of apathy in dementia, as well as possible improvement of cognition and instrumental activities of daily living. There is some evidence to support the use of prazosin for the treatment of behavioral symptoms in patients with agitation or aggression, and there is currently an ongoing multicenter trial evaluating the use of prazosin in adults with Alzheimer dementia. Treatment with the combination dextromethorphan-quinidine resulted in a significant decrease in agitation and aggression in one randomized placebo-controlled trial in patients with probable Alzheimer dementia. A 2020 systematic review and meta-analysis examining the use of cannabinoids, including tetrahydrocannabinol, dronabinol, and nabilone, for the treatment of neuropsychiatric symptoms was supportive of the efficacy of these agents and found them to be well tolerated. Minimal evidence supports the use of beta-blockers or lithium (Eskalith), and both classes of agents can have significant adverse events that preclude recommending them for use in a frail older adults population. There is minimal evidence

Telegram: @medical_k

www.konkur.in

that buspirone (Buspar) may be efficacious in the treatment of agitation or anxiety in dementia.

Depression. Several antidepressants have been studied for the treatment of depressive symptoms in patients with Alzheimer disease. SSRIs have been the most studied, as there are clinical concerns regarding the tolerability and risk profile of tricyclics and monoamine oxidase inhibitors. A 2018 Cochrane review was not supportive of the efficacy of antidepressants for the treatment of depression in dementia. Similarly, a 2011 review of seven studies with 330 participants found that while two studies found antidepressants to have a benefit over placebo, overall, efficacy was only suggested and not confirmed. There is no data clearly favoring any specific antidepressant; however, because of its very long half-life in the older adults, fluoxetine (Prozac) is not generally recommended. There are no controlled trials of electroconvulsive therapy in the depression of dementia.

Nonpharmacologic interventions may be efficacious in the treatment of depression in dementia and include cognitive stimulation, exercise, massage and touch therapy, multidisciplinary care, occupational therapy, and reminiscence therapy.

Sleep Disturbance. Sleep disturbance is common in dementia, with individuals having decreased nocturnal sleep time, increased sleep fragmentation, and increased daytime sleepiness. A dual approach of enhancing sleep at nighttime through improved sleep hygiene and decreasing nocturnal interruptions, like light and sound, coupled with increasing daytime wakefulness through social and physical activity is important. One small study looking at the effects of trazodone showed improvements in nocturnal sleep time. Melatonin and ramelteon have not been found to be efficacious. There have been no randomized controlled trials of benzodiazepines or the nonbenzodiazepine sedative-hypnotics for the older adults with dementia, but because of their potential for cognitive and gait impairments, they are not recommended.

HEALTH DISPARITIES IN DEMENTIA

There are significant health and healthcare disparities present in dementia diagnosis, risk, and quality of care patients and their caregivers receive. The higher prevalence of dementia in African American and Hispanic

Telegram: @medical_k

www.konkur.in

populations magnifies these inequities. These disparities begin to evolve decades before the diagnosis of dementia is made, and many are related to the modifiable risk factors described above, such as the correlation between lower education and higher dementia risk. Minority and lower socioeconomic communities may be more likely to live in areas with higher exposure to pollution, further exacerbating their risk of dementia during their life course. Additional risks of hypertension, diabetes, and obesity, all carry with them their own contributing social and economic determinants, which then serve to further exacerbate the risk of dementia.

Experiences with discrimination when receiving medical care are common for people of color; half of Black Americans and more than a third of Native, Asian, and Hispanic Americans report that they have experienced healthcare discrimination, with many of these individuals citing discrimination as a barrier to receiving dementia care in the future. When caregivers are surveyed, Black, Hispanic, Asian, and Native Americans have all reported feeling like they are not listened to, that they are treated with less courtesy and respect, and that providers have acted like they were not smart in higher numbers when compared to White Americans. There is a strong desire among people of color to find providers who are culturally competent, but there is little confidence in their ability to do so.

The lack of trust in medical research among many individuals of color, as well as differing knowledge about the symptoms of dementia compared to normal aging, will only serve to worsen these inequities going forward. An awareness of these barriers, as well as a better understanding of the impact of many of these modifiable risks, provides opportunities to advocate for systemic change going forward.

COVID-19 AND DEMENTIA

The COVID-19 pandemic has disproportionately affected older individuals. Individuals with dementia are particularly vulnerable as most rely on other people for at least some if not significant assistance in IADLs and ADLs. An individual's cognitive impairment may also make it difficult to adhere to mitigation measures. Many individuals with dementia live in nursing homes or assisted livings, and as such, were at increased risk of contracting COVID-19 from the communal nature of their residence. The recommendation for social/physical distancing and limitations placed on

Telegram: @medical_k

www.konkur.in

visitation, while important in mitigating disease spread, brought with them significant psychological ramifications, including increased loneliness as well as neuropsychiatric symptoms for many individuals with dementia, both in the community and long-term care settings. In 2020, there were approximately 16% more deaths than expected from Alzheimer disease. In death certificates listing COVID-19 as the primary cause of death, 4% listed Alzheimer disease as one of the multiple causes of death, and 11% listed vascular or unspecified dementia as an additional cause. This discrepancy was even more notable in individuals over the age of 85 who died from COVID-19, where Alzheimer was listed in 8% of death certificates, and vascular or unspecified dementia was listed in 20%. The COVID-19 pandemic also placed increasing stress among caregivers of individuals with dementia, as community supports temporarily closed and opportunities for respite became limited.

MAJOR NEUROCOGNITIVE DISORDER SUBTYPES

Alzheimer Disease

Definition. Dementia of the Alzheimer type is the most common form of dementia. The onset and steady progression of Alzheimer disease tend to follow a characteristic pattern, with diagnosis typically made on the basis of clinical history. However, autopsy studies have shown that up to 15% to 30% of clinically diagnosed Alzheimer dementias do not actually show pathologic changes indicative of Alzheimer disease. With the emerging knowledge in the field of biomarkers, diagnostic clarity is gradually shifting to a future where there are both clinical symptoms and objective pathologic changes needed for a diagnosis of Alzheimer dementia. While there is a better understanding of Alzheimer dementia than many other forms of dementia, there is still much to understand to be able to provide preventative strategies and treatments that can alter the disease course. There have been tremendous advances in the last decade in the understanding of the pathophysiology and genetics of Alzheimer disease. However, treatments are limited to symptomatic relief and modest delays of progression. Given the high prevalence in older age and advancing age of the population, Alzheimer disease is a growing problem affecting the lives of not only the sufferers but also their families.

Telegram: @medical_k

www.konkur.in

History. Alois Alzheimer first described the illness in 1906 when he reported the case of a 51-year-old woman with a progressive cognitive disorder marked by memory loss, confusion, topographical disorientation, aphasia, and prominent neuropsychiatric manifestations of persecutory delusions, misidentifications, and behavioral disturbances. At her death 4 years later, the autopsy revealed profound atrophy, amyloid plaques, and neurofibrillary tangles.

Comparative Nosology. According to the DSM-5, a diagnosis of probable major neurocognitive disorder due to Alzheimer disease is made when the criteria for major neurocognitive disorder are met, and there is either evidence of a causative genetic mutation or the individual shows impairment in memory and learning, in addition to one other cognitive domain. There must also be a steadily progressive decline, and there is no evidence of another etiology of the cognitive impairment. Diagnosis is further classified into subtypes of with or without behavioral disturbance.

Specific criteria for Alzheimer disease were also defined by the National Institute of Neurological and Communicative Disorders and Stroke—Alzheimer disease and Related Disorders Association Work Group (NINCDS-ADRDA) in 1984. These diagnostic recommendations were revised in 2011 by the National Institute on Aging-Alzheimer's Association (NIA-AA) workgroups. The 2011 guidelines identified three stages of Alzheimer disease: the preclinical stages of Alzheimer disease, MCI due to Alzheimer disease, and dementia due to Alzheimer disease. For a diagnosis of probable Alzheimer dementia, an individual must first meet the criteria for dementia described above; additionally, the symptoms should be of insidious onset, and there must be a report of worsening cognition. The diagnosis of probable Alzheimer disease has additional descriptors for the incorporation of documented decline or when it is diagnosed in a carrier of a causative Alzheimer disease genetic mutation. A diagnosis of possible Alzheimer disease dementia can be made when there is an atypical course, or an individual is showing signs of a dementia with mixed etiologies. Finally, the 2011 NIA-AA guidelines described a third category of diagnosis for when the criteria for probable Alzheimer disease dementia is met, and there is biomarker evidence supporting the diagnosis.

Since 2011, additional biomarkers have become recognized, and it became important to identify a more biologically based approach to the

Telegram: @medical_k

www.konkur.in

diagnosis of Alzheimer disease, particularly for observational and interventional studies. Utilizing a combination of cognitive staging and a biomarker profile, the NIA-AA updated its guidelines in 2018, with the main goal being to define and stage Alzheimer disease across the entire spectrum, ultimately helping to shift the diagnosis from a clinical set of symptoms to one defined by its pathologic process. While this framework is currently only intended for research purposes, it does provide an approach to think about Alzheimer disease as a continuum and allows for the incorporation of new biomarkers as they become available. It should be noted, however, that relying merely on biomarkers for diagnosis could lead to problems with a predictive accuracy of the diagnoses of MCI and dementia. Those individuals who are biomarker positive for Alzheimer disease but are cognitively unimpaired should only be considered at risk for progression to dementia, as the diagnosis of Alzheimer dementia should be based on both clinical and biologic factors. In addition, sole reliance on biomarkers for a specific dementia at one point in time has the potential to exclude additional etiologies of dementia that may also be present. Biomarkers will be discussed more in-depth below.

Epidemiology. 6.2 million Americans are estimated to have Alzheimer dementia in the year 2021. With the aging of the population, projections estimate that by the year 2060, 13.8 million people over the age of 65 will have Alzheimer disease, with 6.7 million of those individuals being over the age of 85.

The prevalence of the disease increases with age, with 5.3% of individuals age 65 to 74 estimated to have Alzheimer dementia, 13.8% of individuals between the ages of 75 to 84, and 34.6% of individuals over the age of 85 estimated to have Alzheimer dementia. More women than men in the United States have Alzheimer dementia, with 12% of women over age 65 compared to 6% of men. One of the main reasons for this disparity is the longer life span of women on average compared to men, but other possible contributing causes include differences in biology, as well as environmental and geographical or cultural factors. Older Black and Hispanic Americans are more likely than older White Americans to have Alzheimer or other dementias, with 18.6% of Black Americans and 14% of Hispanic Americans over the age of 65 having Alzheimer dementia, compared to 10% of White Americans. This difference is largely believed to be due to differences in medical comorbidities, such as

Telegram: @medical_k

www.konkur.in

cardiovascular disease and diabetes, as well as health and socioeconomic inequities. Due to projected increases in the age of the population of the United States, each state is expected to experience an increase of prevalence of at least 6.7%, with the West and Southeast portions of the country expected to have the largest increases.

Currently, these prevalence estimates are based on symptomatic clinical diagnosis, but as the field moves toward the incorporation of diagnostic biomarkers, the prevalence of Alzheimer dementia may actually be lower, as 10% to 30% of individuals who were thought to have Alzheimer dementia did not show Alzheimer related neuropathologic changes on autopsy. Conversely, the prevalence of those with Alzheimer disease may rise in the future, as biomarker-based diagnoses become more common, as 30% to 40% of cognitively unimpaired individuals show Alzheimer disease-related pathology on autopsy or have abnormal amyloid biomarkers.

Etiology. The etiology of Alzheimer disease is multifactorial. Mutations or copy number variations within several genes that result in the cleavage of amyloid precursor protein (APP) into Aβ invariably lead to early-onset Alzheimer disease within affected families. In contrast, late-onset Alzheimer disease is a complex disorder in which risk is influenced by multiple genes, environmental factors, and by their interactions.

GENETICS

Early-Onset Alzheimer Disease. Mutations at three genetic loci associated with early-onset Alzheimer disease have been identified. The first identified Alzheimer disease gene was the APP gene located on chromosome 21. Over 30 different mutations in APP that can cause Alzheimer disease have been identified in fewer than 100 families worldwide. More recently, families with duplications of APP, leaving the mutation carrier with a total of three copies of the gene on their two chromosomes, have been reported. This is similar to the increased risk of Alzheimer disease associated with trisomy 21. A second Alzheimer disease locus was found on chromosome 14, presenilin-1 (PS1). More than 180 mutations in the PS1 locus have now been reported in several hundred families throughout the world. The onset of symptoms for those with PS1 mutations is often before age 50, though later ages are possible. Like the APP mutations, PS1 mutations appear to act as autosomal

Telegram: @medical_k

www.konkur.in

dominant traits with nearly complete penetrance (i.e., inheriting a single copy of the mutated gene is sufficient to cause disease in all individuals). A third Alzheimer disease gene has been localized to chromosome 1 and termed presenilin-2 (PS2). These mutations appear to be rare; only a few families of different ethnicity have been identified with PS2 mutations. Although the PS2 mutations are autosomal dominant, they may not be fully penetrant. PS2 mutations generally lead to the onset of Alzheimer disease symptoms before age 65. There has been conflicting information on the proportion of early-onset cases attributable to mutations in APP, PS1, and PS2. Some reports have suggested that PS1 mutations may account for most early-onset familial Alzheimer disease cases. Others have reported that a more realistic estimate is 20% or fewer of such cases, with PS2 and APP accounting for 1% and 5%, respectively. For the remainder of individuals with early-onset familial Alzheimer disease, it is unclear whether other causative single-gene mutations will be identified or if these will prove to be multigenic in origin.

Late-Onset Alzheimer Disease. The first gene to have an established relationship to late-onset Alzheimer disease was apolipoprotein E, with an increased risk of Alzheimer disease found in individuals carrying the epsilon 4 allele (APOE4) in both familial and sporadic cases. The risk of Alzheimer disease increases, and the mean age of onset of Alzheimer disease is earlier, as the number of epsilon 4 alleles an individual carries increases from 0 to 2. A single copy of the APOE4 allele confers an approximate two- to four-fold increased risk while two APOE4 alleles increase the risk by approximately four- to eightfold. The magnitude of the risk associated with APOE4 may vary by age, and ethnicity, with the risk, attenuated in older individuals and in African American and Hispanic individuals (relative to Caucasians). In contrast, the risk conferred by APOE4 may be increased in individuals of Japanese ethnicity. It is generally estimated that APOE4 accounts for up to 50% of the genetic contribution to late-onset Alzheimer disease. Nevertheless, carrying one or even two APOE4 alleles is neither necessary nor sufficient for the development of Alzheimer disease. It has been estimated that for those who are disease-free at age 65, at most 50% of APOE4 homozygotes will develop Alzheimer disease within their lifetimes, thus limiting the use of APOE4 genotype as a predictive test. Alternatively, when APOE4 testing is added to the evaluation of individuals clinically diagnosed with cognitive

Telegram: @medical_k

www.konkur.in

symptoms consistent with dementia, it tends to lower the sensitivity but enhance the specificity of the diagnosis of Alzheimer disease.

Recent genome-wide association studies have identified 40 known susceptibility loci in Alzheimer disease in European populations. Implicated genes thus far include *APOE, CR1, BIN1, TREM2, CLU, SORL1, ADAM10, ABCA7, CD33, SPI1, PILRA, HLA-DRB1, CD2AP, PT2KB, PICALM, CASS4, SPI1, MS4A4A,* and *MS4A6A*. Most Alzheimer disease loci do not yet have functional variants or genes associated with them. In addition, genomic research is still needed in more diverse populations.

AMYLOID-β PROTEIN AND HYPERPHOSPHORYLATION OF MICROTUBULE-ASSOCIATED PROTEIN τ. The identification of causative mutations in early-onset familial Alzheimer disease has been a key piece of evidence indicating the causal role of Aβ protein in Alzheimer disease. As noted above, extra copies of APP via mutation or trisomy of chromosome 21 result in Alzheimer disease. It is noteworthy that, as assessed in animal and in vitro systems, the expression of the identified mutations in APP, PS1, and PS2 that lead to early-onset familial Alzheimer disease all result in overproduction and/or increased aggregation of Aβ. These genetic findings have also provided the key to understanding how APP is metabolized in the brain into Aβ. In brief, APP protein is cleaved by three enzymes, α-, β-, and γ-secretase. Cleavage by β-secretase then γ-secretase generates Aβ, while cleavage by α-secretase yields a nontoxic peptide.

More recently, the pathway from the overproduction of Aβ to the development of cognitive deficits has been substantially elaborated. It has been appreciated for a number of years that the strongest correlate of cognitive impairment in individuals with Alzheimer disease is loss of synapses across cortical regions. Substantial evidence now indicates that self-aggregation of Aβ into soluble low-n oligomers is a primary source of synaptotoxicity in Alzheimer disease. Soluble Aβ oligomers exist in equilibrium with fibrillar deposits of Aβ in plaques. Plaques themselves form substantial space-occupying lesions in the cortex of individuals with Alzheimer disease and serve as a site for inflammatory responses. Both these mechanical and inflammatory processes may further contribute to synapse loss and neuronal death.

Telegram: @medical_k

www.konkur.in

In addition to the direct effects of Aβ on synapse loss, Aβ may lead to synapse loss and neuronal death via other downstream effectors. In a healthy brain, tau is a highly soluble and unfolded protein. Mainly found in axons, it is involved in the formation of tubulin into microtubules. Aβ contributes to the hyperphosphorylation of microtubule-associate protein τ (MAPT), which subsequently enhances its aggregation into neurofibrillary tangles. This consequently causes synapse loss and neuronal death independent of the effects of Aβ. Aggregation of α-synuclein also occurs in some individuals with Alzheimer disease and can contribute independently to cognitive impairments. At present, however, whether the aggregation of α-synuclein is enhanced by a mechanism related to Aβ is not known.

As the pathologic cascade in Alzheimer disease progresses, other brain changes may become evident. For example, numerous neurochemical abnormalities have been demonstrated on autopsy and with functional neuroimaging in Alzheimer disease in later disease stages. These include deficits in acetylcholine (ACh), norepinephrine, serotonin, dopamine, γ-aminobutyric acid (GABA), glutamate, corticotrophin-releasing hormone, and somatostatin. The most robustly described neurochemical deficits are in the cholinergic system. The activity of choline acetyltransferase, the enzyme responsible for the final step of ACh synthesis, is substantially reduced in patients with Alzheimer disease. This has been confirmed in the autopsy of patients with at least a moderate stage of the illness but not in patients with mild illness. This is particularly evident in the nucleus basalis of Meynert and several neocortical regions. This finding has led to the successful development of efficacious therapies directed at the enhancement of cholinergic function.

As excitatory synapses onto dendritic spines are particularly affected by Aβ-induced synaptic loss, it is not surprising that reductions in glutamate receptors, which are predominantly located at postsynaptic sites on dendritic spines, have been described in Alzheimer disease. The relationship between Aβ-induced synapse loss and glutamate receptors is complex. Aβ appears to destabilize dendritic spines, resulting in retraction and synapse loss via modulation of the function of both α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid (AMPA) and *N*-methyl-D-aspartate (NMDA) classes of postsynaptic glutamate receptors. It is therefore not surprising that memantine (Namenda), a low-affinity NMDA

Telegram: @medical_k

www.konkur.in

antagonist that functions to modulate the activation of NMDA receptors, has been shown to be of benefit in Alzheimer disease.

RISK AND PROTECTIVE FACTORS. In addition to the above-discussed risk and protective factors for dementia as a whole, there are some additional factors more specific to Alzheimer dementia which will be reviewed below.

Age remains the greatest risk factor for developing Alzheimer disease.

Epidemiologic studies have suggested that people with less education are at increased risk of developing Alzheimer disease. Functional neuroimaging findings of patients with Alzheimer disease indicate that people with higher educational attainment or higher premorbid intellectual functioning but similar levels of dementia severity have more severe findings on neuroimaging.

TBI can increase the rate of cognitive decline in the older adults and is associated with an increased risk of developing dementia, and in particular, Alzheimer disease. There is evidence that head trauma can lead to overexpression of APP, increase inflammatory mediators, and cause Aβ deposition in the brain. The effects of traumatic injury on Aβ may be mediated by the APOE genotype.

Estrogen's role in the development of Alzheimer disease remains unclear. On a neuronal level, estrogen increases the density of a synaptic population lost in Alzheimer disease, excitatory synapses onto dendritic spines, in both hippocampus and cortex. It also may interact with APP processing to increase brain Aβ concentrations. However, prospective studies of estrogen treatment in patients with Alzheimer disease have yielded little evidence of cognitive enhancement or reduced cognitive decline. Similarly, results from the Women's Health Initiative indicated no prevention of cognitive decline with estrogen replacement therapy in women aged 65 years or older and evidence of increased incidence of dementia in those women receiving combined estrogen/progesterone replacement therapy. The argument has been made that the timing of the hormone replacement (i.e., more effective during the perimenopausal or very early postmenopausal periods) may be the critical variable in this; however, current recommendations are that hormone therapy is not to be used in the prevention of dementia.

Several lines of evidence suggest a role of the immune system in Alzheimer disease. Neuropathologic studies demonstrate that the brains of patients with Alzheimer disease have increased concentrations of acute

Telegram: @medical_k

www.konkur.in

phase reactants, cytokines, and complement protein when compared to age-matched controls. A review evaluating the role of NSAIDs in the prevention of dementia showed an association in observational studies between NSAID use and reduced dementia risk; however, the one randomized controlled trial that was included showed no effect of NSAID use on the prevention of dementia. Results from one randomized controlled trial indicate that timing of NSAID use may be important, with NSAID use possibly having an adverse effect on individuals in later stages of Alzheimer disease pathogenesis but who have not yet clinically progressed to dementia. The use of NSAIDs for the prevention of Alzheimer disease is most likely precluded by offsetting risks of bleeding and cardiac toxicity.

Oxidative stress has been postulated to contribute to Alzheimer disease. For example, Aβ can damage and kill neurons by inducing oxidative stress, as can the microglial inflammatory reaction surrounding plaques. Increased markers of oxidative stress have been found in the brains of subjects with MCI, suggesting that these processes may be altered relatively early in the disease course. Thus, antioxidants have been evaluated for evidence that they are neuroprotective. However, a 2011 Cochrane review examining the effects of the antioxidant vitamin E in three studies found no convincing evidence of its beneficial effects on the treatment of Alzheimer disease or MCI. Studies have also not provided sufficient evidence to support treatment with the antioxidant ginkgo biloba.

Diagnosis and Clinical Features. As described above, Alzheimer dementia has a gradual and insidious onset, and there must be two cognitive domains affected, as well as functional impairment. The most common presentation is an amnestic one, in which the primary deficits are in the learning and memory domain. There are also nonamnestic presentations, where the prominent impairment could be in the language, visuospatial, or executive functioning domains. Individuals will have increasing difficulty functioning in their daily activities as the disease progresses.

Biomarkers. As described above, the National Institute on Aging and Alzheimer's Association described a biomarker profile for the diagnosis of Alzheimer disease. Biomarkers are evidence of pathologic change happening in vivo. Biomarkers in Alzheimer disease include those found

Telegram: @medical_k

www.konkur.in

in CSF and imaging studies. In Alzheimer disease, biomarkers can be split into three different groupings.

The first group is indicative of aggregated Aβ or an associated pathologic state and includes cortical amyloid PET ligand binding or low CSF $A\beta_{42}$ or $A\beta_{42}/A\beta_{40}$ ratio. Several agents for PET-amyloid imaging have recently been approved for use. The absence of tracer retention during PET-amyloid imaging indicates that dementia is unlikely to be due to Alzheimer disease (Fig. 10.3–1). The second grouping is indicative of aggregated tau or neurofibrillary tangles or an associated pathologic state and includes CSF phosphorylated tau, or cortical tau PET ligand binding. The third set of biomarkers is indicative of neurodegeneration or neuronal injury and is not necessarily specific to Alzheimer disease and can be evident in other non-Alzheimer disease dementias; these biomarkers include CSF total tau, anatomic MRI, and FDG PET. Quantification of change in global (whole brain and ventricles) and regional (entorhinal cortex, hippocampus, corpus callosum) volumes in patients with Alzheimer disease frequently demonstrate group differences in comparison to cognitively intact older adults patients, with MCI patients intermediate (see Fig. 10.3–2 for an example MRI in a patient with Alzheimer disease). Currently, SPECT and FDG-PET are not established as stand-alone diagnostic tests. However, the addition of SPECT or FDG-PET can increase the diagnostic accuracy of an expert evaluation and can be particularly useful in differentiating individuals with Alzheimer disease from those with an FTD.

Course and Prognosis. The disease typically causes a gradual decline initially in short-term memory and language function. Initially, there is MCI, which may not be recognized by family members or be clinically relevant as there is no significant functional impairment. Gradually these impairments in short-term memory and language worsen until they start to interfere with the ability to perform instrumental activities of daily living.

FIGURE 10.3–1. Pittsburgh Compound B (PIB) binding in normal aging and Alzheimer disease (AD). Comparison of PIB images (*top row*), magnetic resonance images (MRIs) (*center row*), and fluorodeoxyglucose (FDG) images (*bottom row*) from a cognitively normal subject (71-year-old patient; Mini-Mental State Examination [MMSE] score of 30) and two mild AD cases. AD-1 (*center column*) was a 68-year-old patient, had an MMSE score of 26, showed marked PIB accumulation compared to controls but a normal FDG scan. AD-2 (*right column*) was a 69-year-old patient, had an MMSE score of 21, also showed marked PIB accumulation, and an FDG scan typical for AD showing temporoparietal and frontal hypometabolism. Scale bars indicate standardized uptake values (SUVs) for PIB and FDG. Note that the dynamic range of PIB is twice that of FDG. (Courtesy University of Pittsburgh Amyloid Imaging Group.)

Typically, several years pass between the onset of early symptoms and recognition of deficits and presentation to medical attention. There is often a precipitating factor that alerts families to the cognitive impairment and

Telegram: @medical_k

www.konkur.in

prompts them to seek medical attention. The precipitating event can be an intercurrent medical illness that causes delirium, at which time families will look back and, in retrospect, recognize early symptoms of decline in the past. There may be a loss, such as the death of a spouse, that unmasks deficits in functions that had previously been performed for the patient by the deceased. Sometimes symptoms are identified during a change of residence, after which the affected individuals are required to learn their new environment and are unable to meet these demands, calling their families' attention to their impairment.

After the initial presentation, a gradual progressive decline in cognitive function ensues and extends eventually to all cognitive domains, including motor functioning (apraxia) and perception (agnosia). The rate of decline is not necessarily steady as there may be periods of plateau followed by periods of accelerated decline.

As the illness progresses, there will be greater functional impairment and greater dependency needs. The attendant loss of independence may be very difficult for the individual with Alzheimer dementia to accept; depressive symptoms may be evident if their level of insight is not fully impaired. Alternatively, if there is agnosia and a lack of insight into their deficits and impairment, the acceptance of additional help for their functional impairments can be quite difficult. Safety issues become of great concern, especially such things as leaving on the stove and burning food or pots or causing a fire, or driving and the increased risk of traffic accidents. Patients may forget to eat or take their medications, thus becoming malnourished and exacerbating their concurrent medical problems. The level of care and supervision required will increase over time as the illness progresses. Initially, daily checking-in may suffice. Later, help several hours per day, particularly around meals, medications, bathing, and dressing, is often required. As the disease progresses, delusions, hallucinations, and agitation become more prevalent. Eventually, total care and constant supervision for assurance of safety are needed.

FIGURE 10.3–2. Magnetic resonance image of an individual with Alzheimer disease. Three plane views of the brain of a patient with probable Alzheimer disease at the time of their entry into the University of Pittsburgh Alzheimer Disease Research Center. Note there is significant atrophy in the hippocampus and related structures in the mesial temporal lobe (seen in the upper left image) and cortical atrophy in the frontal and temporal neocortex.

In the final stages of Alzheimer disease, parkinsonian symptoms may be present, mobility and gait are impaired, and the risk of fall is great. Eventually, patients will be bedridden. Swallowing impairments are

Telegram: @medical_k

www.konkur.in

common. Patients will often succumb to pneumonia or other infections. Palliative care is helpful in the end-stage to provide comfort measures and support for the family to ensure a peaceful and dignified death.

Neuropathology. Neuropathologic changes in the brain begin years before a dementia diagnosis is made. Macroscopically, the brains of early Alzheimer disease patients may appear grossly normal or with atrophy confined to the hippocampus and often most easily recognized by the increased volume of the inferior horn of the lateral ventricles. As the disease progresses, widened sulci throughout the cortex and increased ventricular size are seen. Atrophy in the posterior temporal, parietal, and frontal lobes is often the most prominent.

FIGURE 10.3–3. Photomicrographs of Alzheimer disease neuropathology. **(A)** Deposition of insoluble fibrillar Aβ into plaques begins in the neocortex, labeled here using an antibody against Aβ and appearing as reddish-brown deposits (*arrows*). **(B)** Bielchowsky stain of neocortex from an individual who died in advanced stages of Alzheimer disease (Braak stage VI). The Aβ plaques appear as dark brown in this preparation (*arrows*) and can be seen to be associated to varying degrees with dystrophic neuronal processes (*arrowheads*) in which insoluble microtubule-associated protein τ (MAPT) aggregates appear as black deposits. This neurofibrillary pathology also appears extensively throughout the neuropil, and several neurofibrillary tangles can be seen (*open arrowheads*). **(C)** Bielchowsky stain of neocortex from an individual who died in a less advanced disease stage (Braak stage

Telegram: @medical_k

www.konkur.in

IV). Though some neurofibrillary tangles are still evident (*open arrowheads*), the degree of neurofibrillary pathology in the neuropil is substantially diminished. **(D)** Isolated neurofibrillary tangles (*open arrowheads*) in the entorhinal cortex that are seen in normal aging (Bielchowsky stain). Notice the lack of Aβ plaques and limited neuropil involvement. (All images obtained at 200× magnification, and provided courtesy of Dr. Ronald L. Hamilton, Department of Pathology, Division of Neuropathology, University of Pittsburgh School of Medicine.)

Microscopically, the characteristic lesions of Alzheimer disease are amyloid plaques and neurofibrillary tangles. Amyloid plaques are the defining lesion of Alzheimer disease, composed of insoluble deposits of fibrillar Aβ (Fig. 10.3–3). Surrounding this central core are dystrophic neurites, microglial cells, and reactive astrocytes. Amyloid plaques are first found throughout the neocortex, followed by the entorhinal cortex and hippocampus, then subcortical regions.

The second major histopathologic feature is the neurofibrillary tangle. Neurofibrillary tangles are intracellular inclusion bodies, which contain paired helical filaments composed of aggregates of hyperphosphorylated MAPT (see Fig. 10.3–3). Neurofibrillary tangles are first found in the entorhinal cortex and spread from there to the hippocampus and lateral temporal lobe, then more widely through the neocortex. The presence of neurofibrillary tangles is not pathognomonic for Alzheimer disease, as they are the principal lesion in MAPT-related FTDs. Additional pathologic features of Alzheimer disease include abnormal aggregation of α-synuclein, which may be detectable in as many as one-half of individuals with Alzheimer disease. These aggregates most commonly are found as thread-like deposits or as intraneuronal inclusions (Lewy bodies) in the amygdala and transentorhinal cortex, though Lewy bodies may also be present in the neocortex. Other neuropathologic abnormalities described in this disease include neuronal loss, most markedly in the entorhinal cortex and hippocampus. Later in the disease, loss of cholinergic neurons in the nucleus basalis, as well as loss of brain stem noradrenergic and serotonergic neurons, occurs. Granulovacuolar degeneration and the presence of Hirano bodies, most commonly affecting pyramidal neurons in the hippocampus, may be found.

The major pathologic protein aggregates found in Alzheimer disease and the overlap with other neurodegenerative dementias are summarized in Table 10.3–6.

www.konkur.in

Management. Nonpharmacologic management should be utilized throughout the course of illness. The below sections will discuss pharmacologic measures specific for the management of Alzheimer dementia.

CHOLINESTERASE INHIBITORS. The first class of medications approved by the U.S. Food and Drug Administration (FDA) for the treatment of Alzheimer disease was the cholinesterase inhibitors: Tacrine (Cognex), donepezil (Aricept), rivastigmine (Exelon), and galantamine (Reminyl). These agents are reversible inhibitors of the enzyme acetylcholinesterase, which degrades Ach in the synaptic cleft, thereby increasing the availability of intrasynaptic Ach.

These agents have all been shown in multiple randomized, double-blind, placebo-controlled trials to slow cognitive decline in mild to moderate Alzheimer disease. These medications have been associated with a modest decrease in long-term cognitive impairment over time and have also been associated with reduced mortality risk; galantamine was also associated with a reduced risk of developing severe dementia in a matched cohort study. Patients who have a good response to cholinesterase inhibitor treatment can expect to stay in their homes for 3 to 8 months longer. There are limited trials in severe Alzheimer dementia. Donepezil is the only cholinesterase inhibitor FDA-approved for the treatment of severe Alzheimer dementia. There are no data on whether or how to switch from one agent to another.

Common side effects are related to cholinergic excess and include nausea and vomiting, decreased appetite and weight, increased gastric acid secretion, muscle cramps, bradycardia with syncope, and sleep disturbances. They may induce or exacerbate urinary obstruction, worsen asthma or chronic obstructive pulmonary disease, and cause seizures. Tacrine can cause reversible hepatotoxicity; because of this common risk and the four times per day dosing, tacrine is now rarely used.

Cholinesterase inhibitors should be used with caution in patients with gastric ulcer disease, sick sinus syndrome or conduction defects, asthma or chronic obstructive pulmonary disease, or cerebrovascular disease. The only contraindication is hypersensitivity. The tolerability of these different agents is variable, so if patients do not tolerate one agent, an alternative should be tried. If gastrointestinal side effects are particularly

Telegram: @medical_k

www.konkur.in

problematic, individuals can be switched to transdermal patch preparations (see Table 10.3–7 for dosing guidelines).

Patients should be titrated gradually to the maximally tolerated dosage as there is a dose-dependent response. If there is a continued rapid decline despite the medication, it can be discontinued. However, if there is a stabilization of symptoms or slowing of decline, which is the desired response, the medication should be continued. The duration of treatment is unclear. Placebo-controlled studies demonstrate efficacy for up to 6 months to 2 years, depending on the agent. Discontinuation of cholinesterase inhibitors has been associated with marked deterioration and regression of cognition to levels of the placebo control group. There is some suggestion that after cholinesterase treatment has been interrupted for 6 weeks or more before being restarted, patients do not return to the cognitive level they were at before the medication was discontinued. Case reports have described intense hallucinations, difficulty sleeping and concentrating, agitation, changes in mood, and delirium with abrupt discontinuation of donepezil.

MEMANTINE. Memantine is a noncompetitive NMDA receptor antagonist that may modulate excitatory signaling and have neuroprotective actions.

Memantine has been studied in mild, moderate, and severe stages of Alzheimer disease. It is FDA-approved for use only in moderate to severe Alzheimer disease and has demonstrated efficacy for both cognitive and functional improvement over placebo. It has been studied as monotherapy and in addition to stable doses of donepezil and is effective and well-tolerated when added to the cholinesterase inhibitor. There are no data for use longer than 6 months duration. It is generally well tolerated with drop-out rates comparable to placebo. Infrequent adverse events include confusion, dizziness, headache, sedation, agitation, falls, and constipation (see Table 10.3–7 for dosing guidelines).

MONOCLONAL ANTIBODY TREATMENTS. Aducanumab (Aduhelm) is an amyloid beta-directed antibody, and was approved by the FDA in 2021 for the treatment of Alzheimer's disease through their Accelerated Approval pathway. This pathway allows for the approval of treatments for serious or life threatening illness where there is the expectation of clinical benefit despite some uncertainty and when the therapy may provide an advantage over existing treatments. This approval was based on a surrogate endpoint of the reduction of beta amyloid plaque, as there was conflicting data in two phase 3 clinical trials surrounding the reduction of clinical decline. The treatment will now need a post-approval trial demonstrating clinical benefit. This is the first disease modifying therapy approved by the FDA for Alzheimer's disease, and is the first medication approved by the FDA for Alzheimer's disease since 2003.

Intravenous lecanemab (Leqembi) was also granted accelerated approval for the treatment of Alzheimer disease in early 2023, with a

Telegram: @medical_k

www.konkur.in

recent phase 3 trial demonstrating a reduction in brain amyloid levels and less cognitive decline. It is recommended that it should be used in patients with mild cognitive impairment or mild dementia, the population in which treatment was studied in clinical trials. Due to concerns about developing amyloid-related imaging abnormalities or ARIA, a type of brain swelling or bleeding brain, imaging monitoring is recommended for both these agents.

OTHER MEDICATIONS. Other medications, including vitamin E, ginkgo biloba, NSAIDs, hormone replacement therapy, selegiline, ergoloids, and antiamyloid therapies, have been studied for the prevention and/or treatment of cognitive decline in Alzheimer disease, but placebo-controlled trials have not shown sufficient efficacy.

Frontotemporal Dementia

Dementia associated with atrophy of the frontal and temporal lobes encompasses both sporadic and familial diseases. The hallmark of FTD is a progressive change in personality and behavior, with variable degrees of language and other cognitive impairment. Especially when it presents in midlife, it can be a significant clinical challenge to distinguish FTD from primary psychiatric disorders. In late-life presentations, it can be difficult to distinguish from a frontal-predominant presentation of Alzheimer disease.

Definition. FTD, as used here, is meant to identify a group of clinical syndromes characterized by progressive circumscribed atrophy of frontal and temporal lobe cortices, identified as frontotemporal lobar degeneration. FTD includes two broadly accepted subgroups: behavioral-variant FTD (bv-FTD); and language-predominant FTD (including progressive nonfluent aphasia and semantic dementia). The spectrum of presentations of frontotemporal lobar degeneration also includes the motor syndromes of CBD, PSP, and motor neuron disease, as there are both clinical and pathologic overlaps among these.

History. Arnold Pick, in the late 19th and early 20th century, provided the initial descriptions of the clinical syndrome of a dementia with associated circumscribed atrophy of the frontal and temporal lobes. Alzheimer subsequently described associated neuropathologic abnormalities, including the presence of intraneuronal inclusions and

Telegram: @medical_k

www.konkur.in

ballooned neurons. The inclusions were later named Pick bodies, and the syndrome of dementia with frontotemporal atrophy and Pick bodies was named Pick disease.

Comparative Nosology. Consensus criteria for the diagnosis of FTD were first published in 1998. This group recognized that the prototypic clinical presentation of *FTD* is disturbances of personality and behavior or impairments of language (primary progressive aphasia or semantic dementia).

The diagnostic criteria for the bv-FTD were updated most recently in 2011 by the International Behavioral Variant FTD Consortium. The updated criteria are meant to provide greater sensitivity and more flexibility in the diagnosis of FTD in its earlier stages. For a diagnosis of possible bv-FTD, three of six behavioral and cognitive symptoms must be demonstrated (behavioral disinhibition; apathy or inertia; loss of sympathy or empathy; perseverative, stereotyped or compulsive/ritualistic behavior; hyperorality or dietary changes; and executive or generation deficits with relative sparing of memory and visuospatial functions). A diagnosis of probable bv-FTD requires the criteria for possible bv-FTD, as well as significant functional decline and imaging consistent with bv-FTD. In 2011, an international workgroup published criteria for the language-predominant forms of FTD: progressive nonfluent aphasia (also known as nonfluent/agrammatic), semantic dementia, and added a third variant, logopenic. Descriptions of these variants can be found later in this section.

The DSM-5 includes both a behavioral variant and a language variant in its description of major frontotemporal neurocognitive disorder. The behavioral variant is characterized by a decline in social cognition or executive functioning, as well as behavioral disinhibition, apathy or inertia, loss of sympathy or empathy, perseverative, stereotyped or compulsive behavior, and hyperorality. The language variant is characterized by a prominent decline in language abilities, with difficulties seen in speech production, word-finding, object naming, grammar, or word comprehension. In both variants, there is an insidious onset, with gradual progression and a relative sparing of learning, memory, and perceptual-motor functioning.

Epidemiology. In early age of onset dementia, the prevalence and incidence of FTD have been reported to be similar to that of early-onset Alzheimer dementia. FTD is the third most common form of dementia,

Telegram: @medical_k

www.konkur.in

following Alzheimer dementia and DLB, and is the second most common form in patients younger than 65. Incidence rates have been reported to be 3.5 per 100,000 person-years in a 45 to 64 years age group and 3.3 per 100,000 person-years in a 50 to 59 years old age group. In population-based studies conducted in the United Kingdom and the Netherlands, prevalences of FTD of 3.6 to 15 cases per 100,000 individuals in mid- to late-life have been reported. Age at presentation is most commonly in the sixth decade, but this can range from the third to the ninth decade. The data on the role of gender is mixed. A 2005 study examining the demographic characteristics of FTD did find a male predominance in the behavioral variant and semantic dementia and a female predominance in progressive nonfluent aphasia.

Etiology. FTD occurs in both sporadic and familial forms. A family history is present in up to approximately one-third to one-half of cases, typically with an autosomal dominant pattern of transmission. The etiology of the sporadic forms is currently unknown.

GENETICS. The most common genetic mutations in familial FTD include those in the microtubule-associated protein tau (*MAPT*), progranulin (*PGRN*), and chromosome 9 open reading frame 72 (*C9orf72*) expansion mutations. FTD attributed to *MAPT* mutations tends to present as the behavioral variant and at younger ages compared to FTDs attributable to other mutations. FTD attributed to *PGRN* mutations also tends to present as the behavioral variant, and neuropsychiatric symptoms are common. About half of patients with *PGRN*-associated FTD have extrapyramidal symptoms, and early language involvement is more common in *PGRN*-associated FTD compared to FTDs attributable to other mutations. The *C9ORF72* mutation, which is a hexanucleotide expansion, typically presents as the behavioral variant-FTD, motor neuron disease, or a combination of the two. Apathy, disinhibition, loss of empathy, and executive dysfunction are common. This mutation is the most common cause of ALS-FTD, and is associated with transactive response DNA-binding protein (TDP-43). Approximately 26% of familial and 5% of sporadic FTD cases may carry *C9ORF72* expansions. Mutations in *GRN* found on chromosome 17 that result in loss of function may account for up to 5% to 10% of FTD cases. Mutations in vasolin-containing protein (*VCP*) present with common symptoms of behavioral change, executive

Telegram: @medical_k

www.konkur.in

dysfunction, and aphasia, and mutations in transactive DNA-binding protein (*TARDBP*) are associated with both behavioral and semantic subtypes and can present with and without motor neuron disease. Genetic testing should be considered if one first-degree relative is affected with mutations in *GRN*, *MAPT*, or *C9orf72*, and testing for *C9orf72* should be considered for individuals with behavioral variant FTD or in individuals with late-onset psychiatric disorders and one first-degree relative with FTD or ALS.

Diagnosis and Clinical Features. The temporal evolution of symptoms and their neuroanatomical correlates are important in the diagnostic clarification of the differing variants.

In the bv-FTD, apathy, disinhibition, and loss of self and other awareness are early signs. Family members and loved ones may be concerned that the individual is experiencing a midlife crisis of some sort, and often a psychiatric disorder is suspected as the underlying etiology of this change in behavior early on.

Behavioral disinhibition can be characterized as socially inappropriate behavior or a loss of manners or decorum. An individual may begin to make impulsive, rash, or careless actions. Apathy or inertia can also be seen. There may also be an early loss of sympathy or empathy, with an individual displaying diminished reactivity to other's needs or feelings, or diminished social interest, interrelatedness, or personal warmth. Individuals may be less supportive of a spouse's health problems. Perseverative, stereotyped, compulsive, or ritualistic behaviors can also be seen. These may range from simple repetitive movements to more complex or compulsive behaviors, like collecting specific objects or hoarding. Stereotypy of speech, as well as mental rigidity, can also be seen. Individuals may display hyperorality or dietary changes, including altered food preference, such as eating foods that are just one color or binge eating. Neuropsychological testing reveals executive function deficits, with relative sparing of memory and visuospatial functioning. Individuals with the behavioral variant often have very limited insight into their alterations of behavior.

About 20% of individuals with the behavioral variant also show signs of parkinsonism, with an akinetic rigid form present in about 60% of these individuals and tremor predominant present in 40%. Five percent to ten percent of individuals with FTD have co-occurring motor neuron disease

Telegram: @medical_k

www.konkur.in

as well, with symptoms including muscle wasting, weakness, and fasciculations. The motor neuron disease may occur prior to, during, or after a diagnosis of FTD has been made. These individuals have ubiquitin and TDP-43 positive inclusions in the lower motor neurons of the spinal cord and the granular cells of the hippocampus. FTD and motor neuron disease are felt to be part of the same clinical spectrum of TDP-43 pathology.

Three different language variants have been described.

Core features of the semantic variant, also known as semantic dementia, include impaired confrontation naming and impaired single-word comprehension. Other diagnostic features include impaired object knowledge, surface dyslexia (difficulty with recognition of irregular sounding words, like yacht), or dysgraphia. Individuals may substitute categories for words (“food” for “apple”) and eventually may refer to all nouns as “things.” As the disease progresses, speech becomes empty of content. Repetition and speech production are usually spared. Those individuals with the semantic variant but who have right-sided predominant atrophy may show some early behavioral features, including emotional detachment or lack of empathy, dysfunction in emotional processing, compulsions, or may also have impairments in facial recognition.

The nonfluent/agrammatic variant, also known as progressive nonfluent aphasia, requires one of the two core features for a diagnosis: agrammatism in language production or effortful, halting speech not consistent with apraxia of speech. Speech is often described as slow and labored. Speech sound errors are made, and there is abnormal prosody. There may also be impaired comprehension of syntactically complex sentences. Single-word comprehension and object knowledge are spared. Individuals with progressive nonfluent aphasia tend to have more insight into their deficits and maintain social norms; if atrophy progresses to the right frontal regions, behavioral symptoms are likely to follow.

Core features of the logopenic variant include impaired single-word retrieval in spontaneous speech and naming and impaired repetition of sentences and phrases. Speech is slow due to word-finding problems. There may be phonologic errors in speech and naming. Single-word comprehension, object knowledge, and motor speech are spared, and there is a lack of agrammatic errors, with preservation of articulation and prosody. As some of these individuals go on to show amyloid pathology

Telegram: @medical_k

www.konkur.in

on autopsy, this variant may actually be a less common variant of Alzheimer disease, particularly if these individuals show a longitudinally stable logopenic pattern.

FIGURE 10.3–4. Patterns of atrophy (frontotemporal lobar degeneration [FTLD]) in patients with frontotemporal dementia. Telegram: @medical_k

www.konkur.in

Biomarkers. Currently, there are no established biomarkers for the diagnosis of FTD. In practice, the use of MRI with T_1 and FLAIR sequences, including coronal cuts, is helpful to establish the presence of circumscribed frontal and/or temporal atrophy (Fig. 10.3–4).

In the behavioral variant of FTD, there is early degeneration of the paralimbic structures of the ventromedial prefrontal cortex, anterior cingulate cortex, and anterior insula on neuroanatomical imaging. MRI may demonstrate volume loss in the prefrontal cortex, anterior temporal regions, insula, anterior cingulate, striatum, and thalamus. In individuals where there is diagnostic uncertainty and without clear frontotemporal atrophy on CT or MRI imaging, SPECT or FDG-PET can be considered, with preference given to FDG-PET imaging if possible. PET or SPECT imaging would reveal hypoperfusion or hypometabolism in the frontal or anterior temporal regions in the behavioral variant, with specific changes evident in the uncinated fasciculus, genu of the corpus callosum, and cingulum, superior and inferior longitudinal fasciculi, and inferior fronto-occipital fasciculus.

In primary progressive aphasia, atrophic changes evident on MRI begin asymmetrically, occurring primarily in the left hemisphere. Imaging may demonstrate predominant anterior temporal lobe atrophy or predominant anterior temporal hypoperfusion/hypometabolism on SPECT or PET. In the semantic variant, there is decreased activity in the left superior longitudinal fasciculus, corpus callosum, left cingulum, left orbitofrontal, inferior frontal, anterior temporal, and inferior white matter regions. In the nonfluent variant, functional neuroimaging findings may include decreased activity in the left uncinated fasciculus, inferior longitudinal fasciculus tracts, corpus callosum, and cingulum, with sparing of the occipital white matter, brainstem, and cerebellum. In the logopenic variant, MRI, SPECT, or PET scans show predominant left posterior perisylvian or parietal atrophy, hypoperfusion, or hypometabolism.

In CSF studies, one would expect CSF amyloid-β_{42} to be normal, while CSF tau levels may be normal to increased due to the neurodegeneration occurring.

Differential Diagnosis. Not surprisingly, given the frequent initial presentation of progressive alterations in behavior, psychiatric syndromes are often initially suspected in individuals with FTDs, with up to 50% of individuals with the behavioral variant of FTD first being diagnosed with a

Telegram: @medical_k

www.konkur.in

primary psychiatric disorder, most commonly depression. Individuals with FTD caused by mutations in *C9ORF72* can often present with prodromal psychiatric symptoms, including symptoms suspicious of bipolar disorder, obsessive-compulsive disorder, and schizophrenia. In GRN mutations, visual hallucinations and delusions develop in up to a quarter of patients at some point in their illness. The Neuropsychiatric International Consortium for Frontotemporal Dementia (NIC-FTD) developed guidelines to assist with distinguishing bv-FTD from primary psychiatric disorders. In addition to a detailed history of symptoms, the NIC-FTD supports the use of FTD-specific scales, such as the Frontal Behavioral Inventory, the Stereotypy Rating scale, the DAPHNE, and the Frontotemporal Dementia versus Primary Psychiatric Disorder Checklist. A bedside exam should look for the presence of parkinsonism, upper motor neuron signs, and tests of executive function, all of which may be helpful in distinguishing between bv-FTD and a primary psychiatric disorder. Social cognition is typically more impaired in bv-FTD. Atrophy in the frontal or anterior temporal lobes makes a diagnosis of bv-FTD more likely. Serum or CSF neurofilament light chain markers, which are indicative of neurodegeneration, may be helpful in the differentiation of bv-FTD from primary psychiatric disorders as well.

Differential diagnosis may also include the other causes of dementia, commonly frontal predominant presentations of Alzheimer disease, particularly if the logopenic variant of primary progressive aphasia is diagnosed, or the combination of cognitive impairment and parkinsonism found in DLB. The absence of amyloid binding is helpful in ruling out AD-related pathology. The presence of parkinsonism requires that one also consider the diagnoses of CBD and PSP. For example, the additional symptoms of progressive parkinsonism, axial rigidity, and supranuclear gaze palsy would indicate an FTD with PSP. Motor symptoms of asymmetric rigidity and apraxia may signal an associated CBD. Both PSP and CBD will be discussed in further detail below.

Course and Prognosis. The course of FTD is one of progressive deterioration. With progression, the differing initial presentations described above frequently merge, and ultimately loss of other cognitive functions may occur. Motor symptoms can precede, emerge concurrently, or follow the onset of the changes in behavior, personality, and language. On average, survival is eight years from symptom onset and 4 to 5 years from

Telegram: @medical_k

www.konkur.in

diagnosis. Those individuals with FTD and motor neuron disease have a significantly shorter survival time compared to those without motor neuron disease. Overall, individuals with FTD show more rapid cognitive and functional decline than those individuals with Alzheimer disease.

Neuropathology. The pathologic examination has been essential in revealing the underlying processes resulting in FTD. Macroscopically, FTD is characterized by focal atrophy of the frontal cortex, the temporal cortex, or both. Atrophy is usually symmetric, though asymmetry is sometimes present. The Consortium for Frontotemporal Lobar Degeneration has elaborated guidelines for the neuropathologic assessment of cases with frontotemporal lobar degeneration. A systematic survey of frontal, temporal, and parietal cortices and the hippocampus with histologic stains and immunocytochemistry using antibodies directed against τ, ubiquitin, or P62 (sequestosome-1) and α-synuclein is recommended to identify lesions associated with the frontotemporal lobar degenerations and to exclude other neurodegenerative dementias. Further evaluation of additional brain regions, including the basal ganglia, midbrain, brain stem, and spinal cord, with the above staining approaches, immunocytochemistry for TDP-43 and for τ isoforms, and molecular genetic identification of mutations may also be necessary to achieve specific diagnoses.

Using these approaches, the frontotemporal lobar degenerations can be divided into two major groups, one with τ-positive inclusions, another with τ-negative and ubiquitin/P62-positive inclusions. These two presentations do not account for the behavioral versus language-predominant presentations of FTD, which are presumed to relate more to the location of pathology. The associated motor syndromes, however, do demonstrate selective associations with these pathologic groupings, as do genetic etiologies.

The frontotemporal lobar degenerations with τ-positive inclusions include classically described Pick disease, CBD, PSP, and dementia due to MAPT mutations. These subtypes can, to some extent, be distinguished by the pattern of lesion location and morphology, as revealed through the use of antibodies that nonselectively recognize phosphorylated τ. However, distinguishing among subtypes may be more reliably achieved through the use of antibodies selective for τ isoforms.

Telegram: @medical_k

www.konkur.in

The second major group is the frontotemporal lobar degenerations with τ-negative ubiquitin/P62-positive inclusions. The most frequent pathologic presentation in this group and the most frequent pathologic presentation among all cases of frontotemporal lobar degenerations is the presence of intracellular inclusions positive for TDP-43. It is now recognized that many cases formerly classified as dementia lacking distinctive histologic features are TDP-43 positive and that if dementia lacking distinctive histologic features exists, it is quite rare. FTDs with TDP-43 lesions can occur with or without associated motor neuron disease. FTDs due to *GRN* and *VCP* mutations are TDP-43 positive, while those due to *CHMP2B* mutations are ubiquitin/P62 positive and TDP-43 negative. FTD due to *C9ORF72* presents with both TDP-43 positive and ubiquitin/P62 positive/TDP-43 negative inclusions, the latter most often found in the cerebellum.

Management. Similar to other dementias, nonpharmacologic management should be integrated throughout the course of the dementia process and are the first-line for the treatment of neuropsychiatric symptoms. Currently, there are no treatments for the cognitive deficits associated with FTD and no treatments to prevent the progression of the underlying pathologies. Data does not support the use of cholinesterase inhibitors or memantine, and there is some concern that these medications can worsen behavioral symptoms. Symptomatic use of trazodone, second-generation antipsychotics, SSRIs, and anticonvulsants may help agitation, disinhibited, and aggressive behavior. Typically, SSRIs are first-line pharmacotherapy treatments for FTD, with three small open-label studies providing some evidence for the use of SSRIs, although these are not FDA-approved for the treatment of FTD. Second-generation antipsychotic medications should be used with caution and close observation, as individuals with FTD may be more sensitive to extrapyramidal side effects. Stimulants may be helpful with risk-taking behaviors and disinhibition, but data is limited.

Corticobasal Degeneration

CBD can present as a syndrome with both clinical and pathologic heterogeneity, with the clinical syndrome being more reflective of the neuroanatomical distribution of pathology than a particular histology.

Telegram: @medical_k

www.konkur.in

Definition. The clinical syndrome of CBD has core features of progressive asymmetric rigidity and apraxia, as well as cortical and basal ganglia dysfunction.

Comparative Nosology. This clinical entity was first identified in 1967 in three individuals with a progressive asymmetrical akinetic-rigid syndrome and apraxia. It was later renamed CBD in the early 1990s.

The term corticobasal syndrome (CBS) is sometimes used to describe the clinical features seen, reserving the term CBD for the histopathologic diagnosis. Other names for this syndrome that have been used in the past include corticonigral degeneration and corticobasal ganglionic degeneration. In 2013, an international consortium published diagnostic criteria for the diagnosis of probable CBD and a broader set of criteria for possible CBD. Possible CBD includes phenotypes that may be consistent with CBD but which may also overlap with other tauopathies, such as PSP or FTD.

Epidemiology. The age of onset has been reported to range from 45 to 77.

Etiology. CBD is, for the most part, a sporadic disorder. The h1 haplotype of the MAPT gene has been associated with the development of this disease.

Diagnosis and Clinical Features. For a diagnosis of probable sporadic CBD, there must be insidious onset with gradual progression for at least one year, no family history of the disease, and an age of onset of at least 50 years of age. For a diagnosis of the broader possible CBD, there is no minimum in terms of age of onset, and family history and a genetic mutation affecting τ are both permitted. There are four major phenotypes of CBD described; these include CBS, frontal–behavioral–spatial syndrome, nonfluent/agrammatic primary progressive aphasia, and PSP syndrome. There is also increasing evidence for a predominant cognitive phenotype as well.

CBS is one of the more common presentations of CBD. Clinical features of probable CBS include asymmetric presentation of limb rigidity or akinesia, limb dystonia, and limb myoclonus, as well as orobuccal or limb apraxia, cortical sensory deficit, and alien limb phenomenon. Possible CBS shares similar clinical features, but they may be symmetric.

Telegram: @medical_k

www.konkur.in

PSP syndrome is only considered a phenotype of possible CBD; clinical features of this include one CBS symptom and three of the following symptoms: axial or limb rigidity or akinesia, postural instability or falls, urinary incontinence, behavioral changes, supranuclear vertical gaze palsy or decreased velocity of vertical saccades. Tremor is a common presenting symptom in CBD, but in contrast to tremor in Parkinson disease, tremor in CBD is minimal at rest and amplified with action. Furthermore, symptoms are not responsive to L-dopa therapy. Neuropsychological testing may reveal impairments in attention and concentration, executive function, language, and visuospatial function; learning and memory are often spared. Aphasia and apraxia of speech may also be evident, as can depression and apathy. Features of an FTD with behavioral disturbance can also be seen, with executive dysfunction, behavioral or personality changes, or visuospatial deficits present in the frontal behavioral spatial syndrome phenotype. Dementia is common in pathologically confirmed cases of CBD.

Biomarkers. There are no CSF or serum biomarkers available for diagnosis. On structural imaging, asymmetrical cortical atrophy can be seen, particularly in the frontoparietal regions; atrophy is more prominent in the hemisphere contralateral to the side of the symptoms. There may also be asymmetrical atrophy in the basal ganglia and cerebral peduncles. SPECT and PET can have asymmetrical hypoperfusion in the parietal and frontal cortex and basal ganglia. In dopamine transporter imaging, there is an asymmetric reduction in tracer uptake in the nigrostriatum, with greater reductions seen contralateral to the more clinically affected side.

Differential Diagnosis. The presence of parkinsonism on examination causes one to include the other Parkinson plus syndromes in the differential. There is a significant overlap between CBD and PSP; those individuals with the CBD phenotype of PSP syndrome are more likely to have PSP, but only autopsy provides a definitive diagnosis. Individuals with CBD may have underlying PSP pathology, and those with the classical symptoms of PSP may have CBD pathology. Differences in cognitive impairments may be helpful in distinguishing PSP and CBD. In PSP, there is predominant axial rigidity, as opposed to the progressive asymmetric rigidity seen in CBD. In contrast to Parkinson disease, the tremor typically seen in CBD is minimal at rest and amplified with action,

Telegram: @medical_k

www.konkur.in

and the parkinsonian symptoms are typically not responsive to dopaminergic medications. Visual hallucinations should cause one to consider DLB. FTD should also be considered. Finally, the focal nature of deficits in CBD should also lead to the consideration of vascular dementia, but one would expect to see infarcts on imaging in this case.

Course and Prognosis. Symptoms are usually asymmetric at first, but most often, the rigidity and apraxia begin in an upper limb and then spread about two years into the disease course to either the ipsilateral lower limb or the contralateral upper limb. Median survival time has been reported to be about 6 to 7 years.

Neuropathology. On neuropathologic examination, there is focal cortical neuronal loss, typically in the frontal, parietal, or temporal lobes, as well as neuronal loss in the substantia nigra. The pathologic features of CBD include Gallyas/tau-positive astrocytic plaques and threads, particularly in the superior frontal gyrus, the superior parietal gyrus, pre- and postcentral gyri, and the striatum. Tau-positive oligodendroglial coiled bodies may be evident. Ballooned neurons are considered to be a hallmark feature but are not required for a diagnosis.

Management. Symptomatic treatments of the motor symptoms include botulinum toxin for focal dystonia, propranolol or primidone for tremor, and clonazepam for myoclonus, as the parkinsonism present is not typically responsive to L-dopa therapy. The importance of physical, occupational, and speech therapies has been emphasized.

Progressive Supranuclear Palsy

Definition. PSP is a gradually progressive disorder with progressive supranuclear gaze palsy, postural instability and falls, and parkinsonism.

Comparative Nosology. In 1963, a case series on PSP was published; initially described as “heterogeneous system degeneration,” this report detailed eight patients who had impairments in ocular gaze, spasticity of facial musculature with dysarthria, and at times dysphagia, nuchal rigidity, and dementia. This was officially termed PSP in 1964.

Formal diagnostic criteria were initially proposed in 1987. In 1996, the National Institute for Neurological Disorders and Stroke and the Society

Telegram: @medical_k

www.konkur.in

for PSP (NINDS-SPSP) refined the diagnostic criteria. At the time, core features included age of onset over the age of 40, with vertical supranuclear palsy or both vertical supranuclear palsy and prominent postural instability with falls in the first year of symptoms; this presentation is referred to as Richardson syndrome. However, this combination of symptoms failed to capture many of the other phenotypes presented earlier in the disease process. As such, this criteria was most recently updated in 2017 by the International Movement Disorder Society, with additional emphasis placed on the domains of akinesia and cognitive dysfunction, with the goal of promoting earlier diagnosis. For a diagnosis of PSP to be made, there must be sporadic occurrence of illness, occur in an individual age 40 years or older, and there must be a gradual progression of PSP-related symptoms, which fall into the four functional domains of oculomotor dysfunction, postural instability, akinesia, and cognitive dysfunction.

Epidemiology. The average annual incidence rate of PSP for ages 50 to 99 has been estimated to be 5.3 per 100,000 person-years. The incidence rate rises with increasing age, with an estimated incidence ranging from 1.7 for ages 50 to 59 to 14.7 person-years for ages 80 to 99. Incidence has been noted to be slightly higher in men. However, given previous diagnostic constraints, and when accounting for other clinically variant PSP phenotypes, the true prevalence is likely higher.

Etiology. PSP is considered to mostly be a sporadic disease. The H1 haplotype of the MAPT gene has been associated with PSP; inheritance of two copies of the H1 haplotype is considered to be a genetic risk factor. A large genome-wide association study identified *STX6*, *EIF2AK3,* and *MOBP* as additional risk alleles. Areas on chromosome 11 containing the DNA damage-binding protein 2 (DDB2) and the lysosomal acid phosphatase 2 (ACP2) have also been identified as areas of interest.

Diagnosis and Clinical Features. The median age of onset is 63. Diagnosis has typically been made about 3 to 4 years after symptom onset. The 2017 Movement Disorder Society criteria describe four functional domains of symptoms that may be evident, with each domain including symptoms that carry with them a variable degree of certainty pertaining to the diagnosis. Each of these domains is described as follows, with their respective symptoms in decreasing order of certainty as

Telegram: @medical_k

www.konkur.in

they pertain to the diagnosis of PSP. Oculomotor dysfunction may include vertical supranuclear gaze palsy, slow velocity of vertical saccades, and frequent macro square wave jerks or “eyelid opening apraxia.” Postural instability is characterized by repeated unprovoked falls within 3 years, a tendency to fall on the pull-test within 3 years, or the individual taking more than two steps backward on the pull-test within 3 years. An individual meeting the criteria for akinesia may show progressive gait freezing within 3 years, parkinsonism which is akinetic-rigid, predominantly axial and levodopa resistant, or parkinsonism with tremor and/or asymmetric predominance of limbs and/or levodopa responsive. Cognitive dysfunction may manifest as a speech or language disorder such as which is seen in the nonfluent variant of primary progressive aphasia or progressive apraxia of speech, or it could manifest as frontal cognitive or behavioral presentations, which could include apathy, slowed thinking, dysexecutive syndrome, reduced verbal fluency, and impulsivity, or CBS. Supportive features in the diagnosis may include levodopa resistance, hypokinetic, spastic dysarthria, dysphagia, and photophobia. Taking various combinations of the above symptoms into account, there are multiple clinical phenotypes of PSP, which include PSP with Richardson syndrome, PSP with predominant parkinsonism, PSP with progressive gait freezing, PSP-CBS, PSP with predominant speech or language disorder, PSP with predominant frontal presentation and PSP with predominant cerebellar ataxia. Most patients eventually progress to show the constellation of symptoms evident in Richardson syndrome. Individuals who meet the criteria for PSP-CBS have at least one cortical sign (apraxia, cortical sensory deficit, alien limb phenomenon) and one movement disorder sign (limb rigidity, akinesia, or myoclonus) which can be asymmetric or symmetric.

Biomarkers. Imaging findings may include predominant midbrain atrophy and atrophy of the superior cerebellar peduncles on anatomical MRI. On MRI, atrophy of the midbrain tegmentum, sometimes referred to as the morning glory sign because of its concave appearance, and the hummingbird sign, in which the atrophy of the rostral midbrain as seen on midsagittal images, looks like a hummingbird has high specificity for PSP but lower sensitivity. On SPECT and PET imaging, there is frontosubcortical hypoperfusion and hypometabolism; these changes are usually symmetric. There may be hypometabolism predominant in the

Telegram: @medical_k

www.konkur.in

midbrain relative to the pons on [^{18}]FDG-PET imaging, as well as postsynaptic striatal dopaminergic degeneration on [^{123}]IBZM-SPECT or [^{18}F]-DMFP-PET.

Neurofilament light chain concentrations may be elevated in both CSF and plasma, with higher baseline plasma concentrations associated with faster progression of symptoms.

Differential Diagnosis. Given the variable presentations of PSP, the differential can be quite broad. Imaging can be useful in patients with sudden onset or step-wise progression of the disease to help exclude stroke, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) or severe cerebral amyloid angiopathy. CSF biomarkers which are present in Alzheimer disease, as well as positive β-amyloid PET imaging, may be helpful in excluding PSP. The CBS phenotype is a rare phenotype of PSP, and those who meet the criteria for this fall under the category of possible PSP, but probable 4-repeat tauopathy, as both CBD and PSP, are an accumulation of the 4R tau isoform. In younger patients, it is recommended that Wilson disease, Niemann–Pick disease, hypoparathyroidism, neuroacanthocytosis, and neurosyphilis be excluded based on appropriate laboratory work-up. Whipple disease should also be considered in younger patients who present with atypical neurologic features in addition to gastrointestinal symptoms, arthralgias, and fever. In patients whose illness appears to be rapidly progressive, prion disease and paraneoplastic encephalitis should be considered and ruled out. Given the progressive parkinsonism present in PSP, Parkinson disease should also be considered on the differential. FTD and CBD should also be considered, given the symptom and neuropathologic overlap.

Course and Prognosis. Survival time after symptom onset is about 5 to 9 years.

Neuropathology. Neuropathologic exam is the gold standard for diagnosis. On neuropathologic examination, there are neurofibrillary tangles and neuropil threads composed of tau proteins in the basal ganglia and brainstem. The presence of tau-positive astrocytes in these areas is supportive of the diagnosis. There may also be neuronal loss, neurofibrillary tangles, tufted astrocytes, and oligodendroglial coiled bodies.

Telegram: @medical_k

www.konkur.in

Management. Similar to CBD, there is a poor response to L-dopa. Physical, occupational, and speech therapy may be helpful for symptomatic management throughout the course of the disease.

Dementia with Lewy Bodies

Introduction. DLB is now considered to be the second most common cause of dementia after Alzheimer disease in the older adults. Operationalized diagnostic criteria for DLB have been defined and revised over the past decade. DLB shares some clinical and pathologic features with both Alzheimer disease and Parkinson disease. As a result, complete discrimination among these syndromes, even at autopsy, may not be possible.

Definition. DLB is neurodegenerative dementia characterized by a progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Dementia must be present for a diagnosis of DLB to be made. Memory impairment need not be prominent or persistent early in the course of the illness. Deficits of attention and frontal executive skills, and visuospatial ability may be more prominent early in the course. The core features of DLB include (1) fluctuating cognition with pronounced variations in attention and alertness, (2) recurrent, complex visual hallucinations, which are typically well-formed and detailed, (3) spontaneous motor features of parkinsonism, and (4) REM sleep behavior disorder. Supportive clinical features include severe sensitivity to antipsychotic agents, repeated falls and syncope, transient unexplained loss of consciousness, severe autonomic dysfunction, hypersomnia, hyposomnia, hallucinations in other modalities, systematized delusions, apathy, anxiety, and depression. Indicative biomarkers include reduced dopamine transporter uptake in the basal ganglia demonstrated by SPECT or PET, abnormal (low uptake) ^{123}iodine-MIBG myocardial scintigraphy, and polysomnographic confirmation of REM sleep without atonia. Supportive biomarkers include relative preservation of medial temporal lobe structures on CT/MRI scan, generalized low uptake on SPECT/PET perfusion/metabolism scan with reduced occipital activity plus/minus the cingulate island sign on FDG-PET imaging, and prominent posterior slow-wave activity on EEG with periodic fluctuations in the pre-alpha/theta range.

Telegram: @medical_k

www.konkur.in

History. Lewy bodies, the intracytoplasmic, spherical, eosinophilic neuronal inclusion bodies, identified originally in subcortical nuclei as one of the hallmarks of idiopathic Parkinson disease, have also been identified in the brain stems and cortex of older adults with dementia. Lewy body disease was first described in 1984 by Kosaka, who distinguished "diffuse" Lewy body disease, where Lewy bodies are present throughout cortical regions, from "brainstem-predominant" Lewy body disease, where Lewy bodies are present primarily in brain stem nuclei, and a "transitional type," which is intermediate between the two. Clinical and neuropathologic diagnostic criteria were published by the Consortium on Dementia with Lewy bodies in 1996 and revised in 2005.

Comparative Nosology. Several historical terms have been used to describe what is now referred to in general as DLB. These terms reflect the overlap clinically and pathologically with Alzheimer disease and Parkinson disease and include Lewy body variant of Alzheimer disease, Alzheimer disease with Parkinson disease changes, dementia associated with cortical Lewy bodies, diffuse Lewy body disease, and senile dementia of the Lewy body type.

The first consensus clinical criteria for DLB were published in 1996. These criteria defined the core clinical features and those clinical features that were supportive of the diagnosis. The presence of one core feature was required for a diagnosis of possible DLB and at least two core features for probable DLB. The distinction between DLB and Parkinson disease with dementia was operationalized by requiring evidence of dementia within one year of the motor symptoms for a diagnosis of DLB. The criteria did not exclude patients who simultaneously met clinical and/or pathologic criteria for a diagnosis of Alzheimer disease. The criteria for DLB were revised in 2005, with efforts made to clarify the overlap of DLB with Parkinson disease and Alzheimer disease.

Though the 1-year rule for differentiating DLB and Parkinson disease with dementia was recommended in research use, clinically, the criteria were clarified to indicate that DLB should be diagnosed when dementia precedes or is concurrent with parkinsonian symptoms and should not be diagnosed when dementia arises in the "context of well-established Parkinson disease." It was also noted that any such distinction, however, may be seen as arbitrarily dividing a continuum of presentations due to underlying Lewy body disease.

Telegram: @medical_k

www.konkur.in

Criteria for the diagnosis of DLB were most recently revised in 2017 by the Dementia with Lewy Bodies Consortium Fourth Consensus and places emphasis on both clinical features and diagnostic biomarkers. Clinical features are considered core or supportive, while biomarkers are considered indicative or supportive. For a diagnosis of probable DLB, two or more clinical features should be present with or without the presence of indicative biomarkers, or only one core clinical feature is present, but with one or more indicative biomarkers. For a diagnosis of possible DLB, only one core clinical feature of DLB is present, with no indicative biomarker evidence, or one or more indicative biomarkers are present, but there are no core clinical features.

The DSM-5 incorporated the 2005 criteria in the diagnosis of major neurocognitive disorder with Lewy bodies. For a diagnosis of major neurocognitive disorder with Lewy bodies, an individual must have two core features or one suggestive feature with one or more core features; if an individual only has one core feature or one or more suggestive features, then a diagnosis of possible neurocognitive disorder with Lewy bodies is made.

Epidemiology. The prevalence of DLB is dependent on whether clinical or pathologic criteria are used and what patient population is studied. As a consequence of these confounds and the unclear clinical and neuropathologic boundaries between DLB, Alzheimer disease, and Parkinson disease dementia in early diagnostic criteria, there remains uncertainty regarding the incidence or prevalence of DLB. The prevalence of DLB in populations over 65 has been found to range from 0.1% to 5%. Clinical studies suggest that DLB likely accounts for 15% to 35% of all dementia patients. One population-based study calculated the incidence of DLB to be 3.5 per 100,000 person-years, with a peak incidence in the 70- to 79-year age group. Neuropathologic studies conducted to date are best understood as describing the frequency of Lewy body pathology in community samples, where it is typically the third most common chronic neuropathologic change after lesions of Alzheimer disease and vascular lesions, and often in combination with both of those.

Etiology. Lewy bodies are comprised of abnormal fibrillar deposits of α-synuclein. Normally, α-synuclein is a protein located in presynaptic axon terminals and is presumed to have a role in synaptic function. Mutations and copy number variations in the gene encoding α-synuclein, *SNCA*,

Telegram: @medical_k

www.konkur.in

result in disorders with Lewy body pathology, including DLB and Parkinson disease. Mutations in β-synuclein, *SNCB*, and *GBA* resulting in DLB have also been described. Mutations in other genes (*LRRK2, EIF4G1, VPS35, PARK2, PINK1*, and *PARK7*) are associated with autosomal dominant or recessive Parkinson disease. Their relationship with DLB, however, is not clear. The APOE ε4 allele has also been associated with an increased risk of DLB. The causes of most cases of sporadic DLB remain unknown.

Diagnosis and Clinical Features. The essential feature of DLB is a progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Attention, executive functioning, and visuospatial processing deficits are more likely to be evident earlier than deficits in memory or naming. Memory impairment may become more evident with the progression of the illness.

CORE CLINICAL FEATURES. The four core features of DLB are (1) fluctuating cognition with pronounced variation in attention and alertness, (2) recurrent visual hallucinations that are typically well-formed and detailed, (3) spontaneous motor features of parkinsonism, and (4) REM sleep behavior disorder. REM sleep disorder was added as a core clinical feature in the DLB Consortium's updated 2017 guidelines, and as such, was not considered one at the time of DSM-5 publication.

Fluctuation in cognitive function and pronounced variation in attention and alertness is common in DLB and often occur earlier in DLB compared to other dementias. Fluctuation may occur rapidly in minutes to hours or slower with weekly or monthly variation in the level of attention or alertness. Patients may exhibit daytime drowsiness and lethargy with lengthy naps (hypersomnia), followed by periods of confusion upon awakening. They may have reduced awareness of the environment, manifest as staring into space. They may even appear to "switch off" or go blank at times. There may be episodes of disorganized speech. Then there may be periods of marked lucidity during which patients appear to spontaneously remit. Global performance may fluctuate with cognition, attention, and alertness, with periods of pronounced impairment in functioning alternating with periods of normal or near-normal functioning.

Visual hallucinations occur early in the course of DLB, whereas, in Alzheimer disease, hallucinations are generally a later complication. The

Telegram: @medical_k

www.konkur.in

visual hallucinations are usually recurrent, well-formed, detailed, and tend to persist. Visual hallucinations occur in up to 80% of individuals with DLB and often feature people, children, or animals. Seeing inanimate objects or writing on the walls and ceiling is not infrequent. Patients may have delusional explanations of the hallucinations, or they may have insight into their unreality. Emotional responses to hallucinatory experiences can range from indifference to amusement to fear. Visual hallucinations may be more common during periods of reduced consciousness and exacerbated by visual impairment. Patients with visual hallucinations demonstrate more profound visuoperceptual dysfunction compared to those without hallucinations. Visual hallucinations correlate with a higher density of Lewy bodies in the anterior and inferior temporal lobe and amygdala, as well as reduced occipital perfusion in the primary and secondary visual cortex.

Spontaneous motor features of parkinsonism are another core feature. Symptoms of parkinsonism include bradykinesia, rest tremor, or rigidity; only one of these symptoms is needed to fulfill these criteria. If dementia onset precedes or is concurrent with the onset of parkinsonian symptoms, a diagnosis of DLB is warranted. The most common extrapyramidal symptoms noted in DLB are rigidity and bradykinesia, followed by hypophonic speech, masked facies, stooped posture, and a slow and shuffling gait. Postural instability is also common. The parkinsonism seen in DLB tends to include greater postural instability, gait impairment, and facial immobility compared to those patients with Parkinson disease without dementia. Resting tremor may occur but is less common in DLB than in Parkinson disease.

REM sleep behavior disorder is now considered a core feature of DLB and is characterized by vivid and often frightening dreams during REM sleep accompanied by lack of muscle atonia allowing for “acting out of dreams.” Patients respond to vivid visual images with vocalizations, thrashing about, arising from bed, and often moving about violently. Bed partners are therefore at risk of injury. Patients usually have little or no recall of their dreams or these episodes. The diagnosis can be confirmed by polysomnography. REM sleep behavior disorder may predate the emergence of parkinsonism or dementia by many years; that is, REM sleep behavior disorder may be a manifestation of an evolving synucleinopathy.

Telegram: @medical_k

www.konkur.in

SUPPORTIVE CLINICAL FEATURES. Severe neuroleptic sensitivity is present in about half of patients with DLB. They will demonstrate acute onset or exacerbation of parkinsonism and impaired consciousness with even a low dose of a first- or second-generation antipsychotic agent. Even though some patients may tolerate antipsychotics, this does not preclude a diagnosis of DLB. Sensitivity to antipsychotics has profound treatment implications in DLB. Visual hallucinations, hallucinations in other modalities, and delusions are common, but the standard treatment for these psychotic symptoms, namely antipsychotic medications, can cause severe adverse effects. Therefore, in DLB, antipsychotics should generally be avoided in the treatment of psychotic symptoms.

In addition to visual hallucinations, patients may also have hallucinations in other modalities, as well as a sense of presence and visual illusions. Systematized delusions may arise to provide an explanation for the hallucinations or other perceptual disturbances. They are often complex and bizarre as compared to the less well-developed delusions in Alzheimer disease. The most common delusions in DLB are persecution and theft, phantom boarders, television characters in the room, spousal infidelity, and Capgras syndrome (delusional misidentification syndrome).

Repeated falls are common in DLB, although they are not limited to this subtype of dementia. In DLB, falls are generally not associated with focal neurologic signs and symptoms as would be present in balance disorders or transient ischemic attacks. Syncope may be associated with brain stem and autonomic nervous system Lewy body pathology. Transient loss of consciousness may represent an extreme form of fluctuation in attention and alertness.

Hypersomnia and hyposomnia have also been added as supportive clinical features. Hypersomnia is defined as excessive daytime sleepiness, and hyposomnia tends to occur earlier in DLB than in dementia of the Alzheimer type.

Additional clinical features that are supportive of a diagnosis of DLB are severe autonomic dysfunction, resulting in orthostatic hypotension, constipation or urinary incontinence, and depression, apathy, and anxiety.

Biomarkers. Functional imaging of the dopamine transporter system with SPECT or PET may be used to assess the nigrostriatal dopaminergic system. One would expect to see reduced dopamine transporter uptake in

Telegram: @medical_k

www.konkur.in

the basal ganglia on a DaT (dopamine transporter) scan. This is one of three indicative biomarkers of DLB.

FIGURE 10.3–5. Coronal T1-weighted MRI and ^{123}iodine FP-CIT SPECT images in Alzheimer disease (AD), dementia with Lewy bodies (DLB), and normal controls (NC): **(A)** On the MRI, note the relative preservation of medial temporal lobe volume (rectangles) in DLB, which is similar to NC, whereas atrophy is obvious in AD. **(B)** On the FP-CIT SPECT images, note the minimal uptake in DLB, which is restricted to the caudate (period or full-stop appearance) compared to the robust uptake in the caudate and putamen in AD and NC (comma appearance). (Reproduced with permission from Dr. Val Lowe, Mayo Clinic, Rochester, MN.)

Reduced uptake on metaiodobenzylguanidine myocardial scintigraphy is also considered to be an indicative biomarker of DLB. Postganglionic sympathetic cardiac innervation is reduced in DLB; however, there are additional medical comorbidities as well as medications that may also produce reduced uptake of this.

The third indicative biomarker of DLB is polysomnographic evidence of REM sleep without atonia.

Telegram: @medical_k

www.konkur.in

Supportive biomarkers of DLB include relative preservation of medial temporal lobe structures on CT or MRI scan and generalized low uptake on SPECT/PET perfusion scans with reduced occipital activity, with possible posterior cingulate island sign present on FDG-PET (see Fig. 10.3–5). The third supportive biomarker is prominent slow-wave activity on EEG with periodic fluctuations in the prealpha/theta range.

Differential Diagnosis. DLB overlaps with Alzheimer disease both in terms of clinical presentation and neuropathologic changes. The distinction between DLB and Alzheimer disease is complex. The clinical symptoms are overlapping, and no specific cutoff based on the number or pattern of core, suggestive, and supportive features present is definitive, though the presence of at least two of the core features in the early disease course (fluctuating attention, prominent visual hallucinations, and parkinsonism) indicates DLB with high specificity. However, even patients who present with a typical insidious amnestic syndrome characteristic of Alzheimer disease may have Lewy body pathology at autopsy. There may be overlap with the two conditions not being mutually exclusive and patients meeting criteria for both.

There is also considerable clinical and pathologic overlap and comorbidity between DLB and Parkinson disease. The primary diagnosis should be made based on the temporal relationship of the onset of cognitive and motor symptoms. DLB should be diagnosed when dementia occurs with or before parkinsonism. Parkinson disease with dementia should be diagnosed when dementia develops in a patient with well-established Parkinson disease. Dementia develops in at least 30% of patients with Parkinson disease, and perhaps even up to 78% when patients are followed over 8 years. In cases where there is not a clear temporal relationship between the motor and cognitive symptoms, the term *Lewy body disease* may be useful. For research purposes, the “1-year rule” should be used between the onset of parkinsonism and dementia to distinguish between these two entities. While the distinction is useful clinically, both diagnoses likely to represent a common spectrum of Lewy body pathology with a common pathophysiology of abnormalities in α-synuclein metabolism.

Multiple system atrophy (MSA), which also has α-synuclein involvement, may also be considered in the differential. Clinical symptoms of MSA include parkinsonism, cerebellar ataxia, pyramidal symptoms, and

Telegram: @medical_k

www.konkur.in

autonomic dysfunction. Autonomic dysfunction is necessary for a diagnosis of MSA and includes orthostatic hypotension, erectile dysfunction in males, constipation, urinary symptoms (frequency, urgency, incontinence, and incomplete bladder emptying), and decreased sweating. Dementia is much less common in MSA compared to the other neurodegenerative illnesses with parkinsonism, and according to the second consensus statement, it is a nonsupporting feature of the diagnosis. However, there is recent evidence that certain cognitive domains are affected, with frontal executive dysfunction being the most common and memory and visuospatial dysfunction also showing impairments.

Distinguishing between delirium and DLB can be challenging. Delirium and DLB share several common symptoms. The fluctuating level of alertness and consciousness in DLB is also a hallmark of delirium. Visual hallucinations are also common in both conditions, although they may be less well-formed and less detailed in delirium. DLB, like other dementias, may also increase the risk for a superimposed delirium due to medications, medical illness, and after hospitalization for any reason. Delirium, however, should typically have an acute or subacute onset and a duration limited to the period of exposure to the underlying causal agent. The contribution of medications or other comorbid medical conditions to worsening cognitive, hallucinatory, motor, or behavioral symptoms should be investigated.

Vascular dementia should also be considered in the differential diagnosis. A history of stroke, as evident by focal neurologic signs or brain imaging, makes the diagnosis of DLB less likely. However, white matter lesions in the periventricular and deep white matter regions, microvascular changes, and lacunes may be present in up to 30% of autopsy-confirmed DLB cases, suggesting that a diagnosis of both DLB and cerebrovascular disease may be appropriate in many cases.

CJD may be considered in patients who develop myoclonus, which is also characteristic of a rapidly progressive form of DLB.

Course and Prognosis. DLB has an insidious and gradual onset, with the mean age at onset being 75 years old with a range from 50 to 80 years. There is a slight male predominance. DLB usually presents with one of the core features. It may have a more rapidly progressing course than Alzheimer disease or vascular dementia. Survival time is usually

Telegram: @medical_k

www.konkur.in

about 10 years, although it may be as little as 1 to 2 years. The course is often marked by psychosis and behavioral disturbances, which makes management more complicated.

Neuropathology. Lewy bodies are the only essential finding in the pathologic diagnosis of DLB. Lewy bodies are spherical intracytoplasmic eosinophilic neuronal inclusion bodies (see Fig. 10.3–6). “Classic” Lewy bodies are inclusions with a hyaline core and pale halo and are typically seen in the brain stem nuclei, substantia nigra, and locus coeruleus. Cortical Lewy bodies are less-well-defined spherical inclusions. Lewy bodies are composed predominantly of fibrillar deposits of α-synuclein and can also include neurofilament proteins and ubiquitin. Though Lewy bodies can be detected with hematoxylin and eosin stain and antiubiquitin antibodies, they are most sensitively and specifically labeled with antibodies against α-synuclein. In addition to forming intracytoplasmic inclusions, aggregates of α-synuclein occur in neuronal processes called Lewy neurites. The number of cortical Lewy bodies correlates significantly with cognitive impairment in DLB. There are also other pathologic changes that may be seen in DLB but that are not required for diagnosis. Alzheimer disease pathology, particularly amyloid-containing plaques, is also a common feature in most cases of DLB. In contrast, the presence of cortical neurofibrillary tangles indicates that DLB is less likely. Microvacuolation or spongiform changes may also occur in some cases of DLB.

Management. Evidenced-based treatments for DLB remain limited. However, early diagnosis and detection are essential to allow for proper management of symptoms as well as to reduce harm from potentially prescribed antidopaminergic and anticholinergic medications.

Telegram: @medical_k

www.konkur.in

FIGURE 10.3–6. Photomicrographs of Lewy body pathology. **(A)** Abnormal accumulation of α-synuclein aggregates demonstrated by immunocytochemistry in the amygdala of a subject with dementia. Lewy bodies appear as dense intracellular inclusions (*arrows*), but staining of neuronal processes can be seen throughout the neuropil (*arrowheads*). In individuals in whom Lewy body pathology occurs concurrently with Alzheimer disease, the amygdala is often the only region affected. **(B)** Classic appearance of a Lewy body (*arrow*) in a large pigmented neuron of the substantia nigra. **(C)** Lewy body pathology in the neocortex. Both Lewy bodies (*arrows*) and substantial labeling of neuronal processes in the neuropil (*arrowheads*) are evident. (Magnification for [A] and [B] 200×, for [C] 400×. All images provided courtesy of Dr. Ronald L. Hamilton, Department of Pathology, Division of Neuropathology, University of Pittsburgh School of Medicine.)

NONPHARMACOLOGIC MANAGEMENT. Nonpharmacologic interventions have not been systematically studied in DLB. Strategies to increase levels of arousal and attention through social interaction and environmental novelty may reduce the visual hallucinations and fluctuations in cognition and function. There is preliminary evidence for the role of exercise, cognitive training, and caregiver education to help with the management of behavioral disturbances, particularly agitation and psychosis.

PHARMACOLOGIC MANAGEMENT

Cholinesterase Inhibitors. The cholinesterase inhibitors are the mainstay of treatment for DLB. The strongest evidence exists for donepezil and rivastigmine, with a 2015 meta-analysis showing these medications to have beneficial effects on cognition, hallucinations, delusions, and activities of daily living in individuals with DLB. However, adverse events were more common, particularly with rivastigmine, and

Telegram: @medical_k

www.konkur.in

included nausea, vomiting, anorexia, and somnolence. The rivastigmine patch may mitigate some of the gastrointestinal side effects associated with the oral formulation. Data for the usage of galantamine is limited to an open-label trial.

Memantine. Data in regard to the usage of memantine remains mixed. A handful of studies have shown that memantine is associated with improved quality of life and improvements in global clinical status, goal attainment, caregiver burden, attention, and REM sleep behavior.

Antipsychotics. First-generation antipsychotics are generally not well tolerated in DLB and should be avoided. There is little data to guide the use of second-generation antipsychotics, for which DLB patients may also have a low tolerance. A placebo-controlled study of olanzapine in psychosis in Alzheimer disease looked at a subgroup of patients retrospectively diagnosed with DLB. These patients demonstrated a decrease in positive symptoms of psychosis without worsening of parkinsonism or cognition with olanzapine. However, concern remains about the ability to tolerate antipsychotics in individuals with DLB. A small open-label study of quetiapine for psychosis and agitation in DLB found a clinically significant reduction in symptoms in about half the patients, but several had to discontinue treatment due to somnolence and orthostatic hypotension. In a multicenter randomized placebo-controlled study of 23 individuals with DLB, quetiapine was well tolerated and did not worsen parkinsonism, but there were no significant differences in efficacy between quetiapine and placebo. Risperidone did not appear to be well tolerated in a randomized controlled trial comparing this to citalopram, with individuals with DLB in both treatment groups having high discontinuation rates. Although there are no controlled trials involving the use of clozapine in the treatment of neuropsychiatric symptoms of DLB, given this medication's utility in treating psychosis in Parkinson disease, there may be some clinical value in its treatment of psychotic symptoms in DLB as well. More data is needed regarding the use of pimavanserin, a recently approved atypical antipsychotic for the treatment of Parkinson disease psychosis, for the treatment of psychotic symptoms in DLB.

Antidepressants. As discussed above, citalopram does not appear to be beneficial or well-tolerated in individuals with DLB. There are no other controlled trials of SSRIs or selective and norepinephrine reuptake

Telegram: @medical_k

www.konkur.in

inhibitors (SNRIs). Antidepressants with anticholinergic properties should be avoided.

Benzodiazepines. Clonazepam may have a benefit for the treatment of REM sleep behavior disorder, but like all long half-life, benzodiazepines must be used cautiously in the older adults.

Melatonin and Ramelteon. There is increasing evidence for the potential use of melatonin in REM sleep behavior disorder, but prospective clinical trials are still necessary. There are no studies on the use of melatonin in DLB, but a case series of four patients with DLB utilizing ramelteon, a melatonin agonist, showed a reduction in hallucinations and REM sleep behavior disorder episodes.

Zonisamide. A phase 2 placebo-controlled randomized trial examining the use of zonisamide as an adjunct to levodopa showed improvement of parkinsonism in patients with DLB without worsening of cognitive functioning or psychiatric symptoms. There was an increased risk of adverse effects with increasing dosage, mainly being weight loss and decreased appetite.

Antiparkinsonian Medications. Antiparkinsonian medications, including L-dopa and direct dopamine agonists, may be tried in DLB. Responses are variable but generally less robust than in Parkinson disease. About a third of patients may experience improvement. However, these patients are also susceptible to psychotic symptoms. Given their increased potential for neuropsychiatric complications, initial doses should be small, with gradual increases while monitoring behavioral symptoms. In addition to worsening psychosis, additional potential side effects include postural hypotension, sedation, nausea, and vomiting. Anticholinergic medications are generally not recommended because of the associated cognitive side effects.

Dementia in Parkinson Disease

Cognitive impairment in Parkinson disease is common, with almost a quarter of newly diagnosed individuals displaying some impaired performance.

Telegram: @medical_k

www.konkur.in

Definition. In 2007, the Movement Disorder Society task force published criteria to guide the diagnosis of dementia associated with Parkinson disease. For an individual to be diagnosed with probable Parkinson disease dementia, there must be a dementia syndrome that developed within the context of Parkinson disease. Similar to other dementia syndromes described in this chapter, there must be impairment in more than one cognitive domain, this must be a decline from a previous level of functioning, and there are impairments in daily life independent of those impairments due to the motor or autonomic symptoms. Cognition is impaired in two out of the following four domains (attention, executive function, visuospatial function, and free memory recall), and there must also be the presence of at least one behavioral symptom.

History. Parkinson disease was first written about in 1817 by James Parkinson. In a treatise on the “shaking palsy,” he described six cases he had observed. In 1888, the French neurologist, Jean-Martin Charcot, named this clinical entity after Parkinson.

Comparative Nosology. In the DSM-5, for a diagnosis of major neurocognitive disorder due to Parkinson disease, the criteria for major neurocognitive disorder must be met, the impairment occurs in the setting of well-established Parkinson disease, there is an insidious onset and gradual progression, and the impairment cannot be attributable to another medical condition or mental disorder.

Epidemiology. The prevalence of Parkinson disease increases with age. About a third of newly diagnosed patients with Parkinson disease may demonstrate some MCI. Up to 80% of individuals with Parkinson disease will develop dementia, with roughly 10% of individuals with Parkinson disease developing dementia each year. On average, Parkinson disease dementia is diagnosed 8 to 10 years from the onset of Parkinson disease, but there is a wide range. The age of onset of Parkinson disease is between the sixth and ninth decades; increased duration of illness is a risk factor for the development of dementia.

Etiology. Risk factors for the development of dementia in Parkinson disease include age, more severe parkinsonism, and MCI at initial diagnosis. While APOE ε4 is a known risk factor of Alzheimer disease and has been associated with DLB, evidence is mixed as to whether this plays

Telegram: @medical_k

www.konkur.in

a role in the development of Parkinson disease dementia. The hereditary *SCNA* and *GBA* forms of Parkinson disease have been associated with dementia.

Diagnosis and Clinical Features. As this clinical entity occurs within Parkinson disease, the cognitive impairment should occur at least 1 year after symptoms of Parkinson disease were first noted. On neuropsychiatric examination, impairments in attention, executive function, visuospatial function, language, and memory may be seen. Impaired mental speed may be evident. On memory testing, recognition is better than free recall. Regarding language impairment, word-finding difficulties and impaired comprehension of complex sentences may be seen. Associated neuropsychiatric symptoms that may be present include apathy, depression, anxiety, hallucinations, delusions, and personality changes. Hallucinations have been reported in 45% to 65% of individuals with PDD, and delusions in 25% to 30%. Similar to DLB, individuals may have REM sleep behavior disorder and excessive daytime sleepiness may also be seen.

Biomarkers. MRI imaging may show thinning in the frontal and anterior cingulate regions. Functional MRI may demonstrate reduced synchronization of frontal regions, and PET imaging may demonstrate hypometabolism in parietal and temporal cortices, as well as in visual areas and the frontal lobes. Dopamine transporter imaging is abnormal in Parkinson disease; however, this abnormality does not differentiate Parkinson disease from Parkinson disease with dementia. Cardiac metaiodobenzylguanidine scintigraphy is reduced in Parkinson disease; of note, this test is normal in MSA and PSP. On EEG, those with dementia in Parkinson disease have slower baseline EEG activity than those without cognitive impairment.

Differential Diagnosis. The 1-year rule can be useful in distinguishing Parkinson disease dementia from DLB. The presence of parkinsonian symptoms and cognitive impairment should also cause one to think about other Parkinson plus syndromes, including CBD, PSP, and MSA. The tremor in CBD differs from that typically seen in Parkinson disease in that it is typically minimal at rest and amplified with action, and CBD is often associated with an asymmetric rigidity. The vertical gaze impairment as well the prominent axial rigidity in PSP can aid in distinguishing this from

Telegram: @medical_k

www.konkur.in

Parkinson disease; however, the gaze impairment can be absent in up to 50% of individuals with PSP. The parkinsonism in both CBD and PSP is typically not responsive to dopaminergic medications. In MSA, individuals may display bradykinesia, rigidity, postural instability, and postural tremor; the cerebellar and autonomic dysfunction may be helpful in distinguishing this from Parkinson disease. Of note, in multisystem atrophy, up to 30% of individuals may show some response to dopaminergic medications at some point during the disease process.

Course and Prognosis. The course of dementia in Parkinson disease is progressive over time, although individuals may have some plateaus, as well as fluctuations from day to day. Hallucinations may occur, as can other psychiatric symptoms, particularly apathy. Dementia has been associated with increased functional impairment, nursing home placement, and decreased survival in Parkinson disease.

Neuropathology. Parkinson disease is associated with neuronal loss in the substantia nigra. Lewy bodies, made up of α-synuclein, are present in the cell bodies of the surviving neurons. α-Synuclein pathology is more extensive in Parkinson disease dementia compared to Parkinson disease without dementia, with more global cortical and limbic involvement. Individuals may also have β-amyloid plaque burden as well as the presence of tau neurofibrillary tangles.

Management. Evidence suggests that acetylcholinesterase inhibitors can improve cognition, attention, executive function, and global status and may have beneficial effects on overall activities of daily living; rivastigmine is an approved treatment for Parkinson disease dementia. Memantine has not been shown to be beneficial. Should psychotic symptoms be problematic, attempts to reduce or discontinue antiparkinsonian medications, balancing psychotic and motor symptoms are warranted, with consideration of reduction in L-dopa as a last resort. Pimavanserin, which is a novel 5-HT_{2A} inverse antagonist, is an approved medication for the treatment of delusions and hallucinations in Parkinson disease psychosis. Antipsychotic medication should be used very cautiously. Clozapine is the only antipsychotic medication that has been deemed clinically useful for the treatment of psychosis in Parkinson disease by the Movement Disorder Society Task Force on Evidence-Based Medicine

Telegram: @medical_k

www.konkur.in

Review of Treatments for Parkinson disease. There is insufficient evidence for the use of quetiapine, and olanzapine is not felt to be useful given its significant worsening of motor symptoms.

Dementia in Huntington Disease

Definition. Huntington disease is a rare disorder that is characterized by motor, cognitive, and psychiatric symptoms. The motor symptoms include chorea, or involuntary dance-like movements, and ataxia; the disease inevitably leads to dementia.

History. The clinical entity of Huntington disease was first described by George Huntington in late 1872. In 1993, the mutant gene was identified.

Comparative Nosology. For an individual to be diagnosed with the DSM-5 diagnosis of major neurocognitive disorder due to Huntington disease, there must be clinically established Huntington disease, or risk of this based on family history or genetic testing, in addition to meeting the criteria for major neurocognitive disorder, and there is a gradual and insidious onset.

Epidemiology. The worldwide prevalence of Huntington disease has been reported to be 2.71 per 100,000, with a higher prevalence seen in Europe, North America, and Australia.

Etiology. Huntington disease is an autosomal-dominant inherited disease transmitted through a triplet CAG repeat mutation located on chromosome 4 in the *HTT* gene. This mutation results in a polyglutamate expansion in the Huntington protein. Expression of the abnormal protein ultimately results in neuronal cell death, primarily in the caudate nucleus and frontal lobes. Family history is important in the diagnosis of this disease, and it can be confirmed by genetic testing for the CAG repeat expansion.

Diagnosis and Clinical Features. In addition to the chorea and ataxia, other motor symptoms include bradykinesia, dystonia, and ideomotor apraxia. Both cognitive and psychiatric symptoms can precede motor symptoms. Psychiatric symptoms include personality changes, depression, blunting of affect, irritability, psychosis, and aggressive–

Telegram: @medical_k

www.konkur.in

compulsive behavior, with depression being the most common psychiatric symptom. The dementia is often described as a subcortical dementia, with deficits in processing speed, attention, planning, and sequencing being more common. Memory deficits can be in both declarative and procedural domains. Dysarthria and dysphagia are present in more severe stages.

Biomarkers. Atrophy of the caudate is evident on structural imaging, and striatal atrophy may be seen on imaging before a clinical diagnosis of Huntington disease is made.

Differential Diagnosis. Given the autosomal dominant pattern, obtaining a family history is important. If family history is unknown or if genetic testing is negative, CJD (discussed below) should be considered in the differential, given the ataxia and myoclonus that may be present. The differential for chorea includes both other hereditary and acquired causes.

Course and Prognosis. The age of onset of Huntington disease is typically between 20 and 65 years of age, with the disease itself lasting for about 20 years. Huntington disease is inevitably fatal.

Management. Antidepressants and sedatives can be used for associated mood disorders. Tetrabenazine is an FDA-approved treatment for chorea, but it is recommended that this medication be avoided in patients with uncontrolled depression and a history of suicidality, making this a challenge as psychiatric symptoms are particularly prevalent in Huntington disease. Deutetrabenazine is also FDA-approved for the treatment of chorea; this medication allows for less frequent daily dosing, and data suggests a more favorable adverse effect profile. Dopamine-depleting agents may be used for the treatment of chorea, but there is weaker evidence for the use of amantadine and riluzole compared to tetrabenazine. Antipsychotic medications may be used for the treatment of chorea, in addition to the treatment of agitation and psychosis. The more potent antipsychotic medications may also be beneficial for the chorea, but patients should be evaluated for potentially worsening parkinsonism as well if these are used. Cholinesterase inhibitors have not been shown to have benefits in the treatment of cognitive impairment.

Prion Diseases

Telegram: @medical_k

www.konkur.in

Definition. The prion disorders encompass genetically induced, sporadically occurring, and acquired diseases, all of which can be attributed to a misfolded prion protein, which ultimately leads to a further cascade of misfolded prion proteins. The genetic prion diseases include familial CJD, fatal familial insomnia and Gersttmann–Straussler–Scheinker syndrome (GSS). The sporadically occurring prion diseases include sporadic CJD, sporadic fatal insomnia, and variably protease-sensitive prionopathy. The acquired prion illness include iatrogenic CJD, variant CJD, and kuru.

History. CJD was first termed in 1922 and was used to describe a clinical entity of rapidly progressive myoclonus, ataxia, and dementia, described in earlier case reports. In the 1950s, kuru was discovered in Papua New Guinea and was characterized by truncal ataxia, tremor, and quick progression to dementia and death. Kuru was eventually found to share similar histopathology and transmission properties with CJD. Later it was determined that these infectious agents were proteins, and the term prion was created in 1982 to characterize these proteinaceous infectious particles. In the late 1990s, there was a series of variant CJD cases in the United Kingdom and France, which resulted from the transmission to humans of bovine spongiform encephalopathy, commonly known as mad cow disease, through consumption of contaminated meat products.

Comparative Nosology. The DSM criteria for major neurocognitive disorder due to prion disease include an insidious onset with rapid progression of impairment, and motor features of prion disease or biomarker evidence must be present, and the presentation cannot be attributable to another medical or mental disorder.

Epidemiology. The incidence of sporadic CJD worldwide is 1 per 10^6 and familial CJD is 1 per 10^7 per year. In sporadic CJD, the peak age of onset is 67 years, while the familial and variant form typically occurs in younger individuals. About 15% of prion diseases are genetic. Fatal insomnia usually presents between the ages of 35 and 55.

Etiology. The prion diseases can be sporadic, inherited, and also horizontally transmissible, with about 15% of cases being caused by specific mutations of the prion protein gene. The gene for the prion protein is found on chromosome 20. Underlying these diseases is a misfolding of

Telegram: @medical_k

www.konkur.in

the prion protein, which occurs via a spontaneous or genetically induced mutation. Once this mutation occurs, the pathologic form of the prion propagates. CJD and fatal insomnia are both sporadic and familial. GSS is a familial disease. Iatrogenic CJD has been associated with medical or surgical equipment contaminated with the pathologic prion protein. Transmission through ingestion has also been demonstrated, as seen with Kuru and the practice of ritual endocannibalism in the Foré linguistic group in Papua New Guinea, and also variant CJD through the ingestion of contaminated meat products.

Diagnosis and Clinical Features. Sporadic and familial CJD initially present with memory impairment and confusion, which quickly progress to a cortical dementia-like picture with ataxia; other symptoms may include myoclonus, pyramidal/extrapyramidal dysfunction, visual dysfunction, cerebellar dysfunction, and akinetic mutism. Iatrogenic forms of CJD typically show more cerebellar ataxia at symptom onset. GSS first presents with ataxia, and then dementia develops. Variant CJD often presents with psychiatric symptoms, usually apathy or depression, and painful sensory symptoms in distal extremities; the illness progresses to eventually include symptoms of ataxia, abnormal movements, and cognitive decline. Often GSS presents initially with ataxia or dysarthria and then progresses to dementia; other symptoms that have been reported include memory impairment, spastic paresis, motor impairment, and behavioral disturbances; both age of onset and duration of illness are more variable in comparison to the other prion diseases. In fatal insomnia, there is insomnia, which may be present for months until other symptoms present themselves; additional symptoms may include visual changes, ataxia, myoclonus, and psychiatric symptoms, such as visual hallucinations, personality change, depression, and disinhibition; cognitive impairment and dementia do not appear until much later in the course. Both GSS and Kuru tend to have less cognitive impairment. Kuru typically presents with a rapid course, with symptoms including progressive ataxia, dysarthria, dysphagia, tremor, and motor dysfunction. Both familial and sporadic fatal insomnia presents with sleep abnormalities, neuropsychiatric symptoms, and gait abnormalities. Variably protease-sensitive prionopathy tends to have a longer disease duration, with presentations being more variable depending on the genetic polymorphisms involved.

Telegram: @medical_k

www.konkur.in

Biomarkers. MRI, EEG, and CSF studies may be helpful in making the diagnosis of a prion disease. On MRI, there are high signal abnormalities in the caudate nucleus and/or putamen on diffusion-weighted imaging (DWI) and fluid-attenuated inversion recovery (FLAIR) in CJD. In sporadic CJD, DWI shows restricted diffusion in the cortex, caudate, and/or putamen, as well as abnormal FLAIR hyperintensities in the cortical ribbon. DWI in variant CJD characteristically shows the pulvinar sign. Hypometabolism in the thalamus and cingulate region on PET scan points toward fatal insomnia.

Elevations in 14-3-3, total tau, or neuron-specific enolase in CSF studies have been associated with sporadic forms of CJD. Real-time quake-inducing conversion (RT-QuIC) amplification of CSF prion protein may be helpful in the diagnosis of sporadic CJD.

EEG may be useful in the diagnosis of prion diseases. In sporadic and familial CJD, EEG shows bilateral periodic discharges, with EEG in CJD showing 1 to 2 Hz periodic sharp-wave (often biphasic or triphasic) complexes later in the disease. Iatrogenic CJD has a diffuse slow-wave pattern. Slow waves can also be evident in GSS and fatal familial insomnia.

As of yet, there are no prodromal biomarkers available for the identification of potential disease.

Differential Diagnosis. Given the progressive cognitive impairment and motor features of the prion diseases, the differential is quite broad and includes many of the neurodegenerative conditions that have been discussed in the chapter, including Alzheimer disease, the varying frontotemporal lobar dementias, DLB, CBD, and Huntington disease. Autoimmune and antibody-mediated disorders should be considered on the differential, as well as encephalitis, infectious, and neoplastic causes. The spinocerebellar ataxias, as well as Hashimoto encephalopathy, can also have similar symptom presentations.

Course and Prognosis. Sporadic CJD is most commonly diagnosed in the seventh or eighth decade. The course is rapidly progressive, with the prognosis somewhere between 4 and 6 months. Diagnosis is typically not made until the third month after symptom onset when symptoms are usually quite severe already. The familial form of the disease has a more extended course, typically of 1 to 5 years. The duration of GSS is typically 2 to 6 years, and for fatal insomnia, it is 1 to 2 years.

Telegram: @medical_k

www.konkur.in

Neuropathology. The hallmark clinical feature of sporadic and familial CJD is spongiform degeneration of the cortical gray matter; reactive gliosis is often evident as well. Pathology is usually focused on the neocortex, subiculum of the hippocampus, caudate, putamen, and thalamus. In GSS, there are extensive prion protein plaques with less spongiform degeneration. There is focal thalamic gliosis and minimal spongiform degeneration seen in fatal insomnia. The neuropathology seen in variant CJD includes prion protein plaques surrounded by a halo of vacuolar change with diffuse spongiosis. Neuronal loss and gliosis are seen focally in the thalamus and the inferior olives in fatal insomnia. Spongiform changes and gliosis is seen in variably protease-sensitive prionopathy.

Management. At this time, treatment is limited to symptomatic therapies, including antiepileptic medications for seizure control, clonazepam for myoclonus, and small doses of antipsychotic medications for distressing psychiatric symptoms, including hallucinations and delusions.

Limbic Predominant Age-Related TDP-43 Encephalopathy

Definition. LATE, referred to as LATE, is a TDP-43 proteinopathy with or without hippocampal sclerosis pathology. This is a relatively new diagnosis, with consensus-based recommendations on diagnosis and staging released in 2019.

Epidemiology. LATE typically occurs in patients over the age of 80, who are often characterized as the oldest-old. Rates may be higher in females simply because they have a longer life expectancy compared to males. LATE neuropathologic changes are evident in over 20% of individuals over the age of 80, with this prevalence increasing with increasing age; however, these may not be the sole neuropathologic changes present.

Genetics. TDP-43 is encoded by the *TARDBP* gene. Gene variants on *GRN* on chromosome 17q, *TMEM106B* on chromosome 7p, *ABCC9* on chromosome 3q, and *APOE* on chromosome 19q are all suspected of playing a role in LATE neuropathologic changes. *KCNMB2* is also suspected of playing a role.

Telegram: @medical_k

www.konkur.in

Diagnosis and Clinical Features. LATE presents as a progressive amnestic syndrome, similar to dementia of the Alzheimer type. Individuals with only LATE neuropathologic changes have a more gradual decline, as opposed to those with LATE neuropathologic changes in combination with Alzheimer disease neuropathologic changes. The course typically begins with impairment in episodic memory, then expands to include other cognitive domains, and ultimately affects an individual's independent functional status.

Biomarkers. There are no CSF, serum, or neuroimaging biomarkers yet available. Neuroanatomical imaging may show atrophy in the mesial temporal lobe, inferior frontal, anterior temporal lobes, and the insular cortices. On MRI, hippocampal atrophy is greater in LATE than Alzheimer disease, particularly if hippocampal sclerosis is present.

Differential Diagnosis. Given the similar symptom profile, dementia of the Alzheimer type should be considered in the differential. One autopsy study of 25 individuals with LATE neuropathologic change and no pathologic changes associated with Alzheimer disease or Lewy body disease showed that 67% had received a diagnosis of dementia of the Alzheimer type, and 12.5% had received a diagnosis of vascular dementia. LATE shares some genetic similarities to FTD, and TDP-43 proteinopathy is seen in both FTD-TDP as well as amyotrophic lateral sclerosis. The older age of presentation in LATE should help to distinguish this from FTD-TDP, and the clinical symptoms should distinguish this from ALS.

Course and Prognosis. There are varied reports as to whether those with both LATE neuropathologic change and Alzheimer disease neuropathologic change together have greater cognitive impairment and a steeper decline compared to those with "pure" LATE. The presence of both Alzheimer disease and LATE neuropathologic changes together have been associated with lower total neuropsychiatric symptom burden compared to dementia of the Alzheimer type alone. Those individuals over the age of 90 appear to have a slower decline compared to those individuals 89 years old or less.

Neuropathology. Similar to most dementias, an autopsy provides a definitive diagnosis. 97% of patients with LATE neuropathologic change

Telegram: @medical_k

www.konkur.in

on autopsy initially presented with cognitive symptoms.

The presence of TDP-43 proteinopathy is necessary to make a diagnosis of LATE-neuropathologic changes. TDP-43 protein inclusion bodies can be found in the neuronal cytoplasm, and abnormal TDP-43 accumulation can be present in nuclei and neurites of neurons, as well as in oligodendroglia and astrocytes. The distribution of neuropathology starts in the amygdala, then progresses to the hippocampus, and then the middle frontal gyrus.

Hippocampal sclerosis may or may not be present and is not required to make a diagnosis of LATE, with one autopsy study showing that hippocampal sclerosis was evident in 42% of individuals who had LATE neuropathologic change.

10.4 Mild Cognitive Impairment and Amnestic Disorders

DANIEL VARON, M.D., AND CARMEN ANDREESCU, M.D.

In the past, amnestic disorders referred specifically to "pure" memory deficits, most often defined in the context of substance abuse/dependence or in the context of a general medical condition. However, 20 years ago, a new concept was developed: *mild cognitive impairment* (MCI). As defined by the Report of the International Working Group on MCI, it requires the presence of cognitive decline not warranting the diagnosis of dementia and/or evidence of decline over time on objective cognitive tasks but with preserved basic activities of daily living. Thus, MCI differs from classic amnestic disorders both by its etiology and by the domains of its clinical presentation.

Table 10.4–1.
DSM-V Diagnostic Criteria for Mild Neurocognitive Disorder

A. Evidence of modest cognitive decline from a previous level of performance in one or more cognitive domains (complex attention, executive function, learning and memory, language, perceptual-motor, or social cognition) based on:
   1. Concern of the individual, a knowledgeable informant, or the clinician that there has been a mild decline in cognitive function; and
   2. A modest impairment in cognitive performance, preferably documented by standardized neuropsychological testing or, in its absence, another quantified clinical assessment.
B. The cognitive deficits do not interfere with the capacity for independence in everyday activities (i.e., complex instrumental activities of daily living such as paying bills or managing medication are preserved, but greater effort, compensatory strategies, or accommodation may be required).
C. The cognitive deficits do not occur exclusively in the context of a delirium.
D. The cognitive deficits are not better explained by another mental disorder (e.g., major depressive disorder, schizophrenia).

Specify whether due to: Alzheimer disease, frontotemporal lobar degeneration, Lewy body disease, vascular disease, traumatic brain injury, substance/medication use, HIV infection, prion disease, Parkinson disease, Huntington disease, another medical condition, multiple etiologies, or unspecified.

Coding note: For mild neurocognitive disorder due to any of the medical etiologies listed above, code **331.83 (G31.84).** Do *not* use additional codes for the presumed etiologic medical conditions. For substance/medication-induced mild neurocognitive disorder, code based on the type of substance; see "Substance/Medication-Induced Major or Mild Neurocognitive Disorder." For unspecified mild neurocognitive disorder, code **799.59 (R41.9).**

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:680, 681.

In the revised fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR), MCI was hosted by various provisions (cognitive disorder not otherwise specified [NOS], amnestic disorder NOS). In DSM V, the term mild neurocognitive disorder embraces cognitive disorders NOS and MCI (Table 10.4–1). According to DSM V, amnestic disorder can be classified under Major Neurocognitive Disorders if the severity of the dysfunction is enough to grant this diagnosis.

MILD COGNITIVE IMPAIRMENT

Definition

Although the term MCI has been in use since 1982 as a descriptor of stage 3 on the Global Deterioration Scale, it was later developed by the Mayo Clinic Group as a diagnostic category designed to fill the gap between cognitive changes associated with aging and cognitive impairment suggestive of dementia. The criteria proposed by the Mayo Clinic Alzheimer's Disease Research Center (MCADRC criteria) include (1) memory complaint, preferably confirmed by an informant; (2) objective memory impairment for age and education; (3) preserved general cognitive function; (4) intact activities of daily living; and (5) not demented (Table 10.4–2).

Table 10.4–2.
Mild Cognitive Impairment Original Criteria

1. Memory complaint, preferably qualified by an informant
2. Memory impairment for age and education
3. Preserved general cognitive function
4. Intact activities of daily living
5. Not demented

In 2003, the concept was refined (Table 10.4–3) and expanded to include amnestic and nonamnestic subtypes, which in turn can be subdivided into single- and multiple-domain subcategories. (Fig. 10.4–1). These divisions can be used when trying to approximate the etiology of the MCI syndrome. In 2011, a workgroup assembled by the National Institute on Aging (NIA) and the Alzheimer's Association (AA) delineated specific criteria for the diagnosis of MCI due to Alzheimer disease (AD) (Table 10.4–4), and subsequently, criteria for MCI due to Parkinson disease were formulated as well. Similarly, the DSM-V criteria for mild neurocognitive disorder include specifiers for multiple etiologies (Table 10.4–1). As the availability of biomarkers increases, criteria for each etiology will become progressively more specific.

Historical Perspective

The imprecise border between normal aging-related cognitive decline and dementia-related cognitive impairment has been described for several decades. Thus, in 1962, Kral introduced the terms "Benign Senescent Forgetfulness" (forgetfulness for less important facts and awareness of problems) and "Malignant Senescent Forgetfulness" (memory problems for recent events and lack of awareness). In 1986, the National Institute of Mental Health (NIMH) recommended the term "Age-Associated Memory Impairment" for age-related normal memory changes. However, the validity of this concept was disputed due to diagnostic tests based on the performances of younger adults (Table 10.4–5).

In 1994, the International Psychogeriatrics Association presented the concept of "Age-Associated Cognitive Decline," which described cognitive deficits, including but not limited to memory impairment in the absence of dementia or other affecting cognitive conditions.

Table 10.4–3.
Recommendations for the General Criteria for MCI

General Criteria for MCI
Not normal, not demented (does not meet DSM IV-TR/ICD-10 criteria for a dementia syndrome)
Cognitive decline
Self and/or informant report and impairment on objective cognitive tasks
And/or
Evidence of decline over time on objective cognitive tasks
Preserved basic activities of daily living/minimal impairment in complex instrumental functions

www.konkur.in

"Cognitive Impairment No Dementia" was introduced in 1997 by the Canadian Study of Health and Aging to describe the presence of nondemented cognitive impairment regardless of the underlying process (neurologic, psychiatric, medical). It is thus a more inclusive concept (encompasses those with static encephalopathies who are not necessarily having a progressive worsening cognitive decline).

Several other classifications, including age-consistent memory impairment and late-life forgetfulness, are defined on the bases of performance on various cognitive tests.

The concept of MCI is currently defined in DSM-V as Mild Neurocognitive Disorder. Just as functional impairment is an exclusion criterion for MCI, in Mild Neurocognitive Disorder, cognitive deficits should not interfere with the capacity for independence in everyday activities. Developments in identifying biologic markers for MCI will likely solidify the conceptualization and, hopefully, the treatment of prodromal dementia.

Epidemiology and Etiology of MCI

Various studies on the prevalence of MCI are presented in Table 10.4–6. The recognition that AD pathology may exist in the brain long before the presence of clinical symptoms led to the focus on preclinical stages, with the purpose of characterizing initial impairments that are associated with an increased risk of progression to AD.

The clinical expression of MCI can be viewed as a result of the interaction between several risk factors and several protective factors. The most significant risk factors are related to the different types of neurodegeneration witnessed in dementias. These are clinically expressed in different subtypes of MCI (e.g., amnestic MCI [a-MCI], single domain, is considered to be related to underlying AD pathology; a-MCI, multiple domains, is considered to be related to either AD or vascular dementia type of pathology; while nonamnestic MCI [na-MCI] has been related more closely to dementia with Lewy bodies (DLB) or frontotemporal neurodegeneration). Other risk factors include the apolipoprotein E 4 (APOE4) allele status and cerebrovascular events in the form of either cerebrovascular accident or lacunar disease. The role of chronic exposure to high levels of cortisol, as seen in late-life depression, is also hypothesized to increase the risk for cognitive impairment through hippocampal volume reduction. The notion of "brain reserve" suggests that effects of brain size and neuron density may be protective against dementia despite the presence of neurodegeneration (a larger number of neurons and a bigger brain volume would protect against clinical manifestations of AD despite the presence of neurodegeneration) (Fig. 10.4–2).

MCI Clinical Presentation

The clinical picture of MCI is a function of the criteria used to define it. The MCADRC criteria emphasize memory impairment but do not specify how it should be evaluated. The second criterion (objective memory impairment for age and education) is often interpreted as an objective deficit of memory or another cognitive domain that is more than 1.5 standard deviations below the mean for individuals of similar age and education. The inherent heterogeneity is driven by the novelty of the concept at the time, and the lack of consensus between experts was recognized by the Current Concepts in MCI Conference, which classified MCI into different subgroups, each associated with an increased risk of developing a type of dementia. Thus, a-MCI usually progresses to AD, multiple domains of MCI (md-MCI) may progress to either AD or another type of dementia, while MCI-single nonamnestic domain develops predominantly into non-Alzheimer dementia-like frontotemporal dementia or DLB. With the introduction of the NIA-AA criteria for MCI due to AD, two sets of criteria were outlined: The Core Clinical Criteria meant to be used broadly, in any setting and without requiring any highly specialized tests or procedures and The Clinical Research Criteria, which incorporates the use of biomarkers, intended to be used only in research, academic centers, and clinical trials (Table 10.4–4). Biomarkers

Telegram: @medical_k

www.konkur.in

are not included in the DSM-V criteria for mild neurocognitive disorder due to AD. However, both the NIA-AA working group and DSM V task force acknowledge these biomarkers will most likely make their way into clinical practice once they are adequately validated and widely available.

The correlation between a clinical presentation of MCI and dementia outcome varies. The annual "conversion" rate was 12% in the Mayo MCI sample (compared with 1% to 2% for controls), while the numbers vary from 8% to 100% depending on the setting (community vs. clinical) and the study design (prospective vs. retrospective). Thus, in the Monongahela Valley Independent Elderly Survey (a community-based study), although 10% to 17% of MCI subjects progressed to dementia, 33% to 56% became non-MCI, and half of those returned to normal (Table 10.4–7).

Table 10.4–5.
Terms Related to Mild Cognitive Impairment

Term	Author(s)	Year	Inclusion Criteria	Observations
Malignant senescent forgetfulness (MSF)	VA Kral	1962	Memory difficulties for recent events Lack of awareness regarding the memory deficit	2-year follow-up showed a faster evolution of patients with MSF toward dementia
Age-associated memory impairment (AAMI)	NIMH (T Crook, RT Bartus, SH Ferris)	1986	Age-related memory disturbances leading to (1) subjective concern; (2) functional problem No underlying neurologic illness	Memory tests were validated on young populations, leading to high rates of AAMI in the elderly
Age-associated cognitive decline (AACD)	International Psychogeriatric Association and World Health Organization (R Levy)	1994	Cognitive deficits not meeting the criteria for dementia	Does not include prognosis regarding evolution to dementia Includes several kinds of cognitive decline (not exclusive memory decline)
Cognitively impaired no dementia (CIND)	Canadian Study of Health and Aging	1997	Age 65 and older Multiple cognitive problems not meeting DSM-III-R criteria for dementia	Includes static encephalopathies

DSM-III-R, *Diagnostic and Statistical Manual of Mental Disorders*, third revised edition; NIMH, National Institute of Mental Health.

Table 10.4–6.
Prevalence of MCI in Different Studies

Study	Year	Terminology	Prevalence	Observations
Canadian Study of Health and Aging (Graham et al.)	1997	CIND	16%	CIND with "circumscribed memory loss"—prevalence of 5.3%
Religious Orders Study (ROS) Bennett et al.	2002	MCI	26.4%	The MCI definition in this study is similar to CIND They used a volunteer-based sample
Monongahela Valley Independent Elderly Survey (Ganguli et al.)	2004	MCI	2.9–4%	11–17% progressed to dementia 33–56% reversed to non-MCI
Indianapolis Study of Health and Aging (Unverzagt et al.)	2001	CIND	23.4%	
Cardiovascular Health Study (Lopez et al.)	2003	MCI	6% amnestic MCI 16% multiple domains MCI	21.5% of the md-MCI did not have a memory impairment
Leipzig Longitudinal Study of the Aged (Busse et al.)	2003	MCI	3–20%	Multiple definitions of MCI used
Eugeria Study (Ritchie et al.)	2001	MCI AACD	3.2% for MCI 20.9% AACD	AACD included MCI

AACD, age-associated cognitive decline; CIND, cognitively impaired no dementia; MCI, mild cognitive impairment; md-MCI, multiple domain mild cognitive impairment.

Neuropsychiatric symptoms can appear along with or prior to the cognitive deficits seen in MCI. The concept of mild behavioral impairment (MBI) has been described in the past and has gained more relevance in recent years. This construct describes the emergence of neuropsychiatric symptoms, which can be precursors to cognitive decline and eventually dementia. The description and detection of MBI have been operationalized by the International Society to Advance Alzheimer's Research and Treatment—Alzheimer's Association (ISTAART-AA) criteria. Five subcategories have been proposed, including motivation, affect, impulse control, social appropriateness, and perception/thought content. Rating scales to capture these criteria have been proposed, such as the mild behavioral impairment checklist (MBI-C).

MCI Assessment

Neuropsychological Assessment. Most experts agree that earlier deficits are noted in episodic (vs. semantic) memory. There is no consensus among experts with regard to which memory tests and which cutoffs to use. There is a lack of norms, test scores do not have normal distributions, and test performance is influenced by multiple demographic characteristics. Several experts have proposed that a scale like the delayed recall task from the consortium to establish a registry for AD might be useful in detecting AD in the earliest stages. Brief mental status instruments (like mini-mental state examination) are relatively insensitive for the detection of memory problems in MCI. The Montreal Cognitive

Telegram: @medical_k

www.konkur.in

Assessment (MoCA) has been used as a more adequate way to screen patients with MCI. It has been validated multiple times in different pathologies, populations, and languages. It includes more adequate testing for frontal lobe dysfunction when compared to the Mini-Mental State Examination (MMSE).

The NIA-AA workgroup suggests tests of episodic memory such as the Free and Cued Selective Reminding Test, the Rey Auditory Verbal Learning Test, the California Verbal Learning Test, or the Logical Memory I and II of the Wechsler Memory Scale-Revised can be used. Tests to assess other cognitive domains are also mentioned, including the Trail Making Test for executive function, the Boston Naming Test, letter and category fluency for language, figure copying for spatial skills, and digit span forward for attention.

MCI Subtypes

Clinical classification		Etiology: Degen-erative	Vascular	Psychiatric	Medical conditions
Amnestic MCI	Single domain	AD		Depr	
	Multiple domain	AD	VaD	Depr	
Non-amnestic MCI	Single domain	FTD			
	Multiple domain	DLB	VaD		

FIGURE 10.4–2. Outcome of clinical phenotypes of mild cognitive impairment (MCI) according to presumed etiology. Table 10.4–7.
Conversion Rates from MCI to Alzheimer Disease in Different Studies

Study	Conversion Rate	Observations
Petersen et al. (1999)	12% per year	Clinical sample *N* = 76
Ganguli et al. (2004)	10–17% every 2 years	Community sample
Monongahela Valley Independent Elderly Survey	27% at 10 years	10-year follow-up Fourfold increased risk for progression to Alzheimer disease in MCI group compared with controls
Boston study-Fisk et al. (2005)	18.7% over 3 years	Community volunteers
St. Louis study-Morris et al. (2001)	100% over 9.5 years	Clinical sample
Eugeria study-Ritchie et al. (2001)	11.3% over 3 years	Primary care-based clinical sample
Larrieu et al. (2002)	8.3% per year	Community-based France
QUID Study (Personnes Agees)		40% reverted to normal after 2 years

MCI, mild cognitive impairment.

Biomarkers. Several markers of progression from MCI to AD have been studied in the past two decades. The most well-established biomarkers have been divided into two categories, those that measure amyloid deposition and those that relate to neurodegeneration. Low levels of $A\beta_{42}$ (the 42 amino acid form of β-amyloid) and increased uptake of amyloid positron emission tomography (PET) tracers are associated with fibrillar Aβ deposits. Increased levels of CSF total tau (t-tau) and phosphorylated tau (p-tau), hypometabolism on fluorodeoxyglucose (FDG) PET, and atrophy on MRI are measures of neurodegeneration. The ratio of CSF Aβ levels to t-tau and phosphotau-231 (ptau-231) appears to be the best biomarker in CSF. Locating alterations in the expression of proteins involved in the pathogenetic pathways of AD (proteomic approach) is another approach used to help early detection of AD. Several proteins (cystatin C, β-2 microglobulin, and BEGF polypeptides) have been detected through specific techniques, and currently, there are a number of proteins from both CSF and blood that are implicated in AD pathology. New techniques to accurately identify markers such as p-tau181 and p-tau217 in blood have become available in recent years and will likely allow faster screening and diagnosis of patients at the early stages of the disease.

In 2018, the NIA-AA proposed a new system to define AD more adequately, with the purpose of shifting from a syndromal to a biologic construct. Biomarkers associated with AD were grouped into one of three categories, Aβ deposition, pathologic tau, or neurodegeneration [AT(N)]. Within this framework, living persons can be characterized as positive or negative for all three of these categories independent of their clinical stage. Patients with evidence of an amyloid biomarker (A+) combined with present or absent biomarkers for Tau (T+ or T−), and neurodegeneration (N+ or N−) would be classified within the Alzheimer continuum. Patients with no presence of amyloid (A−) but evidence of tau (T+), neurodegeneration (N+), or both would be classified as having non-AD pathologic change (Table 10.4–8). This framework was recommended for use in research only, with the goal of thoroughly examining its validity. Once this is accomplished, it could eventually make its way to general clinical practice.

Genetics. As MCI is regarded as the prodromal stage for several disorders (AD, frontotemporal, Lewy Body disease, or vascular dementia), different genes are probably related to MCI. Three genes involved

Telegram: @medical_k

www.konkur.in

in rare autosomal dominant forms of AD have been identified: the amyloid precursor protein (*APP*) gene, presenilin-1 (*PSEN1*), and presenilin-2 (*PSEN2*). Screening for each of these mutations will have very limited value for the diagnosis of MCI in the general population unless a clear family history is present. Multiple other genes have been associated with sporadic AD. Among those, APOE has the greatest effect on subjects with MCI. Longitudinal studies have demonstrated that MCI subjects who carry a copy of the E4 allele are at higher risk of progressing to dementia and demonstrate a greater degree of whole brain and hippocampal atrophy. However, testing for APOE genotype is not currently recommended since 75% of people with one copy of the E4 allele remain free of AD, and up to 50% of people with AD do not carry the E4 allele. As the etiology of MCI is heterogeneous, it is likely that a very large number of different genes underlie the pathology of MCI.

Neuroimaging

Advances in neuroimaging studies aim to develop measures allowing the differentiation between MCI and healthy aging as well as within MCI between subjects who will convert to AD or will remain stable over time. This objective has led to a worldwide effort that started in the United States with the Alzheimer's Disease Neuroimaging Initiative (ADNI) and expanded to multiple other countries, including Japan, China, Taiwan, Argentina, and Australia. These studies include a large number of subjects with subjective cognitive impairment, MCI, and mild dementia who are being followed over time. Subsequently, a similar project was developed for Parkinson disease, the Parkinson's Progression Markers Initiative (PPMI).

Table 10.4–8.
Biomarker Profiles and Categories

AT(N)	Biomarker Category	
A-**T**-**(N)**-	Normal AD biomarkers	
A+**T**-**(N)**-	Alzheimer Pathologic change	Alzheimer continuum
A+**T**+**(N)**-	AD	
A+T+**(N)**+	AD	
A+**T**-**(N)**+	Alzheimer and concomitant suspected non-Alzheimer pathologic change	
A-T+**(N)**-	Non-AD pathologic change	
A-T-(N)+	Non-AD pathologic change	
A-T+**(N)**+	Non-AD pathologic change	

AD, Alzheimer disease; A, aggregated Aβ—cerebrospinal fluid Aβ 42, or Aβ 42/Aβ 40 ratio, amyloid PET; T, aggregated tau—cerebrospinal fluid phosphorylated tau, Tau PET; (N), neurodegeneration or neuronal injury—anatomic MRI, FDG PET, cerebrospinal fluid total tau.

Reprinted with permission from Jack CR Jr, Bennett DA, Blennow K, et al. NIA-AA Research Framework: Toward a biological definition of Alzheimer's disease. *Alzheimer's Dementia.* 2018;14(4):535–562. doi:10.1016/j.jalz.2018.02.018.

Structural volumetric studies of MCI subjects showed early changes in the medial temporal structures, reflecting neuronal atrophy, decreased synaptic density, and overall neuronal loss seen in postmortem studies. Volume loss in the hippocampus and entorhinal cortex has been described in MCI. Atrophy of the hippocampal formation and entorhinal cortex measured using volumetric methods and visual rating scales have been reported to predict the rate of progression from MCI to AD. Three-dimensional modeling techniques have localized shape alteration and specific regions of atrophy within the hippocampus. Other methods like tensor-based morphometry allow tracking brain changes in detail, quantifying tissue growth or atrophy throughout the brain, and indicating the local rate at which tissue is being lost. Other innovations in neuroimaging include MR relaxometry, imaging of iron deposition, and diffusion tensor imaging which have been used to assess homeostasis of iron in the gray matter and

Telegram: @medical_k

www.konkur.in

disruption of myelin in the white matter, both of which correlate with incipient pathologic changes in subjects with AD.

Perhaps the most important development has been the advent of PET tracer compounds that visualize amyloid plaques and neurofibrillary tangles. Pittsburgh compound B (carbon-11-PIB) opened the door to imaging amyloid deposition in vivo, but limitations due to cost and half-life of the radiotracer restricted its use to research. The development of fluorinated radiotracers addressed some of these concerns and allowed the approval of these methods by the U.S. Food and Drug Administration (FDA) for clinical use. To date, three compounds have been approved, and guidelines for their use in clinical practice have been outlined (Table 10.4–9). Subsequently, tracers to visualize neurofibrillary tangles have been developed as well and are being studied but are not yet available for clinical use. Specific tracers that visualize amyloid and tangle deposition have allowed investigators to evaluate the pathologic process in vivo and are being used to monitor progression from asymptomatic stages to MCI, dementia due to AD. However, the burden of β-amyloid plaques does not always correlate with the clinical stages, as some MCI subjects can present with a minimal burden similar to healthy controls, while others have an amyloid burden comparable to AD subjects (Fig. 10.4–2) suggesting other factors may be at play. Thus, the combination of several markers further increases the accuracy of the prediction and will probably become the norm as a more specific outline of the disease course is established (Fig. 10.4–3).

MCI Diagnostic Differential

The Cognitive Continuum. The cognitive continuum describes the subtle pathway from age-related cognitive decline to MCI to dementia. Per this model, there is an overlap at both ends of MCI, which indicates that it can be quite challenging to identify the transition points (Fig. 10.4–4). In practice, differentiating MCI from age-related cognitive decline relies mainly on neuropsychological testing, showing a cognitive decline more severe for age and less education. The main differentiation between MCI and a major neurocognitive disorder due to AD resides in the lack of functional impairment in MCI. An attempt to correlate the cognitive changes within this continuum with the underlying pathologic processes has been underway for several years.

www.konkur.in

Table 10.4–9.
Criteria for the Use of Amyloid PET Imaging

Appropriate use would be considered in an individual with the following characteristics:

1. A cognitive complaint with objectively confirmed impairment
2. AD as a possible diagnosis, but the diagnosis is uncertain after a comprehensive evaluation by a dementia expert
3. When knowledge of the presence or absence of Aβ pathology is expected to increase diagnostic certainty and alter management
   a. Patients with persistent or progressive unexplained MCI
   b. Patients satisfying core clinical criteria for possible AD because of unclear clinical presentation, either an atypical clinical course or an etiologically mixed presentation
   c. Patients with progressive dementia and atypically early age of onset (usually defined as 65 years or less in age)

Amyloid imaging is inappropriate in the following situations:

1. Patient with core clinical criteria for probable AD with a typical age of onset
2. To determine dementia severity
3. Based solely on a positive family history of dementia or the presence of APOEε4
4. Patients with a clinical complaint that is unconfirmed on clinical examination
5. In lieu of genotyping for suspected autosomal mutation carriers
6. In asymptomatic individuals
7. Nonmedical use (e.g., legal, insurance coverage, or employment screening)

Aβ, amyloid-beta; AD, Alzheimer disease; APOE, apolipoprotein E; MCI, mild cognitive impairment.

Appropriate use criteria for amyloid PET: a report of the Amyloid Imaging Task Force, The Society of Nuclear Medicine and Molecular Imaging, and the Alzheimer's Association. *Alzheimer's and Dementia.* 2013;9(1):e1–e16. © 2013 by the Alzheimer's Association, and the Society for Nuclear Medicine and Molecular Imaging. doi:10.1016/j.jalz.2013.01.002.

Information gathered from longitudinal studies suggests different pathways during MCI can lead to a similar presentation and pathologic findings when progression to dementia has occurred. In the case of AD, an initial model presented in 2009 suggested the major AD biomarkers became abnormal in a temporally ordered manner with amyloid accumulation (CSF and PET amyloid measures) occurring early, followed by CSF tau, FDG PET, and structural MRI occurring later and leading to clinical changes. The MCI syndrome was thought to become evident once a large portion of amyloid had been accumulated and only minimal neurodegeneration had occurred. A more recent model suggests biomarkers do not occur in sequence but rather become simultaneously more abnormal. Within this model, β-amyloid is considered necessary but not sufficient to produce the AD syndrome, and while its accumulation appears to loosely correlate with the rate of cognitive decline, neurodegeneration biomarkers appear closely associated with a decline in both typical and atypical forms of the disease. The time lag between biomarker evidence and the appearance of clinical symptoms would be moderated by factors such as cognitive reserve and comorbid disorders.

FIGURE 10.4–3. Positron emission tomography images were obtained with the amyloid-imaging agent Pittsburgh Compound-B ([carbon-11]-PIB) in normal control (*far left*), three different patients with mild cognitive impairment (MCI; *center images*), and a mild Alzheimer disease (AD) patient (*far right*). Some MCI patients have control-like levels of amyloid, some have Alzheimer disease–like levels of amyloid, and some have intermediate levels. (Courtesy of William E. Klunk, M.D., Ph.D., University of Pittsburgh, Department of Psychiatry, Pittsburgh, PA. All rights retained.)

FIGURE 10.4–4. Cognitive continuum showing the overlap in the boundary between normal aging and mild cognitive impairment and Alzheimer disease. (Adapted with permission from Petersen RC. Normal aging, mild cognitive impairment, and early Alzheimer's disease. *Neurologist.* 1995;1:326–344.)

Longitudinal data from ADNI and Mayo Clinic has demonstrated some puzzling findings. Patients with MCI followed over time can be subdivided according to their positivity in biomarkers. Some will have only amyloid deposition, others only evidence of neurodegeneration, a third group both amyloid deposition and neurodegeneration and lastly, a fourth group with no evidence of either one. Subjects with evidence of both amyloid deposition and neurodegeneration appear to progress at the fastest rate toward dementia, while subjects with no evidence of either one progress very slowly, if at all. However, those with only amyloid deposition do not progress as quickly as those with only neurodegeneration. In fact, those with neurodegeneration progress almost as quickly as the ones with both amyloid and neurodegeneration in the Mayo sample. These findings speared the evolution of the concept, SNAP (Suspected Non-Alzheimer Pathology), suggesting that some subjects with MCI could have an entity that resembles AD but behaves differently at the pathologic level. In 2019, a consensus workgroup proposed the term limbic-predominant age-related TDP-43 encephalopathy (LATE). LATE is intended to describe a tauopathy where the distribution of TDP-43 is distinct from the one seen in FTLD, is often associated with hippocampal sclerosis, clinically presents with an amnestic dementia syndrome similar to AD, is commonly seen in patients over the age of 80, and could explain the findings seen in some of the subjects with MCI who had been designated as having SNAP. According to the working group's proposal, the term LATE is intended to encompass earlier terms used to designate TDP-43 proteinopathies which may be associated with cognitive impairment such as hippocampal sclerosis, hippocampal sclerosis of aging, hippocampal sclerosis dementia, cerebral age-related TDP-43 with sclerosis, and TDP-43 pathologies in the elderly. In the Rush Memory and Aging Project and Religious

Telegram: @medical_k

www.konkur.in

Orders Study, half the participants had TDP-43 pathology, and approximately 37% had both TDP-43 pathology and AD. This data and other studies seem to suggest mixed pathologies are often the norm in aging brains.

FIGURE 10.4–5. Overview of mild cognitive impairment preceding the diagnosis of dementia. NOS, not otherwise specified. (Reprinted with permission from Petersen RC, O'Brien J. Mild Cognitive Impairment Should Be Considered for DSM-V. *J Geriatr Psychiatr Neurol.* 2006;19(3):147–154. doi:10.1177/0891988706291085; originally adapted with permission from Petersen RC. Conceptual overview. In: Petersen RC. *Mild Cognitive Impairment: Aging to Alzheimer's Disease*. Oxford University Press. Copyright © 2003 by Mayo Foundation for Medical Education and Research.)

The integration of data generated from following subjects who are asymptomatic but have the presence of biomarkers, people with subjective complaints who do not meet the criteria for MCI and very early MCI subjects will allow a much better characterization of all the possible pathologic pathways within the cognitive continuum and their clinical correlations.

Figure 10.4–5 outlines the various etiologic pathways associated with an initial MCI clinical presentation.

Course and Prognosis

The typical rate at which MCI patients progress to AD is 10% to 15% per year and is associated with progressive loss of function (Fig. 10.4–6). However, there are several studies indicating that the diagnosis is not stable in both directions; patients can either convert to AD or revert back to normal. This variability in the course is related to the heterogeneous source of the subjects (clinical vs. community) as well as to the heterogeneous definition criteria used by different studies. a-MCI has been associated with increased mortality (greater in multiple-domains a-MCI than in single-domain a-MCI) (hazard ratio 1.7) when compared with reference subjects.

Epidemiologic studies that followed over time large numbers of community-dwelling subjects, which eventually developed dementia, consistently demonstrate a slow change in cognitive measures with a sharp increase in the rate of decline seen a few years before the clinical diagnosis of MCI or dementia is made. The point in time when this inflection occurs varies from study to study. In some, the rate of cognitive decline increases sharply 5 to 6 years before the AD diagnosis, while in others, the change is seen only 3 years before. Subjects diagnosed with a-MCI appear to present with cognitive changes earlier and decline more rapidly when compared to na-MCI subjects.

The clinical manifestations and rate of decline in MCI are likely not only dependent on the underlying neuropathology but also on a host of factors that can either exacerbate or ameliorate the biologic impact of the underlying disease. Some of these factors include but are not limited to the expression of specific genes, the age of disease onset, baseline brain and cognitive reserve, comorbid medical and psychiatric illness, cerebrovascular burden, and lifestyle characteristics (e.g., diet, physical and cognitive activity). The modulation of some of these factors has been considered a potential way to decrease the likelihood of progression from MCI to dementia.

MCI Treatment

There are no FDA-approved treatments for MCI at this time. MCI treatment involves adequate screening and diagnosis. Ideally, MCI treatment would also include improvement of memory loss, together with the prevention of further cognitive decline to dementia. Cognitive training programs have been reported as mildly beneficial for compensating memory difficulties in MCI. Controlling for vascular risk factors (high blood pressure, hypercholesterolemia, diabetes mellitus) may be a preventive method for those MCI cases underlying vascular pathology. Currently, sensitive tools (imaging techniques or biomarkers) are not available for MCI screening in the general population. In the primary care setting, clinicians should maintain a high suspicion for subjective cognitive complaints and should corroborate these complaints with collateral information whenever possible. Also, identifying reversible causes of cognitive impairment

Telegram: @medical_k

www.konkur.in

(hypothyroidism, vitamin B_{12} deficiency, medication-induced cognitive impairment, depression) can further benefit some of the prodromal dementia MCI cases.

Currently, there is no evidence for the long-term efficacy of pharmacotherapies in reversing MCI. Several epidemiologic studies indicated a reduced risk of dementia in persons taking antihypertensive medications, cholesterol-lowering drugs, antioxidants, and anti-inflammatory and estrogen therapy, but no randomized controlled trials verify these data. With regard to cognitive enhancers, so far, multiple trials designed for a-MCI have reported mostly negative results (Table 10.4–10). Most of these studies were confronted with several problems: (1) obtaining homogeneous samples and identifying potential beneficiaries of treatment; (2) treating a wider population, which led to large percentages of negative responses and problematic side effects; (3) translating the MCI construct into multiple cultures and languages and using AD diagnosis as the primary outcome, given the variability of this diagnosis in different countries. Clinical trials using immunologic methods including active immunization, monoclonal antibodies, and intravenous immunoglobulin (IV IG) therapy have been used in an attempt to reduce the amyloid burden and, in turn, slow or stop disease progression in patients with mild or moderate AD. Many compounds have proven effective in reducing amyloid deposits. However, this effect has not translated so far into clinical improvement. In October 2019, aducanumab, a monoclonal antibody directed at the N-terminus of the amyloid β-peptide, showed modest but significant clinical and functional benefits in a post hoc analysis of two phase 3 trials. Aducanumab was approved to treat patients with MCI and mild dementia due to AD in June 2021, although several experts have questioned the extent of the clinical benefits and the risk-benefit profile, mostly due to the potential for inflammatory brain changes that can be seen on imaging, including vasogenic edema, sulcal effusion, or microhemorrhages. These changes are known as amyloid-related imaging abnormalities (ARIA). Other agents are currently being studied during symptomatic phases of the disease (gantenerumab, donanemab, BAN2401, ALZ-801, plasma exchange). However, many researchers are putting their efforts into treating patients with biologic markers of disease before they develop symptoms. Both subjects with autosomal dominant inherited forms of AD and asymptomatic elderly subjects without genetic predisposition but positive biomarkers are being studied. If positive, these trials could lead the way in treating neurodegenerative disorders during the preclinical stages of disease, preventing people at risk from ever becoming symptomatic.

FUTURE DIRECTIONS

Advances in MCI detection remain paramount for early detection and treatment of AD, as experts agree that disease-modifying treatments for AD will focus on cognitively intact individuals at increased risk. The field of identifying sensitive and specific biomarkers (biologic and neuroimaging markers) will continue to witness exponential development in the coming years.

Table 10.4–10.
Treatment Trials for MCI

Study	N	Duration	Primary Outcome	Results	OBS	Sponsor
Donepezil + vitamin E (Thall et al., 1999)	769	3 years	Conversion to AD	Partially positive (reduced risk of developing AD in the active arm group for the first 12 months)	Amnestic MCI status and the presence of APOE4 allele—predictive of rate of progression to AD	ADCS
Donepezil (Salloway et al., 2004)	269	24 weeks	ADAS-Cog total score; NYU PTIR	Negative	Positive results in secondary outcome measures (ADAS-Cog13)	Pfizer (The Donepezil "401" Study Group)
Donepezil (Doody et al.,2009)	821	48 weeks	ADAS-Cog cognitive subscale, CDR-SB	Minimally positive with a small decrease in ADAS-Cog score in donepezil group. No significant change in CDR-SB	On secondary measures, only global assessment differed significantly in favor of donepezil	Eisai and Pfizer.
Rivastigmine (Feldman et al., 2007)	1,018	48 months	Conversion to AD	Negative		Novartis
Galantamine (Winbald et al., 2008) Two studies	2,048		Progression of CDR score (from .5 to 1) Incident dementia	Negative	Attention assessed by DSST favored galantamine in both studies	Janssen-Cilag and Johnson & Johnson
Piribedil (Nagaraja et al., 2001)	60	12 weeks	MMSE score	Favored piribedil	Mean MMSE change from baseline also favored the intervention group	NIMH
Rofecoxib (Thall et al., 2005)	1,457	3–4 years	Conversion to AD	Negative	Primary outcome favored placebo, while secondary outcomes (ADS-cog, CDR) did not differentiate between rofecoxib and placebo	Merck
Nicotine patch (Newhouse et al., 2012)	74	6 months	Attention on CCPT and global functioning on CGIC	Nicotine improved attention but not global functioning	Secondary outcome measures showed improvements in attention, memory, and psychomotor speed.	
Piracetam	675	12 months	Composite score extracted from eight tests	Negative		UCB Pharma
Ginkgo biloba (DeKosky et al., 2008) (Snitz et al., 2009)	3,069	6.1 years 6.1 years	Incident dementia Rates of change in MMSE, ADAS-Cog and other cognitive domains	Negative Negative	No effect noted in normal cognitive either	NCCAM and NIH
B Vitamins (B12, B6, folic acid) (van Uffelen et al., 2008)	152	1 year	Cognitive function at 6 and 12 months	Negative	Moderate intensity walking improved memory in men and memory and attention in women	TNO-VU University Medical Center

AMNESTIC DISORDERS

Definition

The DSM-IV-TR would provide four diagnostic entities under the category of amnestic disorder: (1) amnestic disorder due to cerebral or systemic medical condition, (2) substance-induced amnestic disorder, (3) amnestic disorder due to unknown etiology, and (4) amnestic disorder NOS. DSM V criteria for mild and major neurocognitive disorder include all these categories (Table 10.4–1).

In the 11th edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-11), amnestic disorder is defined as a severe memory impairment relative to the individual's age and general level of intellectual functioning, not attributable to substance intoxication or substance withdrawal, and presumed to be attributable to an underlying neurologic condition (trauma, infection, tumor, or other disease process affecting specific areas of the brain) or to chronic use of specific substances or medications.

Epidemiology

As discussed in previous editions, data regarding the overall prevalence of amnestic disorders is lacking. The prevalence of alcohol-induced amnestic disorder varies from 0.2% to 4%, while studies of the incidence of transient global amnesia report 5.2 to 10 cases per 100,000 per year.

Telegram: @medical_k

www.konkur.in

Table 10.4–11.
Causes of Amnestic Disorders

Primary Brain Conditions	Notes
Seizure Disorders	
Traumatic brain injury	The fastest-growing cause of amnestic disorder in the United States
Cerebral tumors	Mainly localized around the third ventricle
Stroke	In the posterior cerebral artery territory
Paraneoplastic syndromes (limbic encephalitis)	Focal inflammation of the temporal lobes
Infections (herpes simplex encephalitis)	Preferentially attacks the temporal lobes and produces a hemorrhagic necrosis
Metabolic (hypoxia)	Several causes (respiratory, cardiovascular, metabolic compromise or carbon monoxide intoxication) attacking the sensitive CA1 hippocampal region
Transient global amnesia	Profound anterograde and retrograde amnesia improving over the course of several days
ECT	Retrograde amnesia that usually remits after days/weeks
Systemic Conditions	
Alcohol-induced amnestic syndrome (Korsakoff syndrome)	
Thiamine deficiency	
Hypoglycemia	
Substance-induced amnestic disorder (excluding alcohol) sedative–hypnotics	

ECT, electroconvulsive therapy.

Etiology

The causes of amnestic disorders are listed in Table 10.4–11. The neuroanatomical structures involved in the etiology of amnestic memory have been described inferentially by matching various clinical syndromes with lesions in specific brain areas. These areas include the mamillary bodies, the hippocampus, the amygdala, the dorsomedial, and the midline thalamic nuclei. Bilateral lesions are considered the main culprit, but there are studies reporting unilateral (left regions being more often involved) damage as the cause of amnestic disorders. Some experts differentiate between hippocampal amnesia and diencephalic amnesia, although both manifest with disproportionate impairment of anterograde memory and time-related impairment of retrograde memory (worse closer to illness's onset) while maintaining an intact implicit memory, immediate recall, and attention.

Symptoms

Memory impairment is the core symptom of all amnestic disorders. It includes both anterograde amnesia (inability to learn new information) and retrograde amnesia (inability to recall previously learned information). Short-term memory can also be impaired to a variable degree. Typically, the long-term retrograde memory impairment is temporally graded (more remote memories are better preserved). Immediate recall is usually not affected. Attention and implicit learning (which includes procedural learning as well as other forms of learning without explicit awareness) are also intact.

Associated symptoms include confabulations, changes in personality (apathy, lack of initiative, impulsivity), as well as neurologic symptoms corresponding to the underlying illness (stroke/multiple sclerosis/alcohol-induced amnestic syndrome). The confabulations are more frequent in diencephalic amnesia (prototypical Korsakoff syndrome) than in hippocampal amnesia.

Telegram: @medical_k

www.konkur.in

The following vignette presents the case of Clive Wearing, who developed severe anterograde amnesia following herpes encephalitis. His wife, Deborah Wearing, described his condition in her 2005 book *Forever Today*:

His ability to perceive what he saw and heard was unimpaired. But he did not seem to be able to retain any impression of anything for more than a blink. Indeed, if he did blink, his eyelids parted to reveal a new scene. The view before the blink was utterly forgotten. Each blink, each glance away and back, brought him an entirely new view. I tried to imagine how it was for him…Something akin to a film with bad continuity, the glass half empty, then full, the cigarette suddenly longer, the actor's hair now tousled, now smooth. But this was real life, a room changing in ways that were physically impossible…It was as if every waking moment was the first waking moment. Clive was under the constant impression that he had just emerged from unconsciousness because he had no evidence in his own mind of ever being awake before…"I haven't heard anything, seen anything, touched anything, smelled anything," he would say. "It's like being dead."

Korsakoff Syndrome. In 1889, Sergei Korsakoff described a syndrome of polyneuritis, anterograde amnesia, and confabulations in subjects with chronic alcohol use. He did not, however, differentiate between the acute stage of the illness (the acute encephalopathy had been described 20 years earlier by Carl Wernicke) and the chronic memory impairment. That connection between the acute and the chronic condition was made at the beginning of the 20th century by Karl Bonhoeffer. Later, in the eighth edition of his classic textbook, Emil Kraepelin distinguished between alcohol-related Korsakoff syndrome and Korsakoff syndrome related to other nonalcoholic processes (e.g., neurosyphilis). The etiologic correlation between Korsakoff syndrome and thiamine deficiency caused by poor nutrition associated with chronic alcohol use was described in the early 1930s. Maurice Victor described the corresponding diencephalic lesion in the 1960s. Korsakoff syndrome usually develops secondary to Wernicke encephalopathy, and frequently they are described together (Wernicke–Korsakoff syndrome) (for a description of Wernicke encephalopathy clinical presentation, see chapter on delirium). However, some cases of Korsakoff syndrome develop in the absence of the initial stage of acute Wernicke encephalopathy. Throughout the years, the terms Korsakoff psychosis, Korsakoff dementia, and Korsakoff syndrome have been used interchangeably to describe the clinical presentation of alcohol-induced amnestic disorder.

The overall rates of both Wernicke encephalopathy and Korsakoff syndrome are as low as 0.4% in France (although they have one of the highest per capita consumption of alcohol) and as high as 2% in the United States, Scandinavia, and Australia. It is usually seen in subjects over age 40 (as it follows alcohol use of 20 or more years). Beyond malnutrition, alcohol use induces thiamine deficiency through folate deficiency (which reduces thiamine absorption from the gastrointestinal tract) and through direct damage to the intestinal mucosa.

Primary thiamine deficiency is caused by general malnutrition and other conditions like anorexia nervosa, acquired immune deficiency syndrome (AIDS), hyperemesis gravidarum, thyrotoxicosis, metastatic cancer, hypomagnesemia, long-term dialysis, and congestive heart failure treated long term with diuretics (renal tubular reabsorption of filtered thiamine is exacerbated by furosemide).

Thiamine pyrophosphate (TPP), the active form of thiamine, is involved in three enzymatic reactions essential for the metabolism of glucose and the production of several neurotransmitters, including acetylcholine.

Numerous mechanisms have been suggested to explain the selective loss of neurons found with thiamine deficiency. These include cerebral energy dysfunction, breakdown of the blood–brain barrier, altered glutamate neurotransmission caused by extracellular glutamate and its impaired transport function, together with *N*-methyl-D-aspartate (NMDA) receptor-mediated excitotoxicity, the accumulation of amyloid precursor-like protein, increased free radical production; increased expression of superoxide dismutase consequent to increased microglial response, induction of nitric oxide, and oxidative stress. Changes in a number of central nervous system (CNS) neurotransmitter systems have been reported in thiamine deficiency, suggesting that thiamine is important for normal neurotransmitter function. Acetylcholine, γ-aminobutyric acid (GABA), glutamate, and aspartate are produced primarily through the

Telegram: @medical_k

www.konkur.in

oxidative metabolism of glucose. Serotonin metabolism is also influenced by thiamine deficiency. Cerebrospinal fluid (CSF) levels of 5-hydroxyindoleacetic acid (5-HIAA) were reduced in patients with Wernicke–Korsakoff syndrome. Recent work suggests that thiamine may inhibit serotonin uptake, providing further evidence that thiamine may be acting as a neurotransmitter/neuromodulator as well as a cofactor in brain metabolism and that its deficiency may be associated with behavioral and mood changes. The anatomical lesions described in association with thiamine deficiency include the medial dorsal thalamic nuclei, the mammillary bodies, the fornix, and the cerebellum. The anterior thalamic nucleus has also been associated with thiamine deficiency; it receives input from the mammillary complex and has a major reciprocal connection with the subiculum–presubiculum portion of the hippocampal complex and with the cingulate gyrus. Lesions to these regions (anterior thalamic nuclei, mamillary complex) are related to impaired explicit memory.

Clinically, subjects with Korsakoff syndrome, while maintaining an overall intact intelligence, have a striking inability to form new memories (anterograde amnesia). The retrograde amnesia is less severe, although present to a certain degree (usually for events that occurred shortly before the onset of the illness). Immediate recall and implicit learning (e.g., learning procedures) are preserved. Individuals with Korsakoff syndrome classically present with confabulation, which is explained by most experts as an attempt to cover the memory deficit.

Assessment

Neuropsychological testing usually shows a discrepancy between the performance on memory scales and the performance on a general cognitive scale (a discrepancy between memory performance and overall intelligence).

Laboratory tests show evidence of chronic alcohol use, malnutrition, vitamin deficiency, or systemic illness. Neuroimaging tests are helpful in differentiating between several causes of the amnestic syndrome (mammillary bodies atrophy in Korsakoff syndrome, localized strategic strokes, anoxic lesions of the hippocampal structures, T2-weighted hyperintensities in bilateral temporal poles in herpes encephalitis).

Differential

In contrast to delirium, amnestic disorders evolve on a background of clear consciousness and intact attention, with no perceptual disturbances or mood lability. The amnestic syndrome has no impairment in abstract thinking, judgment, or executive functions. Cognitive impairment in dementia extends to semantic memory, language, and praxis.

Psychogenic amnesia can be differentiated by its presentation (onset after traumatic event, no evidence of substance/general medical condition, amnesia for personal identity, which is conserved in amnestic disorder, and for a circumscribed event, but preserved memory for new events and preserved ability for learning) and its course (abrupt onset and resolution, no residual impairment).

Course and Prognosis

About 25% of patients with Korsakoff syndrome recover; the rest continue to suffer from various degrees of memory impairment. A significant minority needs permanent placement. Most amnestic syndromes have a stable course. A few would recover (such as transient global amnesia or postelectroconvulsive therapy amnesia) or improve (such as amnestic disorder secondary to traumatic brain injury).

Treatment

Treatment with high doses of thiamine (1 to 2 g intravenous daily) is likely to partially or completely reverse Wernicke encephalopathy, but its benefits in the chronic stages (Korsakoff syndrome) are not established. There are case reports but no controlled studies regarding the benefits of donepezil (Aricept), rivastigmine (Exelon), and memantine (Namenda) in treating Korsakoff syndrome. For the other types of amnestic syndrome, the treatment is tailored accordingly to the etiology (acyclovir for herpes encephalitis, hyperbaric oxygen for carbon monoxide poisoning). However, once the amnesic deficit is installed, there are very few pharmacologic options. Most amnestic syndromes have a stable and some even a reversible course (transient global amnesia). Cognitive rehabilitation programs can

Telegram: @medical_k

www.konkur.in

help improve the patient's level of functioning, but so far, none have indicated benefits regarding restoring/improving memory in the impaired domain.

10.5 Cognitive Disorders Due to Another Medical Condition or Substance

ROBERT J. BOLAND, M.D., AND IQBAL AHMED, M.D., F.R.C.PSYCH.

Most cognitive disorders, particularly the dementias, are caused by the disorders already discussed in this section. However, many other medical and neurologic disorders may cause cognitive deficits, and we discuss some of the most common in this section. The DSM-5-TR diagnosis of "Major or Mild Neurocognitive Disorder Due to Another Medical Condition" covers many of these causes. However, the DSM also includes several diagnoses for causes not usually included as types of dementia, such as traumatic brain injury (TBI) or HIV infection. Here we concentrate on cognitive disorders due to other medical conditions, substances, multiple etiologies, and cases when the cause is unknown.

NOSOLOGY

DSM-5-TR includes the following diagnosis:

- *Major or Mild Neurocognitive Disorder due to Another Medical Condition*
- *Substance/Medication-Induced Major or Mild Neurocognitive Disorder*
- *Major or Mild Neurocognitive Disorder Due to Multiple Etiologies*

They also include the residual category of *Unspecified Neurocognitive Disorder*.
For each of the diagnoses (see Tables 10.5–1 to 10.5–5), there are three primary criteria:

1. The patient meets the general criteria for a major or mild neurocognitive disorder (Table 10.5–1)
2. There is evidence for the cause
3. Another cause does not better explain the noncognitive deficit.

ICD-11 lists four specific dementias:

- *Alzheimer disease*
- *Progressive focal atrophies*
- *Lewy body disease*
- *Frontotemporal lobar degeneration*

ICD-11 groups the remaining causes under two diagnoses:

- *Other specified disorders with a neurocognitive impairment as a major feature*
- *Disorders with neurocognitive impairment as a major feature*

The difference between these two diagnoses rests on whether the cause of the impairment is known. These diagnoses are considered residual categories and not defined in any detail.

ETIOLOGY

Many medical conditions and substances can cause cognitive dysfunction. A common strategy for organizing these is to group these conditions based on their primary mechanisms of action, such as neurologic, other medical, and substance-induced causes.

DIAGNOSTIC AND CLINICAL FEATURES

Like any medical or psychiatric illness, diagnosing a cognitive or mental disorder due to another medical condition depends on comprehensive history, detailed physical examination, and appropriate laboratory

Telegram: @medical_k

www.konkur.in

and imaging studies. For the history, specific details of the mental symptoms must be obtained, including presenting features, onset and course, and associated symptoms. More than any other part of the assessment, the description of the presenting features and the timing of onset is the key to the correct diagnosis. We should also explore past medical, psychiatric, and family history, as this can increase the pretest probability of a specific diagnosis and help dictate diagnostic testing. Clinicians should also comprehensively review all prescription and nonprescription medications, vitamins, dietary and herbal supplements, drugs of abuse, and environmental toxin exposures.

Physical examination should include, but is not limited to, cognitive assessment, vital signs, and a comprehensive neurologic examination. Table 10.5–6 outlines several frequently used general cognition tests and specific cognitive domains.

Neuropsychological testing refers to administering a comprehensive battery of multiple tasks evaluating a range of cognitive domains. Examination of specific organ systems is indicated by history and presenting symptoms. Specific findings on the physical examination may narrow the list of potential causative medical conditions (Table 10.5–7). An array of laboratory, brain imaging, and additional diagnostic studies may help diagnose the causative condition (Table 10.5–8). However, performing all possible tests on all patients would be inappropriate and a waste of medical resources. The choice of diagnostic studies should be guided by history, presenting symptoms, and physical examination findings. Table 10.5–9 summarizes the general principles for diagnosing disorders due to another medical condition or substance/medication-induced disorders.

Table 10.5–1.
DSM-5-TR Criteria for Major or Mild Neurocognitive Disorder

Telegram: @medical_k

www.konkur.in

Major Neurocognitive Disorder

Diagnostic Criteria

A. Evidence of significant cognitive decline from a previous level of performance in one or more cognitive domains (complex attention, executive function, learning and memory, language, perceptual-motor, or social cognition) based on:
   1. Concern of the individual, a knowledgeable informant, or the clinician that there has been a significant decline in cognitive function; and
   2. A substantial impairment in cognitive performance, preferably documented by standardized neuropsychological testing or, in its absence, another quantified clinical assessment.
B. The cognitive deficits interfere with independence in everyday activities (i.e., at a minimum, requiring assistance with complex instrumental activities of daily living such as paying bills or managing medications).
C. The cognitive deficits do not occur exclusively in the context of a delirium.
D. The cognitive deficits are not better explained by another mental disorder (e.g., major depressive disorder, schizophrenia).

Specify whether due to:

Note: Each subtype listed has specific diagnostic criteria and corresponding text, which follow the general discussion of major and mild neurocognitive disorders.

- Alzheimer disease
- Frontotemporal degeneration
- Lewy body disease
- Vascular disease
- Traumatic brain injury
- Substance/medication use
- HIV infection
- Prion disease
- Parkinson disease
- Huntington disease
- Another medical condition
- Multiple etiologies
- Unspecified etiology

Coding note: Code based on medical or substance etiology. In most cases of major neurocognitive disorder, there is need for an additional code for the etiologic medical condition, which must immediately precede the diagnostic code for major neurocognitive disorder, as noted in the coding table on pp. 682–683.

Specify (see coding table for details):

- **Without behavioral disturbance:** If the cognitive disturbance is not accompanied by any clinically significant behavioral disturbance.
- **With behavioral disturbance** *(specify disturbance):* If the cognitive disturbance is accompanied by a clinically significant behavioral disturbance (e.g., psychotic symptoms, mood disturbance, agitation, apathy, or other behavioral symptoms). **Coding note:** Use additional code(s) to indicate clinically significant psychiatric symptoms due to the same medical condition causing the major neurocognitive disorder (e.g., **F06.2** psychotic disorder due to Alzheimer disease, with delusions; **F06.32** depressive disorder due to Parkinson disease, with major depressive–like episode). **Note:** Mental disorders due to another medical condition are included with disorders with which they share phenomenology.

Specify current severity:

- **Mild:** Difficulties with instrumental activities of daily living (e.g., housework, managing money).
- **Moderate:** Difficulties with basic activities of daily living (e.g., feeding, dressing).
- **Severe:** Fully dependent.

Coding and Recording Procedures

The following are examples of coding and recording major neurocognitive disorders due to an etiologic subtype *(for more information, see coding table on pp. 682–683 and coding notes in the specific*

Telegram: @medical_k

www.konkur.in

diagnostic criteria for each major and mild neurocognitive disorder subtype):

- **Major neurocognitive disorder due to probable Alzheimer disease, without behavioral disturbance, mild:** G30.9 Alzheimer disease, F02.80 major neurocognitive disorder due to probable Alzheimer disease, without behavioral disturbance, mild.
- **Major neurocognitive disorder due to traumatic brain injury, with behavioral disturbance, moderate:** S06.2X9S diffuse traumatic brain injury with loss of consciousness of unspecified duration, sequela; F02.81 major neurocognitive disorder due to traumatic brain injury, with behavioral disturbance, moderate; F06.34 bipolar and related disorder due to traumatic brain injury, with mixed features.

Mild Neurocognitive Disorder

Diagnostic Criteria

A. Evidence of modest cognitive decline from a previous level of performance in one or more cognitive domains (complex attention, executive function, learning and memory, language, perceptual-motor, or social cognition) based on:
   1. Concern of the individual, a knowledgeable informant, or the clinician that there has been a mild decline in cognitive function; and
   2. A modest impairment in cognitive performance, preferably documented by standardized neuropsychological testing or, in its absence, another quantified clinical assessment.
B. The cognitive deficits do not interfere with capacity for independence in everyday activities (i.e., complex instrumental activities of daily living such as paying bills or managing medications are preserved, but greater effort, compensatory strategies, or accommodation may be required).
C. The cognitive deficits do not occur exclusively in the context of a delirium.
D. The cognitive deficits are not better explained by another mental disorder (e.g., major depressive disorder, schizophrenia).

Specify whether due to:

Note: Each subtype listed has specific diagnostic criteria and corresponding text, which follow the general discussion of major and mild neurocognitive disorders.

- Alzheimer disease
- Frontotemporal degeneration
- Lewy body disease
- Vascular disease
- Traumatic brain injury
- Substance/medication use
- HIV infection
- Prion disease
- Parkinson disease
- Huntington disease
- Another medical condition
- Multiple etiologies
- Unspecified etiology

Coding note: For mild neurocognitive disorder due to any of the medical etiologies listed above, code **G31.84.** Do *not* use additional codes for the presumed etiologic medical conditions. For substance/medication-induced mild neurocognitive disorder, code based on type of substance. For unspecified mild neurocognitive disorder, code **R41.9.**

Specify (behavioral disturbance cannot be coded but should still be recorded):

- **Without behavioral disturbance:** If the cognitive disturbance is not accompanied by any clinically significant behavioral disturbance.
- **With behavioral disturbance** *(specify disturbance):* If the cognitive disturbance is accompanied by a clinically significant behavioral disturbance (e.g., psychotic symptoms, mood disturbance, agitation, apathy, or other behavioral symptoms). **Coding note:** Use additional code(s) to indicate clinically significant psychiatric symptoms due to the same medical condition causing the mild neurocognitive disorder (e.g., **F06.2** psychotic disorder due to traumatic brain injury, with delusions; **F06.32** depressive disorder due to HIV disease, with major depressive–like

Telegram: @medical_k

www.konkur.in

episode). **Note:** Mental disorders due to another medical condition are included with disorders with which they share phenomenology.

Coding and Recording Procedures

The following are examples of coding and recording mild neurocognitive disorders due to an etiologic subtype *(for more information, see coding table on pp. 682–683 and coding notes in the specific diagnostic criteria for each major and mild neurocognitive disorder subtype)*:

- G31.84 Mild neurocognitive disorder due to Alzheimer disease, without behavioral disturbance.
- G31.84 Mild neurocognitive disorder due to traumatic brain injury, with behavioral disturbance; F06.34 bipolar and related disorder due to traumatic brain injury, with mixed features.

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:679–681.

Table 10.5–2.
Major or Mild Neurocognitive Disorder Due to Another Medical Condition

Diagnostic Criteria

A. The criteria are met for major or mild neurocognitive disorder.
B. There is evidence from the history, physical examination, or laboratory findings that the neurocognitive disorder is the pathophysiologic consequence of another medical condition (e.g., multiple sclerosis).
C. The cognitive deficits are not better explained by another mental disorder (e.g., major depressive disorder) or another specific neurocognitive disorder (e.g., major neurocognitive disorder due to Alzheimer disease).

Coding note (see coding table on pp. 682–683):

For major neurocognitive disorder due to another medical condition, with behavioral disturbance, code first the other medical condition, followed by the major neurocognitive disorder due to another medical condition, with behavioral disturbance (e.g., G35 multiple sclerosis, F02.81 major neurocognitive disorder due to multiple sclerosis, with behavioral disturbance). For major neurocognitive disorder due to another medical condition, without behavioral disturbance, code first the other medical condition, followed by the major neurocognitive disorder due to another medical condition, without behavioral disturbance (e.g., G35 multiple sclerosis, F02.80 major neurocognitive disorder due to multiple sclerosis, without behavioral disturbance). *Note:* The severity specifiers "mild," "moderate," and "severe" cannot be coded for major neurocognitive disorder but should still be recorded.

For mild neurocognitive disorder due to another medical condition, code G31.84. (*Note*: Do *not* use the additional code for the other medical condition. "With behavioral disturbance" and "without behavioral disturbance" cannot be coded but should still be recorded.)

For major or mild neurocognitive disorder due to another medical condition: Use additional code(s) to indicate clinically significant psychiatric symptoms due to another medical condition (e.g., F06.32 depressive disorder due to multiple sclerosis, with major depressive–like episode).

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:729, 730.

COURSE AND PROGNOSIS

The course and prognosis of neurocognitive and mental disorders due to other medical conditions and substance/medication depend on the specific medical condition and its response to the treatment or the specific substance/medication involved. The course can range from remission of all symptoms to progressive decline, ultimately leading to death. When the neurocognitive or mental disorder has been of brief duration, and the medical condition is easily identified and responds to treatment, the neurocognitive or mental disorder may improve. However, when the underlying causative condition is long standing or progressive, the causal substance cannot be discontinued, or its effects are permanent

Telegram: @medical_k

www.konkur.in

(e.g., previous environmental toxin exposure), a favorable outcome is less likely even when we can treat the causative medical condition (e.g., neurosyphilis).

Table 10.5–3.
Substance/Medication-Induced Major or Mild Neurocognitive Disorder

Diagnostic Criteria

A. The criteria are met for major or mild neurocognitive disorder.
B. The neurocognitive impairments do not occur exclusively during the course of a delirium and persist beyond the usual duration of intoxication and acute withdrawal.
C. The involved substance or medication and duration and extent of use are capable of producing the neurocognitive impairment.
D. The temporal course of the neurocognitive deficits is consistent with the timing of substance or medication use and abstinence (e.g., the deficits remain stable or improve after a period of abstinence).
E. The neurocognitive disorder is not attributable to another medical condition or is not better explained by another mental disorder.

Coding note (see also coding table on pp. 682–683): The ICD-10-CM codes for the [specific substance/medication]-induced neurocognitive disorders are indicated in the table below. Note that the ICD-10-CM code depends on whether or not there is a comorbid substance use disorder present for the same class of substance. In any case, an additional separate diagnosis of a substance use disorder is not given.

Substance-induced major neurocognitive disorder: If a mild substance use disorder is comorbid with the substance-induced major neurocognitive disorder, the 4th position character is “1,” and the clinician should record “mild [substance] use disorder” before the substance-induced major neurocognitive disorder (e.g., “mild inhalant use disorder with inhalant-induced major neurocognitive disorder”). For alcohol and sedative, hypnotic, or anxiolytic substances, a mild substance use disorder is insufficient to cause a substance-induced major neurocognitive disorder; thus, there are no available ICD-10-CM codes for this combination. If a moderate or severe substance use disorder is comorbid with the substance-induced major neurocognitive disorder, the 4th position character is “2,” and the clinician should record “moderate [substance] use disorder” or “severe [substance] use disorder,” depending on the severity of the comorbid substance use disorder. If there is no comorbid substance use disorder, then the 4th position character is “9,” and the clinician should record only the substance-induced major neurocognitive disorder.

Substance-induced mild neurocognitive disorder: If a mild substance use disorder is comorbid with the substance-induced mild neurocognitive disorder, the 4th position character is “1,” and the clinician should record “mild [substance] use disorder” before the substance-induced mild neurocognitive disorder (e.g., “mild cocaine use disorder with cocaine-induced mild neurocognitive disorder”). If a moderate or severe substance use disorder is comorbid with the substance-induced mild neurocognitive disorder, the 4th position character is “2,” and the clinician should record “moderate [substance] use disorder” or “severe [substance] use disorder,” depending on the severity of the comorbid substance use disorder. If there is no comorbid substance use disorder, then the 4th position character is “9,” and the clinician should record only the substance-induced mild neurocognitive disorder.

The severity specifiers “mild,” “moderate,” and “severe” (for major neurocognitive disorder) and the accompanying symptom specifiers “with behavioral disturbance” and “without behavioral disturbance” (for major or mild neurocognitive disorder) cannot be coded but should still be recorded.

Specify if:

- Persistent: Neurocognitive impairment continues to be significant after an extended period of abstinence.

Telegram: @medical_k

www.konkur.in

Table 10.5–4.
Major or Mild Neurocognitive Disorder Due to Multiple Etiologies

Diagnostic Criteria

A. The criteria are met for major or mild neurocognitive disorder.
B. There is evidence from the history, physical examination, or laboratory findings that the neurocognitive disorder is the pathophysiologic consequence of more than one etiologic process, excluding substances (e.g., neurocognitive disorder due to Alzheimer disease with subsequent development of vascular neurocognitive disorder).
   - *Note*: Refer to the diagnostic criteria for the various neurocognitive disorders due to specific medical conditions for guidance on establishing the particular etiologies.
C. The cognitive deficits are not better explained by another mental disorder and do not occur exclusively during the course of a delirium.

Coding note (see coding table on pp. 682–683):

For major neurocognitive disorder due to multiple etiologies, code first all of the etiologic medical conditions (with the exception of vascular disease, which is not coded), followed by either F02.81 for major neurocognitive disorder due to multiple etiologies, with behavioral disturbance; or F02.80 for major neurocognitive disorder due to multiple etiologies, without behavioral disturbance. If vascular disease is among the multiple etiologic medical conditions, code next either F01.51 for major vascular neurocognitive disorder, with behavioral disturbance; or F01.50 for major vascular neurocognitive disorder, without behavioral disturbance. *Note:* The severity specifiers “mild,” “moderate,” and “severe” cannot be coded for major neurocognitive disorder but should still be recorded.

For example, for a presentation of major neurocognitive disorder, moderate, with a behavioral disturbance, that is judged to be due to Alzheimer disease, vascular disease, and HIV infection, and in which heavy chronic alcohol use is judged to be a contributing factor, code the following: G30.9 Alzheimer disease, B20 HIV infection; F02.81 major neurocognitive disorder due to Alzheimer disease and HIV infection, moderate, with behavioral disturbance; F01.51 major vascular neurocognitive disorder, moderate, with behavioral disturbance; and F10.27 severe alcohol use disorder with alcohol-induced major neurocognitive disorder, moderate, nonamnestic-confabulatory type.

For mild neurocognitive disorder due to multiple etiologies, code G31.84. (Note: Do *not* use the additional codes for the etiologies. “With behavioral disturbance” and “without behavioral disturbance” cannot be coded but should still be recorded.)

For major or mild neurocognitive disorder due to multiple etiologies: Use additional code(s) to indicate clinically significant psychiatric symptoms due to the various etiologies (e.g., F06.2 psychotic disorder due to Alzheimer disease, with delusions; F06.31 depressive disorder due to cerebrovascular disease, with depressive features).

Table 10.5–5.
Unspecified Neurocognitive Disorder

(R41.9)

This category applies to presentations in which symptoms characteristic of a neurocognitive disorder that cause clinically significant distress or impairment in social, occupational, or other important areas of functioning predominate but do not meet the full criteria for any of the disorders in the neurocognitive disorders diagnostic class. The unspecified neurocognitive disorder category is used in situations in which the precise etiology cannot be determined with sufficient certainty to make an etiologic attribution.

Coding note: For unspecified major or mild neurocognitive disorder, code R41.9. (*Note*: Do *not* use additional codes for any presumed etiologic medical conditions. “With behavioral disturbance” and “without behavioral disturbance” cannot be coded but should still be recorded.)

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022:732.

Table 10.5–7.
Specific Neurologic Signs and Symptoms and Associated Medical Conditions

Neurologic Sign or Symptom	Possible Related Medical Conditions
Change in consciousness	Infection, hepatic encephalopathy, substance-induced hypoglycemia (diabetes), thiamine deficiency
Headache	Meningitis, tumor, giant cell arteritis
Tremor	Parkinson disease, alcohol abuse, human immunodeficiency virus–associated dementia, Wilson disease
Gait disturbance	Normal pressure hydrocephalus, stroke, Parkinson disease
Meningeal signs	Meningitis
Involuntary movements	Huntington disease, Parkinson disease, Parkinson plus syndromes such as Lewy body dementia, autoimmune encephalitis
Pathologic reflexes	Creutzfeldt–Jakob disease, hypothyroidism
Motor deficit	Stroke, amyotrophic lateral sclerosis, Parkinson and Parkinson plus syndromes, Huntington disease
Sensory deficit	Stroke, B_{12} deficiency
Gaze palsy	Thiamine deficiency, alcohol abuse
Cranial nerve defect	Stroke
Language disturbance	Stroke, Alzheimer disease, neurosyphilis

TREATMENT

The mainstay of treatment is the correction or amelioration of the underlying medical condition or discontinuation of the offending substance or exposure. Adjuvant treatments include psychopharmacologic interventions and psychotherapeutic interventions.

Table 10.5–9.
General Principles for Diagnosing Disorders Due to Another Medical Condition or Substance/Medication-Induced Disorders

Disorders Due to Another Medication Condition:

- The symptoms of the psychiatric disturbance may be indistinguishable from that of a primary psychiatric disorder.
- Symptoms cannot be better accounted for by a primary psychiatric disorder or reflect an adjustment disorder due to the stress of having a medical illness.
- The disturbance does not occur exclusively during delirium.
- A temporal link between the course of the psychiatric disturbance and the onset, exacerbation, or remission of the medical disorder supports a causal link.
- Treatment of the underlying medical disorder improves the neurocognitive symptoms.
- Evidence from the medical literature supports a link between psychiatric disturbance and medical illness.
- Evidence of atypical features (e.g., late onset, lack of prior episodes, and lack of family history) support a link between the psychiatric disturbance and the medical condition.
- A targeted workup aims to “rule in” a specific medical diagnosis suggested by the patient’s somatic symptoms.

Substance/Medication-Induced Disorders:

- The symptoms of the psychiatric disturbance may be indistinguishable from that of a primary psychiatric disorder.
- Symptoms cannot be better accounted for by a primary psychiatric disorder or psychiatric disorder due to another medical condition.
- The disturbance does not occur exclusively during delirium.
- The symptoms of the psychiatric disturbance arise in the context of initiating or changing the dose of a medication or during intoxication with or withdrawal from a substance and are more than those usually associated with the medication’s use or the substance’s intoxication or withdrawal state and warrant independent clinical attention.
- The absence of psychiatric symptoms supports a link between the psychiatric disturbance and the substance/medication prior to use of the substance/medication, resolution of symptoms within 4 weeks of last substance/medication use, lack of prior similar episodes that occurred independently of substance/medication and the presence of psychiatric symptoms consistent with the extent of substance/medication use.
- Evidence from the medical literature supports a link between psychiatric disturbance and substance/medication.

Clinicians typically use psychopharmacologic interventions to treat associated neuropsychiatric symptoms, including mood or behavioral symptoms, especially when correction of the causal medical condition or withdrawal of the causal substance does not result in remission. However, given the medically compromised nature of the patient, the clinician should be mindful of the possibility of altered pharmacokinetics (e.g., decreased clearance of drugs) and potential drug–drug interactions. Perhaps most important is the frequent lack of empirical evidence supporting psychopharmacologic interventions for these conditions—often, we are treating by analogy—treating a disorder with a given medication because it looks similar to a disorder for which that medication is effective. Although sometimes this is a reasonable strategy, we should remain skeptical when we treat outside the bounds of studied indications and be prepared to discontinue ineffective medications.

Psychotherapeutic interventions in neurocognitive and mental disorders due to medical conditions include behavior approaches used in other neurocognitive disorders, including Alzheimer disease. Other specific interventions promote life-coping strategies, educate patients about illness courses, and bolster supportive networks with family and friends. Detoxification, medication use for cravings and relapse prevention, and a comprehensive rehabilitation program are frequently necessary for mental disorders due to substance use, but relapse rates are high.

www.konkur.in

SPECIFIC DISORDERS

Major or Mild Neurocognitive Disorder Due to Another Medical Condition

Definition. We should reserve the DSM-5 category of neurocognitive disorder due to another medical condition for neurocognitive disorders that are not among the more specific diagnostic categories. Although current evidence is limited, many potential mechanisms exist for the association between specific medical conditions and neurocognitive disorder. For example, direct neurotoxicity and disruption in cholinergic neurotransmission may be common pathways.

For this diagnosis, the evidence must suggest that the neurocognitive disorder is the pathophysiologic consequence of another medical condition. In addition, DSM-5 requires that another neurocognitive disorder (e.g., Alzheimer disease) should not better explain the cognitive deficits. A temporal relationship between the onset of the medical disorder and the onset of the cognitive impairment is strong evidence of an association, as is a reduction or stabilization of the cognitive impairment upon treatment for the causative medical condition. Thus, this is a diagnosis of inclusion, not exclusion, and we should not use it when the cause of the cognitive deficit is unknown (for that, Unspecified Neurocognitive Disorder is more appropriate).

Epidemiology. Given the many possible causes of major or mild neurocognitive disorder due to another medical condition, it is difficult to give a meaningful prevalence of this disorder.

Etiology. Table 10.5–10 lists some of the common causes of cognitive decline due to secondary causes.

Etiology is dependent on the underlying causative medical condition. One example within this category is Wilson disease, an autosomal recessive disorder caused by an enzymatic defect in copper metabolism, resulting in a toxic buildup of copper in the brain. The clinical course includes both cognitive, other neuropsychiatric, and motor symptoms (e.g., tremor).

Structural brain lesions (e.g., tumor, subdural hematoma, and normal pressure hydrocephalus) can cause cognitive impairment by compression of specific neuronal tissue, disruption of the blood–brain barrier, or impedance of cerebral blood flow. In addition, these lesions cause specific cognitive deficits based on the location of the lesion. Normal pressure hydrocephalus classically presents with cognitive impairment, urinary incontinence, and gait abnormality.

Specific metabolic abnormalities include organ dysfunction (e.g., hypothyroidism, diabetes mellitus, hypercalcemia, heart failure, and kidney disease) and vitamin deficiencies. Heart disease can result in cerebral hypoperfusion, and hyper- and hypoglycemia have disrupted cholinergic systems. Kidney disease can cause a buildup of toxic metabolites.

Telegram: @medical_k

www.konkur.in

Table 10.5–10.
Medical Conditions and Substances/Medications Causing Neurocognitive Disorders and Other Mental Disorders

Neurologic
Degenerative diseases (Alzheimer disease, corticobasal degeneration, frontal–temporal dementia [Pick disease], Huntington disease, Lewy body disease, Parkinson disease, prion diseases, progressive supranuclear palsy)
Demyelinating diseases (multiple sclerosis)
Acquired injuries (cerebrovascular disease, chronic traumatic encephalopathy [e.g., dementia pugilistica], traumatic brain injury)
Space occupying lesions (abscess, normal pressure hydrocephalus, subdural hematoma, tumor)
Other Medical Disorders
Metabolic disorders (acid–base imbalance, metabolic brain diseases, disorders of calcium metabolism, DNA repair-deficiency disorders, glucose metabolism disorders, hyperlactatemia, iron metabolism disorders, lipid metabolism disorders, malabsorption syndromes, metabolic syndrome X, inborn error of metabolism, mitochondrial diseases, phosphorus metabolism disorders, porphyrias, proteostasis, deficiencies, metabolic skin diseases, wasting syndrome, water-electrolyte imbalance)
Anemias (aplastic anemia, iron deficiency anemia, sickle cell anemia, thalassemia, vitamin deficiency anemia)
Diseases targeting specific organs (Wilson disease/hepatolenticular degeneration, end-stage organ dysfunction)
Endocrine disorders (adrenal, pancreases, thyroid)
Nutritional disorders (folate deficiency, niacin deficiency, vitamin B1 deficiency, vitamin B12 deficiency
Infectious/inflammatory disorders (human immunodeficiency virus [HIV], slow viruses, e.g., Creutzfeldt–Jakob disease, neurosyphilis, Lyme disease
Autoimmune disorders (giant cell arteritis, N-methyl-D-aspartate Receptor (NMDAR) antibody encephalitis, systemic lupus erythematosus)
Substances
Medications (anticholinergic, anticonvulsants, antihypertensive, anxiolytics/sedative–hypnotics, corticosteroids, immunosuppressants, opioids, stimulants, sympathomimetics)
Substances of abuse[a] (alcohol, cannabis, cocaine, hallucinogens, inhalants)
Toxins (carbon monoxide, heavy metals, lead, mercury)

[a]Many medications can also be abused.

The classic vitamin deficiency associated with cognitive impairment is Wernicke–Korsakoff syndrome, which is due to neurologic damage secondary to B vitamin deficiency, and in particular, deficiency of thiamine (vitamin B_1). While frequently associated with chronic alcohol misuse, Wernicke–Korsakoff syndrome can occur in any clinical situation that is caused by or causes malnutrition (e.g., Crohn disease, chemotherapy). The estimated prevalence of Wernicke encephalopathy in the general population is 2%. Thiamine is involved in glucose and lipid metabolism as well as neurotransmitter metabolism. Wernicke encephalopathy (or Wernicke disease) is classically characterized by ophthalmoplegia, ataxia, and confusion, although this classic presentation is uncommon and a range of neurologic symptoms are possible. If a patient receives adequate parenteral thiamine and other nutritional support, Wernicke encephalopathy is reversible. When Wernicke encephalopathy occurs in the setting of chronic alcohol misuse, most patients progress to Korsakoff syndrome. Dense amnesia with confabulation characterizes Korsakoff syndrome. Recovery from the cognitive impairment of Korsakoff syndrome is less common and less complete. Based on brain imaging, patients with Wernicke–Korsakoff syndrome typically demonstrate atrophy of mammillary bodies and thalamus.

Inflammatory and infectious states (e.g., neurosyphilis, chronic meningitis, and systemic lupus erythematosus [SLE]) may cause cognitive dysfunction, and the mechanisms may vary. For example, SLE may impair the blood–brain barrier and cause microglial activation. Many infections can affect the

Telegram: @medical_k

www.konkur.in

brain. Most recently, the cognitive effects of SARS-CoV-2 have become apparent. However, the exact mechanism is not understood, and both direct neuroinvasion (e.g., via the olfactory nerve or through an ocular route) and transmission via the blood (by penetrating the blood-brain barrier) are possible.

Similarly, specific medications (e.g., anticholinergics), substances (e.g., alcohol), and toxins (e.g., lead) can cause cognitive impairment and dementia, also through varied mechanisms.

Damage or disruption of neurotransmission in areas involved in memory (e.g., hippocampus) can result in persistent amnesia. For example, specific infectious diseases such as herpes simplex can result in encephalitis that primarily targets the medial temporal lobes of the cortex, including the hippocampus. Similarly, anti-NMDA receptor (NMDAR) encephalitis can cause cognitive dysfunction in addition to other neuropsychiatric symptoms. Their effect appears to be mediated through autoantibodies against the GluN1 subunit of the NMDA receptor. This subunit is essential for memory consolidation in the hippocampus.

Diagnosis and Clinical Features. According to DSM-5, the development of new cognitive impairment independent of delirium or another neurocognitive disorder is the hallmark of this diagnosis. In addition, a temporal and causative link between the cognitive impairment and the medical condition or substance must exist (Table 10.5–6).

AG is a 76-year-old woman with congestive heart failure, systolic dysfunction, hypertension, coronary artery disease and atrial fibrillation, osteoarthritis, hypothyroidism, and diabetes mellitus. She had been hospitalized repeatedly over the past year for acute heart failure decompensation resulting in hypotension, dyspnea, and leg edema. She admitted to poor compliance with her medications, contributing to the decompensation of her heart failure. She said that she could not remember to take them and began to have problems with her memory about 1 year ago when she was first hospitalized for congestive heart failure. She was also noncompliant with dietary and fluid restrictions. Prescribed medications included lisinopril, furosemide, metoprolol, aspirin, glipizide, acetaminophen, and levothyroxine.

On initial examination, congestive heart failure seemed well compensated without pulmonary edema and only mild peripheral edema. AG's heart rate was 68, and her blood pressure was 95/45. Given her difficulties with memory, she underwent cognitive testing. AG scored 26/30 on the Montreal Cognitive Assessment, with difficulty on serial sevens. Attention was otherwise intact, but her clock drawing indicated poor planning and inability to indicate the correct time. She also displayed difficulty with problem solving and abstract reasoning. Brain imaging revealed mild small vessel disease but no infarcts. Thyroid-stimulating hormone level was normal, and the only lab abnormalities were a creatinine of 1.5 and glycosylated hemoglobin of 7.9.

She was again hospitalized with hypoxia and pulmonary edema 2 weeks later. She was hypotensive and required pressor support to manage her decompensated heart failure. AG was diagnosed with major neurocognitive disorder due to congestive heart failure with cerebral hypoperfusion without behavioral disturbance.

Laboratory Evaluation. Patients should receive a thorough workup to identify the underlying causative medical condition and ruling out any more common neurocognitive disorders (e.g., cerebrovascular disease). Given the extent of medical conditions that can cause cognitive impairment and dementia, we should tailor the testing to the history and the presenting symptoms. For example, we may order an erythrocyte sedimentation rate (ESR) if an inflammatory disorder is suspected, although ESR is a nonspecific test. Copper and ceruloplasmin levels can be measured if Wilson disease is suspected. A detailed history of the proband and the family is essential to guide this workup. Initial workups usually include structural brain imaging, and functional brain imaging may help differentiate neurocognitive syndromes in specific cases. Lumbar puncture is not routine, but advances in understanding specific CSF markers may help the differential diagnosis, especially if Creutzfeldt–Jakob disease (CJD), neurosyphilis, or other infectious etiology is suspected. Toxicology tests may be appropriate in select cases. Neuropsychological testing can aid in the diagnosis.

Telegram: @medical_k

www.konkur.in

Differential Diagnosis. Ruling out delirium and all other neurocognitive disorders is the most critical part of the differential diagnosis.

Course and Prognosis. Onset may be sudden or slowly progressive. The course is variable depending on etiology. Recovery may occur over the short- and long-term depending on the severity of the initial injury and the persistence of the underlying medical condition.

Treatment. Treatment of the underlying medical condition is the most important therapy. For example, prevention of cognitive impairment is possible in individuals at risk of thiamine deficiency (e.g., secondary to long-standing alcohol misuse or severe malnutrition) through the administration of vitamin B_1, particularly in the intravenous form, as this will prevent the development of Wernicke–Korsakoff syndrome. In addition, memory retraining or using memory aids may have some benefits.

Substance/Medication-Induced Mild/Major Neurocognitive Disorder

Definition. Patients commonly have cognitive impairment when intoxicated or during the acute withdrawal phase from substances and some medication. However, the categories of major or mild substance/medication-induced neurocognitive disorder only apply when the cognitive impairment persists beyond the typical intoxication or withdrawal period. DSM-5 also clarifies that the suspected substance/medication must have a known link to persistent cognitive impairment and that the onset of the cognitive impairment must be temporally associated with exposure to the substance/medication.

Epidemiology. The prevalence of substance/medical-induced neurocognitive disorder is unknown. However, risk factors for developing this disorder include older age, a more extended period of exposure to the substance or medication, poor nutrition, liver disease, and cerebrovascular disease.

Etiology. Persistent cognitive impairment likely reflects the slow recovery of underlying brain function. However, for some patients, the neurocognitive disorder is irreversible. For example, chronic alcohol abuse resulting in thiamine deficiency can cause irreversible Korsakoff syndrome due to permanent damage to the mammillary bodies and thalamus. Table 10.5–10 lists some substances that may cause cognitive deficits. Given the many new drugs, both legal and illicit, such lists are never comprehensive, and the purpose here is to give some typical examples of frequently seen drugs and drug classes.

Diagnosis and Clinical Features. Chronic users of sedative, hypnotic, or anxiolytic drugs can develop an neurocognitive disorder, typically mild and primarily consisting of impairment in memory. However, studies demonstrate that chronic users continue to demonstrate impairment in multiple cognitive domains, especially verbal memory and processing speed, even after 6 months of abstinence.

Chronic cocaine, methamphetamine, opioids, and phencyclidine users risk developing a mild persistent neurocognitive disorder. For methamphetamine, neurocognitive disorder primarily involves impairment in learning, memory, and executive functions. Some evidence suggests that prolonged abstinence (i.e., 14 months) from methamphetamine is associated with recovery in some but not all cognitive domains. Methamphetamine and cocaine use increases the risk of stroke, which can result in additional persistent cognitive impairment.

Chronic inhalation of volatile hydrocarbons, for example, inhalant abuse, can produce impairment in memory, attention, visuospatial and executive functions, and motor abilities. Studies have demonstrated that abstinent individuals can recover over 2 years. However, permanent disability may occur in those individuals with severe abuse or those who had abused leaded gasoline products and developed concomitant lead encephalopathy with cerebellar damage.

As discussed above, chronic alcohol use can lead to confusion (Wernicke encephalopathy) and progress to a dense amnestic state (Korsakoff syndrome). Other substances that can cause amnestic syndrome are cannabis, lead, carbon monoxide, and some insecticides.

Other medications associated with cognitive impairment include steroids, chemotherapy agents, nucleoside reverse transcriptase inhibitors (NRTIs), L-Dopa and dopamine agonists, select antiepilepsy drugs (e.g., topiramate), and medications with anticholinergic properties. Cognitive deficits induced by

Telegram: @medical_k

www.konkur.in

medications typically resolve upon discontinuation of the offending drug. Corticosteroid-induced cognitive deficits typically affect declarative (verbal) and working memory. This is true for acute and chronic treatment, and the pattern suggests that the hippocampus and dorsolateral prefrontal cortex are sensitive to the adverse effects of steroids.

Pathology and Laboratory Examination. Other than toxicology studies to help identify the causative substance/medication, there are no other pathognomonic lab findings or imaging findings for major or mild substance/medication-induced neurocognitive disorder. Therefore, the patient should receive a thorough workup to identify potential medical causes and rule out any more common neurocognitive disorders.

Differential Diagnosis. The differential includes delirium and all other neurocognitive disorders. It is important to remember that persons who misuse substances are more prone to other events associated with cognitive impairment, such as TBI and certain infections, for example, HIV. They may also be more likely to have comorbid psychiatric diagnoses, such as posttraumatic stress disorder (PTSD) and mood disorders, including cognitive dysfunction. In addition, some substances of abuse, such as cocaine and methamphetamine, are associated with an increased risk of stroke, which can also produce cognitive impairment.

Course and Prognosis. For many substances and medications, abstinence leads to improved cognitive function. However, the time course of recovery is highly variable and depends on the substance/medication used, the severity and duration of use, and the presence of other risk factors for cognitive impairment.

Treatment. For neurocognitive disorder, the treatment of choice is the cessation of that substance or medication due to substances and medications. Unfortunately, this may not be possible for some medications. Often, nutritional and other medical support can help improve cognition. For example, prevention of cognitive impairment is possible in individuals at risk for thiamine deficiency (e.g., secondary to long-standing alcohol misuse) through the administration of vitamin B_1, as this will prevent the development of Wernicke–Korsakoff syndrome. Cases of substance misuse will require a comprehensive treatment program, including medication-assisted treatment (MAT), after stabilization.

Major or Mild Neurocognitive Disorder Due to Multiple Etiologies

DSM-5-TR includes this diagnosis for cases where multiple diseases or injuries are likely to have contributed to the cognitive disorder. For example, it is not unusual to see evidence of brain degeneration coexisting with vascular changes, or patients with Alzheimer disease could also have HIV. Similarly, patients with a neurodegenerative disorder may also drink heavily.

Unspecified Neurocognitive Disorder

DSM-5-TR also includes a *Neurocognitive Disorder For Cases With Unknown Etiology*. The analogous ICD-11 diagnosis is *Disorders With Neurocognitive Impairment As A Major Feature, Unspecified*. In cases of this diagnosis, the clinician should pursue continued efforts to identify a cause, which may become more apparent as the disorder progresses.

ACKNOWLEDGMENT

This chapter represents an update and revision of previous chapters in this series, most recently by Jennifer Clare Prins, M.D, and Ellen M. Whyte, M.D. from the last edition. We are indebted to Drs Prins and Whyte for their work and retain much of their prose in this current edition.

Substance-Related Disorders

11.1 Substance Use Disorders: Introduction

JOJI SUZUKI, M.D.

The opioid crisis in the United States, considered by many to be one of the most significant public health disasters of our times, has now entered the third decade. The crisis began in the 1990s with the rise in the use of prescription opioid analgesics to manage both acute and chronic pain, partly in response to the call to make pain the "fifth vital sign." The widespread nonmedical use of these opioids grew dramatically, leading to the dramatic increase in the development of opioid use disorder among those misusing these drugs, which directly contributed to the rise in both intentional and unintentional fatal opioid overdoses. The ever-worsening crisis has now claimed the lives of over half a million individuals. During and after the COVID-19 pandemic, the United States experienced the most fatal period of drug-related overdoses ever recorded in a 12-month period. Instead of prescription opioids, we are now battling heroin and synthetic opioids, notably fentanyl, along with cocaine and methamphetamine. Through all of this, the morbidity and mortality

Telegram: @medical_k

www.konkur.in

associated with alcohol have continued to climb. Of great concern to mental health practitioners, this increase in substance-related suffering is occurring while the rate of suicides and suicide-related behaviors have also climbed dramatically. Some estimate that up to 30% of all overdose deaths are, in fact, suicides. Despite all the efforts in the past decade to combat the opioid crisis, these data suggest we are not winning this war, but instead, we are falling behind. Therefore, this is a call to all mental health practitioners that we must do more to tackle this crisis, given that patients with psychiatric disorders are disproportionally affected by substance use disorders (SUDs).

As in the previous edition, this section provides a series of chapters addressing SUDs for each of the major classes of misused substances as described in the DSM-5-TR's chapter on Substance-Related and Addictive Disorders. The selection of chapter topics is generally based on the categorization of substances as presented in that section, with the exception of anabolic–androgenic steroids. Given the cultural interest and concern with anabolic steroid use, the topic remains here even though there is not a separate steroid use disorder section recognized in the DSM-5-TR. In addition, even though gambling disorder is now in the SUD section, it is not addressed in this section of this textbook and is addressed separately. As one considers the broader categorization of medical disorders that have a core feature that defines them by dysregulation of choice (an inability by the person to control choice in a healthy and reasonable manner), then the inclusion of gambling and drug use disorders is a highly appropriate move on the part of the field. It seems likely that the underlying phenomenology and biology of disorders characterized by this dysregulation of choice share common features, logic, and assumptions that can help psychiatrists and others in the mental health field to better understand these disorders, their etiology, and their treatment. Other disorders that also have a fundamental feature of choice dysregulation, such as eating disorders and sexual disorders, should also be considered in this categorization (in future iterations of DSM), as their biology and

Telegram: @medical_k

www.konkur.in

social circumstances can have features that overlap with the SUDs as well as gambling disorder.

The remainder of this introduction will briefly review some general topics related to SUDs—highlighting the diagnosis of these disorders, the extent of use, and public policy issues. Details of specific disorders, including their treatment, can be found in the subsequent chapters.

The Definition of Substance Use Disorders

SUD is best understood as a chronic biopsychosocial disease, similar to hypertension or diabetes, manifesting as a behavioral syndrome characterized by repeated use of a substance, inability to stop or cut back, accompanied by strong subjective urges, physiologic dependence, and accumulating harm. Sometimes this can be referred to as the "3 Cs" of addiction—loss of control, craving, and negative consequences. The DSM-5-TR criteria indeed fall into these categories.

A significant change with DSM-5-TR from DSM-IV is that there no longer are separate diagnoses of "substance abuse" and "substance dependence." DSM-5-TR merges the criteria for these two diagnoses, unifying them under the term "use disorder" but adding a criterion for craving and removing the criterion for legal problems. These changes have resulted in essentially 11 criteria used to make a diagnosis of an SUD, although it is worth noting that the specific criteria can vary slightly from one class to the next. In addition, instead of conceptualizing SUD as a categorical diagnosis (i.e., either you do or do not have an SUD), the modifiers indicate the severity as mild (2 to 3 criteria), moderate (4 to 5 criteria), or severe (6 or more criteria). Clinical programs, insurers, and researchers often use the cutoff of moderate or severe as the necessary severity for study protocols and the authorization of more intensive levels of treatment services. Additional modifiers are also available, for example, "on maintenance therapy" for opioid use disorders if the patient is being treated with a medication such as methadone or buprenorphine.

Telegram: @medical_k

www.konkur.in

While clinicians are most familiar with the DSM-5 criteria, other criteria and coding for diagnoses are used in clinical practice and for billing purposes—most notably, the ICD-11 coding. ICD-11 differs from DSM-5 in several ways, including the inclusion of problematic use categories of “harmful use” and “dependence.” ICD-11 also has more drug use categories—for example, separating cocaine from other “stimulants, including amphetamines, methamphetamine, or methcathinone.”

Finally, while not diagnostic, the field of addiction research and clinical care continues to use various forms of quantity and frequency of substance use as a metric for determining risk of use, treatment needs, and study outcomes. Such work has primarily focused on alcohol, the identification of standard drinks of alcohol, and daily numbers of such drinks that increase the risk of adverse consequences to use. This work has helped to move the alcohol field forward in its use of the concept of heavy drinking days (HDDs), which can be a useful marker in studies of treatment outcomes. With the growing liberalization of cannabis, there is also an increasing need to measure the quantity and frequency of cannabis use, given the large variety of forms of cannabis that are used widely today. While there are limitations to extending these concepts to other drugs, the overall concept of quantity and frequency of use may have utility for both clinical screening and research purposes, and this is a potential area of development in the coming years.

The Extent of Substance Use Disorders

In the United States, annual surveys of substance use are conducted under the sponsorship of a federal agency, the Substance Abuse and Mental Health Services Administration (SAMHSA). These surveys date back to the 1970s and for many years were titled the “National Household Survey on Drug Abuse,” although the name of these reports was changed to the “National Survey on Drug Use and Health” (NSDUH) as of 2002. Subsequent chapters will address the prevalence of specific types of substances used; however, some overall findings will be noted here based on the 2020 NSDUH

Telegram: @medical_k

www.konkur.in

results. While the focus here in this brief review is on NSDUH data, other surveys in the United States provide complementary data that can be useful for the reader interested in gaining greater knowledge on drug abuse epidemiology. These include the Monitoring the Future (MTF) study of students and young adults, the Treatment Episode Data Set (TEDS), which examines patterns of substance abuse treatment admissions, the National Survey of Substance Abuse Treatment Services (N-SSATS), which assesses treatment programs, the Drug Abuse Warning Network (DAWN), which assesses emergency department admissions related to substances, and other large studies of drug abuse such as the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC).

In 2020, 162.5 million persons in the United States 12 years and older reported past month use (i.e., defined as “current use”) of tobacco, alcohol, or an illicit drug. Alcohol remained the most commonly used substance in the past month, with 138.5 million persons reporting current use. Among those 12 and older, 22.2% (61.6 million) reported a past month binge of alcohol, defined as drinking on the same occasion five or more drinks for men and four or more drinks for women. The data, therefore, suggest that close to half of those who consume alcohol have had a past month binge. Furthermore, 12.8% of those who drink alcohol and 28.8% of those who had a binge episode meet criteria for heavy drinking, defined as five or more episodes of binge drinking within a 30-day period.

Second to alcohol, the most commonly used substances are tobacco (51.7 million persons who meet criteria for current use) and vaping products (10.4 million persons who meet criteria for current use). Prior to 2020, NSDUH did not include questions about vaping, highlighting how rapidly new substance use can emerge; indeed, even though tobacco use has gone down overall, electronic cigarette use has approached epidemic proportions in the United States.

The most commonly used illicit drug is marijuana, with 32.8 million persons with current use, followed by prescription analgesic misuse (2.5 million), prescription sedative misuse (2.2 million), cocaine (1.8 million), hallucinogens (1.8 million), methamphetamine (1.7 million),

Telegram: @medical_k

www.konkur.in

and prescription stimulant misuse (1.5 million). While these findings demonstrate that there is substantial experimentation with illicit drugs, past month use of any illicit drug, cannabis, and nonmedical use of psychotherapeutics generally represents less than 20% of those who have ever used an illicit drug. While this should by no means minimize the extent of drug use, it does demonstrate that many people try a drug but do not go on to regular or problematic use.

Other national surveys are conducted by the European Union and Australia; the former conducts these under the auspices of the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA), and the latter is conducted by the Australian Institute of Health and Welfare (AIHW). In general, findings from Australia, Europe, and the United States are similar (e.g., that there are high rates of cannabis use as the most commonly used illicit drug, that rates of prescription drug use have been a growing concern, and that tobacco and alcohol are more extensively used than illicit drugs). When making cross-regional comparisons (which are not easily done for a variety of reasons, such as the tools that are used), it is notable that the United States reports on drug use for persons 12 and older, the European Union for persons 15 and older, and Australia uses a cutoff of 14 and older.

Finally, while the number of persons or rates of use capture one aspect of substance use, the impact of this use can be lost in such numbers. The Global Burden of Disease study looked at a variety of medical conditions worldwide and found that two of the top five leading causes of disease were substance abuse related—tobacco (fourth) and alcohol use (fifth). Furthermore, according to this survey, illicit drug use in developed parts of the world was the eighth leading cause of disease. While the extent of use is one measure of impact, this evidence of disease burden is a telling measure of the significant effect that drug use has on individuals, their families, and societies.

Treatment

Telegram: @medical_k

www.konkur.in

As alluded to already, SUDs are chronic diseases, which do not allow the disease to be cured, as can be done with acute illnesses such as an infection or a fracture. A consequence of understanding SUD as a chronic disease is that the process of recovery will likely involve multiple episodes of remissions and recurrences over time, just like diabetes or obesity. This requires that treatment should not simply aim at reducing or stopping substance use (i.e., abstinence) but also aim to improve the quality of life and increase the chances of remaining in recovery by addressing the underlying factors that contribute to substance use.

One of the critical messages consistent across the substances listed in this section is that addiction treatment is effective. This efficacy impacts drug use itself, as well as showing an impact on other aspects of lifestyle and health. For alcohol, opioid, and tobacco use disorders, there are numerous FDA-approved pharmacotherapies. For opioid use disorder specifically, the use of medications such as buprenorphine and methadone are life-saving treatments and are considered effective even if prescribed alone without specific psychosocial or behavioral treatments. There are numerous behavioral and psychosocial interventions with a robust evidence base supporting their efficacy. Of great interest is the growing evidence base in support of ketamine and psychedelics in treating SUD, with several randomized trials showing efficacy for alcohol, tobacco, and cocaine use disorders. However, more research on efficacy and safety is needed before they become accepted as legitimate treatment options for SUD.

Finally, the growing body of evidence now points to peer support as well as formal 12-step groups as being effective adjuncts to professional treatment. Indeed, most states now have a mechanism in place to train individuals in recovery to become “peer recovery coaches” (also referred to by other names, such as “peer recovery specialist,” “peer navigators,” or “recovery coach”). These individuals use their “lived experience” of sustained recovery to help, support, and mentor individuals in recovery and often provide services outside the scope of traditional clinical treatments. One of the distinguishing features of these peers is their explicit support for

Telegram: @medical_k

www.konkur.in

multiple pathways to recovery. For example, recovery coaches can support those who do not want to be a member of alcoholics anonymous (AA), or even those who do not want or are not ready to be completely abstinent.

Public Policy Issues Related to Substance Use Disorders

One of the most dramatic changes in recent years related to drug policy is the rapidly evolving move of cannabis from an illicit drug to a potential therapeutic ("medical marijuana") or even to outright legalization for use by adults. This changing legal and social landscape has been rapidly occurring in the United States and other countries and varies considerably at the state level, with some states maintaining cannabis as an illegal drug and others allowing varying degrees of use. The medical use of cannabis has been promoted with little of the traditional evidence base that would provide the foundation for determining the efficacy and safety of a new medication, while the greater availability of legal use for recreational purposes has gained fairly widespread acceptance by the general public despite the known harms associated with recreational use of cannabis.

Other policy issues related to addiction treatment are the removal of the training requirement for obtaining the certification to prescribe buprenorphine, the approval of safe-consumption sites in New York City, and the growing evidence base now pointing to the potential for psychedelic drugs (i.e., psilocybin) to be used therapeutically for SUD. The emergence of psychedelics, most of them schedule 1 drugs, as potential treatment means there may be changes in their scheduling.

SUMMARY

The current drug crisis we are witnessing evolved initially from an opioid crisis but now includes all classes of drugs, such as alcohol and stimulants. This evolving crisis is also occurring in the context of a mental health crisis, made worse by the COVID-19 pandemic. This

Telegram: @medical_k

www.konkur.in

is, therefore, a call to action for all mental health providers, especially psychiatrists. SUDs remain highly prevalent disorders that exact a social as well as a personal burden on the individual, disproportionately affecting individuals with psychiatric disorders. This topic area spans aspects of public policy, neurobiology, ethics, and behavior, and addictions will likely continue to be a major topic area of concern for years to come, as they have been for thousands of years in the past. Of note, the growing body of knowledge about the biologic and environmental aspects of these disorders and how these aspects impact experimentation and problematic or pathologic use have helped to bring SUDs under a medical umbrella and moved forward prevention and treatment efforts. However, much more work needs to be done in understanding the treatment of these disorders. The following chapters in this section provide an overview of these disorders, their neurobiology and social circumstances to use, the behavioral aspects of reinforcement, the extent of substance use, and the treatment of these disorders.

11.2 Alcohol-Related Disorders

MARC A. SCHUCKIT, M.D.

This chapter reviews conditions that affect 20% to 30% of middle-class men and about 15% of women seeking medical care. The typical individual with these diagnoses has a job, lives with their family, and is relatively high functioning, but is likely to die a decade or more prematurely. Almost half will develop temporary, but clinically significant, anxiety or depression, and they carry an enhanced risk for serious medical problems along with a heightened potential for adverse reactions to medications. The condition that is the focus of this chapter costs the United States almost $250 billion a year with worldwide 134 million disability-adjusted life years lost. Despite these characteristics, most physicians have received few hours of training regarding recognizing and treating these disorders, and many physicians, including psychiatrists, feel inadequate in making the diagnosis or treating these alcohol-related conditions.

Alcohol use disorders (AUDs) have special relevance to psychiatry. Alcohol is a potent drug that causes both acute and chronic changes in almost all neurochemical systems, with the result that heavy drinking can produce serious *temporary* psychological symptoms including depression, anxiety, and psychoses. Several pre-existing psychiatric diagnoses, including antisocial personality, bipolar, and schizophrenic disorders, increase the risk for later

Telegram: @medical_k

www.konkur.in

AUDs. In light of the importance of alcohol-related conditions to psychiatric practice, this chapter offers a broad and clinically focused overview of recent developments in the field of AUDs. The following case facilitates the discussion of alcohol-related problems.

JP is a 47-year-old ophthalmologist referred by his internist for psychiatric evaluation. The presenting complaints included depressive and anxiety symptoms, concerns by his wife that he was spending more time alone in his study in the evenings, and that there were times he appeared to not think clearly. The differential diagnosis included a major depressive episode, generalized anxiety disorder, and the early stages of a dementing process resembling Alzheimer disease. The problems had become more prominent in the past year for this man who had graduated from both college and medical school with distinction and was still married and respected by his wife of 28 years and their young adult children. It soon became apparent that heavy drinking was a major contributor to the observed problems and that, in many ways, JP was a typical middle-class person with an AUD.

JP will be used as an example of several major lessons in this chapter.

DEFINITION AND COMPARATIVE NOSOLOGY

Alcohol Use Disorders

Diagnoses in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) are intended to identify clinically significant conditions through criteria that are both reliable and valid. The two major current psychiatric diagnostic systems (DSM-5 and the *International Classification of Diseases* eleventh edition [ICD-11] developed by the World Health Organization) agree that an AUD diagnosis requires repeated impairments in multiple life areas as a

Telegram: @medical_k

www.konkur.in

result of alcohol use. In the DSM-5 criteria published in 2013, an AUD is diagnosed as the repeated presence of at least 2 of 11 major areas of life impairments related to alcohol that cluster together in a syndrome over approximately the same 12-month period. The criteria are very similar to those listed for abuse and dependence in DSM-IV, with the exception that one DSM-IV item was dropped (legal problems) and one new item was added (craving).

In ICD-11, the diagnostic guidelines for *dependence* (items that are labeled as general guidelines, not criteria) require at least two of three central features that were present over 12 or more months. The first of the three elements is impaired control over alcohol and includes craving to use the drug. The second guideline requires that alcohol became an increasing priority in life that took precedence over other activities, interests, or life interests such that alcohol use continued despite repeated problems associated with its use. The third member of the triad relates to the development of neuroadaptation to alcohol as judged by tolerance, withdrawal symptoms, and/or the use of alcohol to prevent or relieve withdrawal. ICD-11 also lists guidelines for a second syndrome, *a harmful pattern of use of alcohol,* which is viewed as a “subdependence” label indicating alcohol use that damaged a person’s own physical or mental health or contributed to harm to others. The latter could include physical harm or a mental disorder directly related to the first person’s own harmful pattern of alcohol use.

Several approaches have been tested as potential alternative AUD criteria and as efforts to divide AUDs into clinically meaningful subgroups. For example, a more severe early onset of an AUD, accompanied by criminality and problems with other drugs, has been labeled as *type 2* or *type B alcoholism.* This approach reflects the fact that most early-onset medical and psychiatric disorders have a more severe course. However, much of the prognostic significance of type 2 or type B alcoholism rests with concomitant conduct disorder and antisocial personality disorder (ASPD) in early-onset substance use disorders (SUDs). As mentioned elsewhere in this chapter, few advantages have been found for diagnostic items related to drinking patterns to a family history of AUDs.

Telegram: @medical_k

www.konkur.in

Severity and Remission

DSM-5 asks clinicians to record the prior year severity of an AUD as *mild* (2 to 3 criteria endorsed), *moderate* (with 4 to 5 criteria met), or *severe* (with 6 or more of the 11 criteria), while ICD-11 has no formal notation of severity. Remission criteria in DSM-5 are based on the fact that the highest risk for relapse is in the first 3 to 12 months of recovery. Thus, early remission occurs if none of the 11 AUD criteria (other than craving) were experienced during the prior 3 months, and the notation of sustained remission indicates that no such problems were experienced for at least 12 months.

Although JP did not fit the erroneous stereotype of a person with an AUD as homeless and jobless, he was fairly typical of the middle-class person with this disorder. The history revealed that alcohol problems had become prominent in his mid-20s, with an age of onset of the AUD (i.e., when two or more of the AUD criteria occurred within the approximate same 12 months) of about 28 years. Problems included tolerance; spending a great deal of time drinking (when JP retired to his office at home and spent most of the evening drinking); and repeatedly exceeding preset amounts and periods of time spent drinking (e.g., setting a limit of two glasses of wine after dinner but consuming two bottles). Consistent with his relatively young age and general good health, JP had never experienced a withdrawal syndrome.

A Brief History of Alcohol and AUDs

Beverage alcohol (ethanol) is a product of fermenting fruit or grain and was probably around before humans walked the earth. Evidence of human consumption of these beverages dates back at least 12,000 years, and alcohol was used as part of ceremonies in Babylon, Greece, and the Roman Empire over 5,000 years ago when this drug was also used for pleasure, nutrition, and for its medicinal properties.

Telegram: @medical_k

www.konkur.in

Repeated drunkenness and associated problems have been noted in almost all civilizations, and related stories are seen in the Bible. Most early consumption involved beer and wine, but distillation of beverages with higher alcohol contents, such as whiskey, dates back to about 1400 AD in Ireland. Laws actually encouraging the consumption of spirits as a way to raise tax revenues appeared in England in the 1600s.

The increased use of ethanol and the enhanced prevalence of drunkenness by the early 1800s became a public health concern and a threat to maintaining a reliable workforce, especially in the context of the industrial revolution. Later in the 1800s, England tried to reverse course and control alcohol use, and a prominent movement toward total abstinence grew in strength in both Europe and America. Following World War I, there were calls for prohibition of alcohol consumption that culminated in national drinking bans, including the 18th amendment to the U.S. constitution (the Volstead Act) in 1920. However, by this point in history, alcohol had become so ingrained in most societies that prohibition was difficult to enforce, and beverage alcohol became legal again in the United States in 1933.

Following the end of Prohibition, alcohol-related problems quickly escalated. The number of people affected and the total costs have been much higher than figures associated with any other drug.

EPIDEMIOLOGY

Prevalence of Drinking, Related Problems, and AUDs

About 90% of Americans have consumed alcohol at some time in their lives, with most beginning in their middle teens (Table 11.2–1). By the end of high school, 80% of students have imbibed alcohol, and more than 60% have been intoxicated. During any year, 70% of individuals were drinkers, with a ratio of the proportions of men versus women who consumed alcohol of approximately 1.3 men to 1.0 women. The highest drinking frequency and quantity usually occur from the late teens to the mid-20s. In 2019, 30% of men and

Telegram: @medical_k

www.konkur.in

22% of women aged 18 and older reported binge, or heavy episodic drinking, defined as an intake on the same occasion of five or more standard drinks for men and four or more for women at least once in the prior month. The rates of drinkers, including those with heavier intake, change over time as a reflection of cohort effects and major life events. A recent example of the latter is the increase in the proportion of drinkers and their frequency of alcohol intake during the coronavirus epidemic.

Table 11.2–1.
Alcohol Epidemiology

Condition	Population (%)
Ever had a drink	90
Current drinker	60–70
Temporary problems	40+
Alcohol use disorder (AUD) lifetime	Male: 15+
	Female: 10+
AUDs in psychiatric patients	30

The percentages listed here are approximations generated across studies.

Men and women with higher education and income are the ones most likely to imbibe, and, among religious denominations, Jews have among the highest proportions who consume alcohol but also have among the lowest rates of AUDs. Other ethnicities, such as the Irish, have higher rates of severe alcohol problems, but are also likely to have higher rates of abstention. Very high levels of alcohol problems are found among most, but not all, Native American and Inuit tribes, with estimates that more than 60% of men and women in some tribes have at some time had an AUD. In the United States, in 2018, the World Health Organization reported that the average person aged 15 or older consumed about 2.4 gallons of absolute alcohol in a year, a figure considerably less than the five gallons of absolute ethanol yearly intake in the 1700s. In 2010, per capita

Telegram: @medical_k

www.konkur.in

consumption ranged from 4.6 gallons in Belarus to 0.05 gallons in Saudi Arabia.

Almost half of drinkers experience temporary alcohol-related problems. One survey noted that the impaired memory for events occurring during a heavy drinking evening (i.e., an alcohol-related blackout) was reported by almost half of drinking men and women, including about 15% who had three or more such experiences in any year. Among relatively well-educated middle-class men, about 30% admitted to having driven while impaired by alcohol, and about 20% had missed school or work because of a hangover or a desire to "party."

The lifetime risk for AUDs is approximately 15% for men and 10% for women, with 1-year prevalence rates of about 6%, figures that are applicable across most socioeconomic and educational levels. Rates among individuals coming to a hospital or visiting a physician's office are almost double that. The peak ages of onset of an AUD are from the early 20s to about age 40. Despite multiple difficulties, most people with AUDs have jobs, families, and relatively high levels of functioning, and, thus, few fit the stereotype of a homeless, unemployed person. It is important to note that between 2001 and 2013, AUDs increased by about 10% overall, including growth of almost 85% in women, and rates increased between 90% and 100% across individuals aged 45 to 64 and those over 65, respectively. At the same time, rates of drinking among adolescents and young adults might have slightly decreased.

The course of AUDs is as predictable as most medical and psychiatric conditions, with an early onset likely to be associated with greater severity. Therefore, if an AUD begins in the midteens, it is often associated with conduct disorder, concomitant drug difficulties, and antisocial behaviors that are likely to predate the alcohol problems. At the other extreme, an onset after age 40 tends to be associated with less severe social difficulties and more subtle AUD signs and symptoms, but a greater likelihood of medical problems.

Comorbid Conditions

Telegram: @medical_k

www.konkur.in

As discussed in more detail later in this chapter, psychiatric syndromes likely to occur at increased rates in heavy-drinking individuals fall into two general categories. The first group includes *alcohol-induced* depressive episodes, anxiety conditions, and psychoses. These resemble independent depressive (e.g., major depressive disorder), anxiety (e.g., panic disorder), and psychotic conditions (e.g., schizophrenia) but are only observed during severe persistent intoxication or withdrawal and are likely to clear spontaneously within about a month of abstinence. The second group involves psychiatric disorders that occur *independently* of alcohol intake but are associated with an increased risk for AUDs, including schizophrenia, bipolar disorder, ASPD, and post-traumatic stress disorder (PTSD).

PHARMACOLOGY AND ALCOHOL'S EFFECTS

Properties and Metabolism of Alcohol

Ethanol (beverage alcohol) is a simple molecule that is well absorbed through the mucosal lining of the digestive tract in the mouth, esophagus, and stomach. The most prominent area of uptake is in the proximal small intestine, which is also the site of absorption of many B vitamins. Ethanol rapidly enters the bloodstream and, reflecting its high solubility in water, is distributed throughout the body.

Wine, beer, and distilled spirits (e.g., whiskey, gin, and vodka) differ in their content of components other than alcohol. These *congeners*, responsible for much of the taste of the beverage, include methanol, butanol, aldehydes, phenols, tannins, lead, cobalt, and iron.

A standard alcoholic drink in the United States is defined as containing 10 to 12 g of ethanol, which is roughly the amount in 12 oz of beer (containing ~3.6% ethanol), 5 oz of table wine (~12% ethanol), and about 1.5 oz of 80-proof spirits (~40% ethanol). For an average 70-kg (155-lb) person with average body fat, one drink is likely to raise the blood alcohol level by approximately 15 to 20

Telegram: @medical_k

www.konkur.in

mg/dL (the same as 0.015 to 0.020 g/dL), with roughly the same amount metabolized in about an hour. Faster absorption from the digestive tract occurs on an empty stomach and if alcohol is taken as a carbonated beverage.

Between 2% and 10% of the alcohol is excreted unchanged through the lungs, kidneys, or sweat, some is broken down in the lining of the esophagus and stomach (especially in men), but most is metabolized in the liver through several pathways that result in the production of acetaldehyde. Most of the process occurs through the actions of alcohol dehydrogenase (ADH) in the cell cytosol, although at high blood–alcohol levels, some alcohol is also broken down in the microsomes of the liver's smooth endoplasmic reticulum (the microsomal ethanol oxidizing system [MEOS]). The ADH process is the usual rate-limiting metabolic step, occurring relatively slowly because of the liver's need to handle the produced hydrogen ions through the actions of a cofactor that is in relatively short supply, nicotinamide adenine dinucleotide (NAD).

Acetaldehyde is destroyed by aldehyde dehydrogenase (ALDH) both in liver cell cytosol and mitochondria. This occurs rapidly so that the average person has low levels of this substance after drinking. This is fortunate because, while low levels of acetaldehyde can be both stimulating and reinforcing, at high levels, this substance can release histamines and catecholamines that contribute to rapid changes in blood pressure along with nausea and vomiting. Variants of ALDH and ADH are related to a higher reaction to alcohol and lower risk for AUDs, especially in East Asian (e.g., Japanese, Chinese, and Korean) men and women.

Alcohol as a Depressant Drug

Acutely, all intoxicants pleasurably change how a person feels, thus enhancing the drive to continue to take the drug despite potential consequences. Such drugs have divergent effects that are best understood by placing them into categories based on their most prominent effects at the usual doses taken. In this scheme, depressants are drugs that produce somnolence and decreased

Telegram: @medical_k

www.konkur.in

neuronal activity but are not powerful in attenuating pain. Thus, alcohol, benzodiazepines, barbiturates, and related drugs are considered central nervous system depressants and produce similar intoxications, are potentially lethal in overdose (especially when multiple depressants are taken together), have cross-tolerance with other depressants, and can produce physical dependence with similar withdrawal syndromes.

Neurochemical Effects of Ethanol

Alcohol has prominent effects on almost all neurochemical systems, with opposite actions during intoxication versus withdrawal. Perhaps the most potent effects are on γ-*aminobutyric acid* (GABA) complexes in the brain, especially on the GABA-A receptor ($GABA_A$), contributing to the sedating, sleep-inducing, anticonvulsant, and muscle-relaxing properties of alcohol. Ethanol also impacts glutamate-gated ionophoric receptors, especially those that bind *N-methyl-D-aspartate* (NMDA), with dampened stimulatory effects during intoxication and heightened activity during withdrawal. Alcohol acutely increases *dopamine* and its metabolites, and chronic drinking changes dopamine receptor numbers and sensitivity, with related effects on intoxication and craving, in part through changes in the pleasure centers in the ventral tegmental area of the brain. Consuming beverage alcohol also increases *serotonin* in the synapses and upregulates serotonin receptors. Lower brain levels of serotonin may be associated with a less intense response to alcohol and with consuming more alcohol per occasion. Finally, in this brief review, alcohol acutely enhances the functioning of the *opioid-related* brain systems and impacts *adenosine*, *acetylcholine*, and *cannabinoid* 1 (CB1) receptors.

Tolerance

With repeated administration, larger doses of alcohol are required to produce the same effects. This phenomenon of *tolerance* also produces an ability to tolerate higher doses of the substance through at least three processes. In *behavioral tolerance,* a person learns

Telegram: @medical_k

www.konkur.in

through practice how to perform tasks effectively while experiencing the effects of alcohol. *Pharmacokinetic tolerance* involves adaptations of alcohol-metabolizing systems to rid the body of alcohol more rapidly. Most importantly, *pharmacodynamic* or *cellular tolerance* reflects an adaptation of the nervous system so that it can function despite high blood alcohol concentrations by resisting the actions of alcohol on the cell.

Once tolerance has developed to one depressant, an individual is likely to demonstrate a similar reaction to a second drug of that class (*cross-tolerance*). Therefore, a person who has been drinking heavily, has tolerance to alcohol, and then stops drinking can be expected in the short run to require a higher dose of other depressants such as benzodiazepines for sleep induction. However, if individuals take two depressant drugs concomitantly, the effect of one drug can magnify, or potentiate, the effects of the other, with a possible lethal outcome.

FT is a 73-year-old emeritus professor at a small liberal arts college in the Midwest. He had no persistent alcohol-related problems prior to his early 60s and used to consume one or two standard drinks (scotch) before dinner. At age 62, he moved to a retirement community in Arizona, where he had more time to play golf, interact with his wife, and socialize with his new friends. In the context of a lack of work obligations and the freedom to increase his hours of socializing, FT slowly increased his alcohol intake. Subsequently, the number of standard drinks required to produce a mild buzz increased from two to four during an evening, and his daily consumption increased to five or six standard drinks most nights.

Blackout

A *blackout* is a memory impairment (*anterograde amnesia*) for the period when a person was drinking heavily but remained awake. This phenomenon is the result of the ability of high doses of any

Telegram: @medical_k

www.konkur.in

brain depressant (e.g., alcohol or benzodiazepines) to interfere with the acquisition and solidification of memory. As many as 50% of drinkers have at some time had a blackout, and repeated experiences of this effect of high doses of alcohol is a warning sign that an AUD may be present.

Sleep Impairment

Alcohol can help a person fall asleep, but after two or more drinks, the sleep pattern can be impaired. A heavy drinker is likely to awaken after several hours and have problems going back to sleep. Alcohol suppresses rapid eye movement (REM) sleep, inhibits stage 4 sleep late in the night, and is associated with frequent alternations between sleep stages (*sleep fragmentation*), with more intense and disturbing dreams late in the night as the blood alcohol levels fall. More intense forms of these problems are seen in individuals with AUDs, for whom sleep stages might not return to normal until three or more months of abstinence. More sleep problems following abstinence are associated with a greater risk for relapse.

Cerebellar Degeneration

Characterized by unsteady gait, impaired standing steadiness, and mild nystagmus, cerebellar degeneration results from combinations of effects of ethanol, acetaldehyde, and vitamin deficiencies. Treatment requires total abstinence and vitamin supplementation, although complete recovery is not usual.

Other Effects on the Central Nervous System

A thiamine deficiency, especially in the context of a pre-existing vulnerability such as a transketolase deficiency, can present as any of several neurologic syndromes now known as alcohol-induced major neurocognitive disorder, amnestic confabulatory type, persistent. Using the more widely accepted prior terminology, this can include a sixth cranial nerve palsy (Wernicke) and a severe anterograde amnesia that is out of proportion to the general level of

Telegram: @medical_k

www.konkur.in

confusion (Korsakoff). These rare conditions are discussed in greater depth in the section “Diagnosis and Clinical Features.”

Effects on the Rest of the Body

One to two drinks per day of any alcoholic beverage might decrease the risks for myocardial infarction and thrombotic stroke, probably through decreasing platelet aggregation and enhancing high-density lipoprotein (HDL) cholesterol levels. An additional potential cardioprotective action, unique to red wine, may occur through antioxidant flavonoids or the inhibition of a vasoconstrictor (endothelin-1). Low doses of alcohol may also decrease the risks for some dementias, peripheral arterial disease, and gallstones. However, any amount of alcohol may be harmful to a developing fetus, and the risks of even one drink per day are prohibitive for individuals in recovery from a moderate or severe AUD, people taking medications that may adversely interact with alcohol, and persons with any of several medical or psychiatric syndromes. Consuming more than three drinks a day increases low-density lipoprotein (LDL) cholesterol, triglycerides, and blood pressure, thus increasing the risk of cardiac disorders and cancers.

Peripheral Neuropathy. Approximately 10% of people with AUDs develop a deterioration of functioning of nerves in the hands and feet, called *peripheral neuropathy.* The symptoms include numbness of the hands and feet, often bilateral, frequently accompanied by tingling and paresthesias. Although the condition is usually relatively mild and often improves with abstinence, in some individuals, the pain and numbness may be permanent.

Gastrointestinal Problems. The gastrointestinal (GI) system can be severely affected by heavy drinking, including an acute and potentially severe inflammation of the esophagus or stomach, often accompanied by vomiting and bleeding. If vomiting occurs in the presence of dilated esophageal veins, as seen with cirrhosis, it can induce a potentially lethal blood loss.

Telegram: @medical_k

www.konkur.in

The liver and the pancreas are also especially vulnerable to alcohol. In the liver, frequent heavy drinking results in the accumulation of fats and proteins in the cells, producing a reversible swelling of the liver, often described as a *fatty liver.* Inflammation of liver cells accompanied by increases in liver function tests is called *alcoholic hepatitis*, which can lead to deposition of excessive amounts of hyalin and collagen near blood vessels in the liver, an early stage of *cirrhosis*, with the latter seen in approximately 15% of patients with AUDs. As damage progresses and liver scar tissue increases, the normal flow of blood through the liver is impaired, dilated veins (or varices) develop from the increased abdominal venous pressure, and fluid seeps from the liver capsule, accumulating in the abdomen as *ascites*. Subsequent liver failure can cause a cognitive impairment known as hepatic encephalopathy.

Perhaps 10% of people with AUDs develop an inflammation of the pancreas or *acute pancreatitis*. This can lead to a chronic irreversible condition with associated impaired sugar metabolism (a form of diabetes).

Cardiovascular Problems. Heavy alcohol intake and associated withdrawal symptoms can increase blood pressure and elevate both LDL cholesterol and triglycerides, enhancing the risk for myocardial infarction and thrombosis. At high doses, alcohol is a striated-muscle toxin with a resulting deterioration in the heart muscle that manifests as beating irregularities and signs of heart failure (*alcoholic cardiomyopathy*). The risks for cardiovascular disease are likely to be observed at even lower alcohol doses in East Asian individuals who have the mutation in ALDH described above in the section on alcohol metabolism. Thus, the leading cause of early deaths associated with AUDs is heart disease.

Blood-Producing Systems. Consumption of four to eight drinks or more per day decreases the production of white blood cells and impairs the ability of those cells to migrate to sites of infection. Such drinking can also affect the stem cells that produce the red blood components, increasing the average size of red cells (the mean

Telegram: @medical_k

www.konkur.in

corpuscular volume [MCV]), and can impair the production of blood platelets.

Cancer. AUDs are associated with high rates of most cancers, especially tumors of the head, neck, esophagus, stomach, liver, colon, lungs, and breast. The association with cancer probably reflects alcohol-related immune system suppression and the direct effects of ethanol and acetaldehyde on mucosal membranes. The heightened rates of malignant tumors remain significant even when the impact of smoking and poor nutrition is considered, and cancer is the second cause of premature death in individuals with AUDs.

Fetal Alcohol Effects

Alcohol and acetaldehyde have deleterious effects on the developing fetus. Both substances cross the placenta and, in high enough doses, can produce fetal death and spontaneous abortion. At least 5% of surviving infants of heavy-drinking mothers evidence mixtures of a *fetal alcohol syndrome* that can include low IQ, a small head, low birth weight, facial abnormalities (e.g., flat bridge of the nose, absent philtrum, and epicanthal eye folds), an atrial septal heart defect, and syndactyly. More subtle offspring behavioral effects of drinking during pregnancy have been reported with even lower alcohol doses. None of these problems are likely to be reversible, and most cognitive defects remain throughout life. Additional less obvious problems are part of a range of *fetal alcohol spectrum disorders* (FASDs), including mild to moderate cognitive difficulties (e.g., impaired executive functioning in attention and planning, problems in letter and word fluency, difficulties with impulse control, etc.), and may carry an enhanced risk for SUDs.

Other Problems

High doses of alcohol adversely affect almost all body systems, cutting a decade or more off the lifespan even for people with higher socioeconomic and educational status. Additional body effects related to AUDs include testicular atrophy; bone fractures; a host of

Telegram: @medical_k

www.konkur.in

eye effects, including cataracts; dental difficulties; skeletal muscle wasting; and greater risk for accidents.

ETIOLOGY

Many factors affect the decision to drink, the development of temporary alcohol-related difficulties, and the development of AUDs. The initiation of drinking depends largely on social, religious, and personality characteristics, although genetic influences linked to impulsivity and risk-taking also contribute. However, the factors that influence the decision to drink or those that contribute to temporary problems might be a bit different from those that add to the risk for AUDs.

Genetic factors are responsible for about 50% to 60% of the proportion of risk for AUDs and operate through several intermediate characteristics that interact with the environment. While each risk component is discussed separately in this chapter, these divisions are heuristic, as it is the combination of psychological, sociocultural, biologic, and other factors that are responsible for the development of severe, repetitive alcohol-related life problems.

Psychological and Sociocultural Theories

Plentiful data support a relationship between *stress* and drinking behaviors, but the strength of the interaction and the directions of the correlations are complex. Retrospective studies focusing on prominent adverse life events often report that higher stress is associated with heavier drinking and related problems. However, prospective studies often find less impact of stress during any one day on alcohol use that same day or in the subsequent 48 hours. In addition, these relationships are bidirectional, with drinking on day 1 also associated with more stress on day 2. At higher doses and especially at falling blood alcohol levels, objective measures of tension in muscles indicate that muscle tension can actually increase. Thus, tension-reducing effects of alcohol may be modest

Telegram: @medical_k

www.konkur.in

and are most obvious in light-to-moderate drinkers, and stress may play a moderate role in causing AUDs.

A person's *expectations* of the effects of alcohol also play a role in patterns of alcohol use. Positive expectations of the impact of excessive drinking on social interactions, alleviating sadness and anxiety, and sexual performance are associated with higher probabilities of heavier drinking. Similarly, the more a person expects that alcohol will interfere with relationships, sexual performance, and other negative outcomes, the less the risk for heavy alcohol intake.

A third characteristic closely linked to attitudes toward alcohol and subsequent drinking patterns is the *perceived pattern of drinking among peers,* where individuals tend to overestimate the alcohol consumption of friends. Thus, they exaggerate the amount of drinking that is acceptable, healthy, and safe, and may be more likely to engage in heavier drinking themselves.

Additional psychological and sociocultural factors related to heavy drinking include the neighborhood in which one lives and the ease of availability of alcohol, a person's income and the money available to buy alcohol, and their education and religious beliefs. Religious beliefs and practices affect alcohol intake through moderating the effects of other characteristics, with less likelihood that poverty, for example, predicts heavier drinking among individuals with closer religious affiliations.

Sociocultural theories are sometimes based on extrapolations from social groups that have high and low rates of AUDs. For example, Jews tend to introduce young children to modest drinking in religious rituals, eschew drunkenness, and also have low rates of AUDs. However, other groups have similar practices, such as French Catholics, but have higher rates of AUDs. Recent studies have found little evidence that introducing children to modest drinking in the home impacts the risks for heavy drinking and alcohol problems. So, cross-cultural comparisons are useful in generating theories, but it can be difficult to establish key cultural practices contributing to drinking-related disorders.

Psychodynamic Theories

Telegram: @medical_k

www.konkur.in

Classic psychoanalytical theory hypothesizes that at least some people with AUDs may have become fixated at the oral stage of development and use alcohol to relieve their frustrations by taking the substance by mouth. However, hypotheses regarding arrested phases of psychosexual development, although heuristically useful, have had little effect on the usual treatment or prevention approaches for AUDs and are not the focus of extensive ongoing research.

Similarly, there is little support for an “addictive personality” that might be associated with lack of control of intake of most substances and some foods. Although pathologic scores on personality tests are often seen during intoxication, withdrawal, and early recovery, many of these characteristics do not predate AUDs, and most disappear with abstinence.

Background on Biologic Contributors

The genetic contribution to the AUD risk involves many different genetically influenced characteristics, and there is no known single alcoholism gene. Using a parallel example from medicine, myocardial infarctions are genetically influenced, but in some families, the genes relate to high blood pressure; in others, the heightened risk is related to genes contributing to high triglycerides; yet others develop heart attacks through a genetically influenced vulnerability toward cardiomyopathy. Each genetic mechanism is moderated by environmental characteristics such as diet, exercise, and smoking. The following sections highlight data supporting the importance of genetic influences in AUDs, and describe biologic mediators (Table 11.2–2).

Importance of Genetic Influences in AUDs

Three lines of evidence support genetic influences in AUDs. First, there is a three- to fourfold increased risk for severe alcohol problems in close relatives of individuals with AUDs, with rates increasing with a greater number of such relatives, a greater severity of their AUDs, and a closer genetic relationship. Second, the rate of

Telegram: @medical_k

www.konkur.in

similarity for severe alcohol-related problems is higher in identical twins of persons with an AUD with whom they share 100% of their genes than in fraternal twins who share only 50%. Third, the risks for AUDs in the offspring of AUD parents are still high even if they were adopted away and knew nothing of the problems in their biologic family.

Table 11.2–2.
Data Supporting Genetic Influences in AUDs

Close family members of individuals with an AUD have a fourfold increased risk.
The identical twin of a person with an AUD is at higher AUD risk than is a fraternal twin.
Adopted-away children of individuals with AUDs have a fourfold increased AUD risk, even if not raised by parents with alcohol problems.

Biologic Mediators of the AUD Risk

As shown in Table 11.2–3, a series of independent characteristics impact the alcoholism risk.

Alcohol Metabolizing Enzymes. Variations in genes on chromosome 12 that control ALDH and genes on chromosome 4 related to ADH can decrease the alcoholism risk. The most potent polymorphism occurs in the mitochondrial low Km ALDH2 gene reflecting the *ALDH2*2* genotype that is seen in about 40% of Japanese, Chinese, and Korean individuals. An *ALDH2*2, 2*2* homozygote inherits a disulfiram (or Antabuse)-like aversive reaction to alcohol because their enzyme cannot efficiently metabolize acetaldehyde, with resulting nausea, vomiting, and unstable blood pressure after one or two drinks and an AUD risk close to zero. Heterozygotes for the ALDH mutation (e.g., with *ALDH2*2, 2*1* alleles) have a mild to modest facial flush after drinking, a higher heart rate, and a more intense (although not necessarily aversive)

Telegram: @medical_k

www.konkur.in

response to alcohol that contributes to a modest decreased risk for AUDs. Variations in ADH genes (e.g., ADH1B and ADH1C) are more prevalent among Asian, Black, and Jewish individuals who experience a slightly increased rate of breakdown of alcohol with a possible increase in acetaldehyde and a modest protective effect for AUDs. These gene variations do not affect the risk for other SUDs.

Impulsivity and Disinhibition. A second genetically influenced mechanism increases the risk for both AUDs and SUDs through genes that affect impulsivity, sensation seeking, and disinhibition. These characteristics are more prevalent in individuals with AUDs, are observed in a substantial minority of their children, and reflect the action of a range of genes, including those coding for $GABA_A$ and CHRM2 receptors. Extreme impulsivity and disinhibition characterize ASPD, where the risk for AUDs and SUDs is about 80%.

Table 11.2–3.
Some Genetically Influenced Characteristics that Affect the AUD Risk

Alcohol-metabolizing enzymes
Impulsivity and disinhibition
Some psychiatric disorders (e.g., schizophrenia and bipolar disorders)
A low level of response (low LR) to alcohol

Independent Psychiatric Disorders. A third genetically influenced mechanism that increases both AUD and SUD risks operates through genes that enhance the vulnerability to several psychiatric disorders. In addition to ASPD, two genetically influenced psychiatric conditions closely tied to AUDs and SUDs are schizophrenia and bipolar disorders. These relationships might reflect the poor judgment associated with these major psychiatric disorders and the impulsivity associated with mania. The link might also relate to an overlap of genes contributing to the predisposition

Telegram: @medical_k

www.konkur.in

toward substance-related problems and those that impact on schizophrenia and bipolar disorder. Some of the relationship might also occur as an individual attempts to moderate their psychiatric symptoms or the side effects of medications through alcohol or illicit drugs.

The Level of Response (or Sensitivity) to Alcohol. A fourth genetically influenced risk factor for AUDs (but not SUDs) involves how a person responds to alcohol. This includes enhanced risks for people who experience greater stimulation at rising blood alcohol levels and those who demonstrate a low level of response (LR) at peak and falling blood levels regarding feelings of intoxication and sedating effects of alcohol. The most thoroughly studied of these characteristics is the low LR, where the need for higher doses to achieve alcohol's effects contributes to larger quantities consumed per occasion. This subsequently affects the choice of heavy-drinking friends, enhances positive expectations of the effects of heavy drinking, and is associated with the use of alcohol to deal with stress. Several genes that may contribute to the low LR have been identified, and functional magnetic resonance imaging (fMRI) studies have highlighted a possible cognitive inefficiency that might make it more difficult for some people to recognize the effects of low alcohol doses. The data indicating that this characteristic is genetically influenced and the identification of some environmental mediators of the effect of a low LR on heavy drinking are being used to develop programs to prevent heavy drinking and AUDs in individuals with low LRs before they develop.

DIAGNOSIS AND CLINICAL FEATURES

AUDs are among the most common of the serious life-threatening behavioral or psychiatric syndromes, and, unfortunately, these repetitive patterns of problems associated with heavier drinking are often not obvious to the clinician. The average man or woman with an AUD does not fit the public stereotype as these individuals are likely to be neatly dressed, show no signs of severe alcohol

Telegram: @medical_k

www.konkur.in

withdrawal, and have a job and a family, but present with a variety of physical conditions or temporary but potentially severe psychiatric complaints. Thus, the clinician must gather a history of alcohol-related life problems from every patient and, if possible, an additional informant and try to determine whether alcohol has contributed to the presenting complaint. Table 11.2–4 lists the alcohol-related disorders in DSM-5.

Diagnosing Alcohol-Related Disorders

This generic term includes AUDs (previously abuse and dependence in DSM-IV), as well as alcohol intoxication, withdrawal, and alcohol-induced conditions.

Telegram: @medical_k

Alcohol Use Disorders

The key to a diagnosis of an AUD is heavy and repetitive use of alcohol to the point of developing recurrent problems. Quantities and frequencies of alcohol intake, while useful, are by themselves not sufficient to establish the diagnosis because of the large variation in the amounts of alcohol required for problems across men versus women, larger versus smaller individuals, and older versus younger people. Repetitive problems indicate that a person keeps using alcohol despite problems, which, in turn, predicts the probability that a return to drinking is likely to be associated with the re-establishment of problems.

As noted above, there are 11 elements in the DSM-5 definition of AUDs. Ten of these items are the same as those listed in DSM-III-R and DSM-IV. The 11th item, craving, describes a strong drive to drink that occurs despite the problems caused by alcohol.

Telegram: @medical_k

www.konkur.in

JP's referring clinician was concerned that little progress was being made with the patient's mood swings and somatic complaints. Therapy, primarily using a cognitive and behavioral approach, had been instituted 6 months previously for the depressive symptoms and irritability that were present most days for the prior year. JP had recently undergone a routine physical examination at work and was noted to have modest hypertension (blood pressure of 145/95) along with blood test results that included an MCV of 92.5 μm^3 and a γ-glutamyltransferase (GGT) level of 53 U/L.

On interview, the patient admitted that his wife had been complaining for several years about his drinking pattern. She had emphasized that in the mornings after drinking, he was more irritable than usual and complained about his restless sleep. Dr P had recognized potential alcohol problems and tried on several occasions to cut back on his drinking. These efforts usually resulted in abstinence of between 2 and 4 weeks, followed by several months of setting limits on his intake, but these always gave way to increased drinking during celebrations, business trips, vacations, or to "deal with" stress. Once ad-lib drinking began, he had to increase the amount consumed per day to achieve the desired effects.

Alcohol Intoxication

The DSM-5 criteria for alcohol intoxication require recent ingestion of ethanol, associated impairment, and at least one of six signs or symptoms. In ICD-11, intoxication is a temporary condition after consuming alcohol that is associated with impaired cognition, coordination, mood, and/or level of consciousness.

As a conservative approach to identifying blood levels that are likely to have major effects on driving abilities, the legal definition of intoxication in the United States requires a blood concentration of 80 mg of ethanol per dL of blood (mg/dL), which is the same as 0.08 g/dL. Many other countries define legal intoxication regarding driving

Telegram: @medical_k

www.konkur.in

as 40 mg/dL, and the limits in Poland are 20 mg/dL. For most people, blood levels as low as 20 to 30 mg/dL are associated with some behavioral changes, a slowing in motor performance, and a decrease in the ability to think clearly, as shown in Table 11.2–5. Blood concentrations between 80 and 200 mg/dL produce more severe problems, including severely impaired coordination (ataxia), lability of mood, and progressively greater levels of cognitive deterioration. Blood alcohol concentrations of 200 to 300 mg/dL produce severe slurring of speech and en bloc *anterograde amnesia* (*alcoholic blackouts*) regarding much of the evening. Further increases in blood levels result in the first level of anesthesia, and the nontolerant person who reaches 400 mg/dL risks respiratory failure, coma, and death.

Table 11.2–5.
Impairment Likely to Be Observed at Different Blood Alcohol Concentrations

Level	Likely Impairment
20–30 mg/dL (0.02–0.03 g/dL)	Slowed motor performance and decreased thinking ability
30–80 mg/dL	Increases in motor and cognitive problems
80–200 mg/dL	Increases in incoordination and judgment errors
	Mood lability
	Deterioration in cognition
200–300 mg/dL	Nystagmus, marked slurring of speech, and alcoholic blackouts
>300 mg/dL	Impaired vital signs and possible death

Table 11.2–6.
Key Elements of DSM-5 Criteria for Alcohol Withdrawal[a]

A. Recent decreasing or stopping regular heavy drinking
B. Accompanied by the development of at least two of the following:
   1. Increased pulse, blood pressure, and/or sweating
   2. Tremor of the hands
   3. Problems sleeping
   4. Gastrointestinal upset
   5. Hallucinations
   6. Inability to sit still
   7. Nervousness
   8. Seizures

[a]A short version of the criteria is offered here. See DSM-5 for complete criteria.

Alcohol Withdrawal

If a person has been drinking heavily over a prolonged period, a rapid decrease in blood alcohol levels can produce a *withdrawal syndrome* characterized by symptoms that are primarily the opposite of what was initially experienced with intoxication. Due to the effects of tolerance described earlier, with chronic exposure to a CNS depressant, the brain adapts by downregulating the inhibitory systems while also upregulating the excitatory system. When the depressant is suddenly removed, the excess excitatory system becomes manifest as withdrawal. Here, withdrawal includes a coarse tremor of the hands, insomnia, anxiety, and signs of autonomic hyperactivity that can include increased blood pressure, heart rate, body temperature, and respiratory rate, as described in Table 11.2–6. In ICD-11, the description of alcohol withdrawal is similar.

Withdrawal phenomena usually begin within about 8 hours of abstinence, peak on the second or third day, and diminish by the fourth or fifth day. The symptoms persist in a milder form for as long as 3 to 6 months as part of a protracted withdrawal syndrome, the symptoms of which might contribute to relapse.

Telegram: @medical_k

www.konkur.in

FT, the retired professor discussed elsewhere in this chapter, went on to experience alcohol withdrawal delirium. He was in relatively good health when he entered the hospital for an elective hernia repair. The brief history in the chart offered no comments regarding his drinking pattern and made no mention of his GGT value of 55 U/L and MCV of 93.5 μm^3. Eight hours postsurgery, the nursing staff noted an increase in his pulse to 110, a blood pressure of 150/100, prominent diaphoresis, and a bilateral hand tremor just before the patient had a grand mal seizure. He awoke agitated and disoriented. Re-evaluation of the history documented an AUD with a consumption of approximately six standard drinks per night. Over the following 4 days, the patient's autonomic nervous system dysfunction decreased, and his cognitive impairment disappeared.

Alcohol Withdrawal Delirium

Less than 5% of alcohol intoxications and withdrawals are accompanied by severe cognitive impairments known as alcohol intoxication delirium and alcohol withdrawal delirium. These conditions require that the patient meet criteria for both delirium and DSM-5 alcohol intoxication or withdrawal.

Telegram: @medical_k

www.konkur.in

Mr T is a 64-year-old lawyer with a 35-year history of an AUD. Alcohol-related problems included tolerance, spending a great deal of time using alcohol (despite a relatively successful career), repeatedly giving up important business and family events because he was too intoxicated or hung over, and significant interference with his relationship with his wife. She complained about his sarcastic wit and lack of care about her interests while drinking heavily.

Mr T had been able to stop drinking on multiple occasions in the past, at which times he experienced a tremor, anxiety, and problems sleeping for several days. He typically self-medicated these symptoms with five or more 10-mg capsules of chlordiazepoxide per day, using pills that had been prescribed for him by his general practitioner in response to his complaints of anxiety and insomnia. Recently, Mr T was diagnosed with moderate hypertension and adult-onset diabetes, and his family practitioner urged him to stop drinking. In recognition of his age and his associated medical problems, it was believed that the current withdrawal would be best treated in a medical setting.

An examination confirmed the withdrawal syndrome along with a mildly decreased hematocrit and platelet count. The evaluation, carried out about 12 hours after his most recent drink, revealed the smell of alcohol on his breath and a blood alcohol level of 50 mg/dL. The patient demonstrated a prominent tremor of both hands along with a pulse of 110 beats per minute, a respiratory rate of 25 breaths per minute, and a blood pressure of 150/96. Mr T complained of feeling agitated and noted that while he was very tired, he was unable to sleep but was otherwise alert and oriented. These symptoms improved greatly by day 5 of abstinence, with mild levels of autonomic overactivity and insomnia gradually disappearing over the next 2 months.

Alcohol-Induced Psychiatric Disorders

Telegram: @medical_k

www.konkur.in

Alcohol-induced psychiatric disorders are clinically meaningful (e.g., interfere with functioning and/or cause severe distress) psychiatric syndromes (e.g., depression) that resemble independent psychiatric disorders (e.g., major depressive disorders) and are in excess of symptoms usually associated with alcohol intoxication or withdrawal. They develop during, or soon after, intoxication or withdrawal from alcohol and are likely to clear within a month of abstinence. Note that independent psychiatric disorders are described in the section below dealing with the differential diagnoses for individuals presenting with an AUD.

For men and women presenting with psychiatric symptoms (e.g., anxiety, depression, or psychoses) with concomitant alcohol-related problems, the first step in establishing a diagnosis of an alcohol-induced disorder is to obtain a chronologic history of the conditions. The focus should be on full psychiatric disorders, not subsyndromal sadness or nervousness, because the full syndromes have the clearest prognostic implications. In this process, a timeline can be useful by noting: (1) the age of onset of alcohol problems severe and repetitive enough for a diagnosis of an AUD; (2) periods of abstinence of a month or more since the AUD onset to determine if a full psychiatric syndrome ever occurred outside the context of problematic alcohol use; and (3) the ages when the patient met criteria for the major psychiatric disorder. If a review of the timeline reveals no evidence that the additional psychiatric syndromes either clearly antedated the heavy alcohol intake or persisted for a month or more after abstinence, an AUD is the major disorder. The additional psychiatric syndromes are likely to be temporary conditions that occurred during alcohol intoxication or withdrawal (i.e., are alcohol induced). DSM-5 lists substance-induced conditions within the clinically relevant sections (e.g., within depressive, anxiety, and psychotic disorders sections). Independent psychiatric conditions in individuals with AUDs are discussed elsewhere in this chapter, including in the section on Differential Diagnoses.

Alcohol-Induced Depressive Disorder. In the context of heavy and repetitive intake of any brain depressant, symptoms of severe

Telegram: @medical_k

www.konkur.in

depression are common and may be labeled as an *alcohol-induced depressive disorder* (see Table 11.2–4). In ICD-11, these conditions are labeled as alcohol-induced mood disorders. This condition includes the same symptoms observed in major depressive disorders, but the alcohol-induced intense sadness markedly improves within several days to 1 month of abstinence without antidepressant medications. Eighty percent of people with AUDs report intense depressions, including about 40% who were depressed for ≥2 weeks at a time, but only about 15% of such men and women have ever had a depression that meets the criteria for a major depressive disorder when they have not been drinking heavily. Although an alcohol-induced bipolar diagnosis is listed in DSM-5, there is no convincing evidence that heavy drinking can mimic a manic episode.

Telegram: @medical_k

www.konkur.in

A consultation was requested on a 42-year-old woman with an AUD who complained of persisting severe depressive symptoms despite days of abstinence. In the initial stage of the interview, she stated that she had “always been depressed” and believed that she “drank to cope with the depressive symptoms.” Her current complaint included a prominent sadness that had persisted for several weeks, difficulties concentrating, initial and terminal insomnia, and a feeling of hopelessness and guilt. In an effort to distinguish between an alcohol-induced mood disorder and an independent major depressive episode, a timeline-based history was obtained. This focused on the age of onset of a DSM-5 AUD, periods of abstinence that extended for at least a month since the onset of the AUD (periods where independent depressions might have been observed), and the ages of occurrence of clear major depressive episodes lasting 2 or more weeks. Despite this patient’s original complaints, there was no evidence of a major depressive episode before her mid-20s when her AUD began, and during a 1-year period of abstinence related to the gestation and neonatal period of her son, she was euthymic. A provisional diagnosis of an alcohol-induced mood disorder was made. The patient was offered education, reassurance, and cognitive behavior therapy (CBT) to help her deal with the depressive symptoms, but no antidepressant medications were prescribed. The depressive symptoms remained at their original intensity for several additional days and then began to improve. By 3 weeks of abstinence, the patient no longer met criteria for a major depressive episode, although she demonstrated mild mood swings for several additional weeks. This case is a fairly typical example of an alcohol-induced depressive disorder in an individual with an AUD.

Alcohol-Induced Anxiety Disorders. Anxiety symptoms fulfilling the diagnostic criteria for alcohol-induced anxiety disorders in DSM-5 and ICD11 are common in the context of acute and protracted

Telegram: @medical_k

www.konkur.in

alcohol withdrawal. Almost 80% of people with AUDs report prominent anxiety during an acute withdrawal episode, and their complaints can be intense enough for the clinician to consider diagnosing a panic disorder, generalized anxiety disorders, social phobia, and other anxiety conditions. However, when psychological or physiologic symptoms of anxiety are observed in people with AUDs only in the context of heavy drinking or within the first month or so of abstinence, the symptoms are likely to diminish and subsequently disappear with time alone. Only a few pre-existing anxiety or stress disorders (e.g., panic disorder, social phobia, and PTSD) have been clearly shown to modestly increase the risk for later AUDs.

Telegram: @medical_k

www.konkur.in

A 48-year-old woman was referred for evaluation and treatment of her recent onset of panic attacks. These episodes occurred two to three times per week over the past 6 months, with each lasting typically between 10 and 20 minutes. Panic symptoms occurred independently of levels of stress and could not be explained by the side effects of current medications or by medical conditions. The workup included an evaluation of her laboratory test values, which revealed a carbohydrate-deficient transferrin (CDT) level of 3.5%, a uric acid level of 7.1 mg, and a GGT value of 47. All other blood tests were within normal limits.

The atypical late age of onset of panic attacks, along with the blood results, encouraged the clinician to probe further regarding the pattern of alcohol-related life problems with both the patient and, separately, her spouse. This documented a history of an AUD with an onset at approximately 35 years of age, with no evidence of a panic disorder before that time. The patient denied having repetitive panic attacks beyond a month of abstinence during her frequent periods of nondrinking that often lasted for 3 or 4 months. A working diagnosis of an AUD with an alcohol-induced anxiety disorder characterized by panic attacks was made, and the patient was encouraged to abstain. She was offered CBT to help decrease feelings of panic and anxiety and was appropriately treated for moderate withdrawal symptoms. Over the subsequent 3 weeks after a taper of benzodiazepines used for the withdrawal, the panic symptoms diminished in intensity and subsequently disappeared.

Alcohol-Induced Psychotic Disorders. About 3% of people with AUDs experience these conditions, described in DSM-5 and ICD 11 as auditory hallucinations and/or paranoid delusions in a clear sensorium that develop in the context of heavy drinking or withdrawal, typically referred to as alcoholic hallucinosis, as coined by Eugene Bleuler. This rate is lower than psychotic conditions noted during intake of high doses of cannabis or stimulants (i.e., all forms

Telegram: @medical_k

www.konkur.in

of cocaine and amphetamines). Many clinicians exclude from this label psychotic symptoms that only occur during the course of a delirium or dementia. The symptoms of alcohol-induced psychoses resemble those seen in schizophrenia, but when the psychotic features develop only in the context of alcohol problems, they are likely to clear spontaneously within a few days to a month of abstinence. It is estimated that <5% of these psychoses occur in individuals who later develop schizophrenia.

Alcohol-Induced Major Neurocognitive Disorders, Amnestic Confabulatory Type, Persistent (Wernicke–Korsakoff Disorder)

One of the more dramatic alcohol-related CNS syndromes is the rare DSM-5 diagnosis of what in the past was referred to as an alcohol-induced persisting amnestic disorder, which is the result of a relatively severe CNS deficiency of thiamine. Similar criteria are offered in ICD-10 as an amnesic syndrome. Some people are at higher risk than others for this condition because of a genetically influenced transketolase deficiency. The syndrome has been historically subdivided into (1) Wernicke encephalopathy, with prominent ataxia and palsy of the sixth cranial nerve, a condition that tends to reverse fairly rapidly with vitamin supplementation; and (2) Korsakoff syndrome, which is permanent in at least a partial form in about 50% of the people affected. Korsakoff syndrome is characterized by a pronounced anterograde and retrograde amnesia along with potential impairment in visuospatial, abstract, and other types of learning. In most cases, the level of loss of recent memory is out of proportion to the global level of cognitive impairment. The patients who recover respond to 500 mg of IV thiamine, two to three times a day for 3 to 5 days, or 100 mg of oral thiamine a day that is usually administered for many months. High-dose IV thiamine is currently considered superior to PO supplementation in preventing and treating Wernicke, because the high serum concentrations are needed to drive thiamine across the blood–brain barrier.

Telegram: @medical_k

www.konkur.in

Alcohol-Induced Major Neurocognitive Disorders (Persisting Dementias)

A poorly studied, heterogeneous long-term cognitive problem that can develop in the course of AUDs was called *alcohol-induced persisting dementia* in DSM-IV and ICD-10. Global decreases in intellectual functioning, cognitive abilities, and memory are observed, but recent memory difficulties are no more prominent than other elements of this condition. Brain functioning tends to improve with abstinence, but perhaps half of patients have long-term and even permanent disabilities. More than 50% of these patients have increased brain ventricle sizes and shrinkage of the cerebral sulci, although these changes are usually reversible with abstinence.

IDENTIFICATION IN CLINICAL SETTINGS AND RELATED LABORATORY TESTS

To establish an AUD diagnosis, a history of alcohol-related life problems must be obtained from the patient and, when available, an additional reliable informant. Because any patient, regardless of their education and income, might have an AUD, everyone should be screened for histories of alcohol-related accidents, interpersonal difficulties, problems at work, and encounters with the law. When a problem is apparent, the clinician should ask more about the situation and about the complaints voiced by others. If an AUD is probable, the diagnostic criteria and drinking history should be reviewed with the patient.

Several simple questionnaires can help screen for problems. The Alcohol Use Disorders Identification Test (AUDIT, Table 11.2–7) uses 10 items to review the pattern of life problems related to alcohol. More simple instruments, such as the CAGE ([need to] *C*ut down [on drinking], *A*nnoyance when asked about drinking, *G*uilt [about drinking], [need for] *E*ye-openers the morning after heavy drinking), are too short to be optimally sensitive or specific. Although the AUDIT is useful, such questionnaires do not diagnose an AUD but

Telegram: @medical_k

www.konkur.in

only highlight individuals who are especially appropriate for a more detailed clinical interview.

Identifying heavier drinkers vulnerable to AUDs is facilitated by the several blood tests noted in Table 11.2–8. These *state markers of heavy drinking* reflect physiologic alterations likely to occur after ingesting about five or more drinks a day over several weeks. One marker with a sensitivity and specificity of about 60% is a level of at least 35 U/L of GGT, an amino acid–transporting enzyme that is temporarily induced by repetitive heavy drinking. Enzyme levels are likely to return to normal after 2 to 4 weeks of abstinence, after which further increases over 20% are useful in identifying a return to drinking. Similar results are seen for the deglycosylated form of the protein transferrin, known as CDT. A value over 3% has sensitivities and specificities of 60% for the consumption of five or more drinks per day for 1 to 2 weeks. With a biologic half-life of about 16 days, this test is also useful in monitoring abstinence. The combination of GGT and CDT is better than either test alone for identification of heavy drinking and monitoring abstinence.

www.konkur.in

Table 11.2–7.
Key Elements of the Alcohol Use Disorders Identification Test (AUDIT)

Telegram: @medical_k

www.konkur.in

Item	5-Point Scale (Least to Most)
1. How often do you have a drink containing alcohol?	Never (score 0) to 4+ per week (score 4)
2. How many drinks containing alcohol do you have on a typical day?	1 or 2 (0) to 10+ (4)
3. How often do you have six or more drinks on one occasion?	Never (0) to daily or almost daily (4)
4. How often during the last year have you found that you were not able to stop drinking once you had started?	Never (0) to daily or almost daily (4)
5. How often during the last year have you failed to do what was normally expected from you because of drinking?	Never (0) to daily or almost daily (4)
6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	Never (0) to daily or almost daily (4)
7. How often during the last year have you had a feeling of guilt or remorse after drinking?	Never (0) to daily or almost daily (4)
8. How often during the last year have you been unable to remember what happened the night before because you had been drinking?	Never (0) to daily or almost daily (4)

Telegram: @medical_k

www.konkur.in

9. Have you or someone else been injured as a result of your drinking?	No (0) to yes, during the last year (4)
10. Has a relative, friend, doctor, or other health worker been concerned about your drinking or suggested that you should cut down?	No (0) to yes, during the last year (4)

The AUDIT is scored by simply summing the values associated with the endorsed response.

Adapted with permission from Babor TF, Higgins-Biddle JC, Saunders JB, Monterio MG. *AUDIT: The Alcohol Use Disorders Identification Test Guidelines for Use in Primary Care*, 2nd ed. Geneva, World Health Organization (WHO); 2001. https://www.who.int/publications/i/item/WHO-MSD-MSB-01.6a, accessed 3/22/23. WHO does not endorse any specific companies, products or services.

An MCV over 91 μm^3 has a sensitivity of about 50% in identifying heavy drinking, but the 120-day lifespan of red cells does not allow MCV to be useful as an indicator of a return to drinking. Other indicators that can be helpful in identifying patients who are regularly consuming heavy doses of alcohol include high normal values of uric acid (e.g., >6.4 mg/dL) and elevations in the usual liver function tests. Useful physical findings include modest elevations in blood pressure, frequent bruising, cancer of the head, neck, or upper digestive tract, an enlarged liver, evidence of cirrhosis, and pancreatitis.

Telegram: @medical_k

www.konkur.in

Table 11.2–8.
State Markers of Heavy Drinking Useful in Screening for AUDs

Test	Relevant Range of Results
γ-glutamyltransferase (GGT)	>35.0 U/L
Carbohydrate-deficient transferrin (CDT)	>3.0%
Mean corpuscular volume (MCV)	>91.0 μm^3
Uric acid	>6.4 mg/dL for men >5.0 mg/dL for women
Serum glutamic oxaloacetic transaminase (aspartate aminotransferase)	>45.0 IU/L
Serum glutamic pyruvic transaminase (alanine aminotransferase)	>45.0 IU/L
Ethylglucuronide (EtG)	>100 ng/mL
Phosphatidylethanol (PEth)	>200 ng/mL

Ethylglucuronide (EtG), a glucuronide metabolite of ethanol, has utility in monitoring abstinence because EtG is present for several days in urine after any consumption of alcohol, hence making this suitable for identifying a recent relapse. Levels above 100 ng/mL are generally considered a positive result, although caution in interpretation is warranted because false positives can result from using alcohol-containing hand sanitizers or mouthwash.

Finally, phosphatidylethanol (PEth) is another metabolite produced only in the presence of alcohol that remains elevated for 1 to 2 weeks following a heavy drinking episode. Testing for PEth requires a blood sample, and levels above 200 ng/mL are generally considered a cut-off for heavy drinking, while negative results suggest abstinence.

www.konkur.in

DIFFERENTIAL DIAGNOSIS

Once a pattern of alcohol-related life problems has been identified, the diagnosis of an AUD may be fairly obvious. However, the differential diagnosis is more challenging when a patient presents with psychiatric symptoms that may indicate an *alcohol-induced psychiatric condition,* as described above in the section on diagnostic and clinical features. It is equally important to identify *independent psychiatric disorders* that predate the AUD and/or continue after at least 4 abstinent weeks. This section offers more detail regarding independent comorbid conditions seen with AUDs.

Antisocial Personality Disorder

ASPD in DSM-5 is based on severe antisocial behaviors beginning before age 15 as conduct disorder and continuing into adulthood. People with ASPD are likely to be impulsive, sometimes violent, and risk-takers who do not easily learn from mistakes. About 80% of people with this disorder develop severe alcohol problems and/or SUDs; they are likely to discontinue treatment prematurely and have relatively poor prognoses in AUD treatment, where they represent about 5% of women and 15% of men. Symptoms of other personality disorders are often observed during intoxication and withdrawal, but other than ASPD and borderline personality disorders, few have been documented to predate the AUD. Thus, it is advisable to defer a diagnosis of additional personality disorders until at least a month after abstinence unless the syndrome clearly antedated the AUD. The treatment of AUDs in patients with independent ASPD involves the same general approaches as for alcohol-related disorders overall, with common sense variations to deal with the interpersonal problems.

Independent Schizophrenia

A second independent disorder associated with elevated risks for both AUDs and SUDs is schizophrenia. Typically characterized by a slow onset of paranoid delusions and auditory hallucinations in a

Telegram: @medical_k

www.konkur.in

clear sensorium and usually beginning in the late teens to the 20s, schizophrenia is likely to be severe, long lasting, and debilitating. Possibly reflecting a lack of long-term psychiatric treatment facilities, people with schizophrenia are sometimes homeless, a situation that, along with impaired judgment associated with their psychoses, may contribute to alcohol- and drug-related problems. There may also be overlap in genetic mechanisms (e.g., related to dopamine) that contribute to AUDs and psychotic disorders. Heavy drinking is likely to undercut the effectiveness of antipsychotic medications, increase mood swings, intensify psychoses, and contribute to a higher probability of repeatedly revolving into and out of inpatient care. AUDs are observed in about 40% of individuals with schizophrenia.

A 34-year-old unemployed, divorced man entered treatment for an AUD. His history revealed seven hospitalizations since age 23 related to schizophrenia and alcohol use. By age 23, the patient had experienced auditory hallucinations and paranoid delusions for the prior year but had not yet demonstrated severe enough problems related to alcohol or other drugs to fulfill criteria for an AUD or SUD. A hospitalization at age 28 was followed by 6 months of abstinence while living in a recovery home, during which time the patient continued to have auditory hallucinations and paranoid delusions without insight. The current hospitalization involved the treatment of alcohol withdrawal while re-evaluating and stabilizing the antipsychotic medications for this man with an independent schizophrenia.

Independent Depressive and Bipolar I Disorders

A third group of conditions that are part of the differential diagnoses of AUDs involves mood-related diagnoses. Substance-induced major depressive disorders are discussed more extensively above under alcohol-induced psychiatric disorders. However, when a major depressive episode occurs before the onset of an AUD or during a period of abstinence, it needs to be treated as an independent

Telegram: @medical_k

www.konkur.in

condition while the clinician also addresses the alcohol-related problems. While some studies indicate that independent major depressions do not increase the risk for later AUDs, pre-existing bipolar I disorder is more closely linked with the AUD risk. This may reflect heavy drinking that began during mania-related hyperexcitability, impulsiveness, and associated poor judgment. As with schizophrenia, there also may be overlap in genetic mechanisms contributing to both bipolar and substance-related disorders. Bipolar II, on the other hand, is difficult to evaluate in patients with AUDs, because their intoxication, withdrawal, and reactions to life problems can mimic hypomania. Bipolar II labels should be reserved for AUD patients with clear hypomanic episodes antedating the AUD or directly observed by the clinician after at least a month of abstinence.

Independent Major Anxiety, Trauma, and Stress-Related Disorders

There is at least a modest association between the risk for AUDs and independent panic disorder, social phobia, and PTSD. Regarding the latter, a delay of many months between the stressful event and the development of PTSD might indicate an impact of alcohol withdrawal or intoxication-related depression or anxiety on subclinical trauma-related symptoms. In these instances, the PTSD might markedly improve with continued abstinence, perhaps falling below a diagnostic threshold for PTSD. In other individuals, however, PTSD was clearly present before the AUD or remained severe during abstinence, in which case, once the acute alcohol-related problems are addressed, the patient should consider longer-term CBT or other evidence-based psychotherapies, as well as medication-based therapies appropriate for PTSD.

Other Disorders

Attention deficit hyperactivity disorder (ADHD) with a childhood onset involves learning problems, difficulties focusing attention, and problems sitting still and following through on tasks. Because these

Telegram: @medical_k

www.konkur.in

children can be disruptive at home and school, and because many are treated with stimulant medications such as methylphenidate, it is possible that they might carry a heightened future risk for AUDs and SUDs. However, studies to date do not uniformly support a close tie between ADHD and later substance-related problems unless the child also met criteria for conduct disorder.

There are also complex relationships between AUDs and SUDs. Men and women with ASPD have a high risk for multiple SUDs, including AUDs. It is also probable that individuals with addiction to opioids and stimulants (cocaine and amphetamines) have an increased risk for AUDs by turning to alcohol to moderate the intoxication or side effects from their preferred drug. However, while many individuals with AUDs have used other substances, most do not meet criteria for an SUD. An exception is tobacco use disorders, which are elevated among individuals with AUDs. This finding may relate to attempts to use tobacco or nicotine-containing products to moderate some of the effects of high doses of alcohol or withdrawal, or a possible genetic relationship between nicotine- and alcohol-related syndromes.

Course and Prognosis of AUDs

Most people with AUDs, regardless of their backgrounds, exhibit general similarities in the time course and prevalence of alcohol-related life difficulties. The differences that do exist mostly reflect characteristics of individuals in society in general and may not indicate unique aspects of their AUD. For example, women in the general population and among those with AUDs have higher rates of independent depressive episodes and are less likely to be violent, have a full-time job, or have police records compared to comparable men. However, some sex differences do exist (e.g., women are likely to begin drinking a few years later than men and may demonstrate a faster escalation of AUD symptoms and faster onset of medical complications—i.e., telescoping effect). Similarly, older individuals in the general population and with AUDs are more likely to have

Telegram: @medical_k

www.konkur.in

medical problems, take multiple medications, and have fewer extensive social support systems compared to younger individuals.

Early Course

Patients with ASPD who develop an AUD are likely to have an early onset of drinking, intoxication, and alcohol-related problems, but that scenario is not applicable to the other 80% of men and 95% of women with AUDs. As shown in Table 11.2–9, the usual person with an AUD has their first drink (other than taking a sip from a parent's glass) between the ages of 13 and 15 years, the first intoxication usually occurs at 15 or 16, and the first minor alcohol-related problem is usually observed in the late teens, milestones similar to what is expected for people in the general population. More severe alcohol-related difficulties begin to cluster together in the early 20s to the middle 30s.

Table 11.2–9.
Clinical Course of AUDs[a]

Age at first drink[b,c]	13–15 years
Age at first intoxication[b,c]	15–17 years
Age at first problem[b]	16–22 years
Age at onset of an AUD	23–40 years
Age at death	60 years
Fluctuating course of abstention, temporary control, alcohol problems	NA
Spontaneous remission in 20%	NA

AUD, Alcohol use disorder.

NA indicates that age of onset does not apply to this item.

[a]The data presented here are based on DSM-IV abuse and dependence, and it is likely that mild AUD (2 or 3 of 11 criteria endorsed) is similar to DSM-IV abuse, while moderate or severe AUD (4+ criteria endorsed) is more similar to DSM-IV dependence.

[b]Same as general population.

[c]While these ages reflect the usual course of alcohol use in individuals without conduct disorder or antisocial personality disorder, an earlier drinking or intoxication is associated with an increased AUD risk.

Later Course

Once a moderate to severe AUD has developed, unless the person abstains, there are likely to be repeated future periods of drinking problems that alternate with periods of abstinence and *temporary* controlled drinking. The usual person with an AUD uses the temporary cessation of drinking problems to convince themselves that alcohol is not really a cause for concern. Those periods of abstinence, lasting days to months, are usually followed by times

Telegram: @medical_k

www.konkur.in

when drinking rules are established and at least temporarily followed. For example, the person might avoid spirits (ignoring that a glass of beer or wine and a shot of whiskey have similar amounts of alcohol) or limit drinking to certain times of the day and under specified conditions. This period of temporary control usually leads to an escalation of alcohol intake, followed by new problems that precipitate new abstinent periods, and the cycle begins again.

An important development in at least 20% of people with AUDs is a spontaneous remission. Here, without recent treatment or self-help group participation, the person spontaneously stops drinking and remains abstinent for extended periods. Such outcomes are most likely for those with fewer alcohol-related problems, more social supports, jobs, greater life stability, and no concomitant ASPD or SUD diagnoses.

The fluctuating course and high rate of spontaneous remission that are typical of the course of AUDs are major reasons why evaluations of potential treatments for these conditions require double-blind controlled studies. Individuals with AUDs are likely to come for treatment at a point when their alcohol problems are the most severe. However, at any time of follow-up, they are likely to be functioning better than at treatment entry. This change reflects both temporal fluctuations in their drinking pattern over time as well as spontaneous and perhaps permanent remissions.

However, if drinking continues, the person with AUDs potentially decreases their lifespan by at least 10 years as a result of the alcohol-related pathologies described earlier in this chapter. This early death also reflects an almost 10% risk for suicide, usually during a depressive episode.

Prognosis

As few as 10% to 20% of people with AUDs ever receive treatment for their disorder. However, once they complete a program, a majority do well and develop long-term, often permanent, abstinence. Good outcomes are most likely in patients who do not have ASPD and in individuals who have a job to go back to and

Telegram: @medical_k

www.konkur.in

close family contacts who offer social support. These attributes predict about a 60% chance for >1 year of abstinence, with 1-year rates associated with a good chance for continued abstinence over an extended period. Individuals with independent major psychiatric conditions, such as ASPD, schizophrenia, and bipolar I disorder, are likely to run the course of their independent psychiatric illness as well.

TREATMENT

The core of treatment for AUDs involves maximizing motivation for abstinence, helping the person restructure a life without alcohol, and minimizing relapse to substance-using behaviors. This CBT-based approach is similar to efforts appropriate for any long-term disorder that requires changes in lifestyle, such as diabetes or hypertension. Much of the challenge for clinicians rests with recognizing the high prevalence of AUDs, how often these conditions involve temporary symptoms of other psychiatric syndromes, and how to use clinical clues, physical findings, and laboratory tests to identify an AUD.

Three general steps are involved in treating the person with an AUD: intervention; detoxification (if needed); and rehabilitation, including relapse prevention. These approaches can begin after life-threatening medical conditions are addressed and psychiatric emergencies treated. Thus, suicidal plans, psychotic features without insight, and alcohol withdrawal delirium require inpatient hospitalizations until the patient is stabilized enough to begin alcohol rehabilitation.

Intervention

The goal is to use the principles of motivational interviewing and brief interventions to help patients recognize the choices they have and the adverse consequences likely to occur if they do not stop drinking. A discussion of the presenting complaint (e.g., insomnia or depression) is a useful way to both show empathy and enhance motivation for change. The emphasis is then placed on discussing

Telegram: @medical_k

www.konkur.in

how alcohol either created or contributed to these problems and reassuring the patient that life changes, potentially including abstinence, are possible. If the person does not respond to the first brief intervention or motivational interview, the same nonjudgmental but persistent approach can be used each time an alcohol-related problem is identified. Many individuals with AUDs take time to realize how alcohol contributed to problems and to be ready and willing to change.

For the physician, the intervention often begins with a "brief intervention," a cost-effective approach that can be used in the clinician's office. It is summarized by the acronym FRAMES: giving Feedback on alcohol risks; emphasizing a person's Responsibility for change; offering Advice; giving a Menu of options to consider; employing Empathy; and emphasizing Self-efficacy, or the ability to change. The goal is to establish an alliance with patients by demonstrating an understanding of their viewpoint while encouraging them to think through consequences associated with alcohol and the way that changing behaviors might yield benefits. During these discussions, it is important to recognize the patient's ambivalence toward abstinence and to monitor the person's readiness to change. Resistance is best handled through discussion and problem solving rather than direct confrontation.

Two 15-minute sessions, along with a workbook available from the National Institute on Alcohol Abuse and Alcoholism (pubs.niaaa.nih.com), can be used to review drinking problems and help the patient understand how life cues contribute to the drinking pattern. Between two visits separated by about 1 month, patients keep notes of their drinking patterns. The second session reviews the same issues and is followed by several short telephone interviews.

Detoxification

Most people with an AUD have relatively mild, if any, withdrawal symptoms when they stop drinking. If the patient is in relatively good health and has a good social support system, the withdrawal

Telegram: @medical_k

www.konkur.in

syndrome associated with alcohol usually resembles a mild flu or bad hangover. The essential first step in detoxification is a thorough physical examination. In the absence of a serious medical disorder or a comorbid SUD, severe alcohol withdrawal is unlikely. The second step is to offer rest, nutrition, and oral multivitamins, including thiamine.

Mild or Moderate Withdrawal. Alcohol withdrawal develops because the brain, adapted to the presence of this drug, downregulates the inhibitory systems and cannot function adequately in the absence of alcohol. Many patients, especially young and healthy individuals, have no clinically significant withdrawal symptoms and can go directly into the rehabilitation phase of treatment. Others will benefit from medications, giving enough of a brain depressant on the first day to diminish symptoms and then weaning the patient off the medication over the course of acute withdrawal, usually over about 5 days. If the symptoms are mild and the person is in good health, this can be done as an outpatient with daily brief visits. Any depressant can work, but most clinicians choose benzodiazepines for their relatively low cost and higher safety. Adequate treatment can be given with either short-acting drugs, such as lorazepam, or long-acting medications such as chlordiazepoxide or diazepam.

An example is administering 25 mg of chlordiazepoxide by mouth three or four times a day on the first day, with a notation to skip a dose if the patient is sleepy. Up to two additional 25-mg doses during the first day can be used if tremor or autonomic dysfunction increases. The first day's dose can be decreased by about 20% each subsequent day, with a resulting need for no medication after 4 or 5 days. However, the prior day's dose should be restored if withdrawal symptoms increase and further decreases in doses delayed a day or two. When using a long-acting agent, such as chlordiazepoxide, the clinician must avoid producing excessive sedation; if the patient is sleepy, the next scheduled dose should be omitted. When using a short-acting drug, such as lorazepam, the patient must not miss any dose because rapid changes in

Telegram: @medical_k

www.konkur.in

benzodiazepine concentrations can precipitate a seizure. Other depressants, including anticonvulsants (e.g., gabapentin) can also be effective but have added dangers and costs compared to benzodiazepines. Some clinicians recommend β-adrenergic receptor antagonists (e.g., propranolol) or α-adrenergic receptor agonists (e.g., clonidine), although these medications do not decrease the risk of seizures or delirium and can mask the intensity of some withdrawal signs that are used to monitor withdrawal severity.

Alternative to this fixed-dose schedule, another option, especially for those with mild to moderate withdrawal, is to adopt a symptom-triggered approach. The gold-standard tool to measure alcohol withdrawal severity is the Clinical Institute Withdrawal Assessment for Alcohol-Revised (CIWA), which can be administered to arrive at a score. Above a certain cut-off, typically 8, medications are administered but withheld if scoring below this cut-off. Studies have shown that a symptom-triggered approach can still treat withdrawal adequately but reduces the duration of treatment and the overall need for medications without increasing the risk of progression to severe withdrawal.

Severe Withdrawal. For the less than 3% of AUD patients with extreme autonomic dysfunction, agitation, and confusion (alcoholic withdrawal delirium or delirium tremens [DTs]), there is no perfect treatment. DTs represent a medical emergency and will usually require treatment in intensive care. The first important step is to determine why such severe withdrawal symptoms occurred, especially whether there is a concomitant medical problem that needs immediate treatment. The withdrawal symptoms in DTs can then be minimized with benzodiazepines (high doses are sometimes required), along with the adjunctive use of an antipsychotic (e.g., haloperidol [Haldol]) to control severe agitation and hallucinations. If the patient does not respond to benzodiazepines, a clinician experienced in treating withdrawal delirium in an ICU can consider inducing a state of arousable deep sleep with propofol or the α-2-receptor agonist dexmedetomidine. Here, higher doses are used on

Telegram: @medical_k

www.konkur.in

the first or second day to control behavior, and the patient is then typically weaned off medications by about the fifth day.

Another 1% of patients in alcohol withdrawal have a single grand mal convulsion, with a peak incidence on day 2. This requires a neurologic evaluation, but in the absence of an independent seizure disorder, a single seizure does not indicate using anticonvulsant drugs.

Protracted Withdrawal. Finally, regarding withdrawal, mild symptoms of anxiety, insomnia, and autonomic overactivity are likely to continue for 2 to 6 months following acute withdrawal. Although no pharmacologic treatment for this syndrome has been identified, a medication discussed below for the rehabilitation phase, acamprosate, might diminish some of these symptoms. It is important to warn patients that some sleep problems or feelings of nervousness might remain after acute withdrawal and consider efforts to help them feel more comfortable because these protracted withdrawal symptoms enhance the probability of relapse.

Rehabilitation

Rehabilitation includes three major components: (1) increasing and maintaining high levels of motivation for change; (2) helping patients readjust to a lifestyle that maximizes functioning and decreases the risk for drinking; and (3) relapse prevention. These steps often begin in the context of acute and protracted withdrawal syndromes and life crises.

No single major life event or psychiatric disorder is a unique cause of AUDs. The effects of earlier causes are likely to have been joined by reinforcing effects of the drug, especially regarding relief of hangovers and mild withdrawal symptoms, and the years of a stressful lifestyle in the context of heavy drinking. This is true even though many people with AUDs believe that the unique cause was depression, anxiety, difficult life events, prior stress, or pain syndromes. However, the alcohol was as likely to have contributed to the mood disorder, accident, or life stress as the other way around.

Telegram: @medical_k

www.konkur.in

The same general treatment approach is used in inpatient and outpatient settings. The selection of the more expensive, but more intense and effective, inpatient mode often depends on evidence of additional severe medical or psychiatric syndromes, severe stresses that would interfere with treatment, the absence of nearby outpatient groups, and/or the patient's nonresponse to outpatient care. The treatment process in either setting usually involves 2 to 4 weeks of care as an intensive period of help, followed by at least 3 to 6 months of less frequent outpatient care. The latter uses a combination of individual and group counseling, avoiding psychotropic medications unless needed for independent disorders, and involvement in self-help groups such as Alcoholics Anonymous (AA).

Counseling. Counseling in the first several weeks to months of recovery focuses on day-to-day life issues to help patients maintain a high level of motivation for abstinence and to enhance their functioning. Psychotherapy techniques that provoke anxiety or that require deep insights may not be beneficial during the early phases of treatment, and, at least theoretically, the added anxiety may impair the ability to abstain.

One goal of these CBT- and motivation-based counseling sessions is to help the patient learn ways to cope with life stresses. The clinician can use modeling and role-playing of situations likely to be encountered while working toward abstinence, along with encouraging patients to practice these skills between sessions. At the same time, individuals work to identify areas of problems in day-to-day functioning, paying special attention to how they react to these challenges and the impact that substance use might have on the outcomes.

To optimize motivation, treatment sessions explore the consequences of drinking, the likely future course of alcohol-related life problems, and the improvement that can be expected with abstinence. Counseling also deals with how to build a lifestyle free of alcohol. Discussions cover the need for a sober peer group, a plan for social and recreational events without drinking, and approaches

Telegram: @medical_k

www.konkur.in

for re-establishing communication with family members and friends. Whether in an inpatient or an outpatient setting, individual or group counseling is usually offered about three times a week for the first 2 to 4 weeks, followed by less intense efforts, perhaps once a week, for the subsequent 3 to 6 months.

Relapse Prevention. The third component of rehabilitation, relapse prevention, begins with identifying situations with high risks for relapse. The counselor helps patients develop ways to identify and cope with craving and with challenging events or emotional states that make drinking more likely. It is also important to remind patients that short-term relapses are not an excuse for returning to regular drinking. Recovery is a process of trial and error, and slips can be clues to help identify high-risk situations and to develop more appropriate coping techniques.

Importance of the Family. AUDs affect many people in the patient's life, and an important aspect of recovery involves helping family and friends understand more about AUDs and how rehabilitation is an ongoing process. Counseling and support for spouses, offspring, and friends can help them work to rebuild key relationships and learn how to avoid protecting the patient from the consequences of drinking, a step likely to undercut the patient's motivation to abstain.

Treatment of Independent Psychiatric Disorders. Regarding some of the independent psychiatric disorders discussed under Differential Diagnoses above, clinicians must treat the patient who has bipolar I disorder with appropriate psychotherapy and lithium and/or valproic acid; use relevant psychological and behavioral techniques for the patient with ASPD; and offer long-term antipsychotic medications to the patient with schizophrenia. The goal is to minimize the symptoms of the independent psychiatric disorder in the hope that a greater level of life stability will be associated with a better prognosis for the patient's alcohol problems. Initial treatment should work to control mania or severe depression along with

Telegram: @medical_k

www.konkur.in

treatment of withdrawal, and alcohol rehabilitation should be considered once the independent disorder is under control. Especially for more severe psychiatric symptoms, concurrent treatment of the AUD and the comorbid psychiatric disorders are recommended, while sequential treatment may be reasonable if the symptoms are less severe.

Possible Medications for the AUD. Patients with AUDs who do not have an independent psychiatric disorder have no clear need for antidepressants or antianxiety drugs after withdrawal in the treatment of their AUDs. Moderate anxiety and insomnia that linger as part of a protracted abstinence syndrome should be treated with CBT, education, and reassurance. Medications, including benzodiazepines, for anxiety and insomnia are likely to lose effectiveness as tolerance develops, and patients sometimes increase the dose and have subsequent problems related to the prescribed drug.

Similarly, although low levels of sadness and mood swings can linger for months, controlled clinical trials indicate little benefit to prescribing antidepressant medications or lithium for the average person with an AUD who has no independent psychiatric disorder. The substance-induced mood disorder is likely to clear before the medications can take effect, and patients who resume drinking while on the medications face potential dangers of alcohol–drug interactions. With little evidence that such medications are routinely effective, the dangers outweigh potential benefits from their routine use.

As is true for most clinical disorders, the use of medications for the treatment of AUDs requires remembering that all treatments have both benefits and risks. Double-blind, controlled studies are important to establish an acceptable ratio of assets to dangers while controlling for the impact of spontaneous remission and fluctuations in patients' conditions that occur over time. The random variation in the course of AUDs, along with the probability that patients are most likely to seek treatment when their problems are most intense, means that the only way to be confident that a medication

Telegram: @medical_k

www.konkur.in

contributed to a good outcome is through controls for spontaneous remissions and fluctuating intensities of drinking problems by also observing outcomes in an appropriate comparison group.

Data from double-blind trials support modest effects for two medications offered in the context of CBT. The first drug is acamprosate, an analog of the amino acid neurotransmitter taurine with a structure that resembles GABA. This medication antagonizes neuronal overactivity related to the excitatory neurotransmitter glutamate, at least in part, by acting as an antagonist to NMDA receptors. Thus, acamprosate may diminish mild anxiety, mood swings, and other sleep difficulties associated with the protracted withdrawal syndrome observed after the first 4 to 5 days of abstinence. Using about 2,000 mg divided into three doses per day, the majority of studies report 15% to 20% better drinking outcomes with active drug compared to placebo, with relatively mild side effects of GI problems such as diarrhea. Although there are no clear guidelines, clinicians often prescribe this drug for 6 months, during which time it is hoped an alcohol-free lifestyle can be developed.

The second promising medication is the long-acting opioid antagonist naltrexone (taken orally or in an injectable form). This agent has been marketed for many years as a treatment for maintaining opioid abstinence and is effective for rehabilitation with highly motivated individuals with opioid use disorder because this opioid blocker drug attenuates an opioid high. Naltrexone works by blocking opioid receptors in the brain with associated decreased activity in the ventral tegmental reward area of the brain and is hypothesized to decrease the rewarding effects of a drink and to diminish craving—interrupting the positive reinforcement from alcohol. The majority of double-blind, placebo-controlled trials supports the superiority of naltrexone with about 15% to 20% better drinking outcomes than for placebo. The side effects for 50 mg per day include mild GI upset and lethargy. Several studies indicated that individuals with a gene variation related to the Asn40Asp location in the gene for the mu-opioid receptor (OPRM1) have better AUD outcomes, but recent studies have reported contradictory results. There is also a 380-mg, once-per-month naltrexone injection,

Telegram: @medical_k

www.konkur.in

which might be particularly useful for noncompliant patients. By avoiding the liver's first pass effect, the injectable formulation may carry less risk of causing hepatotoxicity, which is one of the side effects of naltrexone that limits its use.

The combination of acamprosate (666 mg three times a day) plus naltrexone (50 mg per day or three times a week) may be more effective than either drug alone, while not increasing the side effect profile. However, not all studies agree, and further research is needed.

A third drug of possible interest is the alcohol-sensitizing agent disulfiram, which is usually prescribed at 250 mg per day, the highest dose most patients will be likely to tolerate. The goal is to warn patients that drinking alcohol while taking disulfiram precipitates nausea, vomiting, and changes in blood pressure, and the medication is best used when taken daily while being observed by someone like a relative or pharmacist. However, few data convincingly prove that disulfiram is more effective than placebo, probably because patients on placebo are given the same caveat. Many clinicians have stopped prescribing this agent, partly because of the dangers associated with the drug itself, including mood swings, rare instances of psychosis, a possible increase in peripheral neuropathies, and a rare but potentially fatal hepatitis. Moreover, patients with pre-existing heart disease, stroke, diabetes, and other conditions cannot be given disulfiram because an alcohol reaction could be fatal.

Several additional medications are worth brief mention but have only limited data to support their use. First, while not approved for the treatment of AUDs, the anticonvulsant topiramate has the usual GABA-boosting activity associated with antiseizure treatments along with a glutamate receptor blockade and effects on dopamine. Perhaps related to these combined effects, several studies using topiramate (300 mg per day) in AUD treatment reported improvements in drinking patterns, but studies also noted side effects of mental slowing, decreased concentration, memory impairment, and paresthesias that are difficult for many patients to tolerate. Similar results and side effect profiles, as well as abuse

Telegram: @medical_k

www.konkur.in

liabilities, have been reported for another anticonvulsant, gabapentin, which has been evaluated at between 900 and 1,800 mg/day, but has been reported to have a relatively high dropout rate. Still, there is a growing evidence base for the role of gabapentin in addressing both mild to moderate withdrawal and supporting ongoing abstinence. The misuse liability of gabapentin, notably among those with opioid use disorder, remains a concern and warrants careful consideration. Third, some data indicate that 4 micrograms per kilogram body weight of the serotonin-3 receptor antagonist ondansetron might be beneficial in AUD treatment, particularly in early-onset AUDs with comorbid drug dependence and criminality. Additional medications that have been evaluated for the treatment of AUDs include several selective serotonin reuptake inhibitors (SSRIs, e.g., sertraline up to 200 mg per day), with some evidence that patients with the SS genotype in the promoter region of the serotonin transporter gene may be more likely to respond; the GABA-B receptor agonist baclofen; and some antipsychotic medications, although these medications have not consistently proven to be better than placebo in controlled trials and are not recommended for routine use.

Self-Help Groups. Clinicians should consider the potential importance of “12-step-based” self-help groups such as AA. Similar to what occurs in CBT and relapse prevention, AA participants are encouraged to change the way they view their drinking while building a lifestyle that optimizes sober friends and uses the support of family members. Help from AA is available 24 hours a day, and participants learn they can still enjoy social functions without drinking, while observing models of recovery through the accomplishments of sober members of the group.

Clinicians play important roles by encouraging AA attendance while helping patients select the most appropriate group. Some meetings are comprised only of men or women, and others are mixed; some are mostly attended by blue-collar men and women, whereas others are mostly for professionals; some groups place great emphasis on religion, and others are more eclectic. Patients

Telegram: @medical_k

www.konkur.in

with independent psychiatric disorders may need additional education about AA. The clinician should remind them that some members of AA may not understand their special need for medications and should suggest ways to cope with inappropriate suggestions that important medications be stopped. Although difficult to evaluate using double-blind controls, most studies indicate that participation in AA is associated with improved outcomes.

www.konkur.in

Following the family intervention and at the insistence of his wife and partners, JP agreed to enter treatment. He and his family opted for a more intensive inpatient-based alcohol and drug treatment program of 4 weeks duration. The physical examination on entrance to treatment revealed no major medical problems. Vital signs after 3 days of sobriety were within normal limits except for a slight increase in heart rate (80 beats per minute) and blood pressure (145/90). To treat a mild withdrawal syndrome, 25 mg chlordiazepoxide up to three times per day as needed was prescribed for systolic blood pressure over 140/90, tremor, or other signs of autonomic dysfunction. JP received two doses on his first day of hospitalization, one dose on his second day, and no further benzodiazepines were required.

The core of therapy involved group counseling twice per day, emphasizing the patient's responsibility for the decision to abstain, discussing problems associated with continued substance use, and describing steps that can be taken to help rebuild one's relationship with family, colleagues, and friends. JP cooperated well with treatment, and the discharge planning included a discussion of the possible medications during the rehabilitation phase. After consulting with the patient and the family, both acamprosate (666 mg by mouth three times a day) and naltrexone (50 mg by mouth daily) were prescribed, with the goal of continuing the medications for approximately 6 months.

In addition, couples counseling was carried out with JP and his wife to optimize her understanding of the recovery process and offer her the opportunity of dealing with questions and feelings of frustration, anger, and anxiety that developed during JP's drinking years. The subsequent aftercare outpatient group met twice a week. Steps were taken to help JP identify an AA group with which he might be most comfortable in terms of shared background with members as well as time and location. An Al-Anon group was identified for his wife as well.

JP's course involved two brief relapses in the first 6 months of treatment, each involving a return to alcohol lasting less than 2

Telegram: @medical_k

www.konkur.in

days. The rapid recovery of abstinence was likely to be related to his prior relapse prevention training as well as his return to both AA and aftercare treatment. After the first 6 months, no further relapses were observed over the next year. Currently, JP continues with one or two AA meetings per week and has become involved in outreach from AA, visiting a local hospital and helping to lead an AA group for individuals in early recovery.

11.3 Stimulant-Related Disorders

Rocco A. Iannucci, M.D., and Roger D. Weiss, M.D.

Stimulants in their natural forms, such as the plants *Erythroxylon coca*, *Ephedra sinica*, and *Catha edulis*, have been used by humans for millennia. As a class of substances, they share the acute effect of increasing physiologic and mental arousal through dopaminergic pathways. They include amphetamine-type substances (those with a substituted phenylethylamine structure), structurally dissimilar agents with similar effects (such as methylphenidate), and cocaine. In the United States, cycles of widespread stimulant misuse and associated problems have occurred for more than 100 years. Stimulant use and stimulant use disorders present a staggering burden worldwide, with an estimated 27 million people misusing some form of stimulant in 2019. In the United States, stimulants are responsible for a disproportionately high number of emergency department visits and overdoses, underscoring the potential dangerousness of misusing these substances. In recent years,

Telegram: @medical_k

www.konkur.in

overdoses due to stimulants have risen to alarming levels and have exacerbated the opioid overdose crisis. More than ever, developing and disseminating effective treatment for people with stimulant use disorders remains a pressing public health need.

DEFINITIONS

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) describes 10 stimulant-related diagnoses, which are further categorized into stimulant use disorder and stimulant-induced disorders. Stimulant use disorder is defined in DSM-5 by a cluster of cognitive, behavioral, and physiologic symptoms indicating continued use of stimulants despite significant problems related to or caused by their use. In the 10th revision of the *International Classification of Diseases* (ICD-10), the corresponding amphetamine- and cocaine-related diagnoses are defined by cognitive, behavioral, and physiologic phenomena reflecting persistent use of these stimulants despite harmful consequences and to the exclusion of other activities and obligations. The hallmark of a severe stimulant use disorder is a pattern of compulsive substance use and loss of control over use that interferes with other aspects of life and health. It may involve the development of tolerance and/or withdrawal symptoms, but neither is necessary or sufficient to meet diagnostic criteria for stimulant use disorder. Stimulants share physiologic and subjective effects and a direct impact on dopaminergic function. Other substances with stimulating properties but markedly different mechanisms of action, such as nicotine and caffeine, are classified elsewhere.

Stimulant tolerance is defined in DSM-5 as the need for an increased amount of amphetamine, cocaine, or other stimulants to achieve the same effect, or a diminished response to continued use of a given amount. Tolerance may occur as a symptom of a stimulant use disorder, but it is not included as a disorder itself. On the other hand, stimulant withdrawal is identified as a stimulant-induced disorder in DSM-5. It is defined as a constellation of symptoms opposite to the effects of stimulant intoxication, including dysphoric

Telegram: @medical_k

www.konkur.in

mood and characteristic physiologic changes. Another important aspect of stimulant use disorders is craving for the drug. Individuals with stimulant use disorders describe powerful urges to use the substance. These may arise *de novo* or may be triggered by access to stimulants, environmental cues, or seemingly unrelated stresses.

HISTORY

Cocaine

Cocaine in all its forms is a product of the leaves of the plant *Erythroxylon coca*. This plant is indigenous to the high mountain ranges of South America, where coca leaves have been chewed for at least 15 centuries. With European expansion into the Western hemisphere, the Spanish conquistadores first came into contact with coca use during the 16th century. While at first prohibiting the use of coca leaves, the Spanish subsequently used control over coca distribution to rule and exploit local inhabitants, including paying workers in coca leaves. The Spaniards found in this practice the additional economic benefit of energizing the colonized Indian laborers so they could work long hours in gold and silver mines with little rest.

In turn, the Spanish brought coca leaves back to Europe. However, worldwide use of cocaine products did not begin until the active constituent of coca leaves was extracted, first by Friedrich Gaedecke in 1855 and subsequently by Albert Niemann, who coined the term cocaine in 1859. Early experimentation with cocaine peaked around the turn of that century, with luminaries including Sigmund Freud expounding the virtues of the drug. In the United States, cocaine made its way into medicinal tonics and even soft drinks such as Coca-Cola, of which it remained an ingredient until 1903. In the early part of the 20th century, increased awareness of exaggerated and often patently false claims by the manufacturers of cocaine-containing medicinal products raised public concern about spreading cocaine use. At the same time, tales of cocaine addiction began to circulate, and newspaper reports linked the drug with crime. In 1910,

Telegram: @medical_k

www.konkur.in

President William Taft proclaimed cocaine a national threat. Shortly thereafter, the Harrison Narcotic Act of 1914 was passed, banning the nonmedical use of cocaine and highly regulating its medicinal use. Notwithstanding that cocaine is a stimulant rather than a narcotic, the effect of the Harrison Act was to severely curtail cocaine use, essentially driving it "underground." It remained there, the purview of relatively small communities of people such as jazz musicians and the wealthy and privileged until the 1970s.

The reasons for the widespread use of cocaine after 1970 remain somewhat unclear. At the time, cocaine was largely perceived as a nonaddictive, short-acting, "soft" drug. Furthermore, attitudes among people who had experimented with other drugs in the 1960s left them open to trying a substance then seen as relatively safe. Increased production in the 1980s drove down the price of the drug, and cocaine use spread to groups of people who previously could not afford it, reaching epidemic proportions in the United States in the early-to-mid 1980s. Indeed, between 1976 and 1985, cocaine-related medical emergencies rose to nine times their previous level, and cocaine-related deaths increased 11-fold. The mid-1980s also brought about the advent of an inexpensive, ready-to-smoke cocaine alkaloid called "crack," the use of which was highly reinforcing due to its inhaled route of administration.

Estimates of active cocaine use peaked in 1985 at 5.7 million, or 3% of the U.S. population. After that point, cocaine use began to fall dramatically, with a 20% drop in use between 1986 and 1987 alone and a 66% decrease by 1992. While the precise factors leading to decreased cocaine use after its peak in the 1980s remain unclear, it coincided with a number of possibly related events. In part due to a far-reaching awareness campaign, along with well-publicized celebrity deaths attributed to cocaine, the perceived danger of cocaine use began to increase. The previously glamorous position of cocaine changed as the drug became associated with addiction, overdose deaths, crime, fetal injury, and the stigma of marginalized groups. At the same time, enforcement of antidrug laws became more aggressive, with increased arrests and penalties for cocaine-related offenses.

Telegram: @medical_k

www.konkur.in

It is controversial whether punitive legal approaches have had any beneficial effect on rates of drug use and addiction. What is more clear are the substantial harms of the so-called “war on drugs” experienced by people of color. The Congressional Anti-Drug Abuse Act of 1986 established sentencing standards that disproportionately affected Black Americans who were more likely to use “crack” cocaine while relatively sparing the typically White, wealthier people who tended to use powdered cocaine. Under this law, carrying 100 g of “crack” cocaine was treated as high-level trafficking, while the same treatment was reserved only for those who carried more than 5,000 g of powdered cocaine. Strikingly, this law established sentencing policies under which the possession of 5 g of “crack” cocaine carried the same minimum sentence as 500 g of powdered cocaine without any fact-based rationale. This and similar laws contributed to a persistent inequity: while African Americans are not more likely to use drugs than White Americans, they are more likely to be arrested, convicted, and imprisoned for drug use.

Amphetamine-Type Stimulants

Like cocaine, the use of amphetamine-type stimulants dates back many centuries. Ma-Huang, a form of the stimulant ephedrine, has been used as a Chinese herbal remedy for thousands of years. In 1887, the active ingredient ephedrine was isolated by Nagayoshi Nagai. At the same time, amphetamine was synthesized in Germany by Lazar Edeleanu. Methamphetamine was first synthesized in Japan in 1918. Therapeutic applications of amphetamines in Western civilizations began in the 1930s with the use of amphetamine (Benzedrine) as a bronchodilator. At that time, the cognitive and emotional effects of amphetamines were recognized, including reinforcing properties such as euphoria. Indeed, amphetamines were widely used during World War II to counteract soldiers’ fatigue. Following the war, the first amphetamine epidemic took place in Japan, where surplus military supplies of methamphetamine led to widespread use.

Telegram: @medical_k

www.konkur.in

An increasingly abundant supply of amphetamines in the decades that followed was associated with peaking rates of misuse in the United States during the 1960s. At the end of the decade, regulatory agencies responded with efforts to decrease the manufacture of amphetamines to more closely match medicinal needs. During this period, amphetamines were reclassified as Schedule II medications, reflecting closer government oversight and regulation than in previous decades. Despite these efforts, American misuse of methamphetamine increased dramatically beginning in the mid-1990s as illicit manufacturing sources took over. Methamphetamine use remains a significant problem worldwide, and levels are on the rise in many regions of the United States. While vulnerable to misuse, prescription amphetamines remain useful for therapeutic purposes, including the treatment of attention deficit hyperactivity disorder (ADHD) and some sleep disorders.

COMPARATIVE NOSOLOGY

In diagnosing stimulant-related disorders, clinicians are guided by two sets of clinical criteria. These are delineated in the American Psychiatric Association's DSM and in the World Health Organization (WHO)'s ICD. As is the case for other substance use disorders (SUDs), the advent of DSM-5 heralded a consolidation of previously separate stimulant abuse and dependence diagnoses into one category: stimulant use disorder, with level of severity specified on a spectrum of mild, moderate, or severe. Reflecting the high degree of overlap in drug effects, patterns of use, and symptoms, the previously distinct diagnostic entities for cocaine- and amphetamine-related disorders were combined into one comprehensive category, stimulant-related disorders.

The ICD-11 classification system maintains distinct disorders for different classes of stimulants: cocaine, synthetic cathinones, and stimulants including amphetamines, methamphetamine, or methcathinone. Disorders of stimulant use are identified as primary diagnoses, while conditions caused by stimulant use are considered associated diagnoses. Stimulant dependence (with the particular

Telegram: @medical_k

www.konkur.in

stimulant class identified) is the most severe stimulant use diagnosis, generally corresponding to moderate-to-severe DSM-5 stimulant use disorder. It is diagnosed when a person experiences symptoms in two of three categories: difficulty with or inability to control use, stimulant use taking priority over other activities, or physiologic dependence including withdrawal, tolerance, or use of a stimulant to prevent withdrawal. The other ICD-11 stimulant use diagnoses consist of harmful patterns of use of a stimulant and episodes of harmful stimulant use. These diagnoses are appropriate when criteria for stimulant dependence are not met, but stimulant use is detrimental to the mental or physical health of a person or of others interacting with that person. Stimulant use that increases the risk of health or other problems is categorized with problems associated with health behaviors, using the term hazardous use of stimulant. Key DSM-5 stimulant-related diagnoses and corresponding ICD-11 diagnoses (including conditions caused by stimulant use) are listed in Table 11.3–1.

EPIDEMIOLOGY

Telegram: @medical_k

www.konkur.in

Lifetime cocaine use among Americans in 2019 was estimated at over 40 million people, nearly 2 million of whom had used it in the past month. The number of Americans who have used cocaine in the past year has remained relatively stable from 2015 to 2019, at 5.5 million, representing 2.0% of the population. While fluctuating somewhat year to year, estimates of methamphetamine and prescription stimulant misuse also remained relatively stable from 2016 to 2019. In 2019, past-year use of methamphetamine was estimated at 0.7% of Americans (or 2.0 million people). Past-year nonmedical use of prescription stimulants in 2019 was estimated at 1.8% of Americans (or 4.9 million people). Over 1 million of these Americans had used methamphetamine, and 1.5 million had used prescription stimulants in the past month.

The worldwide burden of psychostimulant use speaks to an even more significant problem. The United Nations Office on Drugs and Crime (UNODC) World Drug Reports estimated that in 2021, roughly 36 million people worldwide had used amphetamine-type stimulants and 22 million people had used cocaine in the past year. Afghanistan and Iraq were highlighted in the report as areas with increasing methamphetamine use. The number of individuals using a substance for the first time in the past year offers a useful measure of potential trends in drug use. Initiation of cocaine use has remained relatively stable since 2013, with 671,000 using the drug for the first time in 2019. The average age at onset of cocaine use was 20.4 years. New onset of nonmedical use of prescription stimulants increased from 603,000 in 2013 to 901,000 in 2019. Likewise, new use of methamphetamines increased from 144,000 in 2013 to 184,000 in 2019.

The National Drug Early Warning System (NDEWS) follows regional trends in selected “sentinel” communities throughout the United States. The NDEWS 2020 report described an increase in methamphetamine-related overdose deaths in multiple sites, particularly in the Western United States, as well as in Florida, Philadelphia, and Maine. Cocaine-related overdoses rose in New York City and other regions. Cocaine was also frequently present in fentanyl overdoses, possibly reflecting the presence of fentanyl in

Telegram: @medical_k

www.konkur.in

cocaine products or the combined use of opioids and cocaine. Data from the National Center for Health Statistics “CDC Wonder” database underscores this concerning trend. Nationally, overdoses due to amphetamines skyrocketed from 547 in 1999 to 16,167 in 2019. Deaths related to amphetamines increased whether or not fentanyl was also present. Overdoses on cocaine increased from 3,822 in 1999 to 15,883 in 2019, with much of that accounted for by deaths also involving fentanyl. Furthermore, cocaine overdose deaths have disproportionately occurred in non-Hispanic Black people, among whom cocaine caused more deaths than did opioids in the period from 2000 to 2015.

The National Household Survey on Drug Use and Health (NSDUH) is one of the primary sources of knowledge of patterns and prevalence of drug use among people 12 and older in the United States. NSDUH information on the prevalence and distribution of stimulant use has been available since 1991, and measures of SUDs have been included in the questionnaire since 2000. Males are more likely to use cocaine and methamphetamine and are somewhat more likely to misuse prescription stimulants than are females. Analogous data are not yet collected on gender nonconforming people. Cocaine is used across ethnicities but inhaled “crack” cocaine use is somewhat more common among people identifying as Black or African American. Methamphetamine use has historically been more common among men who have sex with men (MSM). In this group, stimulants are sometimes used to enhance sexual activity and can be associated with risky sexual practices and sexually transmitted diseases. The annual prevalence of cocaine-type stimulant use disorder in the United States in 2019 was estimated at 0.4% of the population or 1.0 million Americans. The age group most heavily affected was 18 to 25 year olds, who remain twice as likely as the general population to have met criteria for cocaine use disorder in the past 12 months. A total of 1.0 million (0.4%) Americans met criteria for methamphetamine use disorder and 550,000 (0.2%) for prescription stimulant use disorder in 2019; again, the 18- to 25-year-old age group was the most heavily affected. The Treatment Episode Data Set (TEDS) is a component of the Drug and Alcohol

Telegram: @medical_k

www.konkur.in

Services Information System (DASIS), a national monitoring network of drug and alcohol treatment in the United States. TEDS provides information on the numbers and characteristics of patients admitted for treatment of SUDs. Data from this survey indicate that admissions for primary treatment of cocaine use disorders decreased from 11.6% to 5.6% of admissions for SUD treatment from 2008 to 2018. In contrast, admissions for amphetamine-type stimulants increased from 6.3% to 10.5% of total admissions in that same time period. As a group, stimulants accounted for 16% of SUD admissions in 2018, following alcohol (29.4%) and opiates (33.6%). The Drug Abuse Warning Network (DAWN) survey of emergency department treatment presents a somewhat more alarming picture. The dangers of stimulant misuse are reflected in the disproportionately high number of emergency department visits caused by this class of substances. Preliminary data from the 2020 DAWN initiative indicate that, as a group, stimulants were the primary reason for 44.8% of substance-related emergency room visits, surpassing those caused by marijuana (22.0%), alcohol (20.9%), and heroin (17.9%). Methamphetamine was the most commonly implicated substance, accounting for 33.7% of substance-related episodes.

"Bath Salts"

Catha edulis, or "Khat," is a plant indigenous to Eastern Africa and Southern Arabia. Psychoactive chemicals released from the plant include cathinone and cathine, compounds with stimulant properties. Khat is used like chewing tobacco, held between the cheek and gums after chewing. NIDA estimates that as many as 10 million people worldwide use Khat, including many in Eastern Africa and the Middle East, as well as an unknown number of immigrants to the United States.

In the mid-2000s, synthetic cathinones began to appear, marketed as "legal high" chemicals, the most common being mephedrone, methylone, and methylenedioxypyrovalerone (MDPV). They were packaged under labels including "screen cleaner," "jewelry cleaner,"

Telegram: @medical_k

www.konkur.in

and most notoriously, “bath salts.” They are generally produced as powders marked “not for human consumption” and can be taken by oral, intranasal, inhaled (smoked), or intravenous routes. These compounds are substituted cathinones that have been chemically modified to avoid regulatory control. There are a large number of specific compounds in the class, and a given package often contains a mix of agents, further increasing risk of toxicity. Recently, synthetic cathinones have been found as adulterants or substitutes for methylenedioxymethamphetamine (MDMA) in products sold as “Molly.” In general, substituted cathinones increase synaptic catecholamine levels by inhibiting the dopamine, serotonin, and norepinephrine reuptake transporters in a fashion similar to cocaine. Most also facilitate catecholamine release, similar to methamphetamine. Animal models indicate strong reinforcing properties of these compounds, which are considered to have high addictive potential.

Drug screens for methamphetamine and PCP may cross-react with some substituted cathinones, but this is not a reliable test. While specific assays for some cathinones are commercially available, gas chromatography remains the most reliable means of detecting synthetic cathinones.

MDMA is another closely related substituted amphetamine with similar pharmacologic properties.

ETIOLOGY

Drug use disorders are believed to result from the complex interplay of cultural, environmental, familial, and neurobiologic influences. Environmental factors such as accessibility and perceived danger or stigma related to use may influence whether an individual initially tries psychostimulants or other drugs. For individuals with stimulant use disorders, environmental precipitants may increase cortisol and other stress-related hormones, increasing the risk for relapse or persistent use of drugs even when there is a desire to stop. Genetic factors may both increase the likelihood of initially using illicit substances and confer genetic vulnerability for developing SUDs.

Telegram: @medical_k

www.konkur.in

Environmental influences can impact epigenetic factors, regulating the expression of genes in ways that affect risk of developing stimulant use disorders.

Mechanism of Action

Neurotransmitter Systems

DOPAMINE. It is well established that stimulants directly produce changes in dopaminergic neurotransmission. In vitro animal studies using radiolabeled cocaine or cocaine analogs demonstrate high amounts of binding in dopamine-rich brain regions, including the caudate-putamen and the ventral tegmental area (VTA). Moderate levels of cocaine binding also occur in the substantia nigra, amygdala, hypothalamus, and locus coeruleus. In humans, cocaine rapidly permeates the striatum, then quickly redistributes out of it with a half-life of about 20 minutes. The time course of self-reported "high" closely follows this pattern of rapid uptake and clearance. Likewise, amphetamines have profound effects on brain reward regions, including the mesolimbic regions (VTA and nucleus accumbens). Furthermore, methamphetamine is distributed even more diffusely and persists longer in the brain than does cocaine.

Dopaminergic projections from the VTA to the nucleus accumbens are most strongly identified with drug-related reinforcement. Cocaine administration causes transient increases in extracellular dopamine levels in these regions by binding to the presynaptic dopamine transporter (DAT), thereby inhibiting dopamine reuptake. Amphetamines not only inhibit dopamine reuptake but are also believed to reverse the function of the DAT. By this mechanism and through promoting the release of dopamine stored in vesicles, amphetamines potently increase synaptic dopamine levels. Transient changes in dopamine levels play a primary role in the reinforcing properties of all psychostimulants. Subjective euphoria appears to be a function of both DAT occupancy (with a threshold of 50% occupancy to be detectable) and rapidity of onset, with the strongest

Telegram: @medical_k

www.konkur.in

responses occurring when dopaminergic neurotransmission is increasing dynamically.

OTHER NEUROTRANSMITTER SYSTEMS. While it is widely accepted that dopamine plays a primary role in the effects of stimulants, more complex models are required to completely understand drug-related behaviors and disorders. By binding to monoamine transporters, psychostimulants can inhibit reuptake of serotonin and norepinephrine as well as dopamine. Other neurotransmitters implicated in stimulant use disorders include glutamate and the inhibitory neurotransmitter GABA. Glutaminergic projections to the nucleus accumbens modulate regional dopamine neurotransmission, and glutamate antagonists can block the behavioral effects of stimulants in laboratory animals. Similarly, GABA affects dopamine neurons in the nucleus accumbens and VTA. Reduced glutamate levels during abstinence that follows psychostimulant exposure lead to the upregulation of AMPA receptors in the nucleus accumbens. Such changes are associated with drug-related behaviors in lab animals, where glutamate antagonists and modifiers can block the reinstatement of drug-seeking behavior.

Learning and Memory

Positive Reinforcement Mechanisms. Stimulant use disorders and related behaviors can be understood as forms of behavioral conditioning. *Operant conditioning* is a type of learning in which the likelihood of a given behavior is controlled by its consequences. *Reinforcers* are those stimuli that increase the likelihood of the behavior in question. As such, stimulants and other substances of abuse operate as powerful reinforcers, increasing the likelihood of behaviors that result in opportunities to obtain drugs (i.e., “drug-seeking behaviors”).

Principles of operant conditioning explain why animals can learn to self-administer reinforcing substances like cocaine. Other drug-associated responses can be accounted for by *respondent conditioning*. In this form of learning, an unconditioned stimulus (one

Telegram: @medical_k

www.konkur.in

that produces a response without training) can be paired with a stimulus that normally does not produce a response. Pairing the two stimuli for a period of time produces a conditioned response, in which the animal responds to the initially neutral stimulus as though the unconditioned stimulus were also present. In this way, drug-associated cues such as paraphernalia, people, or places associated with use, and even times of day, can elicit urges to use stimulants. This phenomenon may also account for cocaine-dependent individuals who experience a subjective “high” while preparing to take drugs, as the practice of obtaining or handling drugs leads to conditioned euphoric responses.

During the early stages of a stimulant use disorder, drug use is reinforced by increased dopamine transmission from the VTA via the medial forebrain bundle to the nucleus accumbens. This fits a classic model of drug addiction based on positive reinforcement, in which cues associated with drug use gain emotional valence through learned associations involving brain regions such as the hippocampus and limbic structures (in particular, the amygdala). Abnormalities in these brain areas, which are involved in essential pathways of learning and memory, are associated with development of stimulant use disorders and other SUDs. Such dysfunction may explain persistent use of psychostimulants to the exclusion of other, natural reinforcers such as food. Conventional reinforcers produce a dopamine response in the VTA and amygdala that attenuates over time. In contrast, the response to stimulants does not diminish in this way, and some laboratory animals will self-administer cocaine in preference to food and water to the point of death.

Respondent conditioning explains the activation of drug cravings by stimuli associated with drug use. Cravings that are induced by priming doses of stimulants involve a brain circuit projecting from the VTA to the medial prefrontal cortex and the nucleus accumbens. Cravings that are induced by associated cues (“people, places, and things”) activate this circuit under influence of the basolateral amygdala and glutamatergic projections in limbic and prefrontal regions. It is also widely recognized that stress can elicit drug craving. This is mediated by expression of corticotropin-releasing

Telegram: @medical_k

www.konkur.in

factor in limbic areas that include the amygdala, modulating the activity of dopaminergic projections from VTA to nucleus accumbens.

Negative Reinforcement Mechanisms. In addition to reward mechanisms described above, a pattern of sustained stimulant use through negative reinforcement (avoidance of the aversive withdrawal/abstinence state) may augment and even supplant positive reinforcement. This is mediated by what may, in simple terms, be thought of as a “dopamine-deficient state” caused by dopamine receptor downregulation, decreased striatal dopamine release, and neurotoxic effects on dopaminergic neuron systems. Other neurotransmitters such as glutamate also show altered function with chronic stimulant misuse. This likely contributes to states of dysphoria and drug craving that occur with cessation of use. Indeed, it has been demonstrated that abstinent methamphetamine users who experience persistently low levels of striatal dopamine activity may be at increased risk for relapse. Lower availability of D2 and D3 receptors in methamphetamine users has also been posited to be associated with increased impulsivity and “steep temporal discounting,” the tendency to disproportionately value small, immediate reinforcers over delayed rewards of greater magnitude. Negative reinforcement could also play a role earlier in the course of the illness, in which attenuation of negative feelings, in addition to the pleasurable effects of the drug, maybe a strong contributor to the ongoing use of the substance.

Compulsive Use. In addition to stimulant use that is compelled by positive and negative reinforcement, stimulant use disorders are marked by what is sometimes termed “compulsive” or “habitual” use. This involves apparently automatic, perseverative drug use even in the face of severe consequences and long after many patients describe loss of previous euphorigenic drug effects. In recent years, preclinical and basic research have elucidated the complexity of stimulant use and its impact on the mammalian brain. Beyond a straightforward model of dopamine stimulation and resulting hypofunction, it is now clear that there are many downstream and

Telegram: @medical_k

www.konkur.in

alternate consequences of stimulant misuse. Changes in the following pathways are associated with chronic, compulsive stimulant use.

CAMP RESPONSE ELEMENT–BINDING PROTEIN. Dopamine receptors act through second-messenger systems that alter levels of cyclic adenosine monophosphate (cAMP). Dynamic interplay between dopamine receptor subtypes leads to alterations in cAMP, which in turn can increase activity of protein kinase A (PKA). PKA levels in the nucleus accumbens are increased with chronic stimulant administration. Elevations in PKA lead to increased activity of cAMP response element–binding protein (CREB), itself implicated in cocaine-related behaviors, including place preference and sensitization.

GENE TRANSCRIPTION. Cocaine and methamphetamine affect gene transcription through transcription factors such as ΔFosB, whose downstream targets include genes that influence synaptic plasticity, and CREB, among others. CREB signaling has been implicated in a host of cellular processes believed to underlie SUDs, including pathways involving the “antireward” gene dynorphin, cell adhesion, synaptic plasticity, and brain-derived neurotrophic factor (BDNF, itself a candidate for impacting cellular mechanisms of addiction). The CREB pathway is also believed to affect function of glutamate, potassium, and GABA receptors that contribute to long-term effects of stimulant misuse.

EPIGENETICS. While various definitions of epigenetics have been put forward, it generally describes the processes by which minor deoxyribonucleic acid (DNA) modifications (such as methylation) and the physical winding of DNA around histones influence whether genes are transcribed. It is clear that these processes are altered in SUDs and that such changes contribute to the process of addiction. Though not proven, there is some evidence suggesting that epigenetic information created by events such as parental trauma,

Telegram: @medical_k

www.konkur.in

substance use, or other adversity can be passed on to offspring, where it may influence the likelihood of SUDs in future generations.

MICRORNA. Gene expression is also regulated at the level of translation, the process by which ribonucleic acid (RNA) is used to code proteins. Small, regulatory RNA strands called microRNAs are known to function as inhibitors of translation by interacting with transcripts, leading to suppression or degradation of coding RNA. Stimulants alter the production of microRNAs, which themselves regulate BDNF, FosB, and CREB. A microRNA transcript called MiR-212, for instance, has been implicated in the alteration of gene expression by cocaine.

OXIDATIVE STRESS, INFLAMMATION, AND NEUROTOXICITY. Methamphetamine has been shown to promote brain inflammatory responses by activating astrocytes and microglia, and by leading to the production of inflammatory cytokines. Preclinical studies suggest that anti-inflammatory drugs can attenuate behavior, reflecting drug reinforcement in rodents. Methamphetamine also has a neurotoxic effect due to the production of highly reactive chemicals, including peroxide and free radicals. It may also lead to excitotoxicity by causing excess activity of glutamate. These effects likely contribute to executive and cognitive dysfunction, stimulant-related psychosis, and an increased likelihood of Parkinson disease in those using methamphetamine.

NEUROENDOCRINE DYSREGULATION AND STRESS. The role of environmental stress in exacerbating or precipitating episodes of mental illness has long been recognized. Individuals with SUDs may experience relapse or increased symptoms in the presence of psychosocial stressors. Animal models of stress and addiction demonstrate that stress-inducing situations (e.g., a shock to the foot) or administration of corticosteroids can increase the likelihood of drug self-administration. Conversely, antagonists of corticotrophin-releasing hormone (CRH) or glucocorticoids decrease stress-induced drug self-administration in laboratory animals by blocking

Telegram: @medical_k

www.konkur.in

CRH activity in the VTA. Drug withdrawal itself is associated with increases in ACTH, corticosterone, and CRH in the amygdala. These changes are associated with the anxiety and craving often seen in early abstinence from stimulants.

COGNITIVE/EXECUTIVE DYSFUNCTION. Habitual drug use involves a pattern of executive dysfunction, poor impulse control, and cognitive inflexibility resulting in difficulty attributing appropriate reward values to stimuli, changing behavior in response to environmental feedback, and inhibiting impulsive or habitual behavior. Chronic stimulant use is associated with anatomic, metabolic, and vascular changes in areas of the brain responsible for such higher-order cognition. Structurally, cocaine and methamphetamine use disorders are associated with reduced gray matter density in the frontal cortex. Other findings include gray matter deficits in limbic areas and low hippocampal volume. Conversely, enlarged basal ganglia (areas important for neurotransmission of dopamine) have been demonstrated with stimulant use disorders. A dose-dependent decrease in gray matter volume of the orbitofrontal cortex is associated with increased compulsivity of drug use. Abnormal connectivity in prefrontal regions is evident in both individuals with stimulant use disorders and their unaffected siblings, suggesting a condition that pre-exists drug exposure. Diminished connectivity between the anterior cingulate cortex (an area active during inhibition of impulses) and the amygdala is associated with an increased risk of relapse in those with cocaine use disorders. Stimulant users manifest decreased blood flow in the prefrontal cortex, with frequent users showing the largest deficits. Decreased metabolic activity seen in frontal regions may persist for months after cessation of use. Metabolic dysfunction in frontal regions, including the orbitofrontal cortex, may be related to the development of compulsive aspects of drug addiction. Individuals with stimulant use disorders show deficits in verbal, spatial, and recognition memory, functions that are generally attributed to the hippocampus. Other prominent deficits include impaired attention, decreased cognitive flexibility, impaired decision making, impulsivity, and poor delayed reward discounting. This pattern of neurobiologic

Telegram: @medical_k

www.konkur.in

vulnerabilities clearly contributes to persistence of maladaptive drug use, even among those for whom substance use causes great suffering.

Routes of Administration and Metabolic Factors

The pharmacokinetic properties of stimulants are strongly influenced by how they are taken. In particular, the time it takes a drug to initially appear in the blood and to reach its peak serum concentration is strongly related to its mode of administration. Smoking and intravenous use of cocaine produce the most rapid pharmacologic and subjective onset of action, as well as faster termination of subjective effects. Cocaine-induced euphoria is more strongly correlated with rate of increase in serum levels than with absolute amount of cocaine ingested. As such, the use of cocaine by these rapid routes is more likely to be associated with progression to compulsive use and cocaine use disorder. Similarly, injecting or smoking methamphetamine is associated with much faster penetration of the blood–brain barrier, on the order of seconds, in comparison to use by oral or intranasal routes. Injecting methamphetamine is typically associated with more severe SUDs and with poorer prognosis.

Cocaine is rapidly metabolized by liver and serum esterases, with a variable half-life on the order of 50 to 90 minutes. In humans, cocaine is catabolized by hydrolysis of its ester groups to benzoylecgonine and ecgonine methyl ester in approximately equal proportions. Neither has biologic activity in humans. In the presence of alcohol, cocaine is converted by liver esterases into ethyl cocaine, or cocaethylene. Cocaethylene produces cocaine-like pharmacologic and subjective effects, has a longer half-life, and may be more toxic than cocaine. Only about 1% to 5% of cocaine is excreted unchanged in the urine, with the rest excreted as metabolites. Urinary benzoylecgonine can generally be detected for 2 to 3 days after a binge, although extremely heavy users may have measurable urinary benzoylecgonine levels as long as 10 to 14 days after last use.

Telegram: @medical_k

www.konkur.in

The half-life of amphetamine in adults is on the order of 13 to 14 hours. Amphetamine undergoes oxidation by liver enzymes (primarily cytochrome P450 2D6) into the active metabolites 4-hydroxyamphetamine and norephedrine and the inactive metabolite alpha-hydroxy-amphetamine. Further oxidation of active metabolites produces the inactive metabolite 4-hydroxy-norephedrine. About 30% of amphetamine is excreted unchanged in the urine, with higher rates of excretion with more acidic urine. The rest is excreted as metabolites. Amphetamine is typically detectable in urine for 3 to 5 days after binge use.

Genetic Factors

Twin studies have allowed an estimate of the genetic component of cocaine use disorder. Estimates from these studies indicate that stimulant use disorders are among the most heritable of psychiatric conditions, with the familial component of cocaine use disorder placed in the range of 60% to 80%. Similarly, a recent study estimated the heritability of amphetamine-type stimulant use disorder at 68%. Some of the apparent genetic susceptibility to cocaine and other stimulant use disorders may be explained by inheritance of traits associated with drug use. In particular, heritable personality characteristics such as a high degree of novelty seeking, stress reactivity, and sensation seeking have been linked with initiation of drug use. Both individuals with stimulant use disorders and their unaffected siblings show deficits in executive function, high levels of trait anxiety, and poor response control. Those with stimulant use disorders show more problems across these domains than do their siblings, suggesting both a genetic state predisposing to drug addiction and exacerbation of deficits with persistent stimulant use.

Given the polygenic nature of drug addiction and the contribution of environmental factors such as availability of drugs, identifying particular genes directly involved in the etiology of stimulant use disorders is challenging. Furthermore, associations between stimulant use disorders and particular genetic loci in one population may not apply to another. It is also likely that some genetic patterns

Telegram: @medical_k

www.konkur.in

are associated with both SUDs and other psychiatric conditions more generally as risk factors, rather than conferring risk for a specific SUD via a straightforward pattern of inheritance. For instance, there are shared genetic risk factors for schizophrenia and some SUDs. Likewise, the gene for the alpha-5 nicotinic receptor subunit (CHRNA5) is implicated in both tobacco use disorder and in cocaine use disorders. The complex nature of genetic pathways related to SUDs is underscored by another study, showing that the same allele encoding a subunit of the nicotinic acetylcholine receptor (CHRNA5) is associated with increased risk of tobacco use disorder, while it appears protective for cocaine use disorders.

Table 11.3–2 lists some known genes associated with stimulant use disorder. Rather than presenting a comprehensive, cohesive genetic pathway, this list illustrates the complex picture that is gradually beginning to emerge, including transcription factors, genes governing epigenetic control mechanisms, monoamine receptors and transporters, and receptors for other neurotransmitters such as GABA, glutamate, opioids, cannabinoids, and nicotine.

DIAGNOSIS AND CLINICAL FEATURES

Stimulant Use Disorder

Stimulant use disorder is characterized by a maladaptive pattern of psychostimulant use accompanied by multiple drug-related problems in different domains. Stimulant use disorder is diagnosed when at least 2 of 11 possible criteria are met. As with other substances, tolerance and withdrawal are neither necessary nor sufficient for a diagnosis of stimulant use disorder. Criteria include (1) stimulant use in greater quantities or durations than intended, (2) persistent desire to curtail use, (3) significant time spent engaging in drug-related behavior, (4) craving for the desired stimulant, (5) recurrent use to the exclusion of other obligations, (6) persistent use despite social or interpersonal problems caused by use, (7) curtailing other important activities due to stimulant use, (8) use when it is physically

Telegram: @medical_k

www.konkur.in

hazardous, (9) use in spite of related physical or psychological harm it causes, (10) tolerance, and (11) withdrawal.

The category of substance that is misused (amphetamine type, cocaine, or other/unspecified) is named. The severity of stimulant use disorder is graded as mild (two to three symptoms), moderate (four to five symptoms), or severe (six or more symptoms). Early remission is defined by the absence of all symptoms for between 3 and 12 months and sustained remission by the absence of all symptoms for more than 12 months. The additional specifier “in a controlled environment” is used when the individual is in an environment where access to stimulants is limited.

HTR2B *Serotonin receptor*
NR3C1 *Glucocorticoid receptor*
ADRA1A, ASDRA2A *Alpha adrenoceptors*
RGS17 *Regulator of receptor signaling via g-proteins*
5HT3A, 5HT3B, HTR2A *Serotonin receptors*
SLC6A4 *Serotonin transporter*
NCS-1 *Dopamine receptor–interacting protein*
OPRD1 *Delta-opioid receptor*
PDYN *Prodynorphin*
CNR 1 *Cannabinoid receptor*
PER2 *Circadian regulator*

While DSM-5 criteria for stimulant use disorder are identical to those for alcohol and opioids, patterns of use may be quite different. Although some individuals with stimulant use disorders are daily users who experience tolerance and withdrawal, many others abstain intermittently between periods of heavy use, either to recover from the effects of the drug or as a result of depleted finances that prevent access to the desired drug. During periods of use, frequency of administration varies based on the duration of drug effects. For instance, cocaine is generally taken more frequently than is methamphetamine, reflecting cocaine's shorter half-life.

Stimulant Intoxication

Stimulant intoxication is marked by the appearance of characteristic symptoms shortly after the use of an amphetamine-type substance, cocaine, or other stimulants. It may occur within minutes after ingestion of the drug. The duration of intoxication is typically briefer for cocaine than other stimulants, due to its shorter half-life. Characteristic symptoms are divided into psychological or behavioral

Telegram: @medical_k

www.konkur.in

and physiologic effects. Psychological symptoms may include changes in mood state, social interactions, or judgment. Physical symptoms include adrenergic effects (changes in heart rate, blood pressure, thermoregulation, psychomotor changes, pupillary dilation), gastrointestinal (GI) disturbances, motor changes, cardiopulmonary symptoms, and neurologic problems. Both a significant psychological disturbance and two or more physical symptoms are required for diagnosis. Severe intoxication can be associated with evidence of toxicity, which may include grand mal seizures, cardiac arrhythmia, hyperpyrexia, and death. The presence of perceptual disturbances is specified when drug-induced hallucinations or delusions occur during intoxication. If such perceptual disturbances are present and there is no insight that they are induced by the substance, the diagnosis of stimulant-induced psychotic disorder should be considered instead.

In susceptible individuals, paranoia tends to worsen during the course of a binge and to appear earlier in the course of subsequent binges as use continues—sometimes referred to as reverse tolerance or sensitization. Psychotic symptoms are common with both cocaine and methamphetamine. They may prompt attempts to “self-medicate” with alcohol or opioids. While cocaine users who experience delusions may complain of symptoms persisting beyond peak plasma cocaine levels, the duration is generally brief, lasting hours in most cases. Typically, paranoia consists of worries that police, drug dealers, or others are pursuing or planning to attack the cocaine user. Perceptual disturbances are usually limited to misinterpretations of existing stimuli (e.g., mistaking a car alarm for a police siren). Psychotic symptoms associated with methamphetamine use may be more difficult to distinguish from primary psychotic disorders. Symptoms caused by methamphetamine generally remit within a week of cessation of use. Persistent symptoms suggest the presence of an underlying psychotic disorder.

Stimulant Withdrawal

Telegram: @medical_k

www.konkur.in

Stimulant withdrawal is common after periods of prolonged or intense use and is marked by dysphoric mood accompanied by two or more characteristic physiologic symptoms: fatigue, vivid and unpleasant dreams, and disturbances of sleep, appetite, and psychomotor activity. Bradycardia, drug cravings, anhedonia, and other depressive symptoms frequently occur.

There is substantial symptomatic overlap between characteristic physiologic symptoms of stimulant withdrawal and the neurovegetative symptoms of depression. At times, depressive symptoms would meet criteria for a major depressive episode were they not the direct consequence of drug use. In such cases, the diagnosis of stimulant-induced depressive disorder should be considered. Suicidal ideation or behavior can also occur in association with stimulant withdrawal and other stimulant-related disorders.

Stimulant-Induced Psychotic Disorder

Brief periods of stimulant-induced paranoia are common when people use stimulants heavily, occurring in 50% to 70% of individuals with cocaine use disorders and nearly 30% of those who use methamphetamine. While paranoia is common with heavy use of cocaine or methamphetamine, the diagnosis of stimulant-induced psychotic disorder is reserved for cases in which symptoms exceed the quality or severity characteristic of stimulant intoxication.

Increased risk of cocaine-induced paranoia is linked to heavy exposure to the drug, as measured by duration and quantity of use. Increased risk is also associated with routes of administration other than intranasal and with co-occurring ASPD or cannabis use disorder. Likewise, methamphetamine-related psychotic symptoms are more likely with heavy use. Psychotic symptoms are also associated with an increased risk of violence among individuals who use methamphetamine. People with ADHD appear at increased risk for either cocaine-induced or methamphetamine-induced psychotic symptoms. There may also be a genetic predisposition to stimulant-induced paranoia. Studies have identified increased levels of

Telegram: @medical_k

www.konkur.in

cocaine-induced paranoia or methamphetamine-induced psychosis in association with variations in several genes, as well as with alterations in epigenetic and microRNA regulation of gene expression.

For some, a more prolonged psychotic reaction may occur, and a subset of individuals who experience a stimulant-induced psychotic disorder will eventually receive a formal diagnosis for a psychotic disorder such as bipolar disorder or schizophrenia. As such, ongoing assessment and monitoring by a mental health professional may be warranted in such individuals.

Other Stimulant-Induced Disorders

Mood changes and anxiety are common with stimulant use, intoxication, and withdrawal. Stimulant-induced depressive, bipolar, or anxiety disorders are diagnosed when the severity of these symptoms warrants treatment and exceeds that usually seen with intoxication or withdrawal. Stimulant-induced mood disorders can resemble depressive, manic, hypomanic, or mixed episodes. Symptoms in the manic spectrum are usually present in the setting of intoxication, while depressive symptoms often occur during withdrawal. Suicidal ideation or behavior can also occur in association with stimulant withdrawal or stimulant-induced mood disorders. Compulsive symptoms such as stereotyped behavior and skin picking are also associated with stimulant intoxication.

Stimulant-induced mood or anxiety disorders are distinguished from mood and anxiety symptoms expected during the typical course of intoxication or withdrawal by their intensity, onset, and time course. While neurovegetative symptoms suggesting a major depressive episode may be present, full criteria for major depressive disorder or hypomania need not be met. Similarly, the diagnostic criteria for stimulant-induced anxiety or obsessive-compulsive disorder require only the presence of prominent anxiety, obsessions, compulsions, or panic attacks in the setting of recent use of a psychostimulant and out of proportion with typical signs of intoxication.

Telegram: @medical_k

www.konkur.in

Other stimulant-induced disorders include stimulant-induced sexual dysfunction, sleep disorder, and unspecified stimulant-related disorder. Stimulants such as cocaine or methamphetamine are at times used for their purported enhancement of sexual function. Chronic use of stimulants is associated with sexual dysfunction either during use or within 1 month of use. Psychostimulants may also produce a sleep disorder, typically characterized by periods of insomnia during intoxication and hypersomnia during withdrawal. Insomnia during stimulant withdrawal is also commonly described. Sleep cycles may be shifted when binges extend into the night or when withdrawal-induced hypersomnia leads to daytime sleeping.

Unspecified Stimulant-Related Disorder

The category of unspecified stimulant-related disorder is used for disorders that do not meet the full criteria for a specific stimulant-related disorder but that nonetheless cause significant impairment or distress.

COMORBIDITY

Studies of the prevalence of non–substance-related psychiatric disorders among individuals with stimulant use disorders have consistently found elevated levels of psychiatric disorders in this population. Results from the community-based Epidemiologic Catchment Area (ECA) Study demonstrated elevated rates of non–substance-related mental disorders in those with cocaine use disorders. In this study, the estimated lifetime prevalence rate for psychiatric disorders was 76% or 11 times that found in the general population; nearly 85% of those with cocaine use disorders also had co-occurring alcohol abuse or dependence. Mood disorders, anxiety disorders, post-traumatic stress disorder (PTSD), ADHD, and psychotic disorders occur at elevated rates in people with stimulant use disorders. These high levels of co-occurring non–substance-related psychiatric disorders are not specific to stimulant use disorders, being observed among people with SUDs more generally.

Telegram: @medical_k

www.konkur.in

Misuse of nonstimulants and co-occurring other SUDs are also common in people with stimulant use disorders, with alcohol and cannabis occurring at particularly high rates and opioid use on the rise in some geographic regions.

TOXICITY AND MEDICAL COMPLICATIONS

Stimulant use can cause medical complications both as a result of its direct toxic effects and because of complications related to methods of preparation and administration. Stimulants are potent sympathomimetic drugs, causing physiologic effects including vasoconstriction, increased heart rate, and elevated blood pressure through adrenergic stimulation. The combination of increased myocardial demand with constriction of coronary blood vessels can precipitate angina pectoris and even myocardial infarction. Methamphetamine can cause cardiomyopathy and cardiogenic shock. Acute hypertension associated with stimulant use can also predispose to arterial hemorrhage, such as hemorrhagic stroke or aortic dissection. Vasoconstriction can involve damage to other end organ, including the brain, kidneys, or intestines. With intranasal use, decreased blood flow to the nasal mucosa frequently causes nasal symptoms (e.g., rhinorrhea, nosebleeds) and mucosal ulceration. A combination of vasoconstriction and bruxism associated with the use of methamphetamine causes markedly poor dentition, or “meth mouth.” Grand mal seizures are common with stimulant overdose and may occur with routine use as well. Furthermore, individuals who misuse stimulants regularly may develop neuropsychological deficits, including problems with attention, learning, and memory. In many cases, these abnormalities persist during periods of abstinence. Furthermore, long-term misuse of amphetamines is associated with an increased risk of Parkinson disease later in life.

Stimulant misuse can also precipitate behaviors that place an individual at increased risk of harm by violence or accidental injury. Unsafe sexual behaviors may lead to transmission of HIV or other sexually transmitted diseases. Driving while intoxicated and other hazardous behaviors may lead to accidental physical harm. Finally,

Telegram: @medical_k

www.konkur.in

the associated illegal behaviors involved in obtaining cocaine or methamphetamine increase the likelihood of being a victim of violence.

Pathology and Laboratory Examinations

The physical and laboratory assessment of patients with stimulant-related disorders focuses on clarifying the diagnosis, excluding other possible diagnoses, and assessing for co-occurring problems or related complications. Metabolites of cocaine and amphetamine can be detected in blood, hair, sweat, saliva, and urine. In clinical practice, urine and blood testing are most useful. Blood testing can be helpful to assess for acute intoxication when very recent ingestion is suspected. Urine testing is often used as a means of monitoring patients for relapses and detecting concurrent use of other illicit substances.

Relative to other substances of abuse, the short half-life of cocaine renders it more difficult to discover occasional use with urine drug screening. On the other hand, with heavy use of cocaine, its breakdown products accumulate in fat tissue. As they gradually diffuse out of this body compartment, cocaine metabolites may be detectable for up to 2 weeks after cessation in some extremely heavy users. Methamphetamine is generally detectable for longer periods of time than is cocaine, on the order of 3 to 5 days after brief use. Synthetic cathinones present more of a challenge, as many are not detectable by routine drug screening. Gas chromatography may be necessary when cathinone ingestion is strongly suspected.

Other examinations are guided by historical or physical evidence of stimulant-related complications. Seizures or other acute neurologic deficits may prompt assessment by brain computed tomography (CT) or magnetic resonance imaging (MRI) to detect physical abnormalities such as hemorrhagic or ischemic strokes. The presence of chest pain or other cardiovascular abnormalities may prompt assessment with an electrocardiogram (ECG) or an assay for serum cardiac enzymes to evaluate for coronary ischemia. Similarly, respiratory symptoms may indicate need for a chest x-ray to rule out

Telegram: @medical_k

www.konkur.in

pneumonitis. Likewise, signs of infection in the setting of injection use may require blood cultures to exclude bacteremia or endocarditis. A history of any drug use by injection places individuals at risk for hepatitis (type B or C) and HIV; testing for these co-occurring medical disorders is thus often indicated.

As described above, chronic stimulant misuse produces changes in levels of stress-related hormones, including CRH and cortisol. Stimulant use can also elevate levels of prolactin, luteinizing hormone, and follicle-stimulating hormone. However, there is little clinical utility to assessing circulating hormone levels in individuals with stimulant use disorders, and such assessments generally are not part of routine care.

DIFFERENTIAL DIAGNOSIS

There is substantial overlap between symptoms of stimulant intoxication or withdrawal and other psychiatric diagnoses. Symptoms suggestive of a manic episode or of a psychotic or anxiety disorder are common during stimulant intoxication. Likewise, stimulant withdrawal frequently involves symptoms of depression and anxiety. Symptoms that are more severe than usually observed suggest a stimulant-induced psychiatric disorder rather than simple intoxication or withdrawal. Typically, stimulant-induced symptoms will attenuate or remit over several weeks with cessation of use. Symptoms that persist following a 1-month period of abstinence or that precede initiation of stimulant use suggest an independent psychiatric disorder.

Cycles of binge use followed by variable periods of abstinence may lead to mood instability; periods of decreased need for sleep, agitation, and other symptoms suggestive of mania may alternate with periods of low energy, dysphoria, and hypersomnia. When a patient presents with such a symptom pattern, which resembles bipolar spectrum illnesses, a careful history and laboratory evaluation to exclude use of cocaine or other psychostimulants is necessary for accurate diagnosis.

Telegram: @medical_k

www.konkur.in

To some extent, the quality of symptoms may provide clues regarding whether they are manifestations of stimulant toxicity or a co-occurring psychiatric disorder. For instance, psychotic symptoms caused by cocaine use generally involve nonbizarre delusions or misperceptions. Tactile hallucinations ("cocaine bugs") also suggest cocaine-related psychosis.

History and laboratory testing can also distinguish stimulant-related symptoms from those induced by other psychoactive substances. In particular, phencyclidine (PCP) and stimulant intoxication share common features.

COURSE AND PROGNOSIS

Severity of stimulant use disorder has been among the most consistently observed predictors of unfavorable outcomes. Surrogate markers of more severe stimulant use disorders, such as heavy baseline use, positive urine toxicology screen prior to treatment entry, withdrawal symptoms, and injection drug use, are all negative prognosticators. In a recent study, fMRI patterns of functional connectivity in the brain predicted treatment response, particularly when baseline cocaine use was taken into account. Other factors associated with better or worse outcomes are presented in Table 11.3–3.

Co-occurring mental illness may also present particular challenges to patients who struggle with stimulant use disorders. Among individuals with severe mental illness treated in a contingency management program, better prognosis was associated with lower levels of psychiatric severity, negative drug screens at onset of treatment, and use of treatment services prior to entering the study. Depression appears to denote a worse prognosis for cocaine use disorder, though some results have contradicted this conclusion. A study demonstrated that anhedonia accounted for the apparently worse outcomes associated with depression more than depression or neurovegetative symptoms themselves. While PTSD may not predict more cocaine use in treatment, it is associated with more persistent impairment overall and with worse outcomes on

Telegram: @medical_k

www.konkur.in

psychosocial measures related to drug use. Two personality characteristics, impulsivity and novelty seeking, are associated with early treatment dropout, as is cognitive impairment.

Table 11.3–3.
Prognostic Factors for Stimulant Use Disorders

Associated with Worse Prognosis	Associated with Better Prognosis
Higher baseline use	Self-help involvement, sponsorship
Injection use	Greater social support
High cortisol levels	Involvement in treatment
Cognitive dysfunction	Employment
Tobacco use disorder	Extended residential treatment (cocaine)
Lower education level	Favorable brain connectivity patterns on fMRI
Other drug use	Higher self-efficacy
Anhedonia	
Impulsivity	

TREATMENT

Intensity of Treatment

Often, the treatment of alcohol, benzodiazepine, and opioid use disorder may be initiated in hospital or detoxification units, where severe or complicated withdrawal can be closely monitored and managed. In contrast, the treatment of individuals with stimulant-related disorders is often begun in outpatient settings, in part because the withdrawal syndrome rarely requires specific medical intervention. This presents an obstacle to many patients struggling to

Telegram: @medical_k

www.konkur.in

break free of compulsive stimulant use in home environments that are not conducive to remission.

In addition to clinical considerations, treatment setting and intensity may be influenced by a host of other factors such as the availability of treatment resources, financial considerations, and patient preference. Factors that may prompt initiation of treatment in an inpatient or residential setting include medical or psychiatric conditions independently warranting intensive treatment, a lack of response at less intensive levels of care, or the need to remove an individual from environmental influences that may sustain drug use.

The severity of co-occurring problems must also be taken into account when selecting a treatment setting. Patients with persistent psychotic or severe depressive symptoms involving suicidal ideation may require inpatient treatment to stabilize their co-occurring condition before outpatient care can be initiated. Inpatient treatment may also be appropriate for patients with multiple drug dependences to provide safe detoxification from alcohol, sedatives, or opioids. Finally, some patients may require medical stabilization for complications of stimulant use such as systemic infection, cerebrovascular accidents, or myocardial infarction and arrhythmia.

Treatment of Intoxication and Withdrawal

There are no reliably effective specific pharmacologic treatments for cocaine or amphetamine intoxication or withdrawal, and supportive care is the mainstay of treatment for these conditions. While self-limited, stimulant intoxication can be complicated by toxic reactions, including paranoia, agitation, seizures, hypertension and its sequelae, and end-organ ischemia. Agitation or paranoia may call for intensive monitoring in a controlled setting and short-term treatment with benzodiazepines or antipsychotic medications. However, most patients will recover spontaneously in a matter of hours to days without the need for pharmacologic therapy. Unlike withdrawal syndromes described for alcohol, benzodiazepines, and barbiturates, stimulant withdrawal is generally milder, self-limited, and not typically associated with delirium or other medical complications.

Telegram: @medical_k

www.konkur.in

Psychosocial Treatments

Psychosocial treatments remain the cornerstone of treatment for stimulant use disorders, particularly given the lack of a clearly effective medication to treat these disorders. Three behavioral models (contingency management, cognitive behavioral therapy [CBT], and twelve-step facilitation [TSF]) have received the strongest empirical grounding for the treatment of stimulant use disorders. Most study of 12-step approaches has focused on treatment of cocaine use disorders.

Contingency Management. Contingency management is a treatment firmly grounded in basic behavioral principles. In this approach, stimulant use disorders are conceptualized as the result of the drugs' powerful reinforcing effects, which supplant other natural reinforcers and aversive conditions that might otherwise halt drug use. In contingency management, competing reinforcers are created and applied to increase the likelihood of desired, nondrug behaviors. In most cases, the behaviors that are reinforced include treatment participation and the provision of drug-free urine samples during testing. Most commonly, contingency management procedures are combined with other active treatments such as comprehensive behavioral therapy programs and/or pharmacotherapy for co-occurring opioid use disorders.

An intermittent reinforcement schedule is commonly employed, in which an element of chance is introduced so that rewards are provided on a variable schedule. In one version of this method, study participants who engage in targeted nondrug behaviors (such as providing drug-free urine samples) are provided chances to draw for prizes that vary in value. This strategy has the advantage of providing robust reinforcement of desired behaviors and decreasing the overall cost of prizes (to an average cost of $200 or less per patient for 12 weeks of treatment). Beneficial results of such an approach have been demonstrated for patients with co-occurring cocaine and opioid use disorders in methadone-maintenance programs as well as for patients with cocaine use disorders treated

Telegram: @medical_k

www.konkur.in

in community settings. Positive effects of intermittent, abstinence-based reinforcement include increased likelihood of drug abstinence and improved treatment retention. Contingency management has also shown efficacy in other populations with cocaine use disorders, including those with co-occurring ASPD, pregnant women, people with HIV, those exposed to tuberculosis, and those with high levels of psychiatric symptoms. Clinical trials have confirmed similar benefits of contingency management in the treatment of methamphetamine use disorders, including in MSM and in those with co-occurring psychiatric disorders.

A recent, large network meta-analysis of psychosocial treatments for stimulant use disorders concluded that contingency management was consistently superior to treatment as usual on the outcomes of abstinence and retention in treatment. Further, contingency management in conjunction with community reinforcement (providing social rewards and support for treatment-related goals) was superior to other treatments assessed, including cognitive behavioral and 12-step–based approaches.

Despite the many trials consistently demonstrating efficacy of contingency management in treatment of people with stimulant use disorders, most patients are unable to access this potentially beneficial treatment, as it is simply not available in many communities. The reasons for this are complex and multifactorial, including a moralistic desire not to “pay patients to get better,” overestimating the actually low cost of the treatment, and logistic and regulatory difficulties of implementation. The end result is that an important tool for helping people with disorders for which too few beneficial options exist is vastly underutilized, to the detriment of patients.

Cognitive Behavioral Therapy. CBT for SUDs is predicated on the theory that maladaptive thought and behavior patterns sustain drug use in individuals with SUDs. CBT theoretically interrupts such patterns by helping patients to identify thoughts, feelings, and events that lead to drug use. CBT techniques for treating drug use disorders generally include providing psychoeducation and practice on skills

Telegram: @medical_k

www.konkur.in

such as avoiding or coping with high-risk situations, monitoring, and challenging drug-related thoughts and beliefs, and scheduling non–drug-related activities. Often, CBT treatments include written homework and other practice assignments between scheduled sessions. Homework adherence is associated with improved outcomes.

The efficacy of CBT in the treatment of cocaine and amphetamine use disorders has been demonstrated in several controlled trials. These trials include a computer-based adaptation for treatment of people with cocaine use disorders, as well as modifications for people of gender and sexual minority backgrounds. As described above, there is some evidence that CBT may be a less effective approach for stimulant use disorder treatment than contingency management, though further study including head-to-head comparisons is needed to definitively establish this. On the other hand, CBT offers the advantage of being much more widely available to patients. It is also a transdiagnostic approach, offering an evidence-based approach to treat the many co-occurring psychiatric and other SUDs that often accompany stimulant use disorders.

The Matrix model is a particularly well-studied example of a treatment approach that uses CBT as a core component. It is a manualized treatment employing elements of several evidence-based approaches, including CBT, family therapy, motivational interviewing, and other behavioral techniques. It has demonstrated efficacy in improving treatment participation and retention as well as in increasing the proportion of methamphetamine-free urine samples provided by patients with methamphetamine use disorders.

Other Psychosocial Treatment Approaches. Treatment that is based on the principles of 12-step recovery is common in clinical practice and has been studied in several well-designed trials. The 12-step model serves as the basis for self-help (often called mutual-help) groups such as AA, Narcotics Anonymous, Cocaine Anonymous, and Crystal Meth Anonymous. In addition to these peer-led groups, treatments based on 12-step principles are used by

Telegram: @medical_k

www.konkur.in

professionals in treating SUDs; the two most widely studied forms of professional treatment based on 12-step principles are individual drug counseling (IDC) and TSF; both encourage patients to attend 12-step meetings and to accept the disease model of addiction that serves as a core principle of 12-step philosophy. Both treatments have shown efficacy in clinical trials of the treatment of cocaine use disorders, particularly for people without co-occurring psychiatric illness. The body of literature regarding the impact of self-help groups in those with cocaine-related disorders is much smaller than that for alcohol-related disorders. There is also very little empirical data regarding the efficacy of 12-step and self-help approaches for amphetamine-type stimulant use disorders.

Motivational interviewing is useful for the treatment of SUDs in general, though it has been studied to a more limited extent for the treatment of stimulant use disorders. Exercise appears to benefit people with methamphetamine use disorders who do not use daily, but it should be considered a potentially useful component of therapy rather than a stand-alone treatment.

Pharmacologic Agents

To date, there are no FDA-approved medications to treat stimulant use disorders. Many agents that have shown promise in preclinical studies, open-label trials, or small double-blind studies have then had mixed or disappointing results in larger clinical trials. Nonetheless, accumulating evidence has recently allowed application of meta-analytic techniques to uncover approaches that show the most promise as future treatments. The following discussion describes potential areas for further research, though none of the medications described can yet be unequivocally recommended as a treatment.

Knowledge of the effects that cocaine and amphetamines have on brain dopamine has led to the investigation of many medications that modulate dopaminergic neurotransmission, including direct and indirect agonists as well as dopamine antagonists. Trials of direct dopamine agonists (e.g., amantadine, bromocriptine, L-

Telegram: @medical_k

www.konkur.in

dopa/carbidopa, pramipexole, pergolide) have largely been negative. Methylphenidate, which increases presynaptic dopamine release, has not shown consistent benefit for stimulant-dependent patients in the absence of co-occurring ADHD. The atypical psychostimulant modafinil has also shown little benefit.

A recent meta-analysis of psychostimulant treatment for people with stimulant use disorders reviewed the effect of treatment with amphetamines, methylphenidate, and modafinil on substance-related outcomes. Conclusions were that stimulant treatment likely showed benefit for abstinence-based outcomes, irrespective of the presence of co-occurring ADHD. These outcomes were largely driven by the impact of relatively high-dose treatment (>60 mg daily) with amphetamines for cocaine use disorders. The use of stimulants did not appear to improve retention in treatment. Concerns regarding the potential misuse or diversion of amphetamine-type stimulants remain an obstacle to widespread adoption as a treatment for people with stimulant use disorders.

Analogous to the use of the opioid antagonist naltrexone in the treatment of opioid dependence, dopamine antagonists have been assessed as potential medications for stimulant use disorders. Antipsychotics appear to be useful for the treatment of psychotic symptoms in people with stimulant use disorders, with some evidence that risperidone may be better tolerated than aripiprazole. However, antipsychotics do not show evidence of improving substance-related outcomes.

In addition to their effects on dopaminergic brain pathways, cocaine and amphetamines act as inhibitors of presynaptic serotonin reuptake. Serotonergic agents, including antidepressants, appear to blunt some of cocaine's reinforcing properties in animal models. However, clinical trials of predominantly serotonergic agents (serotonin-specific reuptake inhibitors, buspirone [BuSpar], and venlafaxine [Effexor]) have been disappointing. Mirtazapine, an antidepressant with novel mechanisms including serotonergic effects, reduced both methamphetamine-positive urine samples and risky sexual behaviors in methamphetamine-use-disordered MSM. Bupropion, an antidepressant believed to have a primarily

Telegram: @medical_k

www.konkur.in

dopaminergic mechanism, improved methamphetamine use among those with lighter use at baseline.

While mood stabilizers as a class do not show evidence of improving substance-related outcomes in people with stimulant use disorders, topiramate has appeared beneficial in some clinical trials. In a 13-week clinical trial for cocaine use disorder, topiramate at a 200-mg-daily dose was associated with increased rates of abstinence. In a subsequent trial, 300-mg-daily topiramate in conjunction with CBT was associated with increases in number of abstinent days and the likelihood of cocaine-free weeks. In a trial involving people with methamphetamine use disorder, topiramate did not increase abstinence rates overall but was associated with decreased methamphetamine use in those who were abstinent at the start of the trial. In yet another study, the combination of mixed amphetamine salts and topiramate was associated with an increased rate of continuous abstinence over a 3-week period in comparison to placebo. A similar finding was seen in a study of topiramate for individuals with co-occurring cocaine and alcohol use disorders (AUDs). Despite these encouraging findings, three negative trials of the use of topiramate to treat cocaine use disorders have been published: two involving patients with co-occurring opioid use disorders and one with individuals using “crack” cocaine.

Disulfiram has long been used in the treatment of AUD because it inhibits acetaldehyde dehydrogenase, an enzyme involved in the metabolism of ethanol. This leads to unpleasant physical symptoms if ethanol is ingested. Initial interest in disulfiram for the treatment of cocaine use disorders was stimulated by the frequent co-occurrence of AUDs with cocaine use disorders. Early studies suggested that disulfiram had an indirect effect on cocaine use, mediated by its effects on alcohol use. However, disulfiram also appears to have a more direct pharmacologic effect on the metabolism of dopamine and cocaine itself; it acts as an inhibitor of dopamine beta-hydroxylase, thereby slowing the breakdown of synaptic dopamine and increasing dopamine levels. Disulfiram has also been shown to increase serum cocaine levels severalfold in pretreated persons. Results from several studies suggest that disulfiram may be of

Telegram: @medical_k

www.konkur.in

benefit to some people with cocaine use disorders, though many do not respond.

Pharmacogenetic studies have described several genes associated with differential responses to disulfiram for treatment of cocaine use disorder, including the alpha-1-adrenoreceptor gene (ADRA1A), ankyrin repeat and kinase domain-containing 1 (ANKK1), the D2 dopamine receptor (D2DR), the methylation enzyme encoded by MTHFR/C677T, variants of the serotonin transporter (5-HTTLPR), dopamine-beta-hydroxylase (DβH), and enzymes involved in serotonin synthesis (TPH2). Notably, allelic differences in DβH are also associated with differential response to doxazosin treatment of cocaine use disorder. Alleles producing normal or increased DβH activity are associated with disulfiram response, whereas alleles producing low activity are associated with doxazosin response.

In an effort to bolster therapeutic effects, medications thought to have complementary mechanisms of action have been combined. As described above, combination treatment with amphetamines and topiramate may be beneficial for treatment of cocaine use disorder. Building on earlier separate studies showing that naltrexone or bupropion might be beneficial for treatment of methamphetamine use disorder in those with lower baseline use, a study combining the two was recently completed. This trial involved subjects with moderate-to-severe methamphetamine use disorder who had used methamphetamine on 18 of the preceding 30 days. Compared to placebo, those treated with a combination of long-acting injected naltrexone and oral bupropion had higher rates of treatment response (measured as abstinence at consecutive time points). In another study of combined medications, buprenorphine along with long-acting injected naltrexone improved cocaine-related outcomes.

Investigational Treatments. A novel approach being studied for the treatment of stimulant use disorders is through immunization, using a therapeutic vaccine to induce antibodies to psychostimulants. Vaccines for cocaine and for methamphetamine are in different stages of development and testing. Creating an effective vaccine against either methamphetamine or cocaine is a

Telegram: @medical_k

www.konkur.in

challenge, given the small size of the compounds (too small to create an immune response independent of immunogenic carriers). It is hoped that more potent vehicles for delivering vaccines will yield better results in the future. Electrical stimulation of the brain, either through transcranial direct current stimulation (tDCS) or transcranial magnetic stimulation (TMS), is being explored as a possible treatment approach for stimulant use disorders. There is some evidence of potential benefit, with most studies assessing measures of executive functioning, craving, and impulse inhibition as target outcomes. Given the alterations in gene expression produced by heavy stimulant use, epigenetic modifiers have also been proposed as a new treatment paradigm. As knowledge of the genetic, cellular, and neurobiologic mechanisms of drug addiction are elucidated, it can be hoped that more effective biologic treatments for stimulant use disorder will someday be available to patients.

11.4 Caffeine-Related Disorders

LAURA M. JULIANO, PH.D., AND MARY MARGARET SWEENEY, PH.D.

Caffeine (1,3,7-trimethylxanthine) is the most widely used mood-altering drug in the world. Caffeine is found naturally in more than 60 species of plants (e.g., coffee, tea, yerba mate, cacao) and belongs to the methylxanthine class of alkaloids, which also includes theobromine and theophylline. Caffeine is also added by manufacturers to various types of beverages, foods, dietary supplements, and medications. Approximately 90% of adults in the United States consume caffeine. Caffeine directly antagonizes the endogenous neuromodulator adenosine, as well as indirectly alters dopamine neurotransmission. Consequently, it affects various neurobiologic and physiologic systems and produces significant psychological effects. At typical dietary doses, caffeine is not associated with any life-threatening illnesses. However, caffeine use can be contraindicated for some medical conditions and medications, and discrete psychiatric symptoms and disorders can result from its use. The ubiquitous habitual consumption of caffeine and its integration into daily customs and routines can lead to an underestimation of the role that caffeine may play in caffeine users' daily experiences and can make recognizing caffeine-associated disorders particularly challenging. Clinicians need to be familiar with the various sources of caffeine and the psychiatric symptoms and disorders that can result from its use.

DEFINITION

Caffeine use is associated with five discrete syndromes in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5-TR) (Table 11.4–1). Four of these syndromes—caffeine

Telegram: @medical_k

www.konkur.in

intoxication, caffeine withdrawal, caffeine-induced anxiety disorder, and caffeine-induced sleep disorder—are formal diagnoses. A fifth syndrome—caffeine use disorder—is included as a condition for further study. The ICD-10 and ICD-11 also recognize caffeine-related disorders, including but not limited to caffeine intoxication, caffeine withdrawal, caffeine dependence (ICD-10 only), caffeine-induced anxiety disorder, and a harmful pattern of use of caffeine.

www.konkur.in

[a]No longer a discrete diagnosis in ICD-11.

HISTORY

Caffeine-containing foods and beverages have been consumed for thousands of years. Tea has been cultivated and consumed in China for more than 2,000 years, and coffee cultivation spread from Ethiopia to Arabia in the 15th century and subsequently became a popular beverage in Arabic cultures during the 16th century. Coffee spread to Europe in the 17th century (along with tea, tobacco, and chocolate). Medical literature during this time described coffee as a useful beverage for a wide variety of conditions, although it is notable that coffee use to induce sobriety was a particularly attractive feature. However, considerable controversy about whether the use of coffee was beneficial or detrimental to health accompanied its expansion into Western cultures, a controversy that is mirrored in contemporary concerns over the use of caffeine. The widespread use of coffee during the 17th and 18th centuries is reflected in the estimate that there were between 2,000 and 3,000 coffeehouses in London by the early part of the 17th century (about one coffeehouse for every 200 to 300 people). Perhaps the most famous of the coffeehouses in London was operated by Edward Lloyd. Like most coffeehouses, Lloyd's was a center of business, especially for insurance agents, and by the end of the 18th century, Lloyd's became the well-known Lloyd's of London insurance company. Coffeehouses also served as a place for intellectual, political, and social discourse. In England, tea consumption eventually supplanted coffee use, with the shift in beverage preference occurring in the first half of the 18th century.

In the United States, a shift from tea to coffee use occurred in 1773 when colonists protesting British taxes threw cargoes of tea overboard in the Boston harbor—the Boston Tea Party. The repercussions of this event continue to the present day; the United States is now the major consumer of coffee in the world. Coffee, a major source of caffeine, is integral to the economic activity of several countries. For example, only crude oil produces more foreign

Telegram: @medical_k

www.konkur.in

exchange earnings than coffee for developing countries. Coffee is the major agricultural import of the United States and is second only in value to oil among all imports. This economic and trade activity underscores the extent to which caffeine is now available and accepted virtually everywhere in the world.

In the late 19th century, caffeine began appearing in various soft drink beverages. While a fraction of caffeine contained in cola soft drink beverages is derived from the kola nut, most caffeine in soft drinks is added—reportedly as a flavoring agent. However, there is little scientific evidence that caffeine functions as a flavoring agent at levels found in soft drinks. In 1997, Red Bull caffeinated energy drink was first introduced in the United States, with hundreds of other brands to follow. Energy drinks and energy shots now represent a multibillion-dollar market in the United States. These products are banned or regulated in some countries due to concerns about their high caffeine levels. In the United States, energy drinks and energy shots can be marketed as dietary supplements, which presently have looser regulations regarding caffeine content and labeling than soft drinks and drugs. In the early 2000s, caffeinated alcoholic beverages became available to consumers. By late 2010, amidst growing popularity of these beverages among young people, these products were removed from the market by manufacturers due to pressure from the U.S. Food and Drug Administration (FDA), who deemed caffeine added to alcoholic malt beverages an “unsafe food additive.” At the present time, caffeine is being added to a wide variety of beverages, foods, dietary supplements, and medications. While the FDA considers how to better define the regulatory boundaries pertaining to caffeine, it is important for health care providers and consumers to remain cognizant of the potential sources of caffeine and its potential adverse effects.

COMPARATIVE NOSOLOGY

The DSM-III (1980) was the first to include caffeine (and tobacco) use disorders. At that time, only caffeine intoxication was included as a discrete syndrome with specific diagnostic criteria. Caffeine

Telegram: @medical_k

www.konkur.in

intoxication has remained in all subsequent editions of the DSM, with no substantive changes in the diagnostic criteria. Caffeine-induced anxiety disorder and caffeine-induced sleep disorder first appeared in the DSM-IV (1994). Caffeine withdrawal was included in the DSM-IV and DSM-IV-TR as a research diagnosis and was included as a formal diagnosis in the DSM-5 and DSM-5-TR with some modifications to the criteria based on a large body of empirical data. Caffeine use disorder was added as a condition for further study in the DSM-5 and DSM-5-TR, as there is growing evidence that some individuals have a profile of symptoms consistent with problematic caffeine use and may benefit from treatment.

The ICD-10, published by the World Health Organization, contains caffeine-related diagnoses under the category of mental and behavioral disorders due to use of other stimulants, including caffeine (F15), that include but are not limited to caffeine intoxication, harmful use, dependence syndrome, and withdrawal state.

The ICD-11 includes a category of disorders due to the use of caffeine (6C48), which includes caffeine intoxication, harmful use, caffeine withdrawal, and caffeine-induced anxiety disorder. Hazardous caffeine use is a new entry defined by caffeine use that increases the risk of harmful physical or mental health consequences warranting advice from health professionals but has not yet caused physical or mental harm to the user or others. Caffeine dependence syndrome is no longer explicitly included in the ICD-11 as a discrete diagnosis. Individuals with disordered caffeine use may display a harmful pattern of use of caffeine, which is described as having caused “clinically significant harm to a person’s physical or mental health” over a period of at least 12 months if use is episodic or for at least 1 month if use is continuous. However, this diagnosis does not recognize other hallmark features of a caffeine use disorder, including unsuccessful attempts or persistent desire to cut down caffeine or caffeine withdrawal. The ICD-11 also has a category of other unspecified disorders due to use of caffeine, which may be used to diagnose problematic caffeine consumption.

Telegram: @medical_k

www.konkur.in

EPIDEMIOLOGY

Caffeine is consumed via beverages (e.g., coffee, tea, yerba mate, soft drinks, energy drinks, or workout supplements), foods (e.g., chocolate, coffee yogurt), dietary supplements, weight loss products, and prescription and over-the-counter medications. Approximately 70% of all soft drinks consumed in the United States have added caffeine, including many types of noncola soft drinks (e.g., orange soda, root beer). During the past two decades, caffeine-containing energy drinks, energy shots, and energy drink mixers (concentrated liquids or powders) have been made widely available to consumers. These products are capable of providing large doses of caffeine, as these products often contain significantly more caffeine per volume than soft drinks or at higher concentrations than recommended. Furthermore, some manufacturers add caffeine to foods that do not naturally contain caffeine (e.g., candy, potato chips, protein bars).

Determining an individual's level of caffeine exposure can be challenging because of the wide variety of products that contain caffeine, large differences in serving sizes, variability in caffeine content across products of the same type, and unknown or undisclosed caffeine amounts in some products. For example, a 12-oz cup of coffee would be estimated to contain approximately 200 mg of caffeine on average but may contain anywhere from 40 mg to 420 mg of natural caffeine depending on the variety, brew strength, and preparation method. A 12-oz caffeinated soft drink can vary from 19 to 69 mg of caffeine, and energy drinks/workout drinks can vary from 25 to 400 mg of caffeine for a can or bottle. There is also wide variability in caffeine levels across foods, medications, and dietary supplements/weight loss products. Table 11.4–2 shows the caffeine content of selected caffeine-containing products.

The most comprehensive epidemiologic data on caffeine use is derived from two main sources. The National Health and Nutrition Examination Survey (NHANES) is given annually to a representative sample of children and adults in the United States and collects information on health and nutrition including all consumed foods and beverages based on 24-hour recall. The Kantar Worldpanel

Telegram: @medical_k

www.konkur.in

Beverage Consumption Panel includes a representative sample of the U.S. population who complete 7-day web-based diaries of beverage consumption. These surveys consistently find a high rate of regular caffeine use among children and adults, with approximately 85% of the population aged 2 years and older consuming at least one caffeinated beverage per day. It is notable that more than 60% of children aged 2 to 5 consume caffeine daily. The prevalence of caffeine use tends to increase with age, with approximately 90% of adult men and women consuming caffeine daily.

More than 95% of all caffeine ingestion comes from beverages. Coffee is the primary source of caffeine among adults in the United States, followed by tea and soft drinks. More than half of adults consume coffee every day, consuming an average of about 3 cups per day. Soft drinks are the primary source of caffeine among children and adolescents, followed by tea and coffee. A review of studies from 1999 to 2011 found increasing use of coffee and caffeinated energy drinks among children and adolescents, with the frequency of energy drink use varying considerably across studies. More recent studies suggest that energy drink use has continued to increase over time, with the largest increases among young adults. A review of 2003 to 2016 NHANES data from more than 33,000 respondents aged 12 to 59 found that the prevalence of energy drink consumption significantly increased over time across all age groups, and per capita consumption increased among young adults. The report also concluded that energy drinks were a major source of caffeine among those who consume them. A nationally representative survey of adolescents conducted in 2014 found that nearly two-thirds had reported ever trying energy drinks, and 41% had used energy drinks in the prior 3 months. It is important to note that sales of energy drinks more than doubled from 2014 to 2021.

Telegram: @medical_k

www.konkur.in

Most caffeine is consumed in the morning, and exposure progressively decreases throughout the day. However, it is more common for caffeinated tea, soft drink, and energy drink consumption to be distributed throughout the day than coffee. Furthermore, adolescents tend to spread caffeine consumption across a day more so than adults. Weekday and weekend levels of caffeine use appear comparable across all age groups.

Determining the absolute level of caffeine exposure in the general population is challenging and estimates tend to vary widely depending on the study sample and methodology. There also tends to be a considerable lag in the time from data collection to publication of data summaries. A report was commissioned by the FDA that summarized the U.S. population's consumption of caffeine between 2003 and 2008. The report was based on the NHANES and NPD Group's Food Consumption surveys, which collected self-reported food consumption using daily diaries for 14 consecutive days from 2,000 households deemed representative of the population. The mean daily caffeine intake among adults (over age 22) was estimated to be 300 mg. Among coffee drinkers, the mean daily caffeine intake was estimated to be 375 mg. Another NHANES-based study estimated the caffeine intake of the U.S. population (>18 years) from 2001 to 2010. Total per capita consumption was 186 mg per day, and among caffeine consumers was 211 mg per day. Fourteen percent of the sample consumed more than 400 mg of caffeine per day. Across various studies, men tend to consume more caffeine than women. Non-Hispanic White individuals tend to consume more caffeine than non-Hispanic Black individuals, with Hispanic individuals falling in between.

ETIOLOGY

In the United States, it is not uncommon for the first exposure to caffeine, usually as coffee or soft drinks, to occur during childhood. Onset of regular use of soft drinks occurs at an earlier age than regular use of coffee or tea. Continued caffeine consumption may be influenced by several different factors, such as the pharmacologic

Telegram: @medical_k

www.konkur.in

effects of caffeine, caffeine's reinforcing effects, genetic predispositions, caffeine withdrawal, characteristics of the consumer (e.g., age, ethnicity), and social norms. About 14% of former consumers of caffeine report stopping caffeine consumption in response to health concerns or unpleasant side effects.

Pharmacology and Effects in the Central Nervous System

Caffeine is well absorbed from the gastrointestinal (GI) tract, with peak plasma concentrations typically occurring within 30 to 60 minutes after ingestion. Caffeine is readily distributed throughout all body fluids and is metabolized by the liver. More than 90% of caffeine is metabolized by the cytochrome P450, isozyme 1A2 (CYP1A2) system. Hence, caffeine is frequently used as a metabolic probe to assess CYP1A2 activity. Caffeine has three primary active metabolites—paraxanthine, theophylline, and theobromine—that also need to be considered in the overall biologic effects of caffeine.

The half-life of caffeine is 4 to 6 hours on average, with large variability across individuals. Caffeine metabolism is affected by various factors, including genetics, age, pregnancy, oral contraceptives, smoking, medications, diet, and diseases. The variability in CYP1A2 activity can be largely explained by a genetic polymorphism involving an A to C substitution. Carriers of the C allele (C/C or C/A) metabolize caffeine more slowly than an A/A genotype. Various other gene polymorphisms are also associated with caffeine metabolism (e.g., CYP1A1, CYP2A6, NAT-2, XO). Although caffeine half-life does not differ between younger and older adults, caffeine half-life is markedly increased in newborns (half-life of 80 to 100 hours) whose liver enzyme system does not completely develop until about 6 months of age.

Caffeine clearance slows down considerably during the second and third trimesters of pregnancy with more than a 50% reduction of CYP1A2 activity by the 24th week of pregnancy. Caffeine's half-life nearly doubles among women using oral contraceptives. There are various other medications that increase or decrease caffeine clearance. Caffeine's half-life increases when taking clozapine,

Telegram: @medical_k

www.konkur.in

fluconazole, methoxsalen, some quinolone antibiotics, cardiovascular drugs including verapamil, propranolol, and warfarin, and bronchodilators including theophylline. Grapefruit juice and liver disease also slow caffeine clearance. Cigarette smoking nearly doubles the speed of caffeine elimination due to the induction of liver enzymes by cigarette smoke (but not nicotine). Caffeine's half-life is decreased by medications including cimetidine, omeprazole, and fluvoxamine.

Caffeine exerts effects throughout the body, including bronchodilation (hence the therapeutic application of caffeine and the related methylxanthine theophylline in the treatment of asthma and apnea of prematurity); modest increases in blood pressure (which are attenuated in caffeine-tolerant individuals); increased production of urine; increases in gastric acid secretion; and increases in plasma epinephrine, norepinephrine, renin, and free fatty acids. Centrally, caffeine affects turnover or levels of various neurotransmitters and functions as a central nervous system (CNS) stimulant.

Numerous investigations have examined the effects of caffeine in the CNS to understand the neurobiologic basis for caffeine's effects. The principal cellular site of action of caffeine is the adenosine receptor, where caffeine functions as an antagonist at both A_{2A} and A_1 receptors. Adenosine serves an important modulatory role in many brain processes and functions (e.g., reduces spontaneous electric activity in the brain, dilates blood vessels in the brain). As an adenosine antagonist, many of caffeine's effects are opposite to those produced by adenosine (e.g., CNS stimulation, constricts blood vessels in the brain). Figure 11.4–1 shows the similarities in the molecular structures of caffeine and adenosine. There is evidence that adenosine receptors form functional relationships, or heteromerize, with other types of receptors, including dopamine and glutamate receptors. For example, some of the behavioral stimulant properties of caffeine are believed to be due to an increase in dopamine activity due to antagonism of adenosine at the A_{2A} to D_2 receptor heteromer. It has also been reported that caffeine increases

Telegram: @medical_k

www.konkur.in

dopamine release in the shell of the nucleus accumbens, an effect believed to be a neuropharmacologic mechanism underlying the addictive potential of drugs. Other mechanisms proposed as mediating caffeine's effects have included the inhibition of phosphodiesterases and effects on intracellular calcium, although these effects may only occur at doses of caffeine that exceed typical human consumption. However, it is not known if these other mechanisms may mediate some of the clinical effects produced when caffeine concentrations are elevated, such as may be the case during caffeine intoxication.

FIGURE 11.4–1. The chemical structures of caffeine (1,3,7-trimethylxanthine) and adenosine. Caffeine is structurally similar to adenosine, an endogenous neuromodulator. Most of the physiologic effects of caffeine, including the central nervous system stimulant effects, are believed to be mediated through adenosine receptor antagonism.

Subjective Effects, Performance Effects, and Reinforcement

Telegram: @medical_k

www.konkur.in

Subjective reactions to caffeine are dose dependent and may vary depending on individual differences in sensitivity and caffeine tolerance. In general, single low-to-moderate doses of caffeine (i.e., 20 to 200 mg) produce pleasurable subjective effects. Studies have shown that such doses of caffeine result in increased ratings on measures such as well-being, alertness, energy, concentration, sociability, and motivation to work. In addition, these doses of caffeine produce decreases in ratings of feeling sleepy or tired. Higher doses of caffeine (e.g., ≥400 mg) are more likely to produce negative subjective effects such as anxiety, nervousness, and jitteriness; however, some individuals may report such negative effects at lower doses (e.g., 200 mg).

Numerous studies have examined the effects of caffeine on human performance. Recent research suggests that some of the variability in performance effects across individuals may be associated with single nucleotide polymorphisms (SNPs) on the CYP12A gene. There is compelling evidence that caffeine improves performance that has been degraded by fatigue, sleep deprivation, prolonged vigilance, or caffeine abstinence. Compared with placebo, caffeine has been shown to improve reaction time, tapping speed, sustained attention (or vigilance), and perhaps memory. A rich literature on the effects of caffeine on exercise performance suggests that, relative to placebo, caffeine (in the range of 3 to 6 mg/kg) reliably enhances performance during long-term (30 to 60 minutes) aerobic exercise, reduces ratings of perceived exhaustion, and improves power output or speed. Some studies, but not all, have also demonstrated caffeine-induced enhancement during short-term, high-intensity exercise and other aerobic and anaerobic sport-specific actions. The most reliable and strongest effects of caffeine on exercise performance are observed during aerobic exercise when caffeine (3 to 6 mg/kg) is consumed approximately 60 minutes prior. High doses of caffeine (e.g., 9 mg/kg) produce no additional benefit and result in negative side effects.

Although animal studies have generally found it difficult to demonstrate that caffeine functions as a reinforcer, well-controlled studies with humans have shown that people choose caffeine over

Telegram: @medical_k

www.konkur.in

placebo when given the choice under controlled double-blind experimental conditions. In habitual users, the reinforcing effects of caffeine are potentiated by its ability to suppress low-grade withdrawal symptoms after overnight abstinence. Thus, the positive subjective effects of caffeine and its ability to ward off the negative effects of caffeine withdrawal contribute to the regular use of caffeine. Studies have also shown that repeatedly pairing caffeine with a novel-flavored drink produces increased preference ratings for the flavor, while pairing placebo with a novel-flavored drink decreases preference ratings for the flavor among abstinent habitual caffeine consumers. These findings suggest that caffeine may play an important role in the development of preferences for specific types or brands of beverages.

Genetics and Caffeine Use

Investigations comparing coffee or caffeine use in monozygotic versus dizygotic twins show higher concordance rates for monozygotic twins for total caffeine consumption, heavy use, caffeine tolerance, caffeine withdrawal, caffeine intoxication, and coffee and tea intake, with heritability ranging from 34% and 77%. Multivariate structural equation modeling of caffeine use, cigarette smoking, and alcohol use suggests that a common genetic factor—polysubstance use—underlines use of these three substances. An analysis of monozygotic and dizygotic male and female twin pairs demonstrated that problematic use of caffeine and nicotine was substantially influenced by genetic factors unique to these licit drugs and distinct from genetic factors found to be common among illicit drugs. Furthermore, problematic use of caffeine was shown to have the greatest substance-specific genetic variance among the five drug dependencies that were evaluated.

Over the past 20 years, there have been numerous studies examining associations between candidate genes associated with the pharmacokinetics and pharmacodynamics of caffeine and patterns of caffeine consumption and caffeine-related effects. Most research has focused on polymorphisms in the adenosine A_{2A}

Telegram: @medical_k

www.konkur.in

receptor gene (ADORA2A), the CYP12A enzyme gene that differentiates fast metabolizers and slow metabolizers of caffeine, and the aryl hydrocarbon receptor gene (AHR), which influences the transcription of CYP12A. ADORA2A polymorphisms have been shown to be associated with various outcomes including caffeine consumption, caffeine sensitivity, and caffeine's effects on psychomotor vigilance, anxiety, startle, sleep, coronary responses, postprandial glucose levels, and blood pressure. Adenosine A_{2A} receptor knockout mice show a reduced preference for caffeine compared to controls. Polymorphisms in the CYP1A2 and ACH receptor genes are most reliably associated with variability in caffeine consumption. Associations between the "fast metabolizer" CYP1A2 variant and better performance outcomes have been observed but are inconsistent across studies. The "slow metabolizer" CYP1A2 variant has been shown to be associated with increased risk for coffee-associated hypertension and myocardial infarction. In addition to the associations described above, recent research has identified dozens of other SNPs and possible associations with caffeine use and effects. However, a consistent pattern of findings across these types of studies has yet to be observed.

Age, Sex, and Race

Population-based surveys reveal that daily caffeine exposure increases with age up until middle age and then begins to slightly decline. Some studies show that men use more caffeine than women, but this effect disappears when accounting for differences in body weight (i.e., mg/kg), employment status, and other covariates. Among adults in the United States, non-Hispanic White individuals typically consume more caffeine than African American, Hispanic, and Asian individuals.

Special Populations

Cigarette smokers consume higher levels of caffeine than nonsmokers. This observation may reflect a common genetic vulnerability to caffeine use and cigarette smoking. It may also be

Telegram: @medical_k

www.konkur.in

due to faster caffeine elimination in cigarette smokers because of cigarette smoke stimulating the CYP1A2 enzyme system. Individuals who consume coffee or energy drinks consume more caffeine daily than those who do not. Preclinical and clinical studies indicate that regular caffeine use can potentiate the reinforcing effects of nicotine. Heavy use of alcohol, alcohol use disorders, and other substance use disorders (SUDs) are also associated with heavy use and problematic use of caffeine. One study found that among pregnant women, a family history of alcohol use disorders was associated with heavy use of caffeine both before and during pregnancy, despite physician advice to cease caffeine use during pregnancy. Another study also showed that a greater proportion of heavy caffeine consumers use benzodiazepines. High daily caffeine consumption has also been found among individuals with a variety of psychiatric disorders, particularly among those with schizophrenia. One twin study found significant positive relationships between caffeine use, caffeine toxicity and problematic caffeine use, and lifetime history of all seven psychiatric disorders that were assessed, including major depression, generalized anxiety disorder, panic disorder, alcohol use disorder, antisocial behavior, and cannabis and cocaine abuse. Interestingly, the authors concluded that shared familial factors accounted for the relationships between caffeine use and the psychiatric disorders, rather than a direct link. Some studies show that caffeine use is positively associated with novelty seeking or sensation seeking as well as legal and management occupations.

CAFFEINE INTOXICATION

Caffeine intoxication has long been recognized as a discrete syndrome associated with the use of a significant amount of caffeine. DSM-5-TR diagnostic guidelines state that the diagnosis is dependent on recent consumption well in excess of 250 mg of caffeine per day, but the syndrome is usually associated with higher doses (e.g., more than 1 g according to the ICD-11). Intoxication can be the result of an acute ingestion of a large amount of caffeine by a person who has not regularly consumed caffeine. Alternatively,

Telegram: @medical_k

www.konkur.in

caffeine intoxication can occur in a person who chronically consumes large amounts of caffeine, which produces a more complicated clinical picture. Interestingly, while intoxication of some psychoactive substances, such as alcohol, is sought out by some people, it appears that most individuals do not actively seek repeated episodes of caffeine intoxication (Table 11.4–3).

Epidemiology

There is an important need for data on the incidence and prevalence of caffeine intoxication in the general population. To date, most studies investigating caffeine intoxication symptoms have involved selected populations (e.g., psychiatric inpatients, college students) using ambiguous or incomplete criteria. Notably, one random-digit telephone survey among 162 caffeine users in Vermont found that two-thirds of respondents reported at least one caffeine intoxication symptom and 7% met the DSM criteria for caffeine intoxication in the past year. One study that assessed more than 3,600 twins found that 29% reported having experienced feeling ill or shaky or jittery after consuming caffeinated beverages. Psychiatric patients may have higher rates of caffeine intoxication than healthy controls. Children and adolescents may be at increased risk for caffeine intoxication because of low body weight, lack of tolerance, and lack of knowledge about the caffeine content of readily available products (e.g., energy drinks). Reports from the Poison Control Center's National Poison Data System provide some information about the rate of adverse effects from caffeine. For example, in the category of single-substance exposures (i.e., not involving caffeine contained in dietary supplements or energy drinks), there were 3,031 cases involving caffeine in 2019. Twenty-seven percent of these exposures were treated in a health care facility. Of all cases, 37% involved individuals aged 5 years and younger, and 57% involved individuals aged 19 years and younger. In 2019, there were 1,724 cases involving nonalcoholic caffeinated energy drinks, 596 cases involving unknown energy drinks, and 232 involving energy products. Seventeen percent of these cases were treated in a health care

Telegram: @medical_k

www.konkur.in

facility, and nearly 60% involved individuals aged 5 years and younger. The American Association of Poison Control Centers has issued an alert for energy drinks, stating that they can be dangerous for children or adolescents. The American Academy of Pediatrics recommends that children and adolescents do not consume energy drinks.

Diagnosis and Clinical Features

Signs and symptoms of caffeine intoxication include restlessness, nervousness, excitement, insomnia, flushed face, diuresis, GI disturbance, muscle twitching, rambling thoughts and speech, tachycardia or cardiac arrhythmia, inexhaustibility, and psychomotor agitation. To receive a DSM-5-TR diagnosis, patients must present with five or more of the symptoms along with clinically meaningful distress or functional impairment. In addition, patients with caffeine intoxication can have fever, irritability, tremors, sensory disturbances, tachypnea, headaches, vomiting, and seizures. A series of case reports based on Poison Control Center data found that a particular energy drink containing 250 mg of caffeine was repeatedly implicated in caffeine intoxication incidents. The most common symptoms reported were hypertension, jitteriness, agitation, tremors, nausea, vomiting, and dizziness. Finally, although rare, it may be possible for a patient to develop delirium from ingesting an acute, extremely high dose of caffeine. Cases of intentional and unintentional fatal overdose from caffeine are rare but have been documented, usually from the ingestion of caffeine in the form of pills or powder.

Pathology and Laboratory Examination

Blood serum levels greater than 100 μg/mL may be lethal, although there have been reports of individuals surviving much greater caffeine serum levels with medical intervention. However, it has also been noted that serum caffeine levels may be a poor indicator of toxicity due to the variable relationship between blood concentration and toxic effects. Urine or blood drug screens can also be used to rule out the presence of other drugs in the body.

Differential Diagnosis

There are various disorders that should be included in the differential diagnosis of caffeine intoxication. These include other substance-related disorders, such as intoxication from other stimulants (e.g., cocaine or amphetamines), and withdrawal from drugs such as

Telegram: @medical_k

www.konkur.in

sedative–hypnotics (e.g., benzodiazepines), alcohol, or nicotine. In addition, other psychiatric disorders (e.g., anxiety disorders, mania, sleep disturbances), somatic disorders (e.g., arrhythmia, hyperthyroidism), and medication side effects (e.g., akathisia) should be considered in the differential diagnosis of caffeine intoxication. The final diagnosis of caffeine intoxication depends on confirming the ingestion of a significant quantity of caffeine prior to the onset of symptoms.

Course and Prognosis

Caffeine has a relatively short half-life (4 to 6 hours), and thus, caffeine intoxication usually resolves quickly and often with no significant sequelae. Some substances including oral contraceptives may significantly increase the half-life of caffeine and thus, increase the risk of caffeine intoxication. Patients with caffeine intoxication generally have a good prognosis, and fatal incidents are rare. The lethal dose of caffeine is generally considered to be about 10 g or the equivalent of 80 to 100 cups of brewed coffee.

Treatment

The first step in treating a patient presenting with symptoms suggesting caffeine intoxication is to confirm the diagnosis. It is important to consider all possible sources of caffeine when considering a diagnosis of caffeine intoxication, including medications, dietary supplements, energy drinks, shots, powders, and beverages that may not be initially recognized as containing caffeine. Because caffeine has a relatively short half-life, short-term management of the patient can be supportive while the syndrome resolves spontaneously. For the patient who habitually consumes large amounts of caffeine and repeatedly experiences episodes of caffeine intoxication, it may be helpful to assist the patient to recognize their total daily caffeine consumption using daily diaries, teach the patient about the adverse effects associated with caffeine, and provide treatment assistance (see Table 11.4–4). In the case of significant caffeine overdose, the patient should receive intensive

Telegram: @medical_k

www.konkur.in

monitoring, symptomatic treatment (e.g., for tachycardia), stomach aspiration, and assessment of serum caffeine level. Caffeine overdose has been successfully treated with hemodialysis or hemoperfusion.

CAFFEINE-INDUCED ANXIETY DISORDER

In addition to anxiety symptoms that are a feature of caffeine intoxication, caffeine consumption can precipitate an anxiety disorder. A caffeine-induced anxiety disorder can be panic disorder, generalized anxiety disorder, social phobia, or obsessive-compulsive disorder, although the patient does not need to fulfill all criteria for one of these disorders to quality for a diagnosis of caffeine-induced anxiety disorder. There has been no research examining this specific DSM-defined caffeine-related disorder, although there have been numerous investigations examining the anxiogenic effects of caffeine and case reports of caffeine-related anxiety disorders. In general, patients with anxiety disorders or anxiety sensitivity report greater anxiety than control subjects after consuming caffeine. Even among individuals who do not have an anxiety disorder, a sufficiently high dose of caffeine can produce panic attacks and increased anxiety ratings. First-degree relatives of patients with panic disorder also show an anxiogenic response to a high dose of caffeine. Polymorphisms in the *ADORA2A* gene are associated with anxiogenic responses to caffeine. Some studies have found that individuals with anxiety disorders, such as panic disorder, use lower levels of caffeine than healthy controls. However, some studies have failed to show a relationship between anxiety disorders and caffeine use, while others have found a relationship between greater caffeine use and anxiety disorders. It seems reasonable to conclude that some but not all individuals with anxiety disorders will spontaneously limit caffeine exposure, which may contribute to ambiguity within epidemiologic data associating caffeine consumption and anxiety disorders.

Telegram: @medical_k

www.konkur.in

Table 11.4–4.
Caffeine Modification Guidelines

Telegram: @medical_k

www.konkur.in

1. *Education*
   Patients should be educated about potential sources of caffeine. Provide patients with a list of common caffeinated products (c.f. Table 11.4–2). It may be helpful to point out that caffeine is present in some noncola soft drinks, foods, and over-the-counter medications and to emphasize the wide variability in caffeine levels within and across product types.
2. *Self-monitoring*
   Caffeine consumption should be self-monitored for 1–2 weeks to determine a baseline level. Calculate daily caffeine exposure in milligrams, considering the caffeine content of specific products, the serving sizes, and the number of servings. If a self-monitoring period is not feasible, treatment providers can determine a rough estimate of total caffeine consumption via patient report. Patients should continue to self-monitor during the caffeine reduction phase of treatment.
3. *Determine a caffeine modification goal*
   Some individuals may be interested in eliminating caffeine entirely while others may wish to reduce their caffeine consumption. Patients should be advised to set a goal of consuming no more than 50 mg per day or to use caffeine only occasionally (e.g., no more than 2 consecutive days) if they want to avoid withdrawal effects when they go without caffeine.
4. *Determine a dose reduction schedule*
   A gradual reduction schedule should help to minimize or prevent caffeine withdrawal symptoms. A reasonable decrease would be 25% of the baseline dose every week or so until the caffeine reduction or cessation goal is achieved. Reduction strategies can be based on caffeine dose in milligrams or number of beverages/servings, as long as all sources of caffeine in the diet have been considered. Caffeinated beverages can either be gradually omitted or can be mixed with decaffeinated beverages with the ratio of caffeinated product decreasing over time.
5. *Offer treatment advice and follow-up*
   Patients may benefit from behavior modification techniques that

Telegram: @medical_k

www.konkur.in

are effective in the treatment of other substance use disorders (e.g., nicotine). Such techniques may include self-monitoring, coping response training, reinforcement for abstinence, identifying barriers to change, social support, and framing withdrawal as a temporary inconvenience. Follow-up with patients to check on their progress.

The diagnosis of caffeine-induced anxiety disorder depends on linking the use of caffeine to the anxiety symptoms of concern. For a patient with a suspected caffeine-induced anxiety disorder, a trial of caffeine abstinence may aid in clarifying the diagnosis. Caffeine-induced anxiety disorder should be diagnosed in patients with caffeine intoxication only if the anxiety disturbance is in excess of that which would be expected from intoxication. Other diagnoses to consider include caffeine intoxication, a primary anxiety disorder, and an anxiety disorder due to a general medical condition.

Telegram: @medical_k

www.konkur.in

Mr B was a 28-year-old single African American male graduate student who was in good health and had no history of previous psychiatric evaluation or treatment. He took no medications, did not smoke cigarettes or consume alcohol, and had no current or past history of illicit drug use. His chief complaint was that he had begun feeling mounting “anxiety” when working in the laboratory where he was pursuing his graduate studies. His work had been progressing well, he felt his relationship with his advisor was good and supportive, and he could not identify any problems with staff or peers that might explain his anxiety. He had been working long hours but found the work interesting and had recently had his first paper accepted for publication.

Despite these successes, he reported feeling a “crescendoing anxiety” as his day would progress. He noted that by the afternoon, he would be experiencing palpitations, bursts of his heart racing, tremors in his hands, and an overall feeling of “being on the edge.” He also noted a nervous energy in the afternoons. These experiences occurred daily and seemed confined to the laboratory (although he admitted he was in the laboratory every day of the week).

When reviewing Mr B’s caffeine intake, it was found that he was consuming large amounts of coffee. Staff made a large urn of caffeinated coffee each morning, and Mr B routinely started with a large mug of coffee. Over the course of the morning, he would consume three to four mugs of coffee (the equivalent of about six to eight 6-oz cups of coffee), and continued this level of use throughout the afternoon. He occasionally had a single can of caffeinated soft drink and used no other forms of caffeine regularly. Mr B estimated he drank a total of six to eight or more mugs of coffee per day (which was estimated to be at least 1,200 mg of caffeine per day). Once pointed out to him, he realized this level of caffeine consumption was considerably higher than at any other time in his life. He admitted he liked the taste of coffee and felt a burst of energy in the morning when he drank coffee that helped him start his day.

Telegram: @medical_k

www.konkur.in

Mr B and his physician developed a plan to decrease his caffeine use by tapering off caffeine. (Details of such a tapering schedule can be found in the section on treatment below.) Mr B was successful in decreasing his caffeine use and had good resolution of his anxiety symptoms once his daily caffeine use had been markedly decreased.

Treatment

There are no studies on the treatment of caffeine-induced anxiety disorder. However, one study reported significant improvements in anxiety symptoms among patients seeking treatment at an anxiety disorders clinic who had been instructed to cease caffeine use for 1 week. Notably, some patients required no additional treatment and had successful discontinuation of anxiolytic medications. In cases of suspected caffeine-induced anxiety disorder, clinicians may want to avoid the use of anxiolytic medications until caffeine use has been eliminated. Clinicians should also be aware that some patients may be hesitant about eliminating caffeine and may express skepticism about the role of caffeine in their anxiety symptoms. In such instances, clinicians should try to encourage patients to take an empirical approach and attempt a caffeine abstinence trial. Gradual reduction is recommended to avoid the aversive effects of caffeine withdrawal (see “Caffeine Withdrawal” section below). General guidelines for caffeine modification can be seen in Table 11.4–4.

CAFFEINE-INDUCED SLEEP DISORDER

Caffeine-induced sleep disorder is characterized by a prominent sleep disturbance (e.g., insomnia, hypersomnia, parasomnia, or mixed) that is etiologically related to caffeine use. Caffeine use is most frequently associated with insomnia. Caffeine-induced sleep disorder should be diagnosed in patients with caffeine intoxication only if the sleep disturbance is in excess of that which would be expected from intoxication. Other diagnoses that should be considered in the differential diagnosis of caffeine-induced sleep

Telegram: @medical_k

www.konkur.in

disorder include caffeine intoxication and caffeine withdrawal, sleep disturbances due to another mental disorder, a primary sleep disorder, and a sleep disorder due to a general medical condition.

Although there are no studies directly examining DSM-defined caffeine-induced sleep disorder, there has been a great deal of research on the relationship between caffeine use and sleep. The closer caffeine is taken to bedtime, the more likely it is to produce disruptive effects on sleep. It has been shown that consuming 200 mg of caffeine before bedtime (the equivalent of about 12 oz of brewed coffee) delays sleep onset and reduces sleep efficiency and total sleep time. Other studies have shown that 200 mg of caffeine taken early in the day can disrupt that evening's sleep.

Sleep disturbances secondary to caffeine use are more likely in people who are not regular consumers of caffeine. Regular caffeine consumers develop some tolerance to the sleep-disrupting effects of caffeine; however, because this tolerance is incomplete, they still may be vulnerable to caffeine-related sleep problems. Genetic factors may also underlie individual differences in the sleep-disruptive effects of caffeine. A polymorphism in the *ADORA2A* gene has been identified as being associated with differential responses to caffeine's effects on both subjective and objective measures of sleep.

It should be noted that caffeine can help to prevent unwanted sleep (e.g., such as when driving long distances) and can have beneficial effects when a person is sleep deprived. Studies have shown that sleep deprivation is associated with decrements in performance on a variety of tasks. Caffeine can reduce these performance decrements but does not completely reverse them.

Treatment

There are no studies on the treatment of caffeine-induced sleep disorder. In cases of suspected caffeine-induced sleep disorder, clinicians may want to discourage the use of sleep medications until caffeine use has been eliminated. Although patients may be reluctant to eliminate caffeine, clinicians should try to encourage

Telegram: @medical_k

www.konkur.in

patients to attempt a caffeine abstinence trial to rule out an etiologic role of caffeine in sleep problems (see Table 11.4–4).

CAFFEINE WITHDRAWAL

It is well documented that chronic caffeine consumption produces physical dependence, which manifests as a characteristic withdrawal syndrome when caffeine consumption is abruptly discontinued or substantially reduced. Caffeine withdrawal is a diagnosis in DSM-5-TR, ICD-10, and ICD-11.

Epidemiology

Studies have examined the incidence of caffeine withdrawal under conditions in which it is experimentally induced. In one study of community volunteers whose average daily caffeine consumption was like that of the general population, 52% of the subjects developed a moderate or severe headache when caffeine withdrawal was experimentally induced under double-blind conditions. Other studies have found that half or more subjects experience symptoms of caffeine withdrawal under double-blind acute abstinence. Symptoms may be detected sooner and be rated as more severe under naturalistic conditions in which individuals are aware that they have missed their usual caffeine dose.

In the United States, it is estimated that more than 85% of the adult population are regular consumers of caffeine, suggesting that there are large numbers of people who potentially could experience caffeine withdrawal. However, there have been relatively few attempts to conduct large-scale population-based assessments of caffeine withdrawal. Studies most often involve convenience samples and have reported caffeine withdrawal rates ranging anywhere from 8% to 58%. In one population-based survey, 71% of individuals who tried to stop using caffeine reported experiencing DSM-IV-TR—defined withdrawal symptoms, and 24% reported having headache plus other symptoms that interfered with performance. In a sample of individuals seeking treatment for

Telegram: @medical_k

www.konkur.in

problematic caffeine use, 96% reported experiencing caffeine withdrawal symptoms upon abstinence. Headache was the most frequently endorsed criterion (i.e., 89%), and 43% of the sample reported that caffeine withdrawal caused functional impairment (e.g., missing work). Caffeine withdrawal has been documented among individuals fasting for medical procedures or religious observances (e.g., fasting during Ramadan, giving up coffee for Lent). Caffeine withdrawal has also been documented in children and adolescents and in neonates born to mothers who consumed large amounts of caffeine during pregnancy. Those who chronically use caffeine-containing analgesics may also be at increased risk of experiencing caffeine withdrawal upon abstinence.

Comorbidity

According to DSM-5-TR, caffeine withdrawal may be associated with major depressive disorder, panic disorder, general anxiety disorder, antisocial personality disorder, alcohol use disorder, and cannabis and cocaine use.

Diagnosis and Clinical Features

A review of the research literature on caffeine withdrawal summarized caffeine withdrawal signs and symptoms reported in 66 studies (Table 11.4–5). Symptoms that were deemed to have the strongest empirical basis included headache, fatigue/drowsiness, difficulty concentrating, mood disturbances (e.g., dysphoric mood, depressed mood, or irritability), and flu-like symptoms (e.g., nausea, vomiting, and muscle pain/stiffness). These five symptom categories are those that appear in the DSM-5-TR. In the DSM-5-TR, a diagnosis is made when a patient experiences symptoms in three or more of these symptom categories along with clinically significant distress or impairment after abrupt cessation or a reduction in caffeine use. Patients can experience withdrawal symptoms even without a concurrent headache, suggesting that the other features of caffeine withdrawal are not simply secondary to the headache. Anxiety was a proposed symptom in the DSM-IV-TR, but anxiety was

Telegram: @medical_k

www.konkur.in

omitted from DSM-5 and DSM-5-TR because it is rarely observed in double-blind studies of caffeine withdrawal. Anxiety may be present under naturalistic conditions in which individuals know that they have missed a usual caffeine dose and anticipate withdrawal symptoms. Other withdrawal signs and symptoms that have been reported in the scientific literature are listed in Table 11.4–5. It is important to note that patients may be unaware of their physical dependence on caffeine and under conditions of caffeine abstinence may misattribute symptoms of caffeine withdrawal to other causes (e.g., illness such as influenza or sleep deprivation).

Table 11.4–5.
Empirically Validated Signs and Symptoms Resulting from Caffeine Abstinence

Strong Evidence	Suggestive Evidence
Headache	Decreased desire to socialize
Tiredness/fatigue	Unmotivated for work
Decreased energy/activeness	Decreased self-confidence
Decreased alertness/attentiveness	Yawning
Drowsiness/sleepiness	Heavy feelings in arms and legs
Decreased contentedness/well-being	Craving/strong desire to use
Depressed mood	Analgesic use
Difficulty concentrating	Increased nighttime sleep quality/duration
Irritability	Impaired behavioral and cognitive performance
Muzzy/foggy/not clearheaded	Decreased motor activity
Flu-like symptoms	Increased cerebral blood flow
Nausea/vomiting	Electroencephalogram (EEG) changes
Muscle pain/stiffness	

Data from Juliano LM, Griffiths RR. A critical review of caffeine withdrawal: Empirical validation of symptoms and signs, incidence, severity, and associated features. *Psychopharmacology.* 2004;176:1–29. doi:10.1007/s00213-004-2000-x.

Caffeine Withdrawal Headache. Headache is a hallmark symptom of caffeine withdrawal. It is usually described as a generalized, throbbing headache that is sensitive to movement and worsened by exercise and the Valsalva maneuver. Headache

Telegram: @medical_k

www.konkur.in

typically begins 12 to 24 hours after last ingesting caffeine, although the onset can occur up to 40 hours after the last dose. It usually resolves in 2 to 4 days, although there have been reports of a protracted headache up to 21 days after caffeine cessation. Caffeine consumption usually rapidly (30 to 60 minutes) alleviates a caffeine withdrawal headache.

Headache is a frequent postoperative symptom. Patients undergoing operative procedures are sometimes required to abstain from all oral intakes prior to the procedure, including their usual daily caffeine. Studies indicate that caffeine withdrawal plays an etiologic role in postoperative headache. Greater caffeine use is associated with a greater risk of postoperative headache in a dose-related fashion. Furthermore, caffeine users given caffeine on the day of the surgical procedure have lower rates of postoperative headache than those given placebo.

Caffeine Withdrawal and Caffeine Dose. Higher daily doses of caffeine are associated with greater probability and greater severity of withdrawal. However, it should be noted that caffeine withdrawal can occur after ingestion of relatively low dosages of caffeine, such as 100 mg per day (the equivalent of about 6 oz of brewed coffee). Caffeine withdrawal can also develop after as few as 3 days of exposure to moderate doses of caffeine (e.g., 300 mg per day). Ingestion of low doses of caffeine (e.g., 25 mg) may lessen the severity of caffeine withdrawal among those who typically consume moderate doses of caffeine.

Severity of Caffeine Withdrawal. Caffeine withdrawal severity can vary from mild (e.g., slight fatigue) to severe (e.g., the worst headache ever experienced). A review of caffeine withdrawal studies found that the incidence of clinically significant impairment in functioning (e.g., unable to work) during caffeine withdrawal ranged from 10% to 55% depending on the study, with a median rate of 13%.

Differential Diagnosis

Telegram: @medical_k

www.konkur.in

Several disorders should be considered in the differential diagnosis of caffeine withdrawal. Caffeine withdrawal can mimic migraine and other headache disorders, viral illnesses, sinus conditions, tension, other drug withdrawal states (e.g., from amphetamines, cocaine), and medication side effects. The final determination of caffeine withdrawal should rest on an evaluation of the pattern and amount of caffeine consumption, the time interval between the last ingestion of caffeine and the onset of symptoms, and the clinical features presented by the patient. Attenuation of symptoms by a dose of caffeine may also be useful in clarifying the diagnosis.

Course and Prognosis

Caffeine withdrawal typically begins 12 to 24 hours after the last dose of caffeine and usually resolves in 2 to 9 days. Most symptoms peak within the first 48 hours of caffeine abstinence. However, it should be noted that there can be considerable variability across individuals in the manifestations, severity, and time course of caffeine withdrawal. Furthermore, it has been shown that the same person can experience different symptoms and different degrees of severity of symptoms across different episodes of caffeine withdrawal.

Treatment

There has been little work done in systematically investigating the optimal treatment for caffeine withdrawal. The symptoms of caffeine withdrawal typically resolve within 30 to 60 minutes of caffeine ingestion. A person with a provisional diagnosis of caffeine withdrawal who continues to be symptomatic after caffeine consumption has been terminated for more than 2 weeks should be carefully re-evaluated. Caffeine withdrawal headaches may also respond to aspirin or other analgesics. If caffeine withdrawal occurs because a person is attempting to cease caffeine use, the clinician may want to advise the patient to taper caffeine consumption over time to lessen withdrawal severity. Caffeine modification strategies are outlined in Table 11.4–4.

www.konkur.in

Ms E was a 32-year-old single White woman employed full time at a local factory. She occasionally used nonsteroidal anti-inflammatory drugs but was taking no regular prescription medications. She had a history of alcohol use disorder, in remission for 9 years, and was otherwise in good health. She first began consuming caffeine when she started college, and her current beverage of choice was coffee. She typically drank four to five mugs of coffee each day, and preferred to drink it without cream, milk, or sugar. She estimated that 5 minutes elapsed between the time she got up in the morning and the time she had her first cup of coffee; her roommate made a pot before Ms E got up, and Ms E immediately poured a mug when she got out of bed. She spaced her mugs over the course of the day, with her last mug either after lunch or with dinner. Physicians had recommended she cut down or stop her coffee use because of complaints of mild indigestion, but she had been unable to do so. Her roommate had also complained about her coffee use at times. Ms E routinely drank hot coffee in her car and had spilled it and burned herself on one occasion. When she had stopped caffeine abruptly, Ms E experienced marked irritability; poor concentration; and a severe, generalized headache. When asked to rate the severity of the headache, she replied that “on a scale of 1 to 10 it’s a 12.” She also had muscle aches, low energy, lethargy, and a craving to drink a mug of coffee. On the day that she had stopped coffee use abruptly, she left work 2 hours early because of problems with concentrating on the job and went to bed several hours earlier than usual. She then returned to her usual pattern of coffee use.

CAFFEINE USE DISORDER

Caffeine use disorder is defined as a cluster of physiologic, behavioral, and psychological symptoms indicative of problematic caffeine use along with difficulty controlling use despite a desire to

Telegram: @medical_k

www.konkur.in

do so. Several research studies have identified adults and adolescents with problematic caffeine use characteristic of caffeine use disorder. In the DSM-5-TR, caffeine use disorder is included as a condition for further study. The DSM-5 workgroup acknowledged the existing body of evidence supporting caffeine use disorder as a clinically significant condition, but also sought to generate additional research to determine its reliability, validity, and prevalence. They also recognized a particular need to associate a diagnosis of caffeine use disorder with clinical distress and functional impairment. The provisional diagnostic framework proposed parallels other SUD diagnoses with a few key exceptions. An SUD diagnosis (referred to in prior editions of the DSM as “substance abuse” or “substance dependence”) requires fulfilling at least two of a constellation of diagnostic criteria that are linked by the theme of problematic use of the drug. The DSM-5-TR-proposed criteria for caffeine use disorder contain a much more restrictive set of criteria than the DSM-5-TR SUD criteria that apply to other drugs (see “Diagnosis and Clinical Features”). Following the inclusion of caffeine use disorder as a diagnosis for further study in DSM-5, additional research has associated caffeine use disorder with distress and functional impairment, and clinical trials have evaluated effective behavioral interventions. It will be important for future research to further characterize the features and prevalence of caffeine use disorder, its clinical significance and prognosis, associated features, and effective treatment strategies to inform the next DSM and clinical practice.

Epidemiology

Caffeine use is common throughout the world. In the United States, more than 85% of persons aged 2 years and older consume caffeine on a given day. Daily caffeine consumption among adult caffeine consumers has been estimated to be upward of 200 mg per day, with approximately 14% consuming more than 400 mg of caffeine per day (the equivalent of about four 6-oz cups of brewed coffee). Given the substantial number of people who consume caffeine regularly and their use of daily dosages that produce mood-altering

Telegram: @medical_k

www.konkur.in

effects, even a very low prevalence rate of caffeine use disorder could represent a nontrivial number of people. A growing number of studies have examined the prevalence of caffeine use disorder in general population samples. For example, a recent online study among adult caffeine consumers in the United States found that 8% of participants met DSM-5-TR-proposed criteria for caffeine use disorder (see “Diagnosis and Clinical Features”). Those who met these criteria reported significantly greater caffeine-related distress and were more likely to report functional impairment due to withdrawal or a physical or psychological problem caused by caffeine relative to those who did not meet the proposed criteria. Other research studies among general samples of adults in the United States, Italy, and Hungary estimated the prevalence of caffeine use disorder (as defined by the three key diagnostic criteria proposed by DSM-5-TR or similar criteria from prior editions) range from 9% to 13%. Studies among persons seeking treatment for problematic caffeine use have found that 72% to 84% of participants meet the key diagnostic criteria found in the DSM-5-TR. The prevalence of problematic caffeine use may be higher among special populations including heavy caffeine consumers, college students, psychiatric patients, and persons with a history smoking, alcohol, or other drug use. Additional data among nationally representative samples and special populations of interest, such as psychiatric patients, will provide further information about the prevalence of caffeine use disorder and associated distress.

Comorbidity

Conditions associated with high levels of caffeine consumption are discussed in the caffeine intoxication section above. Published reports among persons meeting criteria for caffeine use disorder provide support for common comorbidities of alcohol use disorder, cigarette smoking, mood and anxiety disorders, and sleep disorders. For example, in a detailed evaluation of 16 adults with a DSM-IV—defined substance dependence disorder *when applied to caffeine*, about two-thirds had a past history of a psychiatric disorder in

Telegram: @medical_k

www.konkur.in

remission, most commonly SUDs followed by mood or anxiety disorders and eating disorders. Multiple studies have observed a clustering of problematic caffeine use, cigarette smoking, and a history of alcohol use disorder in a subset of subjects, consistent with the known shared genetic vulnerability of these substances. A survey study among U.S. adults found that those with DSM-5-TR—defined caffeine use disorder had greater scores on a general measure of depression, anxiety, and stress, and reported greater sleep problems relative to those who did not meet criteria. Survey respondents who met criteria for caffeine use disorder named anxiety and insomnia as the two most common psychological and physical problems caused or exacerbated by caffeine. The association of broader features of caffeine use disorder, such as the development of tolerance and withdrawal, with multiple psychiatric disorders (e.g., major depression, generalized anxiety disorder, panic disorder) and SUDs (alcohol, cannabis, cocaine) in a large sample of twins provides further evidence of shared vulnerability between caffeine-related problems and other psychiatric conditions.

Diagnosis and Clinical Features

ICD-10 previously recognized caffeine dependence as a diagnosis, but ICD-11 does not include a specific SUD related to caffeine. Nevertheless, caffeine use disorder could be characterized with ICD-11 as a “disorder due to use of caffeine” with a “harmful pattern of caffeine use,” or “other unspecified disorders due to use of caffeine.” As stated previously, caffeine use disorder is listed as condition for further study in DSM-5-TR, and symptoms characteristic of caffeine use disorder could be categorized as unspecified caffeine-related disorder according to DSM-5-TR. Caffeine use disorder as proposed by DSM-5-TR includes nine criteria; however, endorsement of the following three specific criteria is necessary for a diagnosis: (1) a persistent desire or unsuccessful efforts to cut down or control caffeine use; (2) continued caffeine use despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by caffeine; and (3)

Telegram: @medical_k

www.konkur.in

withdrawal, as manifested by either: (a) the characteristic withdrawal syndrome for caffeine, or (b) caffeine (or a closely related substance) being taken to relieve or avoid withdrawal symptoms. The restrictive criteria for caffeine use disorder put forward by DSM-5-TR can be compared with a DSM-5-TR diagnosis of SUD for drugs other than caffeine, which requires the endorsement of only 2 of 11 possible criteria. The aim of using more restrictive criteria for caffeine use disorder is to limit the diagnosis to the most clinically important cases of problematic caffeine use. The nine possible criteria for caffeine use disorder overlap with other SUD criteria, except for two features that DSM-5-TR excluded for caffeine, specifically: (a) important social, occupational, or recreational activities given up or reduced because of substance use or (b) recurrent use of substance in situations in which it is physically hazardous. Because the criteria for caffeine use disorder are still evolving, more information is needed about the extent to which the proposed criteria and closely related criteria for SUD appropriately characterize those with caffeine-related distress or functional impairment. Initial item response analysis of the DSM-proposed diagnostic criteria for caffeine use disorder found that craving and use of more caffeine/use over a longer period than intended were commonly endorsed by study participants but were less informative with respect to caffeine use disorder severity. By contrast, failure to fulfill major role obligations and persistent or recurrent social or interpersonal problems resulting from caffeine use were less commonly endorsed but were characteristic of high caffeine use disorder severity. Individuals who consume higher daily amounts of caffeine may be more likely to meet criteria for caffeine use disorder, but caffeine use disorder has been associated with a wide range of daily caffeine use and primary sources of caffeine. For example, one study involving individuals seeking treatment for caffeine use (84% diagnosed with caffeine use disorder) observed caffeine use ranging from 200 to 2,667 mg daily. Persons meeting criteria for caffeine use disorder have been found to be consumers of coffee, tea, soft drinks, energy drinks/shots, or a combination of sources.

Telegram: @medical_k

www.konkur.in

Differential Diagnosis

Habitual use of caffeine is so commonplace that many clinicians do not recognize caffeine as a substance capable of producing problematic outcomes. Because of this, caffeine consumption is not routinely assessed, and a clinical syndrome of caffeine use disorder may be easy to overlook. Other SUDs and related syndromes should be included in the differential diagnosis of caffeine use disorder, such as intoxication or withdrawal related to other stimulant drugs. Symptoms of caffeine use disorder overlap with diagnoses of DSM-defined caffeine intoxication and caffeine withdrawal, which should also be considered in the differential diagnosis. Because anxiety and sleep disturbance have been commonly reported as problems caused or exacerbated by caffeine use by those who meet diagnostic criteria for caffeine use disorder, the presence of underlying anxiety disorders and sleep disorders should also be evaluated.

Course and Prognosis

The natural course and prognosis for patients with a diagnosis of caffeine use disorder is not known. Continued use of caffeine despite repeated efforts to discontinue caffeine use is one of the key characteristics of caffeine use disorder. Although clinical trials implementing gradual caffeine reduction programs have shown success in sustained reductions in caffeine use (see “Treatment”), relapse to caffeine use after treatment has also been observed. This suggests that caffeine use disorder may be characterized as a chronic relapsing disorder like use disorders associated with other drugs.

Treatment

Current recommendations for addressing caffeine use disorder include caffeine reduction to mitigate the effects of physical or psychological problems caused or worsened by continued caffeine use. Gradual caffeine reduction over a period of weeks is recommended to avoid the potential aversive effects of withdrawal

Telegram: @medical_k

www.konkur.in

that can occur with sudden caffeine cessation, especially among heavy consumers. Although clinicians may recommend that patients modify caffeine use for various conditions (e.g., anxiety, insomnia, tachycardia, pregnancy), they may not realize that caffeine modification may be challenging for some patients. In fact, individuals diagnosed with caffeine use disorder have reported being unable to follow their doctors' recommendations to modify caffeine use. Thus, it should not be assumed that clinician suggestion to modify caffeine use will be sufficient for successful behavior change. Patients may not be aware of all sources of caffeine in their diet and patient education may be necessary. Effective strategies for caffeine reduction may include education about the effects of caffeine and common sources of caffeine, self-monitoring of daily use, coping response training, social support, and reinforcement for decreased use. SUD treatment approaches such as relapse prevention and motivational interviewing could also be applied to the treatment of caffeine use disorder. Two randomized clinical trials among persons seeking treatment for caffeine use evaluated the effectiveness of a manualized brief intervention for caffeine reduction over a period of 6 weeks. One study included a 1-hour counselor-guided session to introduce the treatment manual, caffeine diary, weekly caffeine goals, and cognitive behavioral strategies for caffeine reduction, whereas the other study presented the treatment manual to the participant very briefly (i.e., less than 5 minutes) and the participant implemented caffeine reduction independently. The treatment manual provided to the participants consisted of facts and information about caffeine, strategies for caffeine reduction based on the principles of relapse prevention, a caffeine diary, and instructions on calculating weekly caffeine goals during caffeine reduction. Both studies observed sustained reductions in caffeine use following treatment relative to a waitlist control group. Although the success of the self-implemented manualized intervention for caffeine reduction is promising for practical application, there may well be persons with more complex presentations of caffeine use disorder with psychiatric and medical comorbidities that would benefit from additional psychosocial and medical support. These initial studies have

Telegram: @medical_k

www.konkur.in

provided evidence that caffeine reduction improves DSM-defined caffeine-related distress; however, more information is needed to evaluate the potential benefits of caffeine reduction on common comorbid symptoms such as anxiety and sleep, as well as to evaluate the efficacy of the intervention in special populations. Table 11.4–4 provides suggested guidelines for caffeine use modification.

Ms G is a 38-year-old female who is married with four children. She works part time as a dental assistant. Ms G presented to the primary care clinic with flu-like symptoms. She complained of nausea, heavy feelings in her arms and legs, muscle aches, and extreme lethargy. She also said she had a pounding headache that was one of the worse headaches she had ever experienced. Ms G said that her symptoms began around 2 PM the day prior and she left work early because she could no longer function. She called her mother to help care for her school-aged children as her husband was away on a business trip. Upon examination, Ms G's heart rate and blood pressure were within normal limits and she was afebrile. An assessment of Ms G's caffeine use revealed that she consumes three cups of black drip coffee each morning. Ms G reported that she had not had caffeine the last two mornings because she had given it up for Lent. Ms G said that she was unaware of her physical dependence on caffeine because she hadn't gone more than a day without caffeine since her last pregnancy 9 years ago. Ms G was diagnosed with caffeine withdrawal syndrome. Ms G chose to drink a small cup of coffee and her symptoms resolved after approximately 45 minutes.

Telegram: @medical_k

www.konkur.in

Ms S is a 45-year-old Caucasian female who presented for assistance with problematic caffeine consumption, or what she described as her “caffeine addiction.” Ms S is married and has two elementary school—aged children and works full time as a nurse for a large research hospital. She takes no prescription medications, does not smoke, and has no history of psychiatric problems. She reports occasionally drinking alcohol on the weekends. She reports having tried marijuana a few times in college and has no other history of illicit drug use. She began regularly consuming caffeinated beverages while in college, and her consumption increased to its present levels during nursing school. Her primary source of caffeine comes from diet cola, which she consumes daily. She reports drinking coffee or tea only on occasion (e.g., when dining with friends). Ms S has her first soft drink within 5 minutes of waking up in the morning and then continues drinking diet colas throughout the day until around 6 to 8 PM in the evening. She typically consumes a total of eight 20-oz diet cola bottles each day, the equivalent of about 600 mg of caffeine. She and her husband have argued about her soft drink use in the past, especially during her pregnancies. However, she continued to consume diet colas during both of her pregnancies. Ms S described having attempted to give up diet cola many times, with her most recent attempt a few years prior. She said that after going cold turkey on the first day of Lent, she experienced excruciating headaches, extreme fatigue, irritability, and an inability to function properly at work. She said that she returned to drinking diet colas after 3 days of “misery.” Ms S reports that her motivation for ceasing her diet cola consumption at this time is health related. She is having increasing difficulties with urinary incontinence and, furthermore, feels that her diet cola consumption is generally not healthy. She is also presently complaining of sleep difficulties and anxiety that she attributes to the ailing health of her mother, although she acknowledged that her caffeine use could also be contributing to these symptoms. Ms S reported that she was interested in completely eliminating

Telegram: @medical_k

www.konkur.in

diet cola from her diet rather than reducing her consumption. Ms S and the therapist developed a schedule to gradually reduce her soft drink consumption over a period of 4 weeks and completely eliminating soft drinks on week 5 (i.e., six bottles to four bottles to two bottles to one bottle to zero bottles). The therapist provided a booklet that described the effects of caffeine and caffeine withdrawal, and that contained tips for how to cope with temptations to consume caffeine and caffeine withdrawal symptoms should they occur. Ms S was advised to substitute noncaffeinated drinks during the times that she normally consumed diet colas, and she identified carbonated water as a desirable alternative. A follow-up appointment was scheduled for 5 weeks later. At the 5-week follow-up, Ms S reported that she had reduced her consumption to two 12-oz diet colas per day. At the 6-month follow-up, Ms S reported having "been off" diet colas for the past 3 months. She reported having headaches for the first few days after abstaining from caffeine but that they were tolerable, especially if she took ibuprofen. Ms S reported that her problems with urinary incontinence and poor sleep had both improved, and she felt confident that she could continue to refrain from diet cola consumption.

Caffeine Use and Nonpsychiatric Illnesses. Numerous studies examining the relationship between caffeine use and physical illness have not identified any significant health risk from nonreversible pathologic consequences of caffeine use, such as cancer, heart disease, or human reproduction. However, caffeine use is often considered to be contraindicated for various conditions, including generalized anxiety disorder, panic disorder, primary insomnia, gastroesophageal reflux, urinary incontinence, and pregnancy. In addition, the modest ability of caffeine to increase blood pressure and the documented cholesterol-elevating compounds in unfiltered coffee have raised the issue of the relationship of caffeine and coffee use to cardiovascular disease. Finally, there may be a modest association between higher daily caffeine use in women and delayed

Telegram: @medical_k

www.konkur.in

conception, higher rates of miscarriage and stillbirth, and lower birth weight. However, there are studies that have not found such associations, and effects when found are usually with relatively high daily doses of caffeine (e.g., the equivalent of five cups of brewed coffee per day). For a woman who is considering pregnancy, especially if there is some difficulty in conceiving, it may be useful to counsel elimination of caffeine use. Similarly, for a woman who becomes pregnant and has moderate-to-high daily caffeine consumption, a discussion about decreasing her daily caffeine use may be warranted. Caffeine may possibly offer protective effects against some diseases, most notably Parkinson disease.

11.5 Cannabis-Related Disorders

Janni Leung, Ph.D., Wayne D. Hall, Ph.D., and Louisa Degenhardt, PH.D.

Cannabis is the most widely used illicit drug in the world, with an estimated 192 million past-year users worldwide in 2018 (3.9% of the global adult population). The global prevalence of cannabis use disorder is 0.3%, which is 23.8 million people. Over the past 50 years, cannabis use has become part of youth culture in many developed societies, with first use occurring in the mid- to late teens.

Telegram: @medical_k

www.konkur.in

Cannabis is the fourth most commonly used psychoactive drug among adults in the United States, after caffeine, alcohol, and nicotine.

HISTORY

Cannabis preparations are obtained from the plant *Cannabis sativa*, which has been used in China, India, and the Middle East for approximately 8,000 years, primarily for its fiber and secondarily for its medicinal properties. Cannabis was introduced to Europe in the early 19th century by Napoleon's army returning from Egypt, and later in the same century to Britain for medical use by an Irish surgeon on his return from India. Cannabis was most often used in Europe for fiber and, to a lesser extent, for therapeutic purposes. It was first used recreationally by Parisian bohemians in the late 19th century.

Recreational cannabis use was introduced to the United States in the 1930s from Mexico and spread via jazz musicians to cities in the Northeastern United States. Its use was banned in the United States in 1937 and most other developed countries in 1961 under the UN Single Convention on Narcotic Drugs. Recreational cannabis use among bohemians in the United States in the 1940s and 1950s spread to the U.S. youth population in the late 1960s. Use increased dramatically in the United States during the 1970s before peaking in the early 1980s. It then declined until the early 1990s and stabilized at a lower level before beginning to increase among adults in the 2010s.

In the 1990s and 2000s, citizen-initiated referenda legalized the use of cannabis for medical purposes in around half the states of the United States. Recreational cannabis use was legalized by state referenda in Colorado and Washington State in 2012, Alaska and Oregon in 2014, and since then, in 15 states. To date, these policy changes have had minimal effects on cannabis use and cannabis-related harm in the United States, but this may change as cannabis is fully commercialized if legalization becomes national U.S. policy.

CANNABIS PREPARATIONS

The cannabis plant occurs in male and female forms. The female plant contains the highest concentrations of more than 100 cannabinoids unique to the plant. Delta-9-tetrahydrocannabinol (THC) is the cannabinoid that is primarily responsible for the psychoactive effects of cannabis. It is found in the resin that covers the flowering tops and upper leaves of the female plant. Most of the other cannabinoids are either inactive or only weakly active, although some, such as cannabidiol (CBD), may modulate the effects of THC and may have therapeutic uses.

Until recently in the United States, the most common cannabis preparations were marijuana, hashish, and hash oil. Marijuana is prepared from the dried flowering tops and leaves of the plant. Its potency depends on the growing conditions, the genetic characteristics of the plant, the ratio of THC to other cannabinoids, and the part of the plant that is used. The flowering tops have the highest THC concentration, with much lower concentrations in the leaves, stems, and seeds. Varieties of cannabis cultivated for hemp fiber usually contain very low levels of THC. Cannabis plants may be grown to maximize their THC production by the sinsemilla method (“without seed”), in which only female plants are grown together.

Cannabis concentrates or extracts are increasingly commonly used preparations. For example, butane hash oil (BHO), commonly known as honey oil or dabs, is prepared using butane pushed through a container of cannabis trimmings to extract cannabinoids into a honey-like substance. Cannabis resin is prepared by pressing cannabis with heat. THC vape juice and oil are prepared by extracting THC oil from cannabis buds and then adding it to a base liquid.

Cannabis edibles have also increased in popularity. Cannabis may be ground and then baked in the oven or heated with water and oil to make a butter that can be used to prepare sweets. Edibles may also be prepared by adding concentrates to a dish when cooking. Cookies and brownies, gummies, sparkling drinks, tea and coffee, chocolates, and popcorn are some commercial edible products that

Telegram: @medical_k

www.konkur.in

have appeared since U.S. state-level jurisdictions began enacting legalization of medical and nonmedical cannabis use within their borders.

The average concentration of THC in marijuana sold in the United States has increased in recent years, from 0.5% in 1970 to 9% in 2008 and 17% in 2017. The sinsemilla variety may contain as much as over 20% THC. Hashish or hash consists of dried cannabis resin and may contain 2% to 8% THC. Hash oil is obtained by extracting THC from hashish (or marijuana) in oil, and it may contain between 15% to 20% THC. Cannabis extracts and concentrates obtained by chemical processes may contain over 70% THC.

METHODS OF USE

Cannabis has traditionally been smoked as marijuana in hand-rolled cigarettes, or joints, which may include tobacco to assist burning. The use of a water pipe, or bong, is also a popular way to smoke all cannabis preparations, probably because it delivers a larger bolus dose of THC and maximizes the delivery of a given amount of cannabis. Cannabis can also be administered using a vaporizer to avoid the respiratory risks from inhaling the smoke from a cannabis joint.

Hashish may be mixed with tobacco and smoked as a joint or in a pipe, with or without tobacco. Because hash oil is extremely potent, a few drops may be applied to a cigarette or joint, or the oil may be heated and the vapor inhaled. Cannabis users typically inhale the smoke or vapor deeply and hold their breath to maximize the absorption of THC by the lungs.

The oral route of administration may also be used by eating edible cannabis products. In experimental studies, THC is often swallowed in gelatine capsules containing THC dissolved in sesame oil. In India, cannabis may be consumed in the form of *bhang*, a tea brewed from the leaves and stems of the plant. THC is not water soluble and so is not readily injected. Almost all cannabis users in the United States smoked cannabis in joints or used bongs or vaporizers until the 2000s because the chemistry and pharmacology

Telegram: @medical_k

www.konkur.in

of cannabis made smoking or inhaling the most efficient way to obtain THC. Since the legalization of cannabis, first for medical and later recreational use, the vaporization of cannabis flower and concentrates and the use of cannabis edibles has increased.

COMPARATIVE NOSOLOGY

Cannabis use disorder and problematic cannabis use have been topics of considerable research, codified in the most recent editions of the two major diagnostic classification systems. The 11th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-11), released in 2018, includes a diagnosis of cannabis dependence characterized by a strong internal drive to use cannabis manifested by impaired ability to control use, increasing priority given to use over other activities, and persistence of use despite harm or negative consequences. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), released in 2013, includes the category of cannabis use disorders by severity. In 2022, a text revision was released (DSM-5-TR) with no changes for cannabis use disorders. ICD-11 includes a category of *harmful use* that attempts to capture problematic cannabis use that does not satisfy criteria for dependence but nonetheless causes harm. The concordance between ICD-11 and DSM-5 is good for comparisons of dependence and severe cannabis use disorder but poor for comparisons of harmful and mild cannabis use disorder.

EPIDEMIOLOGY OF CANNABIS USE

Prevalence

In the United States, two major annual surveys of illicit drug use have been conducted since the early 1970s. These are the Monitoring the Future nationwide survey of high school seniors, college students, and young adults conducted annually since 1975; and the National Household Survey on Drug Use and Health

Telegram: @medical_k

www.konkur.in

(NHSDUH), which has surveyed household samples of adults annually throughout the United States since 1972.

In 2020, 46.4% of a U.S. national sample of persons aged 12 years and older reported that they had used cannabis at some time in their lives, 21% had done so in the past year, and 11% in the past month (Fig 11.5–1). Lifetime use increased from 16% among those aged 12 to 17 years to 52% in those aged 18 to 25 years, 59% among those aged 26 to 34, and decreased with age to 32% among those aged 65 or older. Rates of discontinuation of use were high: 55% of adults who had used cannabis at some time in their lives had not done so in the past year and 75% had not done so in the past month. Past-month cannabis use was more common among men (14%) than women (9%) and most common among those aged 18 to 25 years (23%).

The NHSDUH series from 1974 to 2000 show that rates of past-month cannabis use increased throughout the 1970s, peaked in 1979, and declined steadily throughout the 1980s to reach their lowest level in 1992 before increasing again after 1995. Between 2007 and 2014, cannabis use declined in the past year and past month; between 2016 and 2019, cannabis in the past-year use increased from 18% to 21%.

The Monitoring the Future project has estimated the prevalence of cannabis use among secondary school students, college students, and young adults since 1975. These surveys have revealed long waves of cannabis use among U.S. adolescents since 1975. Among 18 year olds, lifetime prevalence peaked at 65% in 1980, before falling to nearly half by the early 1990s, but increasing again after that time to 42% in 2006. Prevalence reduced a little through 2007 to 2008, with some rebounds, and then remained relatively stable at around 45% from 2017 to 2020.

Telegram: @medical_k

www.konkur.in

FIGURE 11.5–1. Prevalence of cannabis use by gender and age according to the U.S. National Household Survey on Drug Use and Health (2019). Note: Numbers are per 100 per year. (From SAMHSA. *Key Substance Use and Mental Health Indicators in the United States: Results from the 2019 National Survey on Drug Use and Health*. Center for Behavioral Health Statistics and Quality, Substance Abuse and Mental Health Services Administration; 2020.)

The use of cannabis in the past year among 12th graders peaked at 51% in 1979 and fell to 22% by 1992. It increased to 32% in 2006 and has been around 35% in recent years. Experience with synthetic

Telegram: @medical_k

www.konkur.in

THC (K2/Spice) was uncommon, with 2.4% of 12th graders reporting its use in the past year. Marijuana vaping in the past year has increased rapidly from 10% in 2017 to 22% in 2020. The discontinuation of cannabis use has declined between 1979 to 2020, with fewer of those who had used cannabis 10 or more times ceasing their use by age 18. Among those who have ever tried cannabis, 16% used it on a daily basis in 2020. Most of those who ceased use had not had a great deal of experience with cannabis. Although most users of other illicit drugs also had used cannabis, trends in the use of other illicit drugs were independent of the trends in cannabis use.

Attitudes and Beliefs Toward Cannabis

Changes in young people's beliefs about the risks of cannabis use seem to be responsible for both the reduction in use between 1979 and 1991 and the rise in its use after 1992. There is a strong negative correlation over time between the rates of cannabis use and the perceived risks of using it and perceived disapproval of use by peers. Between 1979 and 1992, a marked increase in perceived risk and a smaller increase in personal disapproval preceded a large decline in use. Perceived risk was relatively steady through the 1990s. Since the 2000s, there have been decreases in the perception that cannabis use is risky among both adolescents and adults. There has also been a reduction in the disapproval of regular cannabis use.

The changes in the perceived risks and benefits of cannabis use have been associated with a steep increase in support for cannabis legalization between 1990 and 2016. Younger males were the most supportive of legalization, while older adults aged 50 and over were the least supportive in the beginning, but the proportion of supporters has steadily increased.

Legalization of cannabis so far has had little impact on the prevalence of uptake in young people. However, people who were already using cannabis have used it more often after legalization,

Telegram: @medical_k

www.konkur.in

probably in response to increased marketing of cannabis products, greater access, and large reductions in cannabis retail prices.

Patterns of Use

Cannabis use is common among young people in many high-income countries. Many young adults in Europe, the United States, Canada, Australia, and New Zealand have tried cannabis. Most stop using in their 20s based on available data, such as those in the United States. Very few engage in daily cannabis use over a period of years. In the United States and Australia, about 10% of those who ever use cannabis become daily users, and another 20% to 30% use weekly. The pattern of use in developed countries differs from that in traditional cannabis-using countries, such as Egypt and India, where recreational cannabis use is uncommon and heavy cannabis use is largely confined to socially marginalized groups in the population.

Only a small proportion of cannabis users use the drug for several years or more. Daily or near-daily use over a period of years is the pattern with the greatest risk of producing adverse health and psychological consequences. Daily cannabis users are more likely to be male and less well educated; they are also more likely to regularly use alcohol and to have experimented with other illicit drugs such as amphetamines and other psychostimulants, hallucinogens, sedatives, and opioids.

Correlates of Cannabis Use

Age. First use of cannabis typically begins in the mid- to late teenage years, and the heaviest use typically occurs in the early 20s. Rates of cannabis use remain relatively high during the early 20s and decline during the late 20s. The majority of young adults who experiment with cannabis have done so by age 18, and in the United States, rates of use have, until recently, declined steadily from the mid-20s into the early 30s. There is some evidence that in recent U.S. cohorts, regular cannabis use is more likely to continue into the 30s. In recent surveys, cannabis use has also become more

Telegram: @medical_k

www.konkur.in

common among older adults aged 65 and older, perhaps in part because of increased use for medical reasons.

Gender. Rates of recreational cannabis use in the user's lifetime, the past year, and the past week are consistently higher among males than females. The same is true for daily use and long-term daily cannabis use. Cannabis use for medicinal reasons is common in both genders, with females more likely to use medicinal cannabis for headaches or migraines, nausea or vomiting, problems sleeping, and anxiety symptoms.

Income. In the United States, cannabis use has been positively correlated with income and paid work in adolescence. However, heavy cannabis use impacts cognitive function and capacity to work. Adolescents who use cannabis regularly have lower educational attainment, limiting their choice of occupation and reducing their income later in life. More recent evidence suggests that the liberalization of cannabis use has shifted regular use toward groups with lower incomes. Cannabis users with lower incomes are more likely to use daily or near daily, be less in control of their use, and spend a larger proportion of their income on cannabis.

Socioeconomic Status. The relationship between cannabis use and socioeconomic status has been weak. Higher rates of cannabis use are sometimes found among individuals from lower socioeconomic status, but in the past two decades, there has been no consistent relationship between parental education and cannabis use among 12th-grade students in the United States. Those whose parents used cannabis are more likely to use cannabis themselves. Variations in the relationship between parental socioeconomic status and cannabis use in their children may be explained by changes in use among different income groups across different periods and cohorts. Since 2000, regular cannabis use has become concentrated among less well-educated Americans without college educations, particularly among blue-collar males.

Telegram: @medical_k

www.konkur.in

Ethnicity. In the Monitoring the Future surveys, adolescent student samples from several years have to be combined to make reliable comparisons of prevalence rates between the three largest ethnic groups. Previously, these have shown that White students had higher rates of cannabis use than African American students. Rates of use by Hispanic students generally fall in between. In recent years, the differences have narrowed as cannabis use has increased among African American and Hispanic students. White students are more likely to have tried synthetic cannabis than African American students, but the highest rates were seen among Hispanic 12th graders. There has been a considerable increase in support for cannabis legalization among all three racial groups during the 2000s, in students and adults, with White and African Americans more likely to support cannabis legalization than Hispanics.

Availability. As a general rule, the more available a drug is, the more often it is likely to be used. This has been true for alcohol consumption: the larger the number of licensed outlets and the longer the hours of trading, the higher the levels of community alcohol consumption and alcohol-related problems. There is limited evidence that this is also the case for cannabis use. Self-reports from surveys on how easy it is to obtain cannabis have shown very little change over long periods of time during which rates of cannabis use have risen and fallen in the United States. The recent legalization of retail cannabis stores and declining cannabis prices have increased availability, but, to date, this has largely increased the frequency of use among current users rather than increased cannabis use in the population.

PHARMACOLOGY OF CANNABINOIDS

Laboratory research with animals and humans has demonstrated that the primary psychoactive constituent in cannabis is THC. THC and other cannabinoid agonists produce their effects by interacting with an endogenous cannabinoid signaling system. There are at least two types of cannabinoid receptors (CB1 and CB2). The CB1

Telegram: @medical_k

www.konkur.in

receptor is found primarily in the brain and mediates the psychological and behavioral effects of THC. The CB2 receptor, located mostly outside the central nervous system, is associated with the immune system and appears to modulate inflammatory responses. CB1 and CB2 receptors belong to a large group of G-protein–coupled receptors, membrane proteins that are involved in modulating chemical signaling between nerve cells via neurotransmitters.

CB1 cannabinoid receptors are found in brain regions known to be involved in mood, motor control, memory formation, regulation of food intake, pain modulation, sleep, and immune and reproductive functions. The fact that cannabis disrupts short-term memory is consistent with the abundance of CB1 receptors in the hippocampus, the brain region most closely associated with memory. The CB1 and CB2 receptors respond to endogenous cannabinoid ligands that occur naturally in the brain. These ligands include anandamide and 2-arachidonyl-glycerol (2AG).

Some active compounds found in cannabis have effects that are independent of cannabinoid receptors and endogenous cannabinoids. For example, both THC and CBD can be neuroprotective through their antioxidative activity. Other likely examples of receptor-independent cannabinoid activity are modulation of activity in membrane-bound enzymes (such as adenosine triphosphatase [ATPase]), arachidonic acid release, and perturbation of membrane lipids. An important caveat is that concentrations of THC or CBD used in studies of cellular effects are generally much higher than the concentrations of THC or CBD that would be achieved in humans who smoke herbal cannabis, although this may change with the increased use of high-potency cannabis products.

A typical joint of between 0.5 and 1.0 g of cannabis contains between 5 and 150 mg of THC. Twenty percent to 70% of the THC is found in the smoke that reaches the lungs; the rest is lost in sidestream smoke. Only 5% to 24% of the THC in a joint reaches the bloodstream when cannabis is smoked. Two to 3 mg of THC will produce a brief high in an occasional user, and a single joint may

Telegram: @medical_k

www.konkur.in

provide enough THC for two or three such users. A heavy cannabis smoker may use five or more joints per day.

Different methods of using cannabis produce differing absorption, metabolism, and excretion of THC. When cannabis is smoked or vaporized, THC is absorbed from the lungs into the bloodstream within minutes. It is first metabolized in the lungs and then in the liver. The metabolite 9-carboxy-THC can be detected in blood within minutes of smoking. Peak blood levels of THC are usually reached within 10 minutes of the first puff and may happen before the end of the smoking session. They rapidly decline to about 5% to 10% of their initial level within an hour as THC is metabolized and distributed to fatty tissues, including the brain.

When swallowed, THC takes 1 to 3 hours to enter the bloodstream, delaying the onset of its psychoactive effects. The metabolite, 11-hydroxy-THC, which is 20% more potent than THC, is found in high concentrations after cannabis is swallowed.

THC and its metabolites are highly fat soluble, so they may remain in the fatty tissues of the body for long periods of time. THC and its metabolites may accumulate in the body of chronic users because of their slow rate of clearance. THC may be detected in the blood for several days, and traces may persist for several weeks; it may be stored in body fat for more than 28 days.

It has been argued that the medical literature may underestimate the adverse health effects of cannabis because it is based on the use of less potent forms of cannabis than those that have become available in the past several decades. The average potency of cannabis has increased along with an earlier age of first use and more regular use of more potent forms of cannabis. The effects of these changes on risks of dependence and acute harms from cannabis use are not yet well characterized.

DIAGNOSTIC AND CLINICAL FEATURES

Cannabis Dependence

Telegram: @medical_k

www.konkur.in

For much of the 1960s and 1970s, cannabis was not regarded as a drug of dependence because it was not believed to produce tolerance or a withdrawal syndrome. The adoption of a broader concept of dependence in the late 1970s and early 1980s reduced the importance of tolerance and withdrawal in defining dependence and placed more emphasis on the compulsion to use, a narrowing of the drug-using repertoire, rapid reinstatement of dependent use after abstinence, and the high salience of drug use in the user's life. Since the 1980s, a cannabis dependence syndrome has been identified as a common experience in regular cannabis users.

Cannabis Use Disorder in DSM-5 or DSM-5-TR. Changes in the DSM-5 or DSM-5-TR criteria from the fourth edition version for cannabis and other drug use disorders raise questions about the relevance of epidemiologic studies that used earlier DSM diagnostic criteria. In earlier versions of the DSM, cannabis abuse and dependence were separate diagnostic categories within the cannabis use disorder category. In DSM-5 and DSM-5-TR, cannabis use disorders are diagnosed consistently without separate criteria for abuse or dependence. Studies that compared how the criteria affect prevalence showed that more people are classified as having moderate to severe cannabis use disorders when using the DSM-5 criteria than the DSM-IV criteria, and a slightly different group is diagnosed.

The National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) study estimated that in 2001 to 2002, 1.5% of U.S. adults met DSM-IV criteria for past-year cannabis use disorders. In 2012 to 2013, the NESARC-III study found that 2.5% of adults in the United States met DSM-5 criteria in the past year. Yearly population surveys conducted by the National Surveys on Drug Use and Health study estimated that, between 2002 to 2017, the past-year prevalence of cannabis use disorders remained stable at around 1.5% based on DSM-IV criteria, while it increased slightly from 2.1% to 2.6% based on DSM-5 criteria.

Telegram: @medical_k

www.konkur.in

The Risk of Cannabis Use Disorder. People who use cannabis daily or near daily over weeks to months are most likely to become dependent. Longitudinal studies that followed young people into adult life found that 1 in 10 of those who have ever used cannabis developed dependence later in life. The risk increased to 1 in 3 among those who used cannabis regularly.

Research is underway to provide risks of cannabis use disorders defined in DSM-5 or DSM-5-TR. A recent survey found that one in three adults who have used cannabis had met the criteria for a cannabis use disorder at some time in their lives. Future longitudinal studies can use DSM-5-TR to assess the risk of cannabis use disorder among people who have used cannabis by the severity of the disorder.

As a rule, the earlier the age of first use, the more often cannabis has been used, and the longer it has been used, the higher the risk of dependence. Other factors that predict a higher risk of dependence include poor academic achievement, conduct disorder in childhood and adolescence, nonconformity and rebelliousness, personal distress and maladjustment, poor parental relationships, parental history of drug and alcohol problems, and heavier cannabis use.

Clinical Populations. Only a minority of people with a cannabis use problem seek treatment. In 2017, cannabis was the primary drug of concern for 12.4% of clients admitted to U.S. addiction treatment agencies. There were 244,117 treatment admissions with cannabis as the primary substance in 2017, compared to 240,271 admissions in 2015. There has also been an increase in the number seeking treatment for cannabis problems in the Netherlands, where the personal use of cannabis was decriminalized in the mid-1970s. This suggests that increased treatment seeking in the United States is not solely due to legal coercion. Common symptoms among people seeking help to cease cannabis use include an inability to stop using cannabis, feeling bad about their cannabis use, procrastinating, a loss of self-confidence, memory loss, and withdrawal symptoms when they stop using.

Telegram: @medical_k

www.konkur.in

Intoxication

Most young people report using cannabis to experience a “high,” that is, mild euphoria, relaxation, and perceptual alterations, including time distortion, and the intensification of ordinary experiences, such as eating, watching films, listening to music, and engaging in sex. When used in a social setting, the high may be accompanied by infectious laughter, talkativeness, and increased sociability.

Cognitive changes include impaired short-term memory and attention, making it easy for the user to become lost in pleasant reverie and more difficult to engage in sustained goal-directed mental or physical activity. Motor skills, reaction time, motor coordination, and many forms of skilled psychomotor activity are impaired while the user is intoxicated, increasing the risks of accidents if users drive an automobile.

Intoxication Delirium

Psychotic symptoms, such as delusions and hallucinations, may occur at very high doses of THC and in lower doses in individuals with a vulnerability to psychosis, for example, a first-degree affected relative.

High doses of THC have been reported to produce visual and auditory hallucinations, delusional ideas, and thought disorders in normal volunteers. In cannabis-using cultures, such as India, a “cannabis psychosis” has been reported among heavy users of cannabis. In these cases, psychotic symptoms were reportedly preceded by unusually heavy cannabis use and remitted after a period of abstinence.

The existence of a cannabis psychosis in Western cultures is still a matter for debate. In its favor are case series of cannabis psychoses and a small number of controlled studies that compare the characteristics of cannabis psychoses with those of psychoses in individuals who were not using cannabis at the time of hospital admission. Critics of the hypothesis emphasize the fallibility of clinical judgments about etiology, the poorly specified criteria for diagnosing cannabis psychoses, the dearth of controlled studies,

Telegram: @medical_k

www.konkur.in

and the striking variations in the clinical features of “cannabis psychoses.” Nevertheless, there is robust evidence base for cannabis-induced psychotic disorder, with cannabis being a substance that carries an elevated risk of causing this reaction compared to other substances.

Cannabis and Schizophrenia

Schizophrenia and regular cannabis use are associated in community surveys and clinical populations. A substantial number of longitudinal studies also suggest that regular cannabis use can precipitate schizophrenia in vulnerable individuals and exacerbate its symptoms in those who have already developed the disorder. For example, a follow-up of Swedish conscripts found that cannabis use reported in adolescence predicted an increased likelihood of receiving a diagnosis of schizophrenia over a 35-year follow-up. The Swedish findings have been supported by prospective studies in Australia, France, Germany, the Netherlands, and New Zealand that have all found associations between self-reported cannabis use in young adults and later reports of psychotic symptoms. A meta-analysis of these studies provided strong support for the hypothesis that regular cannabis use, especially early-onset cannabis use and use of cannabis with a high THC content, can precipitate schizophrenia.

Meta-analyses of these studies have found that those who had ever used cannabis had 1.4 times higher odds of psychotic symptoms. The odds increased 2.1 times among regular cannabis users and were nearly four times higher in persons who used more potent forms of cannabis. Young people with psychoses or psychotic symptoms who use cannabis have an average age of first episode 2 years earlier than those who did not use cannabis. People with a first episode of psychosis who stop using cannabis have better clinical outcomes than those who persist in using it.

These findings suggest that cannabis use precipitates schizophreniform disorders in vulnerable individuals. It is less certain whether cannabis use can produce psychotic disorders that would

Telegram: @medical_k

www.konkur.in

not otherwise have occurred. Most of the 274 Swedish conscripts who developed schizophrenia had not used cannabis, and only 7% of cases of schizophrenia could be attributed to cannabis use. Trends in the *treated* incidence of schizophrenia, particularly of early onset, acute cases, during the 1970s and 1980s, when cannabis use increased among young adults in the United States and Australia, have been unclear. Recent studies in Britain and Switzerland have suggested that the incidence of psychoses may have increased in recent birth cohorts with high rates of cannabis use.

The hypothesis that cannabis use is a *contributory* cause of schizophrenia (one factor among others that increase the likelihood of developing the disorder) is more plausible than the alternative hypotheses that (a) persons with schizophrenia use cannabis as a form of self-medication or that (b) cannabis use is associated with other drug use (e.g., amphetamines) that are linked to schizophrenia or (c) of an increased genetic vulnerability to schizophrenia.

Epidemiologic studies have tested the self-medication hypothesis by measuring the temporal sequence between cannabis use and psychosis and only conducting analyses on data from those participants who reported no symptoms before the use of cannabis. Other studies have specifically recruited participants who reported no history of psychotic symptoms or statistically controlled for a prior history of symptoms of mental disorders. These studies report that cannabis use usually preceded the onset of schizophrenia symptoms, suggesting that cannabis use increases the risk of psychosis rather than psychosis increasing cannabis use. Prospective studies of outcomes in people with psychoses who used cannabis before diagnosis and discontinued their use afterward are inconsistent with the self-medication hypothesis. In systematic reviews, people with psychoses who discontinue cannabis use have much lower rates of relapse and fewer positive symptoms than those who continue to use cannabis.

A variety of studies have assessed genetic explanations of the association between cannabis use and schizophrenia. These include studies of the size of the association in cohorts of persons with varying degrees of genetic relationship (e.g., twins, parents, siblings,

Telegram: @medical_k

www.konkur.in

cousins, and unrelated), Mendelian randomization studies, and studies that have adjusted the association for polygenic risk scores for cannabis use and psychosis. These studies suggest that there are shared genetic risks for both cannabis use and psychosis and that emerging psychosis increases the risks of cannabis use, but there is also consistent evidence that cannabis use plays a small contributory causal role in the development of psychosis.

A contributory causal role for cannabis use is biologically plausible. Psychotic disorders involve disturbances in the dopamine neurotransmitter systems: Drugs that increase dopamine release produce psychotic symptoms when given in large doses (e.g., methamphetamine), and neuroleptic drugs that reduce psychotic symptoms also reduce dopamine levels. THC appears to increase dopamine release; hence it can potentially produce psychotic symptoms. Most directly, double-blind provocation studies indicate that THC produces dose-related increases in psychotic symptoms in persons who do and do not have schizophrenia.

Cannabis and Anxiety

Some cannabis users report acutely increased anxiety, panic, and a fear of going mad. These experiences are most often reported by naive users who are unfamiliar with the effects of the drug, including some patients given THC for medicinal reasons. More experienced recreational users may also report these effects if they use more potent forms of cannabis than usual or if they use the oral route, in which case they may find it difficult to titrate their cannabis dose and experience more pronounced effects of much longer duration than usual.

There is mixed evidence on the relationship between cannabis use and anxiety. Some epidemiologic studies have found associations between cannabis use and specific anxiety disorders, but in some studies, the relationship was no longer significant after common risk factors were taken into account. Some people may use cannabis in an effort to cope with feelings of anxiety, but the regular use of cannabis for this reason may worsen their anxiety symptoms and

Telegram: @medical_k

www.konkur.in

may add cannabis dependence to their problems, undermining their ability to cope.

Changes in Heart Rate and Blood Pressure

The most immediate effect of smoking cannabis is a 20% to 50% increase in heart rate that occurs within a few minutes to a quarter of an hour of use. Changes in blood pressure can also occur that depend on posture: blood pressure is increased while the person is sitting and decreases on standing. A sudden change from lying down to standing up may produce postural hypotension and feelings of light-headedness and faintness. These are often the earliest indications of cannabis effects in naive users.

The cardiovascular risks of cannabis smoking are probably highest in older adults who have a higher underlying risk of cardiovascular disease. Younger adults with undiagnosed cardiovascular disease who use higher doses of THC may also be at risk. A French study, for example, found that 9.5% of 200 cannabis-related hospitalizations in the Toulouse area between January 2004 and December 2007 were for cardiovascular disorders. This included several cases of myocardial infarction and a fatal stroke in young adults who had no other risk factors for these disorders. An analysis of data between 1990 to 2014 from the U.S. National Vital Statistics System suggests that rates of cardiac deaths had increased in states that had passed medical cannabis laws, especially in males, and in states with a more lax approach to cannabis dispensing.

Cannabinoid Hyperemesis Syndrome

Cannabinoid hyperemesis syndrome (CHS) is a syndrome of cyclical vomiting, nausea, and abdominal pain reported by chronic heavy cannabis users. The symptoms are temporarily relieved by taking a hot shower or bath and ceasing cannabis use. The number of presentations of this syndrome to emergency departments increased at a large hospital in Aurora, Colorado, after cannabis legalization. Rates have also increased nationally across all hospitals in the United States, but it is unclear how much of the increase is due to

Telegram: @medical_k

www.konkur.in

increased cannabis use and how much to increased detection of cannabis use among cases of a cyclical vomiting syndrome.

Withdrawal and Tolerance

Regular use of THC leads to the development of tolerance to its behavioral and physiologic effects and withdrawal if use ceases. Cannabis withdrawal symptoms typically begin within 24 to 48 hours after cessation of use and may last for 1 to 2 weeks. There are typically no serious risks for individuals going through withdrawal if they are otherwise healthy. The relatively long half-life and complex metabolism of cannabis may explain the fact that cannabis withdrawal syndrome is less intense than that for alcohol or opiates. Animal studies suggest that animals repeatedly dosed with THC show withdrawal symptoms such as scratching, face rubbing, and shakes when given a cannabinoid antagonist.

The DSM-5 or DSM5-TR diagnostic criterion for cannabis withdrawal is met when three or more of the following signs develop within a week of cessation: irritability, anger, or aggression; nervousness or anxiety; sleep difficulties (such as insomnia or disturbing dreams); decreased appetite or weight loss; restlessness; depressed mood; and at least one physical symptom causing severe discomfort from abdominal pain, shakiness or tremors, sweating, fever, chills, or headache. A diagnosis should cause clinically severe distress or impairment in social or occupational settings or other important areas of functioning. Studies of people who have used cannabis regularly and who had to stop using (e.g., due to being in the hospital) report decreased mood and appetite and increased irritability, anxiety, physical tension, and physical symptoms. PET scan studies in humans showed that decreased CB1 cannabinoid receptors were associated with more severe withdrawal symptoms. Administration of CB1 agonists, such as dronabinol/nabilone or nabiximols can reduce withdrawal symptoms. Double-blind trials of a cannabis extract, Sativex, relieved withdrawal symptoms in cannabis-dependent persons undergoing treatment for cannabis dependence.

Disorders Not Otherwise Specified

Amotivational Syndrome. There are case study reports of an "amotivational syndrome" in chronic heavy cannabis users that is characterized by a lack of motivation and interest in activities other than using cannabis. Controlled field studies in the 1970s did not support such a syndrome, although their value was limited by small sample sizes and the restricted sociodemographic characteristics of the participants. Laboratory studies of sustained heavy daily use did not support the syndrome, although these typically involved short periods of drug use in healthy youth, and they made minimal demands on volunteers. Current empirical research does not support such a specific syndrome. The behavior reported among heavy, chronic cannabis users is better described as an effect of chronic daily intoxication that is common among dependent cannabis users.

Cognitive Impairment. The fact that cannabis use acutely impairs cognitive functioning has raised concerns that chronic cannabis use may chronically impair cognition, with particular concerns for youth development and cannabis-impaired driving. There is clinical, electrophysiologic, and epidemiologic evidence that long-term cannabis use produces impairment in the higher cognitive functions of memory, attention, organization, and integration of complex information. Deficits in verbal learning, memory, and attention in regular cannabis users have generally but not always been related to the duration and frequency of cannabis use, the age of initiation, and the estimated cumulative dose of THC received. Impairment is clearest while users are intoxicated. There is some recovery after abstinence, but it is uncertain if cognitive function fully recovers after the cessation of cannabis use.

A longitudinal study in a Dunedin birth cohort suggested that sustained heavy cannabis use over several decades produces declines in cognitive performance that may not be wholly reversible. This study assessed changes in IQ between ages 13 (before cannabis was used) and 38 in 1,037 New Zealanders born in 1972 to 1973. It found that early and persistent cannabis users, who used

Telegram: @medical_k

www.konkur.in

throughout adulthood, had an average decline in levels of IQ by 8 points greater than those who had not used cannabis at all and cannabis users who had not used cannabis in this sustained way. Nevertheless, other similar longitudinal studies fail to show any drop in IQ among heavy users; therefore, more research is needed to better understand the long-term impact of cannabis use on cognition.

Effects on Adolescent Development. Longitudinal studies of adolescents indicate that chronic heavy cannabis use may adversely affect adolescent psychosocial development. Interpretation of this evidence is complicated by the fact that many of the risk factors for these adverse developmental outcomes precede cannabis use and also make it more likely that a young person will become a regular user of cannabis. These outcomes include minor delinquency, other substance use, poor educational performance, nonconformity, and poor social adjustment.

Among U.S. adolescents in the 1970s and 1980s, the typical sequence of initiation into drug use was that alcohol and tobacco use preceded cannabis use, which, in turn, preceded the use of hallucinogens, amphetamine, heroin, and cocaine. In general, the earlier the age of first use of any drug and the greater the involvement with the drug, the more likely a young person will use the next drug in the sequence. The specific order in which particular drugs are used depends on the availability, marketing, and levels of use among adults in a given society at the time.

The role of cannabis in this sequence is debated. The hypothesis that cannabis use has a pharmacologic effect that increases the risk of using later drugs in the sequence is not the most compelling explanation. More plausible hypotheses are that the sequence of drug involvement reflects a combination of (a) the early recruitment to drug use of nonconforming and deviant adolescents who are more likely to use alcohol, tobacco, and illicit drugs; (b) a shared genetic vulnerability to become dependent on alcohol, cannabis, and tobacco; and (c) the socialization of cannabis users in an illicit drug-using subculture that increases the exposure, opportunity, and encouragement to use other illicit drugs. Recent prospective studies

Telegram: @medical_k

www.konkur.in

that have controlled for many of these factors and studies of twin pairs discordant for cannabis use have reduced the magnitude but failed to eliminate the apparent “gateway effect” of cannabis. Such studies may not be able to disentangle the complicated relationships to produce conclusive answers on the pharmacologic effects of cannabis. This leaves open the possibility of some form of pharmacologic sensitization, in addition to social selection in illicit drug use, which, however, is unlikely to be a cannabis-specific feature.

In adolescents, regular cannabis use is associated with a higher risk of failing to complete high school and job instability in young adulthood. The complication in interpreting this finding is that young people who regularly use cannabis had lower academic aspirations and poorer school performance *before* they started using it. When taking these differences into account, the relationship between cannabis use and poor educational performance persists but is more modest in size. Nonetheless, the effects of cannabis and other drug use on educational performance and underachievement limit the choice of adult occupation, level of income, choice of mate, and quality of adult life.

There is some evidence that heavy cannabis use has adverse effects on family formation and increases involvement in drug-related crime. However, the strong associations found in cross-sectional survey data are more modest in longitudinal studies that control for associations between cannabis use and other variables that predict these adverse outcomes. The relationship between cannabis use and crime may also change with the legality of cannabis use and sales.

Flashbacks. There are case reports of flashbacks in which users re-experience symptoms of cannabis intoxication days or weeks after last using cannabis. It has been difficult to decide whether these are (a) rare events that coincide with cannabis use; (b) the effects of other drugs that are often taken together with cannabis; (c) rare consequences of cannabis use that only occur at doses that are much higher than those used recreationally; (d) the result of unusual

Telegram: @medical_k

www.konkur.in

forms of personal vulnerability; or (e) the results of interactions between cannabis and other drugs. Such recurrence of perceptual symptoms is well documented among those using hallucinogens, which is often precipitated by the use of cannabis.

ADVERSE EFFECTS OF CANNABIS USE

Psychomotor Effects and Driving

Cannabis intoxication impairs a wide range of cognitive and behavioral functions that are involved in safely driving automobiles or operating machinery. These effects are generally larger, more consistent, and more persistent in tasks that require sustained attention. Animal studies showed that THC impairs balance, movement, and mobility. Recreational doses of THC produce similar impairments in human performance on laboratory tests and standardized driving courses to blood alcohol concentrations (BACs) of between 0.07% to 0.10%. Studies of the effect of cannabis use on driving performance on driving courses and on the road have found more modest impairments, probably because cannabis-impaired drivers drive more slowly, and take fewer risks, than alcohol-impaired drinkers. Regular cannabis users may be more aware of their psychomotor impairment than alcohol users.

Epidemiologic studies have found that self-reported cannabis use was associated with an approximately twofold relative risk of hospitalization for accidental injury, which has persisted after controlling for alcohol and tobacco use in men. Studies that have measured THC in blood have found a dose–response relationship between THC in blood and the risk of accidents. The combination of THC and alcohol produces more impairment and increased accident risk. The size of the risk of accidents among cannabis users is more modest than that for alcohol, but it is still of potential public health significance given the high prevalence of cannabis use among young males.

There is mixed evidence on the impacts of cannabis legalization on motor vehicle accidents. Overall, rates of motor vehicle accidents

Telegram: @medical_k

www.konkur.in

have declined in the United States since the early 2000s. Roadside testing and surveys in California did not detect increases in the prevalence of drivers with THC in oral fluid after cannabis was decriminalized in 2010. On the other hand, investigations of the Fatality Analysis Reporting System have shown an increase in the prevalence of drivers testing positive for cannabinoids in blood/urine among those involved in a fatal motor vehicle accident. It is unclear how much of this increase is explained by increased testing for cannabis use.

The Cardiovascular System

The acute toxicity of cannabis and cannabinoids is very low. There are no cases of fatal cannabis poisoning in the human medical literature. Animal studies indicate that the dose of THC required to produce 50% mortality in rodents is extremely high by comparison with the equivalent doses of other pharmaceutical and recreational drugs. The lethal dose also increases as one moves up the phylogenetic tree, suggesting that the lethal dose in humans could not be achieved by smoking or swallowing cannabis.

In healthy young cannabis users, the cardiovascular effects of cannabis use are likely to be of minimal clinical significance because tolerance develops to the effects of THC, and young, healthy hearts will only be mildly stressed. These changes in heart rate and blood pressure may be less benign in older adults with hypertension, cerebrovascular disease, and coronary atherosclerosis. Several epidemiologic studies suggest that cannabis use may provoke a myocardial infarction in middle-aged adults with underlying heart disease. The public health implications of these effects may increase as the cohort of continuing cannabis users from the late 1970s and early 1980s enters old age, the period of maximum risk for atherosclerosis in the heart, brain, and peripheral blood vessels.

There are recent case reports of serious cardiovascular events in young males who are very heavy daily cannabis smokers. Hospital data between 1990 and 2014 showed increased rates of cardiac-related deaths following the passage of medical cannabis policies,

Telegram: @medical_k

www.konkur.in

especially in older men, and in states with more a lax approach to cannabis dispensing. Epidemiologic studies are needed to evaluate the impact of more potent cannabis products on the cardiovascular system, given their increased availability on legal cannabis markets in some states in the United States.

Given the growing popularity of edibles, however, the possibility for inadvertent exposure to large doses becomes highly problematic, particularly for young children who may accidentally consume these products. Indeed, there are numerous case reports of severe cannabis exposures requiring medical treatment among pediatric patients following legalization of medical and recreational cannabis.

The Respiratory System

Regular cannabis smoking impairs large airway function and causes symptoms of chronic bronchitis such as coughing, sputum, and wheezing. It is possible that chronic cannabis smoking increases the risks of respiratory cancers because tobacco and cannabis smoke contain similar carcinogenic substances and tobacco smoke has adverse effects on the respiratory system. Case-control studies of aerodigestive tract cancers and cannabis smoking have produced conflicting findings, and their results are often unclear because most of the cannabis smokers in these studies also smoked tobacco. A recent meta-analysis of these studies concluded that there was at most a weak association between regular cannabis smoking and lung cancer. The increasing trend of vaping instead of smoking a combustible cannabis cigarette probably means lower respiratory harm from cannabis use, but the long-term impacts of vaping are yet to be studied.

Cellular Effects and Cancers

There is very weak evidence that THC alters cell metabolism and deoxyribonucleic acid (DNA) synthesis in the test tube. There is stronger evidence that cannabis *smoke* produces mutations in cells in the test tube and in live animals and hence is a potential cause of cancers of the lung and upper aerodigestive tract.

Telegram: @medical_k

www.konkur.in

Aerodigestive tract cancers have been reported among young adults who have been daily cannabis users. A systematic review and meta-analysis concluded that the relationships between cannabis exposure and cancers of the lung and upper aerodigestive tract, and also head and neck cancers, were not statistically significant after adjusting for tobacco and alcohol use. These observations were based on studies with few cannabis-only smokers. Future investigation is needed given the changing patterns of cannabis use in the population. There is weak evidence for an increased risk of cancers among children born to women who smoked cannabis during pregnancy. Three studies of very different types of cancer have reported an association with maternal cannabis use. However, none of these studies was designed to study the role of cannabis use in these cancers, so replication is required. There have not been any increases in the rates of these cancers that parallel increased rates of cannabis use over the past three decades.

There is more consistent evidence of an increased risk of testicular cancer among cannabis users. A case-control study that found an increased risk of nonseminoma testicular cancer has been replicated in two case-control studies. These found a doubling of risk for nonseminoma testicular tumors and found that the risk increased with earlier initiation and more frequent use. The effect is also biologically plausible since cannabinoid receptors are found in the male reproductive system.

Immunologic Effects

Cannabinoids impair cell-mediated and humoral immunity in rodents and reduce resistance to bacterial and viral infections in animals. Cannabinoid receptors are expressed in cells of the immune system in animals and humans, although their clinical significance is unclear. Cannabis smoke also impairs the functioning of alveolar macrophages, the first line of the body's immune defense system in the lungs. The clinical relevance of these findings is uncertain because the doses that produce these effects have been high, and

Telegram: @medical_k

www.konkur.in

extrapolation to the doses used by humans is complicated by the fact that tolerance may develop to these effects.

The limited experimental and clinical evidence in humans suggests that the adverse effects seen in animals are not replicated in humans. There is no conclusive evidence that cannabinoids impair immune system function in humans, as measured by T lymphocytes, B lymphocytes, macrophages, or immunoglobulin levels. There is suggestive evidence that THC impairs T lymphocyte responses to mitogens and allogeneic lymphocytes. The clinical and biologic significance of any immunologic effects of cannabis use is uncertain because there is no robust epidemiologic evidence of increased or decreased rates of infectious disease among chronic heavy cannabis users.

Reproductive Effects

Chronic administration of THC disrupts the male and female reproductive systems in animals. It reduces testosterone secretion and sperm production, motility, and viability in males, and disrupts the ovulatory cycle in females. There are inconsistent findings on whether cannabis use has these effects on humans.

Use During Pregnancy

Cannabis use during pregnancy produces babies with smaller birth weights, possibly because of a shorter gestation, and probably by the same mechanism as cigarette smoking. There is no clear evidence that cannabis use during pregnancy increases the risk of birth defects due to the fetus' exposure to cannabis in the uterus. Infants exposed to cannabis in the uterus may show transient behavioral and developmental effects during the first few months after birth. These effects are small by comparison with those caused by tobacco use during pregnancy, and they have not been observed in all studies. In previous studies of women who used cannabis during pregnancy, co-use of other substances such as tobacco and alcohol was common. We currently have little data to single out the effects of cannabis on birth outcomes. Future studies may provide

Telegram: @medical_k

www.konkur.in

answers, given that prenatal prevalence of tobacco and alcohol use has decreased, but the use of cannabis has not, especially in women with nausea and vomiting, along with increased marketing of cannabis to manage morning sickness.

LABORATORY EXAMINATIONS

Cannabinoids can be detected in the head hair, pubic hair, urine, sweat, saliva, and blood of people who use cannabis. They are stored in the fat cells of the body and so can remain in the body for a more extended period than other drugs, and THC may be detectable in urine for up to 11 weeks after use. Some research has suggested that higher concentrations of cannabinoids may be found in pubic than head hair. THC may be detected in saliva and sweat, but the concentration in these fluids tends to be lower than in urine, and in some cases, may not be detected in these fluids.

Cannabinoid levels in the blood vary between individuals and depend on the dose received and the individual's history of cannabis use. Blood levels of THC typically ranged between 0 and 500 ng/mL after flower cannabis use and up to over 1,000 ng/mL after using 70% to 90% THC concentrates that can be purchased from dispensaries. The level depends on the potency of the cannabis and the time since use. Levels of THC in blood above 10 to 15 ng/mL indicate recent use, although it is difficult to be precise about how recent. A more precise estimate of time since last use is provided by the ratio of THC to 9-carboxy-THC. When the blood concentrations of THC and 9-carboxy-THC are similar, cannabis has been used in the past 20 to 40 minutes, and hence suggests a high probability of intoxication. These relationships are less clear in regular users.

Cannabis intoxication impairs skills required to drive a motor vehicle, so it would be desirable to have a measure of cannabis intoxication similar to the breath test for alcohol intoxication. The major challenge is the lack of a simple relationship between THC metabolites in blood and psychomotor impairment, because THC can be detected after intoxication effects have passed. Saliva tests for THC may provide evidence of recent use that can be confirmed

Telegram: @medical_k

www.konkur.in

by analyses of THC levels in the blood. Consensus is yet to be reached on a level of THC in the blood that provides evidence of impairment analogous to the use of BACs of 0.05% or 0.08%. The American Automobile Association for Traffic Safety position is that we do not currently have scientific evidence to support a quantitative THC threshold for cannabis-impaired driving. The U.S. states of Colorado and Washington have defined driving with blood THC greater than 5 ng/mL as evidence of cannabis-impaired driving that must be supported by evidence of behavioral impairment.

With repeated frequent use of cannabis, THC accumulates in fatty tissues in the human body, where it may remain for considerable periods. The significance of this storage for users is unclear. It would be a serious concern if THC were a highly toxic substance that was physiologically active while stored in body fat. THC is not, however, a highly toxic substance, and it is inactive while stored in fat.

More recently, a study utilizing near-infrared spectroscopy was able to reasonably identify impairment from cannabis by examining signal in the prefrontal cortex. Given the challenges in using blood levels to infer impairment, such alternative methods may become important adjuncts to toxicology testing.

TREATMENT

Cannabis Use Disorder and Withdrawal

Cannabis use disorder and cannabis withdrawal symptoms can hinder quitting. In patients treated for cannabis use disorders, 54% of outpatients and 87% of inpatients report clinically severe symptoms of withdrawal. Randomized controlled trials have compared different ways to assist cannabis-dependent persons to stop using cannabis. Most people with cannabis use disorders, who are otherwise healthy, benefit from supportive care.

Behavioral interventions to help with cannabis withdrawal include psychoeducation and coping skills training. Information is provided to the patient about what they should expect regarding symptoms and time course, and ways to manage symptoms (e.g., exercise or hot

Telegram: @medical_k

www.konkur.in

baths to manage irritability, avoiding excessive caffeine to address restlessness, consuming nutritious food to counter decreased appetite, and keeping in mind that symptoms are temporary).

Psychosocial interventions for adults with cannabis use disorders include cognitive behavioral therapy (CBT), motivational enhancement therapy (MET) including brief MET (bMET), contingency management, social support counseling, drug education counseling, relapse prevention, mindfulness meditation, and mutual-help groups, based on the 12-step approaches (Marijuana Anonymous). CBT, MET, relapse prevention, and contingency management have received more research attention; findings showed that they are more effective than placebo and treatment as usual. Studies have reported that combining CBT and MET, as well as contingency management results in better outcomes.

For adolescents seeking treatment for cannabis use disorders, psychosocial interventions include individual-, group-, or family-based interventions. In addition to CBT, MET, and contingency management for the individual adolescent, studies have shown positive outcomes from family therapy.

The type of intervention used may depend on time, access, personnel, and health service system costs. Contingency management is costly with more provider burden, and the approach may be resisted by some providers. CBT typically involves more sessions over a longer period than MET. Brief interventions, telephone-based interventions, and online interventions are lower in costs, but research has not yet established their effectiveness for these emerging modes of interventions.

There is an absence of approved pharmacologic treatments for cannabis use disorders. A few studies have found that CB1 agonists (e.g., dronabinol or Sativex) can provide relief for people with higher severity of withdrawal symptoms but do not improve rates of long-term abstinence. Zolpidem and other benzodiazepines (nitrazepam) have been used to manage sleep problems. Studies of medications to manage mood, sleep, or craving have produced mixed results. Systematic reviews found limited support for the effectiveness of selective serotonin reuptake inhibitors (SSRIs), the antidepressant

Telegram: @medical_k

www.konkur.in

bupropion, the anxiolytic buspirone, and the selective noradrenaline reuptake inhibitor atomoxetine. Of note, a phase 2 trial for CBD did show improved cannabis use outcomes compared to placebo, raising the possibility for the therapeutic potential of CBD.

Therapeutic Effects of Cannabinoids

When taken for medicinal purposes, cannabinoids are primarily used to relieve symptoms rather than treat diseases. They may be used, for example, to relieve nausea and vomiting caused by cancer chemotherapy and muscle spasticity and chronic neuropathic pain in neurologic disorders such as multiple sclerosis (MS). The following cannabinoid-containing products have been authorized for medical use:

- Dronabinol: oral capsules containing synthetic THC for (1) anorexia in patients with acquired immune deficiency syndrome (AIDS) and (2) nausea and vomiting associated with cancer chemotherapy.
- Nabilone: oral capsules containing a synthetic cannabinoid similar to THC for the same indications as dronabinol.
- Nabiximols: an orolingual preparation containing approximately equal quantities of THC and CBD cannabis extracts approved for the treatment of muscle spasticity resulting from MS.
- CBD: an oral solution for the treatment of seizures associated with Lennox–Gastaut syndrome or Dravet syndrome in children.

Evidence from controlled clinical trials indicates that cannabinoids relieve the symptoms of some illnesses when used as adjunctive treatments and usually only after a patient has failed to respond to recommended treatments.

Chronic Noncancer Pain. Cannabis and cannabinoid products are increasingly used to manage chronic noncancer pain. A systematic review of existing evidence found limited effectiveness of cannabinoids on neuropathic pain, fibromyalgia, rheumatoid arthritis, and chronic noncancer pain in general. There is some evidence that

Telegram: @medical_k

www.konkur.in

cannabinoids were more effective than placebo in pain management, but positive effects were more commonly observed in 1-day studies, with smaller or no effects in studies with 3 months or longer follow-up. Numbers needed to treat to benefit and to harm analyses showed that cannabis was only modestly superior to placebo.

Nausea and Vomiting. Controlled clinical trials have compared the antiemetic effects of oral THC with either a placebo or an antiemetic drug in patients with nausea and vomiting related to cancer chemotherapy. Cannabinoids were more effective than placebo in reducing nausea and vomiting in adults receiving chemotherapy, but patients were more likely to withdraw due to adverse side effects. Systematic reviews have concluded that THC and other cannabinoid agonists had similar effectiveness to older antiemetic drugs in treating chemotherapy-induced nausea and vomiting. There is a lack of research comparing cannabinoids with newer antiemetic drugs such as ondansetron.

Wasting Syndrome and Appetite Stimulation in HIV/AIDS. THC was approved in the United States in 1999 for use as an appetite stimulant in patients with AIDS-related wasting syndrome based on a few small clinical trial cases that a systematic review found provided weak evidence for its effectiveness. A meta-analysis found no difference between cannabinoids and placebo in treating nausea or vomiting in HIV patients but did find increased appetite and side effects on mental health. The advent of highly effective antiretroviral therapy means that very few HIV-infected persons now develop AIDS and require appetite stimulation.

Muscle Spasticity and Multiple Sclerosis. Muscle spasticity is the increased resistance to passive stretching of muscles. Involuntary contractions may occur, which can be painful and debilitating. About 90% of MS patients develop muscle spasticity, as do a substantial proportion of patients with spinal cord injuries. Systematic reviews of trials of the effects of pharmaceutical cannabinoids on these MS symptoms have found that they are

Telegram: @medical_k

www.konkur.in

modestly effective in reducing symptoms of pain and muscle spasticity and produce mild to moderate adverse events.

Movement Disorders. Movement disorders are caused by abnormalities in areas of the brain connected to the motor cortex that produces abnormal skeletal muscle movements in the face, limbs, and trunk. The movement disorders most often mentioned as candidates for medical use of cannabinoids are dystonia, Huntington disease, Parkinson disease, and Tourette syndrome. Two small trials found limited evidence that cannabis is useful for treating any of these disorders. A review of the evidence concluded that pharmaceutical THC did not improve symptoms of Tourette syndrome and increased rates of adverse events.

Epilepsy. There are controlled trials indicating that CBD can reduce the frequency of seizures in some genetic epilepsy syndromes in children. A systematic review of trials of CBD as an adjunctive treatment for treatment-resistant epilepsy in children showed that it was more effective than placebo at reducing seizure frequencies and improving quality of life, but it increased risks of adverse events. CBD (which has no psychoactive effects) is not a controlled substance, and it has been approved by the U.S. Food and Drug Administration and medicines agencies in other countries as an adjunctive treatment for these types of epilepsy (Epidiolex).

Glaucoma. Glaucoma is a condition that damages the optic nerve via high intraocular pressure (IOP) and can produce blindness if untreated. Cannabis has been used as a potential treatment for reducing pressure in the eye. A systematic review to search for good quality evidence on medicinal cannabis for the treatment of glaucoma identified one trial conducted with six participants. The trial's findings did not support that cannabinoids (THC, CBD, and CBD spray) were effective in treating glaucoma. There are reports from lower quality studies that cannabis and THC taken orally, by topical eye drops, or intravenously reduce IOP by 25%, but the effect lasts only 3 to 4 hours, which would not help to prevent blindness.

Telegram: @medical_k

www.konkur.in

Other Uses for Medicinal Purposes. Patient advocacy groups have campaigned for the right to use cannabinoids to treat a variety of conditions for which there is limited evidence of efficacy. These include anxiety, post-traumatic stress, depression, sleep, neurologic conditions, and inflammatory bowel diseases. For many of these conditions, there is limited or no robust scientific evidence to support their effectiveness, and in some instances, the evidence has found adverse effects from their use. Strong levels of advocacy for cannabinoids used for conditions that do not yet have an empirical basis has often stemmed from personal perceptions, case reports, and anecdotal evidence often uncritically communicated through traditional and social media.

CONCLUSION

The definition of cannabis-related disorders has evolved over time. The prevalence of cannabis use in youth and adults has fluctuated across years with changing social attitudes and policies. A 2020 U.S. population survey showed that 46% of persons had ever used cannabis and 21% had done so in the past year. Cannabis use by vaping has been an increasing trend in U.S. adolescents. Approximately 1 in 10 people who use cannabis develop cannabis dependence later in life, and the risk increases to 1 in 3 among those who use cannabis daily or near daily.

With the liberalization of cannabis use in the United States, there has been a boom in new cannabis products offering higher THC concentrations at lower prices promoted via social media. THC interacts with the brain to affect mood, motor control, cognition, memory, pain, and the immune system. The use of cannabis, especially high THC products, has been linked to negative outcomes, such as psychosis, cardiovascular events, hyperemesis syndrome, respiratory problems, cognitive impairment, and a range of withdrawal symptoms.

Only a minority of people with cannabis use problems seek treatment. Trials have found positive treatment outcomes from behavioral interventions and support, and psychosocial interventions

Telegram: @medical_k

www.konkur.in

such as CBT, MET, and contingency management. No pharmacologic treatments have been approved for cannabis use disorders. There has been increasing attention on the therapeutic use of cannabinoids to relieve symptoms of medical conditions such as nausea and vomiting, chronic pain, MS, and epilepsy. With the population's evolving relationship with cannabis, research is warranted on more effective treatments for cannabis use disorders and more rigorous evaluations of the use of cannabinoids to treat psychological and physical health conditions.

11.6 Hallucinogen-Related Disorders

Brian S. Barnett, M.D., and Joji Suzuki, M.D.

Many substances can, if consumed in sufficient quantity, dramatically change one's perception, cognition, mood, affect, social relatedness, sense of meaning, and sense of self. However, hallucinogens are unique in their ability to profoundly alter these aspects of consciousness without simultaneously inducing delirium. They are broadly conceived in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Text Revision (DSM-5-TR), with the hallucinogen class of substances encompassing a wide range of sources (naturally occurring, semisynthetic, or fully synthetic), structures, mechanisms of action, effects, durations of action, and potential for harm/therapeutic benefit. Nevertheless, the more commonly encountered hallucinogens include 5-methoxy-N, N-dimethyltryptamine (5-MeO-DMT), dimethyltryptamine (DMT), lysergic acid diethylamide (LSD), mescaline, psilocybin, and other serotonin 2A receptor agonists; entactogens such as 3,4-methylenedioxymethamphetamine (MDMA); dissociative arylcyclohexamines such as phencyclidine (PCP) and ketamine; and kappa-opioid agonists such as salvinorin A.

The utility of grouping such a wide array of compounds into a single class, as well use of the term *hallucinogen* to describe them, are subjects of debate. Though hallucinogen remains the official term for these compounds, as per the DSM-5-TR, it is an imprecise descriptor given both its narrow focus on the perceptual aspects of the complex alterations of consciousness these compounds produce and the fact that many hallucinogens actually produce illusions much more commonly than strict hallucinations. Alternatively, sometimes these compounds have been referred to as *club drugs* given their propensity, particularly for MDMA or ketamine, to be used in club settings. However, the term *psychedelic*, derived from combining the Greek terms psykhē, or "mind," and dēloun, or "make visible, reveal," has been proposed to describe hallucinogens in a broad sense and, in particular, classic hallucinogens—those hallucinogens with effects primarily mediated by agonism or partial agonism at the 5HT2A receptor. This term emphasizes the profound effects on sense of self occasioned by classic hallucinogens and has already displaced hallucinogen within common parlance. PCP and related arylcyclohexamines such as ketamine have historically been referred to as *dissociatives* or *dissociative anesthetics* but are classified as hallucinogens in the DSM-5-TR and are increasingly placed under the umbrella of psychedelics. The terms *empathogen* and *entactogen*

Telegram: @medical_k

www.konkur.in

have been proposed for 3,4-methylenedioxymethamphetamine (MDMA) and related compounds whose effects are dominated by feelings of emotional closeness to others. The term *entheogen* has also been used to refer to hallucinogens when the spiritual or religious aspect of the experience produced is of primary importance.

The DSM-5-TR recognizes two categories of hallucinogens: PCP and related arylcyclohexamines, and "other hallucinogens," which comprises several distinct and sometimes overlapping classes of hallucinogens. Because of the great diversity of drugs labeled hallucinogen, each of the main classes of hallucinogens will be discussed briefly before we present the hallucinogen-related disorders. Characteristics of hallucinogen classes are summarized in Table 11.6–1. Photographs of commonly used synthetic hallucinogens and sources of commonly used naturally occurring hallucinogens are featured in Figure 11.6–1.

Psychiatry and hallucinogens share a complicated, still-evolving relationship that has been the subject of renewed interest in recent years. Considered primarily as substances of misuse by the field for much of the last half-century, some hallucinogens, such as LSD, were once employed as adjuvants to psychotherapy, while ketamine and esketamine have recently joined the psychiatric armamentarium. Still more, such as MDMA and psilocybin, may soon join or rejoin it if clinical trials continue to demonstrate promising therapeutic results. Should the clinical applications of hallucinogens become more widespread, one concern is that harms from nonmedical use, rarely encountered by clinicians now, may be seen with increasing frequency in years to come. Therefore, improved training for clinicians on prevention and treatment of adverse effects secondary to hallucinogen use, as well as expanded research into identifying predictors of and treatments for these effects, may prove instrumental for minimizing hallucinogens' societal harms should they come into broader clinical use.

HISTORICAL OVERVIEW

Some hallucinogens, such as ayahuasca and peyote, have been employed ritualistically for spiritual and medicinal purposes by indigenous peoples for millennia. In the New World, hallucinogen use among these groups was suppressed by colonial conquerors for centuries. Today, use of some hallucinogens by indigenous groups for spiritual purposes, such as peyote use by members of the Native American Church within the United States, is now legally protected. However, possession of fungi- and plant-based hallucinogens remains illegal across the world, though a growing movement to decriminalize possession is currently underway.

Telegram: @medical_k

www.konkur.in

Hallucinogens first came to mainstream attention in Western culture in the 1950s, following the discovery of LSD's psychoactive effects in 1943 by Swiss chemist Albert Hoffmann of Sandoz Laboratories. In subsequent decades, enthusiasm developed regarding potential psychiatric applications of LSD and other serotonergic hallucinogens. LSD was initially employed by psychiatrists to produce a "model psychosis" capable of aiding clinicians in better understanding psychotic disorders. Prior to LSD's discovery, no other compounds at the submilligram dose were known to produce profound alterations in cognition and perception, leading to speculations that LSD may resemble an endogenous ligand responsible for psychosis and other mental illnesses. Mescaline's potential for producing a model psychosis had been explored to a lesser degree starting in the 1920s, though the compound did not gain the mainstream scientific attention of LSD. The utility of employing LSD as a potential tool for inducing psychosis was eventually determined to be limited since true hallucinations are more frequently produced by other compounds, such as stimulants. Subsequently, scientific interest in hallucinogens in the 1950s and 1960s gradually shifted to potential therapeutic applications.

During those decades, psychiatrists and psychologists administered LSD to thousands of patients. Some studies from that period demonstrated promising findings for LSD in the treatment of alcohol use disorder, opioid use disorder, and cancer-related psychological distress. However, interpretation of study findings from this period is complicated by the fact that studies were often poorly designed, and results were sometimes misrepresented. Research into LSD's therapeutic potential at that time was also sullied by unethical studies conducted by the U.S. military, the Central Intelligence Agency, and academic investigators.

Nonmedical use of serotonergic hallucinogens became widespread among young people in the 1960s, with hallucinogen intoxication leading to severe negative reactions becoming a common problem encountered by clinicians. In a 1972 cross-sectional study of 2,411 U.S. adults, while only 4.6% of all respondents reported lifetime LSD use, that number rose to 22.0% of 18 to 21 year olds and 18.2% of 18 to 25 year olds.

Due to concerns about potential harms associated with nonmedical hallucinogen use, some supported by data and some not, such as "bad trips," psychotic sequelae, suicide, and accidental deaths, by the early 1970s, possession of most serotonergic hallucinogens in the United States and many other countries was declared illegal. Research into serotonergic hallucinogens' therapeutic potential largely ceased for the next several decades due to funding and administrative barriers, though it has resumed in recent years.

Along with serotonergic hallucinogens, arylcyclohexamines are important hallucinogens from a public health perspective. Their history begins with the synthesis of PCP in 1926 and its initial use as an anesthetic in the late 1950s. Once on the market, PCP was found to induce postoperative dysphoria and

Telegram: @medical_k

www.konkur.in

psychosis in many patients, and use in humans was discontinued in 1965. That same-year nonmedical use of PCP started, and associations between PCP intoxication with bizarre and violent behavior quickly drew attention. PCP eventually came to be considered the most serious drug problem in the United States. However, nonmedical use peaked in the late 1970s. In 1979, it was estimated that 14.5% of persons aged 18 to 25 years had used PCP. In 1988, the rate was 4.4% for those between ages 18 and 25. 12.8% of high-school seniors reported use in 1979, which decreased to about 3% from 1987 to 1995. Emergency department (ED) visits related to PCP increased fivefold between 1974 and 1979 and then subsequently declined. Today, PCP is encountered by clinicians in only a few, primarily urban, areas of the United States.

Ketamine, another arylcyclohexamine, was discovered in 1962 and approved by the U.S. Food and Drug Administration (FDA) as an anesthetic in 1970. Though less potent than PCP and having a considerably shorter duration of action, ketamine's side-effect profile proved superior to PCP's, though some patients still experience dissociative and psychotic effects. Ketamine became popular in the rave scene in the 1980s, particularly in locations in Asia, such as Hong Kong, where ketamine has been the drug of choice for those attending raves. Ketamine was not federally scheduled as a controlled substance in the United States until 1999 when it was added to Schedule 3. Nonmedical use of ketamine is relatively uncommon in the United States currently, though it is increasing and associated with serious harms such as ulcerative cystitis in heavy users. Medical use of ketamine remains widespread for a variety of indications, including anesthesia and treatment of acute agitation. More recently, ketamine has gained interest as a rapid treatment for depression, culminating in the approval of esketamine by the FDA for treatment-resistant depression in 2019 and major depressive disorder with acute suicidal ideation or behavior in 2020.

EPIDEMIOLOGIC OVERVIEW OF HALLUCINOGEN USE

According to the 2019 National Survey on Drug Use and Health (NSDUH), 16% of Americans aged 12 years and older have used a hallucinogen at least once, while 2.2% and 0.7% have used one in the last year and month, respectively. This makes hallucinogens the fourth most commonly used class of illicit drugs in the United States, following cannabis, opioids, and stimulants. Rates of past-year/past-month use are highest in the 18- to 25-year-old age group (7.23/1.95%) and lowest in the >25-year-old group (1.41/0.5%). Peak age for lifetime use is age 26 to 34 (23.46%), while for past-year and past-month use, the peak is age 21 to 25 at 7.8% and 2.1%, respectively. Among U.S. 12th graders in the 2020 Monitoring the Future (MTF) study, 7.5%, 5.3%, and 1.8% reported lifetime, past-year, and past-month use of hallucinogens, respectively.

While rates of hallucinogen use had been fairly stable since 2002, it appears that lifetime hallucinogen use is now rising. In the 2017 MTF study, 1.9% of 8th graders, 4.2% of 10th graders, and 6.7% of 12th graders reported lifetime hallucinogen use compared, respectively, to 3.0%, 4.8%, and 7.5% in 2020. According to the NSDUH, among people aged 12 years and older, the lifetime rate of hallucinogen use rose from 15.5% in 2017 to 16.0% in 2019. From 2015 to 2019, past-year use of LSD, the most commonly used hallucinogen, rose from 0.55% to 0.87% in the United States.

In 2019, as with most substances, more men (19.7%) had used a hallucinogen in their life than women (12.6%). Lifetime use was most common among White (19.3%), American Indian/Alaskan Native (23.4%), and individuals of more than one race (25.7%). Rates of hallucinogen use were somewhat higher in the Western United States and urban counties. Notably, since 2006, significant increases have been seen in the use of DMT, AMT, 5-MeO-DIPT, and *Salvia divinorum*. Table 11.6–2 summarizes additional information on hallucinogen use estimates from the NSDUH, as well as estimates for 12th graders from the MTF survey.

In a 2019 study, alcohol, cannabis, cocaine, stimulant, and club drug/other drug use disorders were associated with past-year hallucinogen use, while alcohol, cannabis, cocaine, heroin, nicotine, opioid, stimulant, and club drug/other drug use disorders were associated with lifetime hallucinogen use. Cocaine, nicotine, and club drug/other drug use disorders were associated with lifetime hallucinogen use disorder. Regarding psychiatric disorders, having any personality disorder was associated with past-year and lifetime hallucinogen use, while personality disorder and post-traumatic stress disorder (PTSD) were associated with lifetime hallucinogen use disorder.

Regarding potential mental health sequelae from hallucinogen use, population-level studies have identified no associations between lifetime serotonergic hallucinogen use and negative mental health outcomes during the

Telegram: @medical_k

www.konkur.in

previous year, including depression, anxiety, psychosis, suicidal thoughts, suicidal plans, and suicide attempts. Nevertheless, these studies do not imply that individuals using these substances may not be harmed; therefore, caution is warranted in interpreting their findings.

Given increasing media attention on positive findings from clinical trials of hallucinogen-assisted therapies for mental health conditions and substance use disorders (SUDs), clinicians could face new challenges in coming years if patients seek to self-treat with hallucinogens. Though its prevalence is unknown, hallucinogenic microdosing, the act of taking serotonergic hallucinogens at doses that do not alter consciousness in the hopes of improving emotional well-being or enhancing cognition and creativity, has gained increasing media attention in recent years. However, recent placebo-controlled trials of microdosing, though few in number, have failed to identify benefits for patients, and a 2021 prospective study of individuals microdosing in the community found that positive expectations predicted improved mental health outcomes, suggesting a strong role for expectancy in perceived benefit.

HALLUCINOGEN SUBCLASSES

NMDA Receptor Antagonists

The DSM-5-TR recognizes a class of PCP-type substances explicitly including PCP, ketamine, cyclohexamine, and dizocilpine. The primary effects of these drugs are mediated by noncompetitive *N*-methyl-D-aspartate (NMDA) receptor antagonism. Other drugs sharing this mechanism of action include dextromethorphan (DXM) and nitrous oxide (the latter usually categorized as an inhalant because it is a gas). PCP and ketamine bind to PCP binding sites on the NMDA receptor and block the ionophore channel, decreasing influx of calcium and sodium ions. The highest densities of PCP receptors are found in the dentate gyrus, hippocampus, and anterior forebrain. Downstream effects of inhibition of NMDA receptor–mediated glutamatergic neurotransmission include a secondary increase in glutamate release in the medial prefrontal cortex and an increase in pyramidal cell firing, probably due to blockade of NMDA receptors on γ-Aminobutyric acid (GABA)-ergic inhibitory interneurons. In rats, noncompetitive NMDA receptor antagonists also increase extracellular prefrontal and mesolimbic dopamine levels, probably by stimulating glutamate release in the ventral tegmental area and dorsal raphe nuclei. The effects on dopamine release are thought to mediate the reinforcing effects of these drugs, as well as hyperactivity and stereotypic movements. At very high doses, PCP blocks monoamine transporters, but ketamine does not—possibly accounting for greater stimulation and reward with PCP than ketamine. At even higher doses, PCP blocks sodium and potassium channels, which may contribute to the

Telegram: @medical_k

www.konkur.in

incidence of seizures following PCP overdose. In animal models, behavioral effects of NMDA antagonists are attenuated by enhancers of NMDA receptor–mediated neurotransmission, such as glycine and D-serine. Some effects are also attenuated by D2 and 5HT2A receptor-blocking agents.

Effects of PCP and Related Drugs. Sometimes termed *dissociatives* or *dissociative anesthetics*, a prominent feature of intoxication with these compounds is a sense of separation of mind from body, accompanied by anesthesia with preserved airway reflexes. These drugs can also produce hallucinogenic effects, including visual illusions or true hallucinations, other sensory changes, altered thought processes, labile or inappropriate affect, anxiety, and paranoia or other delusional ideation. PCP intoxication, in particular, can be associated with unpredictable and potentially violent behavior. It is also associated with nystagmus, ataxia, hypertension, tachycardia, and muscular rigidity.

The duration of acute effects depends on the specific drug, dose, and route of administration. Serum half-life of PCP in humans is highly variable, averaging about 20 hours. Ketamine has a considerably shorter half-life, about 2 hours. PCP is highly lipid soluble and accumulates in fat. Metabolism is primarily hepatic for both drugs.

PCP and ketamine produce compulsive use in animal models. Monkeys given free access to PCP will self-administer to maintain near-constant intoxication. Patterns of compulsive use of PCP and ketamine are seen in humans as well.

Telegram: @medical_k

www.konkur.in

PCP and related drugs also lower the threshold for brain self-stimulation reward, a characteristic shared with most other addictive drugs. Pronounced tolerance has been demonstrated with PCP in animals and ketamine in humans. A withdrawal syndrome is seen in primates, including vocalizations, bruxism, oculomotor hyperactivity, diarrhea, piloerection, somnolence, tremor, and seizures.

NMDA Receptor Antagonist Model of Psychosis. The use of PCP intoxication as a model for psychosis was proposed in 1959. Although PCP is no longer administered to humans due to its toxicity, ketamine is still employed for investigating the role of altered glutamatergic neurotransmission in the pathogenesis of psychosis. The NMDA antagonist model of psychosis more closely mimics symptoms of schizophrenia than other drug models (e.g., amphetamine or classic hallucinogen). Both PCP and ketamine induce symptoms of thought disorder, including withdrawal, autism, negativism, inability to maintain cognitive set, and abnormal responses to projective testing. Catatonia may also occur. Disturbances in attention, perception, and symbolic thinking are also very similar to those seen in schizophrenia. Both drugs inhibit prepulse inhibition, replicating a well-established neurobiologic marker of schizophrenia. Well-formed hallucinations and delusions are less common and may be absent even in the presence of severe thought disorder. A single relatively low dose of PCP can trigger a full-blown psychotic episode in patients with schizophrenia.

Serotonergic Hallucinogens

There are several distinct and overlapping groups of naturally occurring and synthetic hallucinogens that act primarily by affecting serotonergic pathways but vary greatly in structure, effects, and mechanisms of action. The “other hallucinogen” class defined by DSM-5-TR primarily includes these drugs, though it also contains a variety of other types of hallucinogens.

Classic Hallucinogens. The classic hallucinogens are those drugs whose effects are primarily mediated by agonism or partial agonism at the 5HT2A receptor. The prototypical drug of this class is LSD. Other representatives of this large group of drugs are psilocin (the primary active ingredient in hallucinogenic mushrooms) and its prodrug psilocybin, mescaline (the primary active ingredient of hallucinogenic cacti such as peyote and the San Pedro cactus), and DMT. Structurally, these drugs fall into three main categories. The tryptamine hallucinogens, which include psilocybin/psilocin and DMT, are structurally related to serotonin (5-hydroxytryptamine), containing the indole nucleus and various substituents affecting receptor affinities and drug metabolism. The ergoline class, which includes LSD, consists of the indole structure within a much more

Telegram: @medical_k

www.konkur.in

complicated four-ring molecule. LSD was originally derived from ergot fungus that infects grain and causes ergotism or St. Anthony's fire, outbreaks of which frequently occurred in Europe in the Middle Ages. Other ergolines are found in members of the morning glory family, including *Rivea corymbosa*, *Ipomoea violacea*, and *Argyreia nervosa*. The third group of classic hallucinogens, which includes mescaline and 2,5-Dimethoxy-4-methylamphetamine (DOM), is the phenylalkylamines. While the phenethylamine structure is the basis for amphetamines, phenylalkylamines can have effects similar to LSD, making them likely to be mediated primarily via 5HT2A receptor agonism.

The classic hallucinogens have long provided evidence implicating the serotonergic system in the pathophysiology of psychotic disorders. In the early 1920s, similarities were first described between mescaline intoxication and symptoms of schizophrenia. When Albert Hoffman accidentally discovered the psychoactive effects of LSD in 1943, he described frightening psychotic-like symptoms, including thoughts that he was possessed by a demon and that his neighbor was a witch. This prompted investigation into the use of LSD and other classical hallucinogens as models for understanding the biologic basis of psychosis. In fact, when LSD was first marketed by Sandoz in the 1940s, psychiatrists and medical trainees were encouraged to take LSD in order to gain insight into the schizophrenic experience. Some researchers speculated that schizophrenia might be caused by excess production of an endogenous psychotogenic compound. DMT drew particular attention, with studies showing it produced psychotic-like positive symptoms in normal volunteers and other studies reporting differences in urine and plasma DMT levels between patients with schizophrenia and controls. Although these findings were not consistently replicated, it has been shown that DMT is produced in the pineal gland of rats.

CLASSIC HALLUCINOGEN EFFECTS. The effects of all classic hallucinogens are similar, differing principally in time course, which in turn depends on the particular substance, dose, and route of administration. An important feature of all classic hallucinogens is that the psychological content and emotional tone of the experience are unpredictable but are thought to be strongly influenced not only by the dose and particular drug taken but also by the mental state, psychological preparation, and intention of the person taking the drug (mental "set"), and the environment in which the effects are experienced ("setting"), including the broader cultural context. For example, one early LSD study found that the severity of adverse psychological reactions varied based on how study staff interacted with participants, with less severe adverse reactions occurring when staff were instructed to be warmer and the study setting was more relaxed. Support for the role of culture's impact on the classic hallucinogen experience comes from observational surveys indicating that the frequency of "bad trips"

www.konkur.in

associated with classic hallucinogens decreased from the mid-1960s to 1975 as conflict over these compounds became less prominent within societal discourse.

Although classic hallucinogens are safe in carefully screened and prepared study participants, in controlled doses, and under ideal conditions, all have some inherent risks. These risks are greatly magnified in uncontrolled settings. People at high risk of adverse outcomes (e.g., people with psychotic disorders or a family history of psychosis) may choose to use these drugs, and preparation and support may be lacking. In addition, under typical conditions of uncontrolled use, the identity and dose of the substance are rarely known with certainty, so overdose or unexpected effects can easily happen. Risks are multiplied when new substances are introduced to the illicit market due to ignorance as to the potency and effects of the compounds as well as to the inherent risks of the drugs.

Somatic effects of classic hallucinogens are typically mild and can include anorexia, chills, tremor, unsteadiness, nausea, vomiting, xerostomia, paresthesias, mydriasis, insomnia, and blurred vision. Pulse and blood pressure may become mildly to moderately elevated. Significant physiologic toxicity is not seen in typically used dosages. Sensory effects are often prominent, including alteration in perception of shape, size, and color and the illusion of movement. With eyes closed, vivid imagery is often perceived, ranging from elementary geometric or fractal patterns to vivid representational images of various kinds. Other sense modalities may be involved, and synesthesia can occur. True hallucinations are uncommon. Affective alterations are extremely variable and can change rapidly and frequently during a single episode of use. Anxiety is common, as are strong cathartic emotional experiences, often related to past or current life experiences. Feelings of bliss, joy, and peace may also occur. Depersonalization, derealization, and paranoia can occur. Distortions in perception of time can occur, most commonly resulting in time seeming to pass slowly. The content of the subjective experience may be dominated by personal psychological concerns (conflicts, relationships, grief, and loss), symbolic representations of archetypal themes (heroic quests, interactions with mythologic figures), or spiritual matters. Particularly in high doses, mystical-like experiences may occur, typically including ineffable feelings of unity and transcendence of space and time, which are experienced as deeply positive, sacred, and meaningful.

An important exception regarding the effects of classic hallucinogens is that of the NBOMe class of hallucinogens, often sold as LSD due to their high potency and similar subjective and physiologic effects. NBOMes, the N-benzyl-methoxy analogs to the 2C-x family of phenethylamine hallucinogens, were initially developed as highly specific 5HT2A receptor agonists for neuroimaging research. Unlike LSD, however, NBOMes have been implicated in numerous

Telegram: @medical_k

www.konkur.in

hospitalizations for severe complications, including seizures and severe toxidrome requiring prolonged ICU stays, as well as fatalities.

Tolerance to LSD develops very rapidly, with significant decreases in the effect of subsequent doses after a single dose. This effect may be due to downregulation or internalization of 5HT2A receptors and is completely reversed within a week of abstinence. DMT may be an exception to this effect, as marked tolerance is not observed. Cross-tolerance exists among LSD, mescaline, and psilocybin, further evidence of a shared mechanism of action.

DIFFERENCES AMONG CLASSIC HALLUCINOGENS. Classic hallucinogens differ principally in potency, duration of action, and traditional patterns of use. LSD is one of the most potent drugs known, with noticeable effects beginning at approximately 25 µg. Because of its high potency, LSD is often distributed on small squares of blotter paper, which are held in the mouth to allow buccal absorption prior to swallowing. Effect onset usually occurs within 60 minutes, with peak effects around 3 to 4 hours and total duration of action of 8 to 10 hours. A typical street “hit” (dose) of LSD is currently approximately 50 µg, much lower than the doses of 100 to 250 µg that were typical in the 1960s. This may partially account for the lower incidence of LSD-associated adverse reactions in recent years.

Mescaline is among the least potent hallucinogens, with a dose of 300 to 400 mg estimated to be roughly equivalent to 100 µg of LSD. Mescaline’s onset of action is somewhat slower than LSD’s, and the duration of action is slightly longer (10 to 12 hours). Mescaline is primarily used in the form of peyote or other mescaline-containing cacti, though purified or synthetic mescaline is sometimes found. Humans have used peyote for at least 5,000 years, and it is currently used sacramentally within the Native American Church and by tribes in northern Mexico, including the Huichol. The San Pedro cactus of South America has a long history of ritualistic use as well. Mescaline, at least when consumed as cactus, is associated with more nausea and vomiting than LSD or psilocybin. Its low potency also results in a lower index of safety than other classic hallucinogens. Autonomic hyperstimulation can become problematic in doses above 500 mg.

Psilocybin is intermediate in potency between LSD and mescaline, with a dose of 10 to 15 mg being roughly equivalent to 100 µg of LSD. Psilocybin’s effects are shorter (4 to 6 hours) than those of LSD and mescaline. It is almost always consumed in the form of mushrooms, and mild-to-moderate headache is common for up to 24 hours following psilocybin use.

When taken orally by itself, DMT is not psychoactive due to rapid metabolism by monoamine oxidase A (MAO-A). Therefore, it is normally smoked, or occasionally injected or insufflated. In smoked doses of around 25 mg, DMT produces a brief (15 minutes) and extremely intense experience that can involve

Telegram: @medical_k

www.konkur.in

complete loss of contact with reality, intense visuals, loss of ordinary sense of reality and self, mystical experience, and/or the experience of contact with other worlds or beings. Marked tolerance does not seem to develop to DMT, but frequent use is unusual in any case because of the intense and sometimes overwhelming nature of the experience. Ingestion of an MAO-A inhibitor, either before or concurrently with DMT, can render the compound orally psychoactive. Ayahuasca, an herbal preparation traditionally used in the western Amazon basin, typically contains both monoamine oxidase inhibitors (MAOIs) and DMT. In the typical brew, the MAOIs are harmala alkaloids (harmine, harmaline, and tetrahydroharmine) that come from the *Banisteriopsis caapi* vine, and the DMT comes from the leaves of *Psychotria viridis*. The brew has effects similar to those of classic hallucinogens, although it should be noted that the harmala alkaloids are probably psychoactive to some degree, and they, not the DMT carrier, are traditionally considered the defining and essential ingredient to ayahuasca. Ayahuasca has been used in shamanic traditions in South America for hundreds of years and is used as a sacrament in several syncretic Brazilian religions that developed in the 20th century. More recently, it has been used with increasing frequency in North America and Europe for therapeutic purposes or spiritual exploration. The effects of ayahuasca typically last about 4 hours and are generally similar to those of classic hallucinogens. Nausea and vomiting are common, probably due to the harmala alkaloids, and purging is believed by some to be a valuable aspect of the experience.

MDMA and Related Compounds (Entactogens). A large number of phenylalkylamines, although structurally similar to classic hallucinogens such as mescaline and DOB, have effects quite distinct from those of classic hallucinogens. MDMA, 3,4-methylenedioxy-*N*-ethylamphetamine (MDEA), and numerous other compounds have subjective effects characterized by feelings of closeness and loving acceptance toward others, with less pronounced alterations in sense perception or thought process common to the classic hallucinogen experience. To varying degrees, these drugs have stimulant effects as well. Because of the effects on feelings toward others, they have been termed “entactogens” or “empathogens.” MDMA has attracted interest as a potential adjunct to psychotherapy because it appears to increase tolerance of negative affect and painful memories (e.g., in PTSDs), possibly allowing them to be dealt with more directly and effectively. Unlike the classic hallucinogens, these drugs are moderately reinforcing and therefore have greater potential for compulsive use. MDMA is taken up presynaptically by the serotonin transporter and induces release of serotonin from presynaptic stores. It also acts as a reuptake inhibitor and, particularly at high doses, directly stimulates 5HT2A and other serotonin receptors. Overdose can occur easily because MDMA inhibits its own metabolism by CYP 2D6 and CYP 3A4, resulting in blood levels that increase

Telegram: @medical_k

www.konkur.in

ever more steeply as the dose increases. Given that illicit MDMA is often sold with contaminants or adulterants or contains other substances with no MDMA at all, overdoses or other complications can inadvertently occur from drug–drug interactions such as serotonin syndrome, hyperthermia, or seizures.

ENTACTOGEN EFFECTS. Somatic effects of MDMA include moderate increases in blood pressure and pulse and an increase in body temperature. Although the latter averages less than ½ degree Fahrenheit in clinical research settings, it can be much greater when the drug is used in all-night dance parties (raves), particularly if the user is dehydrated. Trismus and bruxism are common side effects. In high doses, muscle stiffness and rhabdomyolysis can occur. In overdose, seizures and cardiorespiratory collapse can occur. Psychological effects include a heightened sense of closeness to others and a deep sense of well-being or acceptance. The emotional tone tends to be very positive and maybe euphoric at times. However, strong releases of negative emotion can also occur, as well as anxiety and paranoia, although much less commonly than with classic hallucinogens.

Other Serotonergic Hallucinogens. Hundreds of serotonergic hallucinogens have been characterized, and new ones are synthesized continually. Many of these “research chemicals” find their way to the streets, not always accurately labeled or dosed. 2C-B and related compounds (e.g., 2C-E, 2C-I) appear, based on self-reports of users, to have effects that combine aspects of classic hallucinogen and entactogen effects. Other drugs are reported to have unique effects that have not been adequately characterized. Recently, a number of highly potent hallucinogens with novel structures have begun to be marketed that have strong LSD-like effects but considerably greater toxicity. For example, Bromo-DragonFLY, an agonist at 5HT2A, 2B, and 2C receptors, is active in doses under 1 mg, with effects lasting for several days. As indicated earlier, NBOMes are highly potent full agonists at the 5HT2A receptor (LSD is a partial agonist), which are also psychoactive in doses under 1 mg. These drugs appear to be much more toxic than classic hallucinogens and have caused a number of fatalities, often also producing seizures.

Iboga Alkaloids

Ibogaine is a hallucinogenic alkaloid found in several plants, most notably in the root of the *Tabernanthe iboga*. It is used for medicinal and spiritual purposes by the indigenous people of Western Africa and has hallucinogenic effects in doses of 400 to 1,500 mg, producing an intense and often unpleasant experience that can last 4 to 6 hours, with lingering effects felt for up to 2 to 3 days. Although ibogaine acts at 5HT2 and 5HT3 receptors, it also inhibits the serotonin transporter and acts at NMDA, mu-, kappa-, and sigma-opioid, and muscarinic

Telegram: @medical_k

www.konkur.in

and nicotinic cholinergic receptors. Ibogaine attracted the interest of addiction researchers when reports emerged of patients with opioid use disorder losing the desire to use heroin after taking ibogaine. Although initial preclinical and clinical results in the treatment of opioid withdrawal were encouraging, and preclinical work suggested that ibogaine may have therapeutic effects across several classes of drugs, research on ibogaine has been plagued by toxicity concerns, particularly QTc prolongation and sudden death due to cardiac arrhythmias. Currently, there is interest in developing less toxic–related molecules, such as 18-methoxy-coronaridine (18-MC). Although ibogaine is unlikely to be encountered as a substance of misuse, it continues to be used in some treatment centers outside the United States and within underground treatment settings in the United States.

Kappa-Opioid Agonists

Salvia divinorum is a species of sage plant, the leaves of which are used traditionally by the Mazatecs in Oaxaca, Mexico. When purified, the main active component, Salvinorin A, is an extremely potent hallucinogen, active in doses as small as 4.5 μg/kg when smoked. Effects are intense but brief, with a time course comparable to smoked DMT, peaking within 2 minutes and dissipating within about 15 minutes. Effects not only overlap with those of classic hallucinogens but also include dissociative effects and impaired recall of the experience. Users report that the effects are distinct from those of other drug classes, producing intense experiences that may range from pleasant to highly distressing. Injuries from falls may occur due to incoordination, and the experiences can be psychologically unsettling or even traumatic. United States Drug Enforcement Administration (DEA). Many analogs have now been synthesized. The most likely dangers from Salvinorin A appear to be the possibilities of psychologically damaging experiences and unintentional self-harm during the intoxication state. Users of high doses have been reported to become agitated and perform violent, purposeless actions, for example, running into walls.

Anticholinergic Deliriants

Anticholinergic alkaloids from plants of the nightshade family have been used in shamanic practice and witchcraft for millennia. Although one could argue that the hallucinatory states produced by these drugs should be classified as anticholinergic delirium, the DSM-5-TR explicitly lists jimsonweed as an ethnobotanical hallucinogen. There is some logic to this since plants like jimsonweed, henbane, and belladonna have been used specifically for their hallucinogenic properties. These solanaceous plants contain antimuscarinic alkaloids, principally atropine and scopolamine. Synthetic anticholinergics such

Telegram: @medical_k

www.konkur.in

as benztropine and diphenhydramine (an H1 inverse agonist with strong antimuscarinic effects) can produce similar effects in high doses. Anticholinergic effects include dry mouth, mydriasis, blurred vision, increased heart rate, decreased sweating, hyperthermia, seizures, and, occasionally, death. These drugs can produce true hallucinations and other features of delirium, including disorientation, agitation, grossly impaired cognition and memory, and fluctuating mental status.

Differences between and Similarities to Other Substances of Misuse

Despite the great diversity among the classes of hallucinogenic drugs, there is significant overlap in the effects of most of these drugs and differences from other major classes of psychoactive substances. While the DSM-5-TR states that "all drugs that are taken in excess have in common the ability to directly activate the brain reward systems," this is not true of classic hallucinogens, ibogaine, or kappa-agonists. Their effects are neither reliably reinforcing in animal models nor reliably pleasurable to humans. Thus, it is generally accepted that these drugs do not produce compulsive use or true addiction, even though they can certainly be the object of a SUD. In general, people use these drugs because they value the effects for reasons other than primary reward, for example, because they find the experience meaningful, informative, interesting, or transformative. Some clinical trials have also indicated that classical hallucinogens may actually be helpful in treating SUDs.

The nonaddictive nature of classic hallucinogens and their possible SUD treatment potential has received only limited study. One potential explanation for these attributes centers around classic hallucinogens' 5-HT2C receptor agonism. In preclinical models, this type of agonism has been shown to oppose the reinforcing potential of several types of addictive compounds, likely via modulation of dopaminergic activity in the ventral tegmental—nucleus accumbens (NAc) reward pathway.

On the other hand, NMDA antagonists, such as ketamine and serotonergic hallucinogens with entactogen and/or stimulant properties, such as MDMA, do activate the primary reward pathways. The resulting experience is therefore reinforcing to many users. Thus, the usual addictive processes can also motivate continued use of these substances.

COMPARATIVE NOSOLOGY

Table 11.6–3 summarizes the relationships among hallucinogen-related disorders in DSM-5-TR and ICD-11. While DSM-5-TR includes PCP and related compounds as a category of hallucinogens, ICD-11 includes PCP and related substances under "dissociative drugs." Neither classification system recognizes

Telegram: @medical_k

www.konkur.in

a hallucinogen withdrawal syndrome. Hallucinogen intoxication symptoms listed in ICD-11 are similar to those in DSM-5-TR, but not exactly the same: in ICD-11, specific behavioral, perceptual, and physical changes are listed (corresponding to criteria B, C, and D in DSM-5-TR). Finally, while hallucinogen-persisting perception disorder (HPPD) is listed in DSM-5-TR, ICD-11 codes HPPD under "other specified disorders due to use of hallucinogens."

PHENCYCLIDINE AND OTHER HALLUCINOGEN INTOXICATION

Definition

The DSM-5-TR criteria for PCP intoxication and other hallucinogen intoxication are similar but differ in some specifics. The diagnosis of intoxication for both classes of drugs requires recent use of a relevant substance, clinically significant psychological or behavioral disturbance, and the lack of a better explanation for the symptoms (e.g., another mental disorder). Although there is overlap in the symptoms of intoxication for PCP and other hallucinogens, as defined in DSM-5-TR, there are significant differences. Criterion B of PCP intoxication requires disruptive behavior changes, which are more frequent and prominent with PCP use than with other types of hallucinogens. The criteria for other hallucinogen intoxication mention behavioral disturbances in criterion B, but the criteria emphasize problematic psychological changes (criterion B) and perceptual changes (criterion C). Both diagnoses require two or more specific signs and symptoms (criterion C of PCP intoxication and criterion D of other hallucinogen intoxication). These signs and symptoms have no overlap. Signs of PCP intoxication include horizontal, vertical, or rotatory nystagmus, hypertension or tachycardia, numbness or diminished responsiveness to pain, ataxia, dysarthria, muscle rigidity, seizures or coma, and hyperacusis. Rotary nystagmus is a highly specific sign of NMDA antagonist intoxication. For other hallucinogen intoxication, the signs and symptoms include pupillary dilation, tachycardia, sweating, palpitations, blurring of vision, tremors, and incoordination. These signs and symptoms are characteristic of classic hallucinogens and MDMA but may not be seen with all types of "other" hallucinogens.

Unspecified hallucinogen-related disorder	6C49.Z

[a]Onset is specified as during intoxication, not during withdrawal. These disorders are diagnosed instead of intoxication only when the symptoms are sufficiently severe to warrant independent attention.

Epidemiology

Classic hallucinogen intoxication is now encountered much less frequently by clinicians than in the 1960s and 1970s. In addition to decreases in overall frequency of use since then, social learning and changes in patterns of use likely partially account for decreased adverse effects of intoxication. The typical dose

Telegram: @medical_k

www.konkur.in

of illicit LSD currently taken now (25 to 50 μg) is smaller than the 100 to 250 μg doses more commonly used in the 1970s. In addition, today, many users have much more information about the possible effects of various doses of hallucinogens and the importance of set and setting in minimizing negative effects.

There are no data providing accurate estimates of the incidence of hallucinogen intoxication. The rate of DSM-5-TR hallucinogen intoxication is necessarily lower than the rate of use because the former requires significant adverse behavioral or psychological consequences. Data from the Drug Abuse Warning Network (DAWN) provide estimates of drug-related ED visits that provide a relevant measure of cases of drug use that come to medical attention, although the ED visits are not necessarily directly related to the use of the drug. Table 11.6–4 shows the frequency of drug-related ED visits for several classes of hallucinogens based on 2011 data. PCP is the hallucinogen most commonly associated with ED visits, with 24.2 ED visits per 100,000 population. MDMA is associated with 7.2 visits per 100,000 population, and all other hallucinogens are much lower. These numbers are low relative to other substances: the corresponding numbers for other drug classes are stimulants 51.3, marijuana 146.2, heroin 82.7, cocaine 162.1, and alcohol 112.0. Rates are substantially higher for males than for females for each class of hallucinogen. Interestingly, rates are higher in the under-21 age group for the serotonergic hallucinogens but are higher in the over-20 age group for PCP and ketamine, suggesting that perhaps harmful patterns of use are more persistent for the NMDA antagonist drugs than for the serotonergic drugs, consistent with their greater dependence liability and the greater intrinsic danger of their acute effects. In 2004, DXM was associated with 5.7 ED visits per 100,000 population, with higher rates in lower age groups (14.7/100,000 among those aged 12 to 20 years). New data from Project Dawn have not been published since 2011. However, a preliminary report using April 2019 to October 2020 data indicates that of 1,275,925 ED visits in 49 participating hospitals, approximately 400 visits (0.03%) involved LSD, approximately 300 involved PCP (0.02%), and approximately 200 involved other hallucinogens (0.01%). For comparison, approximately 17,800 visits (1.40%) involved stimulants, and approximately 11,200 involved marijuana (0.88%).

Substance Abuse and Mental Health Services Administration, *Drug Abuse Warning Network, 2011: National Estimates of Drug-Related Emergency Department Visits*. HHS Publication No. (SMA) 13–4760, DAWN Series D-39. Rockville, MD: Substance Abuse and Mental Health Services Administration; 2013.

Etiology

Diagnosable hallucinogen intoxication is due to an interaction between the biologic effects of the drug and individual and environmental risk factors. As noted above, risks vary from drug to drug and are greater for higher drug doses, for biologically vulnerable and/or unprepared individuals, and with use in stressful environments lacking support.

Diagnosis and Clinical Features

Hallucinogen intoxication presents as acutely altered mental status and behavioral changes following drug ingestion. Patients seeking clinical care are often agitated and fearful and may worry they are “losing their minds” or experiencing panic or paranoia. Occasionally, users become acutely depressed, which can lead to suicidal behavior during or soon after intoxication. In other cases, patients may present in an expansive, grandiose, or euphoric state resembling mania. Adverse reactions are more common in inexperienced users, with unexpectedly large doses, or under stressful circumstances, but can occur at any time. Recent drug ingestion is critical to diagnosis, but confirmation of this may be difficult to ascertain. It is important to carefully assess for a history of other drug ingestion or exposure and psychiatric and somatic illness and to perform an appropriate physical examination, including neurologic evaluation. All classes of hallucinogens can produce acute anxiety, agitation, inappropriate and labile affect, visual illusions and hallucinations, and paranoia or other delusions. Toxicology testing is recommended to confirm or rule out ingestion of commonly used substances, and if available, testing for the broad range of hallucinogens should be conducted to aid in the diagnostic clarification. While identifying the

Telegram: @medical_k

www.konkur.in

specific substance ingested may not change the clinical management for most patients, some hallucinogens can cause a prolonged toxidrome lasting days or more, in which case analytic confirmation of the hallucinogen can aid in the management as well as patient education following recovery.

PCP and Related Substances. PCP and ketamine may be taken by any route, but PCP is more commonly smoked, while ketamine is frequently injected, snorted, or orally ingested. A typical street dose is about 5 mg for PCP and 100 to 200 mg for ketamine. PCP is manufactured only illicitly, while ketamine is derived both from diverted licit material and illicit manufacture. DXM is usually taken in the form of over-the-counter cough syrup or tablets. These drugs produce a dissociative state with a greater degree of cognitive and neurologic impairment (including the signs listed in the criteria for PCP intoxication) than that produced by classic hallucinogens. Symptoms become more severe with higher doses and may warrant the diagnosis of PCP or ketamine-induced delirium if disturbances of attention and cognition are prominent. With PCP intoxication, typical features include impaired cognition, nystagmus, hypertension, tachycardia, dysarthria, hyperacusis, and increased deep tendon reflexes. Thought disorder is prominent, but hallucinations may also be present. Behavioral symptoms include disinhibition, agitation, panic, rage, aggression, and exaggerated reactions to environmental stimuli.

Medical complications are much more common than with classic hallucinogens. Hyperexcitability, hypertension, or hyperthermia may indicate significant toxicity constituting a medical emergency. Hypertensive crisis can lead to cerebral hemorrhage. Severe hyperthermia can occur. At higher doses of PCP, symptoms of dissociative anesthesia emerge, with numbness and diminished responsiveness to pain. At still higher doses, other receptor effects become prominent, as PCP interacts with monoamine uptake pumps, sigma receptors, sodium and potassium channels, nicotinic and muscarinic acetylcholine receptors, and mu-opioid receptors.

Unpredictable, agitated, and violent behavior occurs more commonly with PCP than with other hallucinogens. Formal thought disorder, delusions, and frank hallucinations can occur, as well as confusion, impairment of motor control, impaired speech, and catatonic-like symptoms. Overdoses of PCP and related compounds can have serious medical sequelae, including seizures, hyperthermia, hypertensive crisis, cerebral hemorrhage, respiratory arrest, coma, and death.

Ketamine intoxication is generally less malignant than PCP intoxication. Medical complications are less common due to the lower potency and shorter half-life of ketamine and because ketamine has fewer significant actions at sites other than the NMDA receptor. Presenting complaints include anxiety, chest pain, and palpitations. Tachycardia and hypertension are common but usually

Telegram: @medical_k

www.konkur.in

much less severe than when seen with PCP intoxication. Rotary nystagmus is possible but uncommon. Death from ketamine intoxication is very rare, except when ketamine is used with other drugs.

PCP or ketamine intoxication is often a sign of moderate or severe SUD, so that should be diagnosed and treated if present.

Classic Hallucinogens. Although patients with classic hallucinogen intoxication can show a wide range of symptoms similar to those of PCP intoxication, physiologic effects are generally mild and unlikely to require specific intervention. Patients with classic hallucinogen intoxication are more likely to remain fully oriented and less likely to be confused or show severe cognitive, verbal, or motor impairment. Anxiety and panic are sometimes observed. Marked mydriasis is a prominent feature of classic hallucinogen intoxication. Mild-to-moderate elevation in blood pressure and pulse may be observed. Overdoses of LSD and psilocybin are not known to cause death.

3,4-Methylenedioxymethamphetamine. MDMA intoxication does not usually cause thought disorder, paranoia, disorganized behavior, or aggression. It usually comes to attention in cases of overdose, in which case symptoms are essentially those of serotonin syndrome: hyperthermia, rigidity, hyperreflexia, seizures, rhabdomyolysis, renal failure, etc. Symptomatic intoxication is more likely to occur in the context of high dose, dehydration, and/or hyperthermia. Overdose can easily occur with MDMA because of the relatively low index of toxicity and the nonlinear pharmacokinetics of MDMA. MDMA inhibits its own metabolism, with the result that a relatively small increment in dose can lead to a much greater increase in blood levels and effects. In high doses, MDMA can cause classic hallucinogen-like effects. Delirium may be present, in which case it would be diagnosed instead of intoxication.

Other Serotonergic Hallucinogens. The effects of many of these drugs have not been adequately characterized. The effects of Bromo-DragonFLY and NBOMe analogs are reported to be similar to those of LSD, but serious adverse effects appear to be much more common, including hypertension, tachycardia, seizures, hyperpyrexia, elevated creatine kinase, vasoconstriction leading to tissue necrosis, and deaths, especially after users mistakenly took very large doses. The high potency combined with a low index of safety makes these drugs much more dangerous than classic hallucinogens.

Ibogaine. Ibogaine intoxication resembles classic hallucinogen intoxication but may include a greater degree of dissociation and confusion, similar to PCP and related drugs. While the acute effects can last 4 to 6 hours, many users report lingering effects that persist for several days.

Telegram: @medical_k

www.konkur.in

Salvia. The effects of *Salvia* intoxication are similar to those of PCP or ketamine intoxication, but the duration (15 minutes or less) makes it unlikely that they will be observed in a clinical setting.

Anticholinergics. Anticholinergic drugs produce true hallucinations in the context of delirium, as described in the section on hallucinogen-induced delirium below. Peripheral signs may be less prominent with agents that are relatively potent centrally (e.g., scopolamine).

Pathology and Laboratory Examination

Urine toxicology may be useful for establishing the acute ingestion of hallucinogens and/or other drugs, although hallucinogens other than PCP and MDMA will not be detected with routine urine drug screens. False-negative screens for PCP are common. Toxicologic screening for other drugs of misuse is useful since more than one drug may have been ingested. Serum, urine, or gastric content samples can be sent to analytic laboratories for specific mass spectrographic analysis, but initial diagnosis and treatment must be from clinical assessment. The dose delivered from plant material is always uncertain.

MDMA intoxication usually comes to the attention of clinicians in cases of overdose, in which case patients may have rhabdomyolysis (elevated creatine phosphokinase), disseminated intravascular coagulation, hyperthermia, and acute renal failure. Deaths have occurred secondary to cerebral edema and seizures secondary to hyponatremia. Hyponatremia occurs much more frequently in women than in men. Cardiac arrhythmias and cardiovascular instability are also possible. Depending on drug–drug interactions, serotonin syndrome may also occur.

Differential Diagnosis

The most important immediate task in the evaluation of cases resembling hallucinogen intoxication is to rule out or treat any medical and psychiatric emergencies present. Since the symptoms of hallucinogen intoxication can overlap with those of psychosis and delirium, it is critical to distinguish hallucinogen intoxication from these disorders. Hallucinogen-induced psychosis may be diagnosed if the symptoms of psychosis dominate the clinical presentation and are beyond (in severity or duration) those typically associated with intoxication. Particularly for PCP, diagnostic boundaries between intoxication, delirium, and psychosis are blurry, and the patient's mental state can fluctuate.

Intoxication with some drugs (e.g., stimulants) and withdrawal from others (e.g., alcohol and sedative–hypnotics) can also cause symptoms mimicking those of hallucinogen intoxication. The principal diagnostic tools include a

Telegram: @medical_k

www.konkur.in

history, if available, urine toxicology, additional laboratory tests to rule out metabolic derangements, and physical, neurologic, and mental status examination, with observation over time. In most cases, acute hallucinogen intoxication will resolve within hours. Except for very long-lasting drugs (DOM, ibogaine) or psychedelics prone to causing prolonged toxidromes (NBOMe), symptoms that last longer than 12 hours may be due to other causes or to hallucinogen-induced psychotic disorder. PCP intoxication can resemble the effects of other toxic drug ingestions or deliria. The combination of nystagmus (especially rotary), ataxia, and hypertension is relatively specific for PCP intoxication.

Course and Prognosis

Uncomplicated hallucinogen intoxication normally resolves when the acute effects of the drug wear off within 12 hours, except for very long-acting hallucinogens such as DOM or ibogaine. Barring medical complications, complete recovery from PCP intoxication within 24 to 72 hours is usual. Uncommonly, hallucinogen-induced disorders may follow hallucinogen intoxication (see below).

Treatment

PCP (or PCP-Like Hallucinogens). Treatment of acute ingestion is supportive, aimed at minimizing medical emergencies (seizures, hypertension, hyperthermia, and rhabdomyolysis) and behavioral consequences. PCP levels and symptoms may fluctuate over many hours (especially with oral ingestion). Ionized PCP may be trapped in the stomach. Activated charcoal may be administered if oral administration is suspected. Sensory input should be minimized. Physical restraint can prevent violent behavior but can also increase agitation and the risk of rhabdomyolysis. Agitation, seizures, and hypertension should be treated primarily with benzodiazepines. Antipsychotics may be useful in cases of relatively mild intoxication, but in more severe cases, they can lower the seizure threshold, cause dystonia, and exacerbate hyperthermia and anticholinergic symptoms. Hyperthermia should be treated with standard cooling measures. Rhabdomyolysis should be treated with intravenous fluids and diuretics. Alkalization of the urine is controversial because there is a theoretical risk of causing increased reabsorption of PCP.

Classic Hallucinogens. Except in cases of delirium or overdose, treatment of acute ingestion of a classic hallucinogen is conservative. Reassurance and a calm and safe environment are the most useful interventions. Anxious or paranoid patients may benefit from reminders that they are under the temporary influence of a drug. Some degree of insight is often preserved. If patients are

Telegram: @medical_k

www.konkur.in

agitated or in severe distress, oral or parenteral benzodiazepines are first-line treatment and are usually sufficient. Antipsychotics should be used only if behavior can not otherwise be managed. Antipsychotics with 5HT2A antagonist effects are preferred. D2 blockers such as haloperidol may worsen symptoms. Restraints should only be used if there is immediate danger of self-harm or assaultive behavior. Patients should be monitored closely, and their mental status should be assessed at frequent intervals due to potentially rapid fluctuations. Support from a sober family member or close friend can be helpful following the resolution of the acute intoxication state. Patients who have had very disturbing or traumatic experiences may benefit from short-term therapy to help integrate the experience and to identify and treat any psychological sequelae. Patients should be reminded that severe reactions could reoccur with future ingestion of hallucinogens. For those experiencing a severe toxidrome from NBOMe or psychedelics such as Bromo-DragonFLY, known to cause toxic reactions, aggressive sedation with benzodiazepines and fluid resuscitation are the mainstays of treatment. If severe serotonin syndrome is suspected, cyproheptadine may be considered in severe cases.

3,4-Methylenedioxymethamphetamine. MDMA intoxication often comes to medical attention in cases of overdose or medical complications. Such patients should be evaluated emergently, and ICU admission may be required. Cardiac monitoring and frequent monitoring of vital signs and mental status should be conducted. Activated charcoal should be administered if recent ingestion is suspected. Cooling measures should be undertaken in cases of hyperthermia. Dantrolene is sometimes used to treat hyperthermia due to MDMA ingestion, but its efficacy is not proven. Seizures, hypertension, and agitation are treated with benzodiazepines. In cases of rhabdomyolysis, intravenous fluids, alkalization of the urine, and furosemide are recommended.

PHENCYCLIDINE USE DISORDER AND OTHER HALLUCINOGEN USE DISORDER

Definition

The DSM-5-TR criteria for PCP use disorder and other hallucinogen use disorder are identical to those for all other classes of substances, with the exception that the criterion for withdrawal does not apply: there is no recognized syndrome of withdrawal in humans for hallucinogens, although there is evidence of clinically meaningful withdrawal following heavy MDMA use and evidence of PCP withdrawal in animal models. As with other SUDs, the SUD severity is specified as mild (2 to 3 criteria), moderate (4 to 5 symptoms), or severe (6 or more criteria).

Telegram: @medical_k

www.konkur.in

Epidemiology

Problematic use of hallucinogens has not been described in cultures where hallucinogens are traditionally employed for religious, healing, or divinatory purposes, possibly due to cultural protections against misuse arising from long-established ceremonial group use. With the sudden increase in hallucinogen use in the 1960s in Western cultures, where there were no established cultural rituals around hallucinogen use, problematic patterns of use emerged and were the focus of considerable concern, in part because hallucinogen (particularly LSD) use was intertwined with the cultural upheaval of those times. Similar problematic patterns arose when MDMA, initially used for therapeutic purposes, became associated with raves in the 1980s.

Today, hallucinogen use disorders are uncommon. The 2019 NSDUH found past-year rates of DSM-IV hallucinogen abuse and dependence of 0.08% and 0.05%, respectively. Hallucinogen abuse was most prevalent among individuals aged 18 to 20 years (0.33% and 0.26%, respectively). In a 2019 study using data from 2011 to 2012, hallucinogen use disorder was similarly uncommon, with past-year and lifetime prevalence of 0.05% and 0.60%, respectively. 6.4% of lifetime hallucinogen users in that study reported lifetime hallucinogen use disorder, while 8.1% of past-year users reported past-year hallucinogen use disorder. Of patients meeting criteria for hallucinogen use disorder, past-year prevalence of mild, moderate, and severe forms was 79.9%, 13.1%, and 7.0%, respectively, and lifetime prevalence was 66.8%, 18.5%, and 14.6%, respectively. Unfortunately, most epidemiologic surveys do not distinguish between the various classes of hallucinogens, meaning little is known about rates of dependence for most individual hallucinogens.

According to a 2006 study, the most common features of hallucinogen dependence were emotional difficulties secondary to hallucinogen use, difficulty controlling use, salience of use, and tolerance. That study found that among individuals 12 to 21 years old initiating hallucinogen use in the previous 2 years, 2% exhibited hallucinogen dependence, and another 10% appeared to be at risk for developing dependence or already in the early stages of dependence. Use of particular hallucinogenic compounds appeared to increase the risk of rapid transition to hallucinogen dependence, with MDMA demonstrating more risk than LSD. In a 2007 study, of 2,035 people who had used any hallucinogen for the first time in the last 24 months, 56 (2.8%) had developed dependence according to DSM-IV criteria. Individuals who first used hallucinogens in early adolescence were at increased risk of developing dependence during this early time frame, while the risk was lower for Hispanic people. Increased risk of developing dependence was also associated with use of mescaline, MDMA, and PCP. In a 2008 study examining characteristics of past-year MDMA users compared to past-year users of other hallucinogens (including LSD, PCP, mescaline, peyote,

Telegram: @medical_k

www.konkur.in

and psilocybin) using NSDUH data from 2005, about 1.4% of the sample had used one or more hallucinogens in the past year. Overall prevalence of hallucinogen use disorder was 0.11%. Both groups were approximately two-thirds male, and two-thirds of both were aged 25 years or younger. Users of other hallucinogens were more likely to be White than were users of MDMA. Mean age of first use was 18 to 19 years in both groups. Most users in both groups used infrequently, with 34% of MDMA users and 22% of other hallucinogen users having 12 or more occasions of use in the past year. Among the past-year users, 4.9% of both groups met DSM-IV criteria for abuse, but 3.6% of the MDMA users versus 2.2% of the other hallucinogen users met criteria for dependence, suggesting that MDMA use may confer greater risk of moderate to severe hallucinogen use disorder than use of other hallucinogens. Frequent hallucinogen use and past-year marijuana use disorder were associated with hallucinogen use disorder among past-year hallucinogen users. In a 2017 study examining all major SUDs except for tobacco use disorder, hallucinogen use disorder was the most likely to occur in people with multiple SUDs, with alcohol use disorder being the least likely.

Etiology

As with other drugs, hallucinogen use disorder likely arises out of multiple interacting biologic, psychological, and social factors. Hallucinogen use disorders differ from other classes of SUD in that classic incentive reward-driven mechanism does not play a central role except for PCP and related compounds and MDMA-type drugs. PCP is avidly self-administered in animal models, and human users frequently show patterns of compulsive use, relapse, etc. Classic hallucinogens are not strongly reinforcing but rather aversive in animal models. Hallucinogens can cause euphoria, but this effect is not reliable, and dysphoric or mixed experiences are common. A withdrawal syndrome is not recognized for any of the hallucinogens. Although some degree of physical dependence is possible with NMDA receptor antagonist hallucinogens and MDMA-like compounds, it is unlikely that continued use is driven by negative reinforcement through relief of withdrawal symptoms. Strong cravings also do not appear to be common in hallucinogen users. Exposure, other drug use, expectancies, and perceived meaningfulness of the experience probably play more important roles.

Diagnosis and Clinical Features

Although the diagnostic criteria for hallucinogen use disorder are identical to those of any SUD, the criteria perform somewhat differently for hallucinogens than for other substances. It seems probable that there would be differences between the various types of hallucinogens as well. In general, hallucinogen use disorders appear to be associated with fewer adverse consequences and lower

Telegram: @medical_k

www.konkur.in

frequency of use than other SUDs. The two criteria most linked to loss of control (inability to cut down or control use and using more than intended) are by far the most difficult items (last to be endorsed) in item response theory studies of hallucinogen use disorder criteria. This suggests that people often continue to use hallucinogens because they enjoy or value the effects rather than due to having lost the ability to regulate use. There is no recognized withdrawal syndrome for the classic hallucinogens, although physical dependence to arylcyclohexamines and MDMA can occur.

True physical dependence does not occur with the classic serotonergic hallucinogens. The SUD criteria most commonly endorsed are spending a lot of time using or recovering from the substance and tolerance. The tolerance criterion is of questionable validity for classic hallucinogens because of the very rapid and reversible development of tolerance. Marked tachyphylaxis lasting no more than a few days can develop following a single dose of a classic hallucinogen such as LSD. This phenomenon does not imply tolerance in the sense of the DSM-5-TR SUD criterion.

Pathology and Laboratory Examination

There are few physical signs or symptoms of hallucinogen use disorders, independent of those of intoxication, though chronic ketamine use is associated with disorders of the GI (gastritis, cholestasis) and urinary tracts (ulcerative cystitis, impaired renal function). MDMA use may be associated with decreased numbers of serotonin transporters and 5HT2A receptors on positron emission tomography (PET) scan, but this is not used diagnostically. Urine, blood, or hair analysis can be used to detect ingestion of hallucinogens. The window of detection is often short, though PCP is detectable in urine for up to 8 days after use. Aside from PCP, other hallucinogens are not included in routine tests.

Neurotoxicity. MDMA is neurotoxic in animal models, and there is evidence of adverse effects on the brains of people who have used the drug extensively. There is fairly consistent evidence of reductions in serotonin transporters and 5HT2A receptors in MDMA users. Neurocognitive deficits in memory and inhibitory control have been found in some studies, although most of these studies are confounded by other drug use. Based on animal data, it seems likely that the neurotoxicity of MDMA may be dose related and mediated in part by hyperthermia. Hyponatremia also could play a role. No adverse cognitive effects have been observed in clinical studies of MDMA in which controlled doses (up to 150 mg) are given on a few occasions. In clinical research settings, the maximum temperature increase is about ½ degree Celsius.

Deficits in memory and executive function have been observed in heavy users of PCP and ketamine. Vacuolization is seen in high doses in animal models with

Telegram: @medical_k

www.konkur.in

PCP and ketamine, possibly contributing to cognitive impairment in association with chronic use in humans. In rodents and primates, the most sensitive brain regions are the posterior cingulate and retrosplenial cortices.

There is no evidence of significant neurotoxicity with classic hallucinogens. Well-controlled trials with large samples have not yet explored this, but studies of long-term ritualistic users of peyote and ayahuasca have revealed no neurocognitive impairments.

Differential Diagnosis

Use of hallucinogens frequently occurs in the context of other substance use. In such cases, it is important to be clear about which symptoms are caused by which substance in order to arrive at the correct SUD diagnosis/es.

Course and Prognosis

Hallucinogen use disorders tend to be short and self-limited. Prevalence rates drop to near zero in people over the age of 50.

Treatment

There is little evidence to guide treatment of hallucinogen use disorders. Since there are no specific treatments or programs for treatment of hallucinogen use disorders, treatment-seeking patients with these disorders are treated within addiction treatment programs designed for other SUDs or multiple addictions. The efficacy of psychosocial treatments that have empirical support for the treatment of other SUDs is unknown for hallucinogen use disorders.

HALLUCINOGEN-PERSISTING PERCEPTION DISORDER

Definition

With HPPD, users re-experience one or more perceptual effects similar to those experienced during previous hallucinogen use, which cause clinically significant distress or impairments in functioning, and are not due to a general medical condition (i.e., migraine with aura, temporal or occipital lobe epilepsy, and temporal lobe infectious illness), better ascribed to another mental condition (i.e., schizophrenia, dementia, and delirium), or due to hypnopompic hallucinations. The perceptual symptoms mentioned as examples in the diagnostic criteria are visual (e.g., geometric hallucinations, image “trails” behind moving objects), but perceptual abnormalities from other sensory modalities and re-experiencing of other aspects of hallucinogen-induced altered states have been reported. The symptoms can occur spontaneously or be triggered by stress, anxiety, exercise, or use of another drug (i.e., cannabis). They can occur episodically or take the

Telegram: @medical_k

www.konkur.in

form of constant perceptual disturbances without an identifiable trigger. The term “flashback” has sometimes been used synonymously with HPPD but is distinguished from HPPD in connoting brief persisting perceptual effects, similar to those experienced during recent hallucinogen use, that do not necessarily cause clinical distress or impairment and can even be pleasurable. Unlike flashbacks, HPPD tends to be recurrent with a continuous or intermittent/paroxysmal pattern of symptoms that is either a slowly reversible or chronic permanent condition experienced as distressing. Today, these two related phenomena are sometimes referred to as HPPD Type I (i.e., flashbacks that are brief) and Type II (i.e., more persistent and disabling HPPD).

History

Persisting perceptual abnormalities (“flashbacks”) following use of hallucinogens were first described over 100 years ago with mescaline. Reports next arose in the 1950s and 1960s, mostly in relation to LSD ingestion. These described prolonged changes in normal perception similar to the perceptual effects produced by hallucinogens, persisting subacutely (weeks to months) and chronically after hallucinogen use. It should be noted that in addition to the classic hallucinogens, some cases of persisting perceptual disturbances attributed to the use of MDMA, ketamine, and cannabis have been reported.

Epidemiology

Although the exact prevalence of HPPD is unknown, it is thought to be rare given the relatively few cases reported out of the tens of millions of doses of hallucinogens used over the last 60 years. The DSM-5-TR reports a prevalence of HPPD of approximately 4.2% among individuals who use hallucinogens. However, a population study using NSDUH data from 2001 to 2004 found no association between lifetime use of psychedelics and past-year use of LSD with past-year symptoms of HPPD-type visual phenomena. HPPD appears to be most prevalent in males, with symptoms developing in late adolescence. It is significantly less common in research settings with careful screening and preparation and has most commonly been associated with street-level LSD.

Etiology

Individual or family history of anxiety disorders and the presence of pre-existing tinnitus, visual “floaters,” and concentration impairments may indicate vulnerability to HPPD. The pathophysiology of HPPD has yet to be conclusively elucidated. However, given the predominance of visual symptoms, their typology (i.e., geometric hallucinations, trailing, and positive afterimages), and that patients typically do not believe the visual phenomena are real, lower levels of the visual pathway in the brain (including the visual cortex) have been

Telegram: @medical_k

www.konkur.in

implicated. However, multiple brain regions may be affected, and the thalamus may be a particular area of interest since nonvisual perceptual stimuli (i.e., auditory and sensory) can also be abnormal in patients with HPPD. Abraham and Aldridge initially proposed that damage to lower-level visual system inhibitory cortical interneurons (which express 5HT2A receptors and release GABA upon activation) were primarily responsible for the mechanism of action of HPPD and could account for visual disturbances by altering the signal-to-noise ratio of incoming visual stimuli. A broader conceptualization of the pathophysiology of HPPD includes a misbalance or dysregulation between excitatory versus inhibitory input in the visual system where both increases in excitation and/or decreases in inhibition could result in the variety of visual disturbances seen in HPPD.

Diagnosis and Clinical Features

The most common perceptual distortions (illusions or hallucinations) in HPPD are in the visual system (i.e., geometric hallucinations, flashes of color, intensification of colors, trails of images of moving objects, positive afterimages, halos around objects, false perceptions of movement in the peripheral visual fields, micropsia, and macropsia), although auditory and sensory distortions have been reported as well. In addition to visual illusions and hallucinations, patients commonly experience depersonalization and derealization symptoms. It is important to note that HPPD is not a psychotic illness since patients are aware that the illusions and hallucinations are not real. However, symptoms may be disabling to those with Type II HPPD, and comorbid anxiety, depression, and suicidal ideation have been described.

Differential Diagnosis

Alternative explanations for unusual perceptual experiences such as visual epilepsy, migraine, delirium, dementia, schizophrenia, hypnopompic hallucinations, PTSD, and other hallucinogen-induced disorders must be considered before diagnosing HPPD. HPPD is easily distinguished from psychotic disorders because symptoms are sensory (primarily visual), delusions are absent, and insight, reality testing, and thought process are intact.

Course and Prognosis

The course of HPPD is variable, with a more benign course for Type I as opposed to a more persistent course for Type II. Symptoms among about half of patients with HPPD cease within 5 years, though they persist for decades in some cases. Symptoms can be worsened by a variety of stimulant drugs, marijuana use, fatigue, exercise, and infections.

Telegram: @medical_k

www.konkur.in

Treatment

Supportive psychotherapy and cognitive behavioral treatment are warranted to help individuals cope with and adapt to their symptoms. Reassurance that the symptoms are due to HPPD, as opposed to an underlying psychotic disorder, may help patients cope. There is no established evidence-based pharmacologic algorithm to treat HPPD, with most data coming from case reports, case series, and open-label trials. Benzodiazepines (e.g., alprazolam, clonazepam) have been shown to reduce some symptoms without leading to disease remission. Their efficacy may be related to their action at the above-mentioned cortical serotonergic inhibitory interneurons with GABAergic outputs. Along these lines, there is some evidence that phenytoin (which, in addition to inhibiting sodium channels, also increases CNS GABA levels and potentiates GABA-mediated postsynaptic inhibition) decreases symptoms. Clonidine in an open-label trial was also shown to alleviate some of the symptoms, suggesting a possible role for sympathetic nervous system activation in the pathophysiology of HPPD. There is some evidence supporting the use of the opioid receptor antagonist naltrexone and typical antipsychotics (haloperidol, trifluoperazine, and perphenazine), although the adverse side effect profile of typical antipsychotics limits their use. The data on the utility of selective serotonin reuptake inhibitors (SSRIs) to ameliorate symptoms are mixed, with some data suggesting efficacy and some suggesting a worsening of symptoms. Risperidone (and possibly the atypical antipsychotics in general) should be avoided as there is evidence that risperidone worsens HPPD symptoms. More controlled trials are needed to establish better pharmacologic treatments for HPPD, which could also help further elucidate HPPD's pathophysiology. Given the absence of proven pharmacologic treatment, avoidance of triggers, especially cannabis, is an important recommendation for patients. Finally, some patients have found that wearing sunglasses, especially indoors, helps ameliorate the visual disturbances.

PCP- AND OTHER HALLUCINOGEN-INDUCED PSYCHOTIC DISORDER

Definition

DSM-5-TR defines hallucinogen-induced psychosis as a syndrome meeting criteria for a psychotic episode having its onset during or shortly following use of a hallucinogen, which persists beyond the usual period of action of the drug, and is not better accounted for by another psychotic disorder or other psychiatric, neurologic, or medical disorder. The disorder must be sufficiently severe to cause significant impairment and/or distress.

Telegram: @medical_k

www.konkur.in

History

Phencyclidine. Although acute intoxication with PCP can closely resemble a psychotic state, persisting psychosis following PCP use was eventually recognized in 1974. These episodes closely resembled severe schizophrenic episodes, often included violent or aggressive behavior, and frequently persisted for weeks despite aggressive antipsychotic treatment before resolving completely. Although the prevalence and attention to this phenomenon have receded as the prevalence of PCP use has decreased, such cases are still seen fairly frequently in areas with prevalent PCP use.

Other Hallucinogens. After LSD became widely used as a recreational drug in the 1960s, it was increasingly recognized that its use was sometimes associated with persisting psychosis, a common example being first use by a teenager or young adult (during the age of typical onset of schizophrenia) who developed first-episode psychosis and went on to develop a chronic course of schizophrenia. However, it has never been conclusively shown that classic hallucinogens can produce a persistent psychosis in someone without an underlying psychotic disorder or diathesis (see “Epidemiology” section below).

Epidemiology

Phencyclidine. PCP psychosis is a well-known presentation in hospitals, but its prevalence is unknown. Increased delusional ideation has been reported among frequent users of ketamine. Ketamine and DXM have been reported to cause persisting psychotic episodes, but much less frequently than PCP. Risk factors also are not well known. Patients with pre-existing psychotic disorders are very sensitive to the psychotogenic effects of PCP, but such individuals would not generally receive the diagnosis of PCP-induced psychosis.

Other Hallucinogens. Reports of new cases of schizophreniform psychoses and related disorders following hallucinogen exposure began to emerge as hallucinogen use became widespread in the United States. Estimates of the prevalence of LSD-induced psychotic episodes as assessed by early psychedelic researchers and clinicians (many administering LSD to psychiatric inpatients) were reported as follows in two major studies of the topic: 0.8/1,000 research volunteers (a single case out of 1,250, where the volunteer was the identical twin of an individual with schizophrenia), and 1.8/1,000 psychiatric patients (7 cases out of approximately 3,850 patients); 0/170 research volunteers and 9/1,000 among psychiatric patients (37 out of 4,300 patients).

A 2018 longitudinal study of 6,788 patients with substance-induced psychoses, including 114 with hallucinogen-induced psychoses, followed for up

Telegram: @medical_k

www.konkur.in

to 20 years, found that 28% of those with a hallucinogen-induced psychosis eventually converted to schizophrenia or bipolar disorder. Notably, patients who experienced psychoses induced by marijuana, amphetamines, and alcohol had higher risks of converting to schizophrenia than patients who experienced hallucinogen-induced psychoses. Rates of conversion to bipolar disorder were higher for patients who experienced psychoses induced by sedatives, marijuana, and alcohol than those who experienced hallucinogen-induced psychoses. Being 16 to 25 years of age at the time of a substance-induced psychosis and self-harming after the episode were associated with higher risk of converting to either schizophrenia or bipolar disorder.

Though classic hallucinogen use can cause transient psychotic-like positive symptoms in normal volunteers and provoke sustained psychosis in vulnerable people with psychotic spectrum illnesses, there is little evidence linking classic hallucinogen use to prolonged psychosis in individuals without a psychotic diathesis. Cross-sectional population-level studies have found no significant associations between psychedelic use and increased rates of any psychiatric symptoms, including psychosis. The prevalence of schizophrenia has also remained relatively stable since first being measured, even though use of classic hallucinogens has fluctuated widely.

Rather than producing de novo chronic psychotic disorders, it appears most likely that hallucinogens precipitate psychosis in people who would inevitably develop it later or that previously unrecognized psychotic disorders may become apparent amid hallucinogen use. In a 2019 longitudinal study of 7,606 individuals with substance-induced psychoses, including 197 with hallucinogen-induced psychosis, familial risk scores for nonaffective psychosis predicted progression from substance-induced psychosis to schizophrenia. This points to hallucinogen and other substance-induced psychoses likely being drug-precipitated disorders in highly vulnerable individuals. Consistent with this hypothesis, in contemporary clinical trials investigating classical hallucinogens, in which participants with personal or family histories of psychotic disorders or bipolar disorder are excluded, there have been no reported cases of prolonged psychosis.

Etiology

Phencyclidine. Although PCP and ketamine intoxication (a transitory state) have been used extensively as a model of psychosis, etiology and pathogenesis of PCP-induced psychosis are not well studied. In animal models, a single dose of MK801 (an NMDA receptor antagonist with particularly strong psychotogenic effects) has been used to model first-episode psychosis. A single injection can cause persisting changes in hippocampal glutamatergic neurotransmission, resulting in loss of synaptic plasticity and deficits in learning and cognitive function, although other behavioral effects gradually resolve.

Telegram: @medical_k

www.konkur.in

Other Hallucinogens. In many cases, the onset of psychosis following hallucinogen ingestion may be due to the expression of underlying diatheses for schizophrenia or bipolar disorder. There is no established etiology for other hallucinogens inducing persisting psychosis, but persistent dysregulation of serotonergic systems is possible. Also, because classic hallucinogens cause downstream effects on glutamatergic neurotransmission similar to those produced by PCP and ketamine, it is possible that persistent changes in glutamatergic systems could play a role in some cases of persisting psychosis induced by classic hallucinogens.

Diagnosis and Clinical Features

A history of recent hallucinogen use is necessary to establish the diagnosis. However, it may be difficult to confirm or rule out recent hallucinogen ingestion. PCP, in particular, is often misrepresented as other drugs. Patients may deny drug use, and drug screens will often be negative.

Phencyclidine. PCP-induced psychosis is often phenomenologically indistinguishable from schizophrenia. Thought disorder and negative symptoms may be prominent, and delusions and hallucinations are not always present.

Other Hallucinogens. Patients with hallucinogen-induced psychosis are younger at onset, have more visual hallucinations and depression, and have a greater prevalence of a family history of mood disorder than non–drug-using patients with schizophrenia. They also have more mood swings, euphoria, grandiosity, hyper-religiosity, and multimodal hallucinations, and more prominent positive than negative symptoms. Thus, the psychosis tends to have elements of mania. If mood symptoms are prominent, the diagnosis of a hallucinogen-induced mood disorder should be considered.

Pathology and Laboratory Examination

Urine drug screens may be useful to confirm recent ingestion of hallucinogens, but routine tests are available only for PCP and MDMA. Physical examination and laboratory findings will be normal following resolution of acute intoxication or delirium and any medical sequelae.

Differential Diagnosis

Hallucinogen-induced psychosis usually resembles schizophrenia but sometimes has manic features as well (in which case the diagnosis of hallucinogen-induced mania should be considered). The symptoms of hallucinogen-induced psychosis may be indistinguishable from those of a primary psychotic disorder. Sudden onset following recent history of

Telegram: @medical_k

www.konkur.in

hallucinogen use strongly suggests the diagnosis. Signs and symptoms of hallucinogen intoxication overlap substantially with those of hallucinogen-induced psychosis, so the diagnosis of hallucinogen-induced psychosis should be used only if the symptoms significantly exceed the expected duration and/or intensity of the intoxication state. The diagnosis of hallucinogen-induced delirium should be used if symptoms occur solely in the course of a delirium. If symptoms persist beyond 4 to 8 weeks, the patient likely has a primary psychotic disorder that was exacerbated or precipitated by hallucinogen use.

Course and Prognosis

Hallucinogen-induced psychoses follow a variable course. At one extreme are cases that resemble intoxication with the substance, resolving rapidly and completely. In other cases, symptoms persist for weeks despite aggressive treatment. This pattern is relatively common with PCP-induced psychosis that has been observed to persist for up to 6 weeks but eventually resolves completely. Finally, there are cases in which the psychosis becomes chronic. In these cases, a diagnosis of primary psychotic disorder is appropriate, most commonly schizophrenia or bipolar disorder.

Treatment

Hallucinogen-induced psychoses are treated much like any other acute psychosis. Hospitalization may be necessary to ensure safety. Since the course of illness is unpredictable, treatment should aim to prevent irreversible consequences of illness and preserve relationships and functional capacity. Chronic psychotic disorders with onset during hallucinogen use are treated like any other case of first-break psychosis, except that particular care should be taken to minimize future harms associated with substance use. Even if symptoms resolve and the patient is not experiencing any further psychotic symptoms, given that a substantial minority of patients will eventually receive a formal psychotic disorder diagnosis, ongoing periodic monitoring and assessment by a mental health provider for psychotic symptoms is strongly recommended, particularly for younger patients.

Phencyclidine. Antipsychotic medications are frequently used to treat PCP-induced psychosis, but data on their efficacy are limited. Benzodiazepines can be used to control agitation. In animal models, atypical antipsychotics are more effective than typical antipsychotics in reversing the effects of PCP. Electroconvulsive therapy (ECT) may be necessary for patients with antipsychotic-resistant PCP-induced psychosis. The use of drugs that modulate NMDA receptor–mediated neurotransmission, such as lamotrigine, glycine, D-serine, and D-cycloserine, as well as group II metabotropic glutamate receptor

Telegram: @medical_k

www.konkur.in

agonists such as the compound LY354470, has been proposed based on preclinical data. However, there are no clinical trials of these agents in PCP- or ketamine-induced psychosis.

Other Hallucinogens. Treatment of other hallucinogen-induced psychosis does not differ substantially from the treatment of other psychoses. In addition to antipsychotic medications, lithium, anticonvulsants, ECT, benzodiazepines, and antidepressants have been used with reported success, but controlled trials are lacking.

PHENCYCLIDINE- AND OTHER HALLUCINOGEN-INDUCED BIPOLAR DISORDER

The diagnosis of substance/medication-induced bipolar and related disorder is used if the patient develops a manic, hypomanic, or mixed episode during or soon after hallucinogen intoxication. Hallucinogen effects on mood are common but usually transient. Mood may fluctuate rapidly. Symptoms resembling those of major depression, mania, or hypomania may appear but rarely persist beyond intoxication. Although this syndrome is not well characterized, manic features are sometimes seen following hallucinogen intoxication, particularly in association with psychosis. Since there are no specific data on treatment of this disorder, treatment should ensure safety, and clinicians should consider medications that are typically effective for similar symptoms. As with most substance-induced disorders, symptoms are likely to remit within days to weeks with cessation of the causative substance. If symptoms persist beyond 4 to 8 weeks, a primary bipolar disorder diagnosis should be considered.

PHENCYCLIDINE- AND OTHER HALLUCINOGEN-INDUCED DEPRESSIVE DISORDER

The diagnosis of substance/medication-induced depressive disorder is used if the patient develops a depressive episode during or soon after hallucinogen intoxication. Depressive symptoms can develop during dysphoric hallucinogen experiences (“bad trips”) and usually resolve with the acute effects of the drug. Evaluation and management of suicide risk are imperative since suicides have occurred under these conditions. Hallucinogen use can also exacerbate a pre-existing mood disorder.

PHENCYCLIDINE- AND OTHER HALLUCINOGEN-INDUCED ANXIETY DISORDER

Telegram: @medical_k

www.konkur.in

The diagnosis of substance/medication-induced anxiety disorder is used if the patient develops an anxiety episode during or soon after hallucinogen intoxication. Clinically significant anxiety (distinct from paranoia or agitation) is rarely reported with PCP or ketamine intoxication but is common during intoxication with *Salvia* and many of the classic hallucinogens. Full-blown panic attacks can occur. These symptoms are self-limited but may be very distressing. Patients usually respond well to reassurance and being in a calm and safe environment. Oral or parenteral benzodiazepines may be useful in extreme and/or persistent cases. There is little or no evidence for persisting hallucinogen-induced anxiety disorders.

PHENCYCLIDINE- AND OTHER HALLUCINOGEN-INDUCED INTOXICATION DELIRIUM

The diagnosis of substance intoxication delirium should be used instead of substance intoxication if disturbances in attention and cognition predominate and are severe enough to warrant clinical attention. Because such symptoms are part of the intoxication syndrome for PCP and related substances, the diagnosis of delirium depends primarily on the severity of the neurocognitive symptoms. This is also true for anticholinergic agents, whose hallucinogenic effects are usually considered to be symptoms of anticholinergic delirium, with features typically including disorientation, agitation, grossly impaired cognition and memory, and fluctuating mental status. For most other hallucinogens, delirium is uncommon but may occur in cases of severe intoxication or may represent a response to serious medical consequences of intoxication (e.g., in cases of overdose of MDMA or other nonclassic serotonergic hallucinogens). Severe toxidromes characterized by prolonged delirium have been reported with NBOMe analog ingestion.

Management of substance-induced delirium is primarily focused on correcting any dangerous medical situations and keeping the patient safe while they recover from the effects of the substance. Aggressive sedation, airway protection, and fluid resuscitations are central to managing substance-induced delirium. Activated charcoal may be administered in cases of ingestion. Specific issues in the treatment of delirium secondary to PCP and related hallucinogens are discussed in the section on PCP and related substance intoxication above.

Treatment of anticholinergic delirium involves supportive care and administration of benzodiazepines. Antipsychotics should be avoided. Use of physostigmine is controversial and should be reserved for cases where it is clear that anticholinergics and no other substances have been ingested.

www.konkur.in

UNSPECIFIED PHENCYCLIDINE-RELATED DISORDER AND UNSPECIFIED HALLUCINOGEN-RELATED DISORDER

This residual category is used to describe situations in which symptoms characteristic of a PCP- or other hallucinogen-related disorder predominate and cause clinically significant distress or impairment but do not meet full criteria for any specific disorder.

11.7 Inhalant-Related Disorders

Cameron J. Davidson, Ph.D., D.W. Svenson, M.A., and Scott E. Bowen, Ph.D.

Inhalants are an assorted group of compounds that readily vaporize at room temperature and are intentionally inhaled for their psychoactive effects. These volatile compounds are used in many household products as solvents, propellants, markers, thinners, cleaning products, and fuels. Some of these

Telegram: @medical_k

www.konkur.in

volatile compounds are also commonly used for their solvent properties, which allow for the dissolution of solids into a liquid form without damaging the structure of the solid. The most common example of this is the use of toluene in glues. When a glue, a liquid mixture of solids and the solvent toluene, is pushed from its tube, the toluene readily vaporizes into the air leaving only the solid behind to set or harden. The same principle is also used in markers and paint. Conversely, to remove a hardened glue, a solvent (containing toluene or some similar compound) may be used to resuspend the solid in a liquid form and allow for removal. The term "*inhalants*" encapsulates a wide range of volatile hydrocarbons, such as toluene, hexane, trichloroethylene, trichloroethane (TCE), xylene, and gasoline, among many others. These compounds and others are grouped together under the term inhalants because of their route of administration, lack of combustion or vaporization, and their shared pharmacologic properties.

Many categorization strategies have been used to organize inhalants, such as product type or form, chemical properties, or shared pharmacologic impacts from a shared pattern of misuse. At present, however, data are too scant to support a more refined classification system than that in the *Diagnostic and Statistical Manual of Mental Disorders,* Fifth edition (DSM-5). Due to the loose inclusion criteria to this category, it is easier to distinguish specific compounds that are not to be included in the category of inhalants. For example, the DSM-5 excludes combusted substances (e.g., tobacco, marijuana, crack cocaine), anesthetic gasses (e.g., nitrous oxide), and nitrites (amyl, butyl, and isobutyl), instead classifying these into specific disorders (e.g., tobacco, marijuana, and crack cocaine) or as other (or unknown) substance-related disorders. However, some disorders associated with the excluded compounds are briefly discussed at the end of this chapter.

Individuals, especially young adolescents (12 to 17 years old), inhale the vapors from these products for the intoxicating effects (see Table 11.7–1). Lifetime inhalant use for eighth graders in 2019 was reported by the Monitoring the Future (MTF) study to be 9.5%, which falls in fourth place of most used intoxicants for this age range only behind alcohol (24.5%), marijuana (15.2%), and cigarettes (10.0%). According to the Substance Abuse and Mental Health Services Administration (SAMHSA), the proportion aged 12 years and older reporting use in the past year is generally low but has been rising. The overall rate reporting "use in the last year" for 2016 was ~0.6%, but rose to ~0.8% in 2019, representing an approximate 30% increase in the usage rates over this time frame. With increasing age, prevalence of past-year inhalant use declines and few people ever meet criteria for inhalant use disorder (IUD). While ~3% of those aged 12 to 17 years reported use (~743,000 people), 1.7% of those aged 18 to 25 years (~577,000 people) reported inhalant use in the last year which represents approximately seven and four times the rate of those aged 26 years

Telegram: @medical_k

www.konkur.in

and above (0.4%; ~822,000 people). Inhalants are associated with multiple problems, including conduct disorder, noninhalant substance use disorders (SUDs), mood, anxiety, and personality disorders, suicidality, history of physical/sexual abuse and neglect, and victimization. For some adolescents, the early time-limited use of inhalants may be a signal of a lifelong problem with risk-taking propensity, novelty seeking, impulsivity, and externalizing behaviors. A comparatively smaller subpopulation chronically uses inhalants, which have been associated with multiple sequelae, including major and minor behavioral problems and toxicity-related organ pathology.

Table 11.7–1.
Commonly Misused Inhalants

Group	Characteristics	Commercial Products
Alkyl nitrites	A nitrite group	"Poppers" Room odorizers
Nitrous oxide	Inorganic anesthetic gas/propellant	Whipped dairy cream chargers, nitrous oxide tanks
Other anesthetics	Gases or volatile liquids	Anesthesia bottles (ether, Halothane, Isoflurane, Desflurane)
Propellants–fuels	Flammable gases that are liquefied under pressure	Cigarette lighters, cooking fuels, hairsprays, central air conditioning units
Solvents	Liquids that dissolve other substances without any change in chemical composition	Paints, paint thinners, glues, inks, lacquers, varnish removers, degreaser agents, spot removers, motor fuels

DEFINITION

The section on inhalant-related disorders in the DSM-5 includes four relevant categories: inhalant intoxication, inhalant use disorder, inhalant-induced disorders, and unspecified inhalant-related disorder. IUD is characterized by clinically significant impairment and/or distress due to a problematic pattern of volatile hydrocarbon inhalation. Inhalant-induced disorders is a broad category and includes disorders that result from the toxic effects of inhaled substances

Telegram: @medical_k

www.konkur.in

(e.g., inhalant intoxication, inhalant intoxication delirium, and inhalant-induced psychotic, depressive, anxiety, and major and mild neurocognitive disorder). The specific inhalant-induced disorders will be discussed later in this chapter. An unspecified inhalant-related disorder diagnosis is more of an "umbrella term" reserved for persons presenting with signs of an inhalant-related disorder who experience clinically significant distress, but who do not meet full diagnostic criteria for any specific inhalant-related disorder or any other DSM-5 substance-related and addictive disorder.

COMPARATIVE NOSOLOGY

The DSM-5 contains the diagnostic criteria and description of specific subtypes of this disorder. These subtypes include IUD, inhalant intoxication, and unspecified inhalant-related disorder and are found in the inhalant-related disorders section of the substance-related and addictive disorders chapter of the DSM-5. Related but associated impacts such as inhalant-induced depressive disorder are included and can be found in the substance/medication-induced depressive disorders section.

The 11th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-11) refers to inhalants as "volatile solvents" and describes their use as "characterized by the pattern and consequences of volatile inhalant use" (6C4B). The use can be classified as a harmful pattern of volatile inhalants that is episodic (6C4B.10), continuous (6C4B.11), or unspecified (6C4B.1Z). The ICD-11 includes a diagnosis of "inhalant withdrawal," whereas the DSM-5 doesn't discuss inhalant withdrawal symptomatology due to a "lack of evidence of significant withdrawal documented in humans similar to that of phencyclidine and/or hallucinogens." The ICD-11 expanded upon the withdrawal diagnosis (6C4B.4) and provided the definition as "a clinically significant cluster of symptoms, behaviors and/or physiologic features, varying in degree of severity and duration, that occurs upon cessation or reduction of use of volatile inhalants in individuals who have developed volatile inhalant dependence or have used volatile inhalants for a prolonged period or in large amounts." Some of the specific signs are defined by insomnia, anxiety, irritability, dysphoric mood, shakiness, perspiration, nausea, and transient illusions. More evidence of a significant but minor or short-lived withdrawal period in humans may lead to changes in the next iteration of the DSM to include diagnostic criteria or description of withdrawal symptomatology.

EPIDEMIOLOGY

The impact on public health from inhalant misuse may be quantified by the prevalence of inhalant use, DSM-5-defined IUD, inhalant-related visits to hospital

Telegram: @medical_k

www.konkur.in

emergency departments (EDs), inhalant-related admissions to drug treatment programs, and deaths associated with inhalant use. Each of these factors will be discussed, outlined, and explored below.

Prevalence of Inhalant Use

The U.S. government sponsors three large nationally representative studies of drug use. The MTF survey assesses 8th, 10th, and 12th graders and the Youth Risk Behavior Survey (YRBS) assesses 9th to 12th graders, whereas residents 12 years of age and older, including adults, living in U.S. households are assessed in the National Survey on Drug Use and Health (NSDUH). Because of differences in sampling and interview methods, the MTF survey and YRBS often show higher prevalence rates of adolescent inhalant use compared to the NSDUH. All three surveys tend to demonstrate similar patterns and trends over time and provide important data related to population statistics and prevalence of drug use generally. More U.S. eighth graders report use of inhalants than any other illicit drug except marijuana (13.4%). In 2019, about 1 in 10 U.S. eighth graders reported inhalant use even once in their lifetime (~9.5), and about half who reported lifetime use also reported use in the last year (~4.7). A little less than half of those reporting use in the last year reported use in the past 30 days (~2.1%). This is in contrast to about 1 in 100 who reported cocaine use (~1.2%), with ~0.7% reporting use in the past year and only ~0.3% reporting use in the past month. The rates of inhalant use in the past year among youths (12 to 17 years old: ~3%) correspond to an approximate population of ~743,000; compared to young adults (18 to 25 years old: ~1.7%) at ~577,000; and adults (25 years old and above; 0.4%) at ~822,000 people. While the rates in the 12 to 17 and 18 to 25 age ranges increased from the previous 3 years, the rate of those 25+ years old has remained relatively stable. The reported increases in the younger two categories resulted in all persons 12 years or older reporting use in the previous year rising from ~0.6% in 2018 to ~0.8% in 2019 (an increase of ~400,000 people). Taken together, these values represent a small but not insignificant portion of ~2.1 million people in the United States in the previous year and ~730,000 initiates of inhalant use, which are greater numbers than cocaine, prescription sedative misuse, methamphetamine, and heroin use. Although the rates of initiation are relatively high, the noncontinuation rate among 12th graders is also very high at ~65%. Considering that rates of inhalant misuse and disorder are higher in other typically underdeveloped nations with many homeless young people, the worldwide number would be much greater.

Between 2005 and 2019, lifetime and annual inhalant use prevalence rates in the MTF survey steadily declined; however, there was also a decline in the perceived harmfulness (e.g., “great risk in the use of inhalants once or twice”). This decline in perceived harmfulness among 8th graders since 2012 represents

Telegram: @medical_k

www.konkur.in

a reversal of the trend for previous years' surveys to report an increase in this belief and declines among 10th graders since 2014. This pattern of increase and subsequent decline may be linked to the discontinuation of a governmental campaign that took place in the mid 1990s to the early 2000s to inform the public of the dangers of inhalant use. This campaign was subsequently terminated after observing a the intended effect of decline in inhalant use. This pattern has been termed "generational forgetting" and results in a situation where the dangers of a drug were discussed and addressed but over the years the perceptions about its dangers are unknown and these drugs are "rediscovered." The declines in perception of risk potentially indicate that an increase in use may be reported on future reports.

The prevalence of inhalant use among adolescents is generally similar between males and females, however, recently the rates of female lifetime use have been higher in 8th (11.3%) and 10th (7.5%) grades than that of males (7.6% and 6.2%) but not in the 12th grade (5.8% male vs. 4.8% female: MTF). The most recent YRBS for 2019 showed that females tended to use at higher rates than males (6.9% vs. 5.7%). There were also differences among sexual identities, with those identifying as heterosexual (straight) having rates around 5% and those reporting "gay or lesbian" or "bisexual" reporting much higher rates of 11% and 15.8%, respectively. American Indian or Alaska natives tend to have higher rates (15.1%) compared to Caucasian (White) (6.3%), Black or African American (7.2%), Hispanic or Latino (6.6%), or multiple races (7.2%). Lowest of all is that of Asian individuals (1.9%). Between 1995 and 2013, a significant linear decline in the prevalence of lifetime inhalant use was noted. More current iterations of the YRBS have shown decreases from 2011 to 2019 with no change between 2017 and 2019 (~ 6.3% report using at least once). Inhalant use prevalence rates varied significantly across the states and large urban school districts participating in the YRBS. Continuation rates can be seen when looking at the past-month prevalence rate compared to the lifetime rate, which are disparate for inhalants, indicating high discontinuation rates. Inhalant use occurs mainly in younger age groups, with the prevalence of past-year inhalant use falling from a peak of around 3.5% to 4.5% at age 14 to less than 1% for all adult inhalant users. Most new users do not endorse regular inhalant use, and more than half report only 1 to 3 days of use in the prior 12 months.

The prevalence of inhalant problems in small, isolated groups or communities and in high-risk populations, including juvenile and criminal justice system–involved persons, may deviate from larger national trends. For example, certain Native American communities experience a high prevalence of these problems, with higher odds of initiation (~2 × comparable Caucasian (White) youth). However, rates of use may vary across communities. For example, in one large recent general population study of two Native American communities assessing persons aged 11 to 17 years who identified as American Indian or Caucasian

Telegram: @medical_k

www.konkur.in

(White), odds ratios were different by tribe for males with Upper Great Lakes having an increased likelihood than their South West peers, whereas females did not differ. These indicate that geographic or ethnic enclaves may have differential rates of initiation and require focused interventions for the specific populations.

Studies of juvenile probationers, incarcerated youth in short- and long-term residential treatment, and youth and adults treated for behavioral problems or other noninhalant substance dependencies have reported lifetime inhalant use prevalence rates ranging from 18% to nearly 40%. This may indicate that inhalant use may be more common among those who have behavioral issues, especially incarcerated youths; however, this is a correlation among a restricted sample, thus, causality cannot be inferred without further investigation.

In countries other than the United States, rates vary from country to country but are high among unhoused children. These children may live on the street in loose-knit juvenile gangs where inhalant use is socially acceptable in their peer group and used to cope or dissociate. Among such children, inhalant use can be very common with prevalence rates reportedly exceeding 70% in some cities. In addition, there may be cultural differences in the specific products inhaled due to their availability or standards set for specific countries.

Prevalence of Inhalant Use Disorder

Prevalence of inhalant use *per se* should not be confused with the prevalence of IUD as defined by the DSM-5, and most users never progress to the formal diagnosis of IUD. Although new surveys using these criteria have not yet been conducted, information about prevalence can be determined using previous iterations of the DSM. Given the changing nature of the demographics as well as declining use generally for inhalants, newer studies need to be undertaken using DSM-5 criteria. Nationally representative surveys suggest that IUD is relatively rare. For example, a national household survey assessed DSM-IV-TR-defined past-year IUDs. From this survey, about 0.1% of the U.S. population (12 years of age or older) met criteria for an IUD in any given 12-month period. As might be predicted from information available regarding inhalant use patterns, the prevalence of past-year DSM-IV-TR inhalant abuse and dependence is somewhat higher (i.e., 0.4%) among youth 12 to 17 years of age. In 2012, the household survey noted that an estimated 34,000 persons in the United States met DSM-IV-TR criteria for inhalant dependence disorder.

Another survey of about 8,000 randomly sampled Americans (15 to 54 years of age) found that 0.3% had been dependent on inhalants in their lifetimes (as defined by DSM-III-R); again, rates of inhalant dependence (0.6%) were higher among younger age groups (15 to 24 years of age). In that study, most people who had tried inhalants had not become dependent on them; only about 1 in 27

Telegram: @medical_k

www.konkur.in

respondents who reported trying inhalants met criteria for lifetime dependence (1 in 13 of individuals aged 15 to 24 years); in contrast, about 1 in 3 individuals reporting nicotine use met criteria for lifetime dependence on that substance. Although prevalence of inhalant use is similar across genders in most studies, inhalant dependence was about four times more likely among males, compared with females.

A nationally representative study of over 43,000 respondents 18 years of age or older found similarly low past-year (0.02%) and lifetime (0.3%) prevalence rates of IUDs (DSM-IV-TR-defined), with most of those individuals meeting criteria for abuse; inhalant abuse and inhalant dependence prevalence rates were the lowest among the drug categories reported (i.e., alcohol, sedatives, tranquilizers, opioids, amphetamines, hallucinogens, cannabis, and cocaine). In that study about one in five lifetime inhalant users met criteria for a lifetime IUD, although prevalence of lifetime inhalant use was relatively low (1.7%) compared to most other studies. Even though women are more likely to use inhalants, lifetime IUDs were about five times more prevalent among men.

Limited data are currently available that help to identify which inhalant users are likely to progress to formal inhalant-related disorders. One national cross-sectional survey found that living in a large metropolitan area, previous use of mental health services, number of delinquent behaviors, multiple other drug use disorders, and number of different inhalants used were associated with a DSM-IV-TR diagnosis of inhalant abuse among past-year inhalant users. Use of mental health services, history of foster care placement, multiple other drug use disorders, weekly use of inhalants, and early age at first inhalant use were associated with inhalant dependence among past-year inhalant users.

Several studies of high-risk populations have identified high rates of IUDs among inhalant users. One statewide survey of incarcerated youth reported that 47% of inhalant users met criteria for lifetime DSM-IV-TR inhalant abuse or dependence. Similarly, a study of 162 young adult inhalant users in St. Louis, Missouri, reported that 47% met criteria for DSM-IV-TR inhalant abuse or dependence. Another large study of youth in treatment for substance use and behavioral disorders reported that 18.3% of inhalant users met criteria for DSM-IV-TR–defined IUDs. Thus, while IUD may be uncommon in the general population, high levels of inhalant use and IUD may prevail in correctional and institutional settings serving at-risk youth and adults. New investigations should be undertaken using the DSM-5 to explore how the changes in usage rates relate to diagnosis of IUD, as both have changed from the previous reports.

Prevalence of Inhalant-Related Emergency Department Visits

The U.S. government monitors drug-related ED visits in hundreds of non-Federal, short-stay, general medical, and surgical hospitals around the country.

Telegram: @medical_k

www.konkur.in

In 2011, among the nearly 2.5 million drug-related ED visits, 51% which involved illicit drugs, inhalants (including nitrous oxide and nitrites and excluding accidental exposures) were implicated in an estimated 10,032 visits (0.8% of ED visits involving illicit drugs); in contrast, there were 505,244 cocaine- and 455,668 marijuana-related ED visits in 2011. Of the ED visits for inhalants, only 23.4% also involved alcohol, which is among the lowest illicit drugs with only heroin (18.6%) and methamphetamine/amphetamine (16.2%) showing lower coinvolvement rates. These data are now about 10 years or older, however, and represent the last iteration of the Drug Abuse Warning Network (DAWN) study observing ED admittance for misused substances. Newer studies should be conducted as the rates of use, as well as the proportions of the sexes and races, have changed over the last 10 years.

Prevalence of Inhalant-Related Treatment Admissions

The U.S. government collected data on 1,935,541 admissions to U.S. addiction treatment programs during 2018. The number of admissions with inhalants listed as the primary substance of misuse was 829, constituting 0.04% of treatment admissions that year. Approximately 60% of inhalant admissions were male and 40% were female. Caucasian (White) accounted for 79% of admissions, African Americans for 7.2%, American Indians/Alaska Natives for 4.0%, Asians/Hawaiians for 0.6%, and “other” races for 9.2%. Approximately 80% of all admissions were for persons aged 20 years or younger. In general, these findings indicate that, although inhalant use is generally considered a problem of childhood or adolescence, most persons treated for primary IUDs are late adolescence to early adulthood.

Prevalence of Inhalant-Related Deaths

The repercussions of abusing inhalants can tragically result in fatalities. Inhalant misuse has been reported to result in death from the direct toxic effects of the chemicals, as well as accidental injury, aspiration, suffocation, flash burns, and many other causes. Inhalant misuse is thought to have direct effects on the heart, increasing myocardial cell depolarization and reducing conductivity, which predisposes the individual to arrhythmias, especially when paired with increased blood concentrations of epinephrine. This has sometimes been termed *sudden sniffing death or sudden sniffer’s death*.

Within the United States, there are several sources available to help in determining the prevalence of mortalities associated with inhalants. First, medical examiner reports are available from numerous jurisdictions and metropolitan areas and some states. Despite this, only four statewide investigations (e.g., North Carolina, Texas, Virginia, Washington) of inhalant-related deaths have been conducted in the United States, and some of these

Telegram: @medical_k

www.konkur.in

data are a decade or older now. A review of 39 inhalant-related fatalities in Virginia between 1987 and 1996 found that deaths were most frequently caused by gas fuels including butane and propane (46%), chlorofluorocarbons (26%), and chlorinated hydrocarbons and alkylbenzenes (21%). The fatalities were mostly male (95%) and Caucasian (White) (95%), with 70% of the deceased being 22 years old or younger (median age = 19). An investigation of 144 inhalant-related deaths in Texas between 1988 and 1998 similarly found that most decedents were male (92%), Caucasian (White) (81%), and relatively young (mean age = 25.6 years). In 35% of cases, the cause of death was inhalation of Freon, followed in frequency by inhalation of chlorinated hydrocarbons (implicated in 25% of deaths), and alkylbenzenes (e.g., toluene) identified in 17% of deaths. A review of 56 inhalant-related deaths in Washington state between 2003 and 2012 revealed that most fatalities were male (88%), occurred in young adults (age 20 or older), and were Caucasian (White) (93%). While 12 different chemicals were associated with the deaths, difluoroethane was reported on 30 death certificates (54%), and gas duster products were named as the difluoroethane source for 12 deaths (no source was reported for the remaining 18 difluoroethane deaths). An examination of 30 inhalant-related deaths in North Carolina between 2000 and 2008 reported that most deaths were males (81%) and Caucasian (White) (93%). However, decedents were somewhat older compared to earlier studies (mean and median ages were 31.2 and 28.0, respectively). Deaths due to “air duster” misuse (i.e., 1,1-difluoroethane) accounted for nearly one-third of all cases, and this compound was the second most identified inhalant following toluene. Finally, the Florida State Medical Examiners Commission identified 54 inhalant-related deaths in 2018 and reported that 81% of these cases involved halogenated agents like 1,1-difluoroethane. In 2017, 68 persons in Florida were identified as having inhalant-related deaths, 54 due to 1,1-difluoroethane use. Taken together, these medical examiner reports suggest that within the United States, adult Caucasian (White) males are at the greatest risk for inhalant-related fatalities. The North Carolina study cited above also noted that most decedents were heavy polydrug users with significant health and mental health impairments.

A second source of information on the prevalence of mortalities associated with inhalants is available from calls to national poison control centers within the United States. The most comprehensive investigation examined all inhalant-related reports made to 60 poison control centers between 1983 and 2008. The highest rate of cases occurred among youth aged 12 to 17 years, peaking at age 14 with nearly three-quarters of all cases being boys. The 35,453 inhalant cases reported involved more than 3,400 different products. The most frequently identified inhalants were propellants, gasoline, and paint. Propellant-related cases (e.g., “air dusters”) increased significantly over the study period, particularly since 2003, and constituted the largest-single category of inhalant-

Telegram: @medical_k

www.konkur.in

related cases. The three inhalants most associated with fatal outcomes were butane, propane, and air fresheners.

In the United States, there are still no national estimates of inhalant-related mortality, and the available data likely contain numerous biases. For example, in many instances, poison control centers may never be contacted regarding an inhalant-related death, and the sometimes nonspecific findings following an inhalant-related death may make proper identification of the cause of death difficult.

In the United Kingdom, a systematic study of inhalant-related mortality (i.e., 2,093 deaths) between 1983 and 2007 concluded that the number of deaths during this interval had declined substantially, particularly among women, and that the mean age at death had increased by more than a decade in males and females. Particularly notable decreases in inhalant-related deaths were observed for children following a 1992 federal advertising campaign that warned parents that their children might be misusing inhalants. The number of inhalant-related deaths peaked in the early 1990s and declined to their lowest in the mid-2000s. In 2005, 45 inhalant-related deaths (9 of which were suicides) were reported. This was the lowest number in the prior 20 years, and this reduction may relate to a parent-focused advertising campaign and/or a ban on the sale of cigarette lighter refills to those under the age of 18. The percentage of glue-related inhalant deaths declined during this 25-year interval, whereas the percentage of deaths due to gas fuels (e.g., butane and propane) increased significantly. In the United Kingdom, butane was implicated in 80% of such deaths. In 4 of 10 of these deaths, there was no evidence of previous inhalant use, and most deaths occurred at home. Inhalant-related deaths were predominantly male. Among 10 to 14 year olds, there were more inhalant-related deaths than deaths associated with other drug misuse (as defined by the Drug Misuse Act of 1971, including cocaine, cannabis, LSD, and opioids, among others).

Telegram: @medical_k

www.konkur.in

A 15-year-old Caucasian (White) boy was admitted to an adolescent day treatment program. His biologic father was identified as a drug dealer, was abusive to his biologic mother, and went to prison for robbery; his parents separated when he was only a few months old, and the patient did not recall ever meeting his father. His mother remarried when he was 12. Reportedly, his stepfather would “get smashed,” hit his mother, get very close to the patient’s face, and “yell at [him] for no reason.” His mother was in the process of divorcing his stepfather. At age 10, the patient began using marijuana, reporting that it helped him “get away” and reduce his anger, and his use rapidly progressed to using “all day every day.” He then tried alcohol, cocaine, and prescription medications (i.e., benzodiazepines and opioids).

The patient reported a history of delinquent behaviors. These behaviors included stealing from his mother’s purse, stealing her prescription medicines, pawning his stepfather’s possessions, truancy, and initiating fights. In sixth grade, he received a drug paraphernalia ticket from the police, although this charge was later reduced to minor in possession of alcohol. He was later charged with accessory to aggravated robbery. The patient was placed on probation, and because of his history of substance involvement, was admitted to a short-term outpatient, mainly group-based treatment program. He was discharged from that program after a few sessions for an inability to remain drug free and suspected use of his mother’s prescription pain medication.

After serving 3 weeks in a juvenile detention center, he was admitted to a day-treatment program. A thorough intake evaluation revealed a history of cannabis, cocaine, alcohol, and prescription drug use disorders, no other mental health concerns, and no relevant medical issues. The patient did well in treatment, attending regularly, receiving above-average scores for his behavior, completing his weekly school contracts and all his initial treatment-related assignments, submitting three times a week to observed urine samples (tested for alcohol, opiates, benzodiazepines, PCP, cocaine, cannabis, and amphetamines), and attending individual and family therapy. Reports from all observers indicated the patient was making progress in treatment. The patient expressed pride in being drug free and staying away from negative peers and began discussing future-oriented prosocial goals. After 1 month in treatment, the patient was progressed to higher privileges, recognizing his treatment progress.

The following week, the client was found by his mother submerged in his bathtub. He had been “huffing” (i.e., inhaling) a common spray used to remove dust from computers (i.e., “air duster,” containing 1,1-difluoroethane) and other surfaces. Although attempts were made to revive him, he later died. This case demonstrates several important points about inhalant use: an

Telegram: @medical_k

www.konkur.in

association with other substance use and conduct disorder, adolescent onset, and the risk of inhalant-related mortality.

Comorbidity

Inhalant users have a high prevalence of multiple comorbid issues/diagnoses. For example, in nationally representative studies of the U.S. population, respondents reporting any inhalant use were significantly more likely to have injected drugs; injection, in turn, is a risk factor for infection with human immunodeficiency virus (HIV) and hepatitis B and C viruses (HBV/HCV). Inhalant use, especially among persons also reporting cannabis use, is a marker for the elevated risk of other SUDs, and inhalant users are more likely to report delinquent behaviors and meet criteria for conduct disorder than inhalant nonusers. In one nationally representative study of adults, for those reporting inhalant use before age 18, more than 40% met criteria for antisocial personality disorder. In that same study, inhalant users showed high rates of mood (48%) and anxiety (36%) disorders, especially among women. A study of 664 nationally representative adult inhalant users found that 40% met criteria for 3 to 5 DSM-IV-TR SUDs, whereas nearly one-quarter (i.e., 22%) met criteria for 6 to 11 such disorders. Virtually all (94%) adult inhalant users met DSM-IV-TR criteria for an alcohol and/or noninhalant drug use disorder. Studies of nationally representative and juvenile justice samples support a link between inhalant use/IUDs and suicidality. Several studies also support an association between inhalant use and a history of child abuse and/or neglect victimization. Although multiple explanations are possible, the etiology underlying this comorbidity has not been well studied; exploratory analyses suggest that the link between early inhalant use and later injection drug use may be explained by a general predisposition to early-onset drug use. In addition to further exploring this link, newer studies should investigate using the DSM-5 criteria as currently little information exists about this relevant, and not insignificant, clinical population, even though the DSM-5 was published/updated almost a decade ago.

Summary

Trying inhalants at least once is comparatively common around puberty and into adolescence, but continued frequent inhalant use is uncommon, and the prevalence of at least monthly use decreases with increasing age. Discontinuation rates by young adulthood are higher for the inhalants than for any other psychoactive drug class. Accordingly, the limited data suggest that IUD is rare in the general population. Related to this, inhalant-related problems are the primary contributor to relatively few addiction treatment admissions. Inhalant-related problems account for a small proportion of drug-related ED contacts and

Telegram: @medical_k

www.konkur.in

are only implicated in a small proportion of all drug-related deaths. One warning, however, is that elevated rates of IUDs are often characteristic of incarcerated and institutionalized youth and adult populations, and these populations are typically not reflected in epidemiologic studies. Similarly, homeless youth and adults, persons living on the street or transiting between different geographic areas, and other marginalized and "hidden" populations, may show higher levels of inhalant use and IUD than are reflected in epidemiologic studies of general and clinical populations. Inhalant users also report numerous barriers to treatment utilization and are commonly coping with multiple comorbid psychiatric disorders and SUDs and impoverished social circumstances that may make it difficult for them to access health care.

The available data suggest that most adolescents who survive a brief experimentation with inhalants and who do not have conduct disorder soon abstain from inhalants and avoid severe pathologic outcomes. However, among adolescents with conduct disorder, perhaps half develop adult antisocial personality disorder. Inhalant problems in these youths often herald serious alcohol and polysubstance use in adulthood, and a small percentage of these youths become chronic, deteriorated, inhalant-dependent adults.

PHARMACOLOGY AND TOXICOLOGY

National surveys regularly report that the inhalants most often misused by U.S. citizens are toluene-containing products (e.g., glues and thinners), gasoline, lighter fluid (which usually contains butane), spray paints, aerosols, degreasers, and correction fluids (see Table 11.7–2). Self-administration of these inhalants results in rapid uptake in the lungs, saturation of the blood, and distribution to the brain. The paraphernalia needed for use is easily attainable such as a bag, rag, worn clothing, hands/nails, cotton balls, inverted aerosols, balloons, or just inhaling directly from the container itself. If using a rag or clothing, these items are sprayed or soaked with the substance and then placed over the mouth and/or nose to inhale the vapors. The act of inhaling these vapors has been termed as "huffing" or "to huff." If using a bag or container, sometimes referred to as "bagging," the mouth is placed at the opening of the bag to inhale the fumes. More dangerously, the bag could be placed over the head to inhale, which can easily cause an accidental suffocation. Finally, the substance could also be directly administered via a spray into the mouth or nose, referred to as "dusting," although a towel or other materials may be used to limit the direct damage to lungs.

This misuse typically involves 15 to 20 deep breaths, which results in rapid intoxication. Once intoxication is achieved, behavioral effects have been reported to persist from 15 to 60 minutes and can be sustained for hours by either perpetual or repeated bouts of inhalation. Rebreathing the exhaled air may

Telegram: @medical_k

www.konkur.in

enhance the effect if the inhalant is exhaled into a bag. While we cannot say with certainty the exact solvent concentration inhaled for various compounds, estimates for one of the most misused inhalants, toluene, vary from 5,000 to 15,000 ppm. This range is several orders of magnitude above the industrial maximum of 100 ppm time-weighted averaged for an 8-hour workday. Even these concentrations for those durations can produce minor temporary performance decrements. Tolerance to the intoxicating effects appears to develop, with individuals increasing the number of tubes of glue they consume over repeated days of use.

www.konkur.in

Toxicokinetic studies for inhalants like toluene show that inhaling these compounds results in very rapid absorption through the lungs that produces a rapid rise in blood concentrations. Toluene and other inhalants can also be absorbed through the skin and the GI tract, which increases total body burden. Both animal and human studies have shown a positive correlation between toluene levels in alveolar air and blood levels. In addition, a recent *in vitro* study showed that certain aromatic hydrocarbons, including toluene, may change the surfactibility of alveolar spaces, which may correspond to the vapor pressure of each solvent when suspended in air. This finding may suggest that not only do solvents impact lung function, but they also exert physiologic changes in the lung that correspond to the solvent's vapor pressure. Toluene is absorbed by both red blood cells, where it binds to the heme protein, and plasma, which enhances toluene transportation to all areas of the body. Given that toluene is a relatively nonpolar, lipophilic compound, it is found concentrated more in tissues that are high in lipids and well vascularized. Due to these properties, as well as toluene being a small molecule, it readily crosses the blood–brain barrier and is found in higher concentrations in myelinated areas. One study in which humans were exposed continuously to 80 ppm of toluene for a 4-hour duration found that toluene blood levels peaked (6 to 7 μmol/L) at approximately 2 hours. Autopsy data from a 16-year-old adolescent boy who died after inhaling glue show that blood and brain toluene concentrations were reported at 20.6 μg/mL and 297 μg/mg, respectively. In another case, a man died after collapsing while painting and being inadvertently exposed to toluene. Toluene levels in his blood and brain were reported at 48 and 80 μg/g, respectively. When consumed with ethanol, toluene blood levels can increase significantly, which can dramatically increase levels of behavioral and physiologic toxicity.

Autoradiography studies have seen elevated levels of radioactivity in body fat and the central nervous system (CNS), including the spinal cord and white matter of the brain, in mice exposed to toluene inhalation. Both toluene and its metabolites leave the body relatively quickly; however, toluene has been shown to remain in adipose tissue for up to a few days. Both human and rodent studies have reported that approximately 80% of toluene is absorbed by the body when inhaled, with increased physical activity increasing the amount of toluene absorbed. Toluene that is not absorbed is later expelled unchanged in breath and urine, with the liver metabolizing the toluene that is absorbed first into benzyl alcohol and is excreted from the body primarily as hippuric acid in urine. While various demographic, genetic, and physiologic factors influence the rate of toluene elimination from the body, toluene concentrations in breath begin decreasing within minutes of exposure, while concentrations in the blood reduce at a much slower rate, taking anywhere from 4 to 10 hours before being undetectable. Elimination of hippuric acid in urine takes longer, and anything greater than a 1-g hippurate per gram creatinine ratio has been suggested as a

Telegram: @medical_k

www.konkur.in

marker for inhalant misuse involving toluene. However, occupational exposure to toluene and some food preparations may also lead to hippurate/creatinine ratios greater than 1.

Understanding of the molecular mechanisms and targets of inhalants has improved within recent decades because of the increase of *in vitro*/*in vivo* studies of these compounds. Unfortunately, the number of inhalants investigated remains scarce, with toluene receiving the most attention. Toluene, like all other addictive substances, alters dopamine levels in the brain. Several studies have shown that toluene exposure either increases or decreases dopamine in the striatum, which may depend on concentration and duration of use. In addition, transient increases in neuronal firing activity have been observed within the ventral tegmental area (VTA). Toluene exposure also produces marked increases in dopamine levels within the prefrontal cortex and other areas related to reward circuitry. Repeated toluene exposure increases the amount of dopamine within the caudate and nucleus accumbens. Accumbal dopaminergic activity may be modulated by activity within the medial prefrontal cortex (mPFC).

While the neurochemical mechanisms responsible for the increased dopaminergic activity are unclear, evidence from studies conducted on midbrain dopamine neurons suggests that dopaminergic alterations may be dependent on *N*-methyl-D-aspartate (NMDA) activations. In line with this sentiment, both the GABAergic and glutamatergic systems have been explored extensively. Toluene influences both ligand-gated and voltage-gated ion channels at concentrations similar to ranges that are inhaled during episodes of voluntary exposure. Although toluene has a simple molecular structure (i.e., a monosubstituted benzene ring with a methyl group), it appears to be rather selective in its neurochemical actions. Studies have proven that toluene will concentration-dependently inhibit the *N*-methyl-D-aspartate receptor (NMDAR), a specific type of ionotropic glutamate receptor associated with excitation. Moreover, toluene is thought to be most selective for the GluN2B receptor subtype. Conversely, while toluene's putative mechanism of action (MOA) is often recognized as inhibition of the NMDA receptor, it appears to have the curious effect of increasing glutamatergic activity in neurons in the mPFC. Toluene has also been shown to affect non-NMDA glutamatergic sites. For example, toluene has been proven to increase the amplitude of excitatory postsynaptic currents in α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPARs), a non-NMDA ionotropic glutamate receptor, which suggests an increase in AMPAR expression on the postsynaptic neuron. Increasing NMDA or glycine concentrations does not overcome toluene's inhibitory effects, suggesting that toluene's effects at this receptor site are noncompetitive. Repeated exposure to toluene reportedly produces an upregulation of NMDARs within certain areas of the brain. Other known inhalants, such as 1,1,1-TCE and several alkylbenzenes (i.e., m-xylene,

Telegram: @medical_k

www.konkur.in

ethylbenzene, and propylbenzene), have been reported to inhibit NMDA-induced currents in both a concentration- and subunit-dependent manner. Thus, at the acute level, NMDAR inhibition seems to be a common MOA for several misused inhalants, with continued exposure altering the expression of these glutamatergic receptor subtypes.

Numerous *in vitro* reports have shown that at the acute level, toluene, TCE, and trichloroethylene increase α1 $GABA_A$ and α1 glycine receptor function via positive allosteric modulation. Conversely, continuous toluene use inhibits spontaneous GABA currents in hippocampal neurons, as well as increasing $GABA_A$ α1 subunit levels in the mPFC while decreasing them in the substantia nigra. This differential GABAergic activity is suggestive of the development of tolerance to the enhancement of $GABA_A$ receptor function following acute toluene inhalation. In contrast, flurothyl, a nonmisused proconvulsant solvent, inhibits $GABA_A$ receptors and acts as a noncompetitive antagonist at $GABA_A$ receptors with no effect on α1 glycine receptors. These results suggest that acute behavioral inhibitory or excitatory effects of inhalants associate well with *in vitro* $GABA_A$ receptor activation or inhibition.

Toluene's receptor selectivity has also been reported for nicotinic acetylcholine receptors (nAChRs), where toluene inhibits α4β2 receptors to a greater extent than α7 nAchRs. Like other sites of action shared among inhalants, nAChRs may serve as another potential shared target. Another widely misused solvent, perchloroethylene, has been shown to be even more potent than toluene in inhibiting the types of nAChRs. However, it is unclear whether inhibition of nAChRs is indeed a common MOA for other misused inhalants.

Toluene also alters P2X adenosine triphosphate (ATP)-gated channel activity. Toluene promotes currents through P2X3 receptors but decreases the function of P2X2 and P2X4 receptors within the ATP-gated channels. Finally, several *in vitro* studies have also shown that toluene, TCE, and trichloroethylene differentially affect 5-hydroxytyptamine (5-HT) receptor function, with the $5\text{-}HT_3$ receptor subtype being a common target. Taken as a whole, findings from these reports indicate that misused inhalants have distinct sites of action on individual channel subunits, and the differences in regional and anatomical subunit expression appear to be important determinants of inhalant effects.

While the behavioral effects of inhalants vary by magnitude and duration depending on the inhalant in question, research in animals examining the effects of exposure to levels of inhalants suggests that many inhalants have similar pharmacologic profiles to CNS depressants like ethanol, barbiturates, and other depressants. At concentrations comparable to those seen in misuse situations, behavioral effects transition from motor excitation to motor dysfunction, ataxia, loss of righting reflex, and finally narcosis or anesthesia. Continuous exposure to higher concentrations of inhalants may result in coma, seizures, and ultimately

Telegram: @medical_k

www.konkur.in

death by respiratory depression. Many inhalants appear to have depressant or inhibitory effects by nature. However, not all misused inhalants show these characteristics. For instance, despite certain alkanes showing CNS depressant properties, several inhaled isoparaffins, branched alkane compounds, have been shown to produce concentration-dependent increases in locomotor activity, and isoamyl nitrite has been shown to produce concentration-dependent changes with lower doses showing increased locomotor activity and higher doses showing no effect, while other inhalants, such as ethyl and butyl-acetate, produce the canonical decrease in locomotor activity. While toluene and other related compounds are depressants by nature, they yield intriguing findings when paired with other inhalants. For example, repeated exposure to toluene and TCE produces sensitization to the motor excitation effects of these inhalants, and repeated toluene exposure interacts with cocaine to increase cocaine's motor effects, suggesting a similar neuropharmacologic MOA.

While clinical studies seldom report seizures from inhalant misuse, rodent models have demonstrated both convulsant and anticonvulsant effects as a consequence of misuse pattern exposures. Sustained or repeated exposure to certain inhalants yields handling-induced convulsions in mice upon cessation of exposure. In one study, mice repeatedly exposed to TCE over multiple days developed handling-induced seizures, as well as an increased sensitivity to pentylenetetrazol-induced convulsions upon cessation of TCE exposure. When these mice were exposed to TCE or toluene vapors, or other depressants (i.e., ethanol, midazolam, or pentobarbital), the number and intensity of seizures decreased. Hence, physical dependence develops to inhalants, and they display cross-tolerance with other inhalants as well as CNS depressants, which may suggest a common mechanism.

Other volatile organic compounds, like flurothyl, a $GABA_A$ antagonist, appear to produce proconvulsant activity. While the mechanisms of these convulsant actions are mostly unknown, high concentrations of any inhalant might have nonspecific and global effects on CNS reactivity. Conversely, the anticonvulsant effects of several inhalants at low concentrations have also been reported. When given as a pretreatment, a single toluene injection has been shown to protect against convulsions brought on by several chemical agents including bicuculline, nicotine, NMDA, and picrotoxin but not strychnine. Protective effects have also been demonstrated for inhaled toluene against NMDA-induced seizures. These anticonvulsant effects may be associated with toluene's potentiating effects on $GABA_A$ receptors or its ability to inhibit NMDA and nicotine receptors, and/or to increase dopamine release. It should, however, be noted that the concentration needed to yield these effects, and the immediate dangers associated with inhalant use, may preclude inhalants, such as toluene, from having any recognized medicinal value as an anticonvulsant. While the authors speculate

Telegram: @medical_k

www.konkur.in

the MOA of this convulsant and anticonvulsant activity to involve NMDA, GABA, or both, these findings require further mechanistic exploration to better parse out the role of each transmitter system. Given that seizure episodes involve excitation of the CNS, often because of glutamatergic or GABAergic activity, it follows that these targets may be responsible for the convulsant and anticonvulsant effects of inhalants. Further, the differential activity observed may be explained in terms of dependence and rebound activity that occurs after binge-pattern use of inhalants. In other words, repeated use followed by cessation of use may result in a rebounding spike in glutamatergic activity or, on the other hand, a sharp decrease in GABAergic activity, thereby causing convulsions in the user.

Because many inhalants act as positive allosteric modulators at the $GABA_A$ receptor site, it is no surprise that animal research has also proven that acute and repeated inhalant exposure produces anxiolytic, narcotic, and sensory effects, as well as alterations in learning and memory. In the elevated plus maze (EPM), toluene and TCE increased the number of entries and time spent in the open arms, comparable to diazepam, which suggests that these two inhalants may have anxiolytic-like effects. In addition, abstinence following toluene exposure has been shown to precipitate a rebound in anxiety-like behavior, and re-exposure to toluene reduces this increase in preclinical models. This finding is noteworthy as anxiolytic drugs characteristically show rebound increases in anxiety upon cessation of continuous use. Further support can be obtained from the defensive burying paradigm, where toluene and other inhalants attenuated the latency to bury an increasingly aversive stimulus. Conversely, flurothyl may have anxiogenic-like effects in that it attenuated both the number of open-arm entries and the time spent in open arms in the EPM paradigm, while apparently having no effect in the defensive burying paradigm at concentrations up to 800 ppm, which is near the seizure threshold for this vapor. Whether other inhalants share this anxiolytic property with toluene and whether tolerance or sensitization occurs with continuous use remains to be determined, albeit there may be challenges with assessing this effect in a preclinical model.

The reinforcing properties of drugs, like inhalants, have been repeatedly demonstrated in animal models. In one study, animals were trained to self-administer toluene and TCE intravenously. In addition to self-administration, many conditioned place preference (CPP) studies with toluene have shown that animals will spend more time on the toluene-paired side of a chamber. Comparable findings have been found for mixtures of other solvents, such as toluene, benzene, ethyl acetate, and methyl chloride. Interestingly, one recent study demonstrated that γ-vinyl GABA, a selective GABA-transaminase inhibitor, blocks the previously established CPP with toluene. Other studies have expanded on these rewarding effects by showing that animals trained to respond

Telegram: @medical_k

www.konkur.in

on one lever after a saline injection and on another lever after a CNS depressant (ethanol or pentobarbital injection) will respond on the lever paired with the depressant, implying that the subjective effect of toluene may be depressant like. Other animal studies using this assay have shown that toluene produces partial substitution for PCP and amphetamine, suggesting that inhalants may share subjective effects with a wider range of drugs than was previously expected.

In addition to effecting behavioral changes via pharmacologic mechanisms in the mesocorticolimbic system, short- and long-term exposure to high concentrations of volatile organic compounds has been shown to produce intracellular oxidative stress and lipid peroxidation in various organs throughout the body, such as the brain and liver. Ordinarily, a balanced level of redox behavior (i.e., oxidation and reduction) is a sign of healthy cellular function, but a shift in the balance between oxidation and reduction may produce cytotoxic effects and pathologic alterations in various organs throughout the body. Both oxidative stress and lipid peroxidation involve reactive oxygen species (ROS) taking electrons from various components within the cell. For example, lipid peroxidation yields alterations in the phospholipid bilayer of the cell membrane by taking electrons from lipid proteins. This pathway may serve as one potential source of toluene's cytotoxic effects. Oxidative stress may serve as a potential pathway through which toluene precipitates long-term cellular and tissue damage and pathogenesis. When compared to its acute pharmacologic effects, toluene's long-term pathogenic effects are not as well documented.

Toluene-induced oxidative stress has been linked to DNA fragmentation and apoptosis. While the literature suggests toluene is altering intracellular levels of antioxidants, such as glutathione peroxidase (GPx), glutathione (GSH), and superoxide dismutase (SOD), the particular pathway is still unclear for, perhaps, many reasons: (1) we cannot say to what extent which ROS are generated by toluene, which may be owing to the transient nature of ROS, thereby making them difficult to observe and measure; (2) toluene very clearly produces apoptosis and DNA fragmentation, but is this the direct consequence of elevated intracellular oxidative stress and lipid peroxidation or a separate mechanism?; (3) like ethanol, toluene is metabolized into a reactive aldehyde (benzaldehyde), which, in a manner similar to ethanol-induced acetaldehyde production, may produce higher levels of oxidative stress than toluene itself; and (4) which compartments in the cell appear to be the greatest source of toluene-induced oxidative stress? To the latter point, toluene is metabolized at various stages in different compartments of the cell. While the particular pathway and components of toluene-induced oxidative stress have yet to be fully elucidated, the authors surmise that the pathologic damage seen in various organs throughout the body is owing to the inhalant's impact on oxidative stress.

Organ Pathology

Telegram: @medical_k

www.konkur.in

Inhalant use greatly increases the potential for injury in mild to severe cases and, in some instances, death. Given that several inhalants have MOAs comparable to those of other drugs involving modulation of GABA and/or NMDA, higher concentrations of the inhalant may result in moderate to severe CNS depression. These effects may be amplified when used in combination with other CNS depressants such as ethanol. In addition to CNS effects, many inhalants have been shown to sensitize the heart to endogenous catecholamines, such that any abrupt physical effort or unanticipated excitement may lead to ventricular arrhythmias and even death. The commonly employed practice of putting inhalants into plastic bags and then placing the bag over the user's head may result in unconsciousness and, potentially, death from suffocation. The user may die from aspiration of either the compound or vomit. Moreover, fatalities have also been reported as a direct result of the inhalant. These include anoxia, asphyxiation, severe injury to the lungs, or cardiac dysfunction. Gas fuels such as butane have been shown to produce laryngeal edema as well as laryngospasm. The severe behavioral and physical deficits associated with inhalant intoxication have resulted in physical trauma (e.g., falling and car accidents) that resulted in fatalities. On a similar note, death has also been reported from fire-related injuries from inhalant combustion, as some inhaled compounds are heated before inhalation or a cigarette was used near where the inhalant was being misused. In addition to the acute and chronic toxicologic effects precipitated from an inhalant's pharmacologic actions in the body, this class of substances has also been shown to produce a host of pathogenic effects in various organs throughout the body.

Chronic inhalant use has been linked to renal and hepatic failure, as well as liver tumors, which can also lead to death. These effects may be the consequence of long-term damage associated with lipid peroxidation and oxidative stress, given that both phenomena are linked to a host of pathologic effects, such as apoptosis, ferroptosis, and mitochondrial dysfunction. In line with this thought, one study found that male Wistar rats exposed to 1,500 ppm of toluene for 4 hours over the course of 7 days showed higher levels of oxidative stress and apoptosis in liver and kidney cells, which may suggest that repeated exposure to toluene produces distortions in cellular redox signaling and, eventually, cell death. Further, given the bioavailability of toluene in lipid-rich regions of the body, it may be that the greater the lipid content, the more susceptible the organ is to insult. Inhalants, such as toluene, have been shown to accumulate in higher concentrations in the liver and kidneys. For example, a pharmacokinetic study demonstrated higher levels of toluene accumulation in the liver, kidney, lung, and fat than other areas, such as the heart and spleen, 30 minutes postinjection in a rodent model. While the particular cause of inhalant-induced tissue damage has not been shown in humans, the combination of preclinical models, sequalae in long-term users, and the postmortem presence

Telegram: @medical_k

www.konkur.in

of tissue damage in lipid-rich areas may, again, suggest that cytotoxicity and tissue damage are the consequence of oxidative stress and lipid peroxidation. While identifying a specific mechanism poses a challenge, it is certain that it is the inhalant that is causing the damage in humans, given what has been observed in clinical literature.

Long-term toluene misuse has been shown to produce ototoxic effects, such as tinnitus and hearing loss. Inhalant misuse has been shown to produce damage to the cardiovascular system, as well as cardiovascular sensitivity to endogenous catecholamines. A few studies have reported renal failure with inhalant misuse because of tubular necrosis. In addition, liver damage, from centrilobular tumors and necrosis, has also been documented. However, it is worth noting that reports of irreversible damage and toxicologic effects in certain organs, such as the liver and kidney, have been inconsistent. For example, some studies report changes in serum hepatic enzymes, whereas others report no changes. Prolonged use of inhalants such as isobutyl nitrite and naphthalene can impede bone marrow production, which can lead to anemia and leukemia. Repeated inhalation of isopropyl nitrite or toluene can produce visual sequalae, such as nystagmus and vision loss. Pulmonary symptoms have also been documented with a plethora of inhalants resulting in chronic coughing, chest pain, shortness of breath, wheezing, and pneumonia. Additional harmful effects include rhabdomyolysis (kidney damage from muscle degeneration) and GI perturbations, such as nausea, pain, and vomiting. The specificity of these effects remains the subject of contention. However, the brain has been shown to be particularly vulnerable to the toxicologic effects at various concentrations, ranging from low to high.

Chronic inhalant misuse can have profound consequences for nervous system functionality, and, especially, the brain, which is high in lipid content. In addition, longer durations and larger magnitudes of inhalant misuse are positively correlated with neuroimaging and neurobehavioral abnormalities. For example, one magnetic resonance imaging (MRI) study showed that young adult chronic users display neurologic abnormalities, which positively correlated with higher ratings on the Halstead–Reitan Battery, an indicator of neuropsychological impairment. This finding suggests that toluene-induced psychological impairment may correspond to increases in white matter abnormalities. Significant cognitive and neurologic deficits have been observed in these individuals and include personality changes, hallucinations, paranoid psychosis, memory deficits, and deficits in information processing, decreased cognitive performance, concentration deficits, speech impairments, impaired judgment, problems with impulsivity, abnormal electroencephalogram (EEG) activity, temporal lobe epilepsy, convulsions, tremors, as well as ambulatory abnormalities. Several imaging and neuropathologic techniques have shown brain abnormalities in those who use inhalants, such as demyelination, shrinkage of brain tissue, and

Telegram: @medical_k

www.konkur.in

white matter damage (leukoencephalopathy). MRI has shown significant atrophy of cerebral, cerebellar, and brain stem tissue, diffuse CNS demyelination, widening of sulci, and ventricular enlargement in long-term users of toluene. As previously suggested, the greatest observations of atrophy were in the lipid-rich white matter areas of the brain, with several cases displaying a loss of differentiation between white matter and grey matter areas. Additional reports using T2-weighted MRI showed that persistent toluene misuse leads to demyelination, as well as significant axonal damage and loss. Numerous rodent studies have corroborated these findings with chronic exposure to higher concentrations of toluene producing deterioration of the frontal cortex, the hippocampus, and brainstem in addition to impairments to dendritic outgrowth and white matter damage. Repeated long-term toluene exposure has been shown to produce neuronal damage to the hippocampus. Finally, several single-photon emission computed tomography (SPECT) studies have shown that chronic inhalant misusers show significant decreases in regional blood flow to the bilateral prefrontal cortices as well as perfusion irregularities in other brain areas. Additional investigations of individuals who have sustained long-term exposure to occupational levels of toluene have shown abnormal cerebral blood flow, as well as atrophy to a number of brain areas.

Given a dearth in the literature, it is challenging to determine whether individuals can reverse neurophysiologic damage and restore cognitive functions after chronic inhalant misuse. As previously described, many of the neuroimaging studies would suggest that any neurobehavioral deficits observed in these individuals would be irreversible. Indeed, several investigations examining former long-term users of inhalants failed to detect any notable improvements in MRI measures of brain pathology or neuropsychological functioning after 5 to 18 months of abstinence. The lack of improvement reported in these studies may be due, in part, to the timing of measurement, because a few studies have reported that neurobehavioral measurements taken 2 years after users discontinued petrol sniffing were significantly improved compared to earlier measurements. While full recovery was not reached, those individuals with the most impairment showed the greatest improvements. Moreover, a small section of the literature has shown that prevention of damage may be achieved through adjunctive therapy with various pharmaceutical agents, such as minocycline (an NF-KB inhibitor); however, this has not been established in the clinical literature.

Maternal Use and Fetal Solvent Syndrome

With prevalence rates for inhalant use proving to be nearly equivalent for adolescent males and females, prenatal solvent exposure poses a unique challenge for childbearing females. Indeed, a recent review of drug misuse

Telegram: @medical_k

www.konkur.in

among females of reproductive age featured toluene-based solvents in addition to other commonly used psychoactive substances during pregnancy. An increasing number of cases of fetal developmental disorders and malformations in the offspring of females who misuse inhalants during pregnancy has been observed in the medical literature. Many of these clinical embryopathy and teratology reports argue that these infants display symptoms of a *fetal solvent syndrome (FSS),* so called because of the similarities to infants gestationally exposed to ethanol who showed signs of *Fetal Alcohol Spectrum Disorder (FASD)*. Females who misuse inhalants during their pregnancies gave birth prematurely to infants with developmental delays. Further, some of these infants displayed physical abnormalities such as a reduction in head size, hypoplastic midfaces and jaws, lower set ears, shortened palpebral fissures, thin upper lips, and deep-set eyes. Additional anomalies reported were downturned corners of the mouth, irregular hair patterns on the scalp, small fingernails with blunted fingertips, abnormal palmer creases, and urinary tract deformities. In certain cases, fetal death was reported in women with histories of inhalant misuse where maternal exposure to the inhalant was extremely high during pregnancy. Follow-up investigations with these FSS infants showed continued developmental delays and deficits such as moderate growth retardation, cerebellar dysfunction, hyperactivity, language impairments, and elevated levels of aggression. It is unclear whether these delays and deficits last into adulthood, as there are no documented clinical therapeutics or remedies for the observed effects of FSS exposure, nor are there follow-up studies of these affected children as they grow into adults. The accompanying stigmatization and discrimination associated with drug use during pregnancy may prevent many inhalant-misusing women from properly accessing needed health care services during pregnancy. To further support findings in human populations, preclinical studies that mimic the high-dose binge-type inhalant use pattern during pregnancy provide additional evidence of an FSS. These animal investigations have reported that the high toluene levels that are observed in maternal tissues and organs are also found in the placenta and fetal tissue, including the brain. These high concentrations of toluene in animals produce a myriad of adverse outcomes, such as physical malformations, growth retardation, delayed ossification of skeletal structures, deficits in coordination and forelimb strength, impairment in memory recall tasks, and changes in amphetamine-induced locomotion. Whether these delays and deficits last into adulthood or whether it is possible to prevent or mitigate these delays and deficits is still unclear.

Patterns of Inhalant Use

Qualitative research has shown that inhalant users report three main use scenarios: (1) using on rare occasions to have fun, (2) using because alternative

Telegram: @medical_k

www.konkur.in

substance(s) could not be used (because of no access or urine drug monitoring), and (3) using in day-long binges. Recent efforts have been made to classify different subtypes of inhalant users. In one study, some inhalant users used many different inhalants, had elevated levels of psychopathology (i.e., depression, anxiety, externalizing behaviors, and substance use), suffered serious family problems, had high levels of affective instability, and used inhalants to help cope with those feelings or problems. Other inhalant users had decreased levels of these problems, many of those individuals had only used one type of inhalant, and these individuals were hypothesized to be "experimenters." A third group used inhalants because they were easy to obtain. Another taxonomic investigation identified three subtypes of adolescent inhalant users based on the social contexts in which they used inhalants. Youth in the class that most tended to use inhalants with friends to celebrate and have a good time and who had difficulties in refusing invitations to engage in inhalant use, or who socialized with groups of youth who used inhalants, had the highest levels of substance use and related problems, psychiatric distress, and psychiatric symptoms, and tended to be more fearless and impulsive, than inhalant users whose use was less dependent on peer and group contextual factors.

Development of Inhalant-Related Use Disorders

Inhalant-related disorders have a multifactorial etiology. First, availability is important in determining the prevalence of drug use disorders. Inhalants are cheap, available in several forms in most households, easily concealed, legal to possess, and simple to consume. In addition to these factors, legislation can vary from state to state, with most states having enacted laws attempting to curb inhalant misuse, but the effectiveness of that legislation needs to be studied. Second, inhalant use is directly rewarding pharmacologically and may be indirectly rewarding though social effects. Several animal models have demonstrated the rewarding properties of these substances (discussed above), and adolescents usually gather in small groups to use inhalants. Use of inhalants facilitates entry into the group, socially reinforcing the use. Third, due to the quick intoxication profile, inhalant users often can evade detection or punishment by parents or authorities. Fourth, inexpensive inhalants may be one of the few exciting and novel experiences available to youths in impoverished and/or isolated communities. This parameter may help to explain the high prevalence of inhalant use on some U.S. and Canadian Native American reservations and among Aboriginal Australians.

In addition to extrinsic factors, intrinsic factors also contribute to inhalant-related problems. Persons with adolescent conduct disorder or antisocial personality disorder are prone to taking extreme risks, and these disorders have

Telegram: @medical_k

www.konkur.in

an increased comorbidity with IUD. Several studies suggest an association of inhalant use and conduct problems. Among youths in grades 7 through 12, inhalant users (compared with others who used no drugs or who used only cannabis or alcohol) had many characteristics suggesting conduct disorder. They accepted cheating more readily, admitted to more stealing, perceived less objection to drug use from their families, liked school less, and reported more sadness, tension, anger, and a feeling of being blamed by others. In addition, school surveys showed that inhalant users were more likely to be involved with other drugs. Similarly, among youths referred to court-mandated education for minor alcohol offenses, those who also had used inhalants reported fewer school honors and more expulsions, truancy, academic failures, criminal offenses, run away behavior, and associations with troubled peers, as well as many more drug and alcohol problems. More of these individuals also had family history of alcohol- or drug-related problems, specifically mothers or siblings. Studies of juvenile probationers, incarcerated youth, and other samples of delinquent and antisocial adolescents report lifetime inhalant use prevalence rates between 30% and 40%. One recent investigation of a large national sample of adult inhalant users concluded that persons with IUD had significantly elevated levels of antisocial conduct, including a variety of early-onset and interpersonally violent behaviors. Some families are burdened by antisocial personality disorder and substance dependence in the adults and by conduct disorder and SUDs (sometimes including IUD) in the adolescent children, and there is growing evidence that genetic factors play a role in these familial disorders. Less respect for parents, less familism (i.e., personal values related to family), less parental monitoring, and experiences of trauma within the family unit have all been related to increased risk of initiation of inhalant use. Even more than other drug users, inhalant users report histories of childhood abuse and/or neglect.

DIAGNOSIS AND CLINICAL FEATURES

Inhalant Intoxication

Inhalant intoxication is a clinical psychological disorder that occurs during, or immediately following, the inhalation and uptake of volatile hydrocarbons into the bloodstream. Hydrocarbon inhalation may be intentional (in the instance of misuse) or unintentional (in the instance of occupational exposures). Inhalation of toxic solvents from common products such as glues or paints, which often contain toluene and/or admixtures of other volatile solvents, can result in a constellation of adverse psychological and behavioral impairments, such as dizziness, incoordination, slurred speech, unsteady gait, lethargy, tremors, depressed reflexes, psychomotor retardation, generalized muscle weakness, blurred vision, diplopia, subjective feelings of euphoria, nystagmus, and stupor

Telegram: @medical_k

www.konkur.in

or coma. Two or more of these signs/symptoms occurring in parallel, or in close temporal contiguity, with inhalation of a hydrocarbon should render a DSM-5 diagnosis of inhalant intoxication. Other reported concomitant factors or pathologic sequelae of inhalant intoxication include vomiting, aspiration of vomitus, bronchospasm, chest pain, cardiac arrhythmias or arrest, accidental burns, seizures, illusions, auditory or visual hallucinations, delusions, perceptions of altered body size, and suffocation in a plastic bag placed over the mouth and nose. The DSM-5 and ICD-11 require that an assessment for IUD coincide with a diagnosis of inhalant intoxication (6C4B.3). Individuals meeting the criteria for inhalant intoxication can have a clinically relevant pattern of use differentiated as mild (6C4B.3XS5W), moderate (6C4B.3XS0T), or severe (6C4B.3XS25). If no comorbid IUD is identified in an individual meeting the criteria for an "episode of harmful use of volatile inhalants," the code is 6C4B.0.

If known, the specific inhalant (e.g., toluene) should be indicated in the DSM-5 diagnosis (e.g., butane intoxication instead of inhalant intoxication). However, many inhaled products are mixtures of psychoactive hydrocarbons, and it is therefore often difficult to identify the specific agent(s) leading to intoxication. Immediate factors that should arouse suspicion for inhalant intoxication include the identification of chemical odors on the breath and/or clothing of an intoxicated individual or the discovery of products that can be inhaled to produce psychoactive effects in the individual's possession. General indicators of increased risk of inhalant intoxication include signs of intoxication in a youth between ages 10 and 17 and in persons who appear intoxicated but who test negative on commonly administered toxicologic screens for substance use (which typically do not test for inhalant use).

No nationally representative estimates are available for the annual or lifetime prevalence of inhalant intoxication. However, it is assumed that inhalant intoxication rates are comparable to those of inhalant use, in general. If it is assumed that most inhalant users experience intoxication at least once in their inhalant-using experiences, then lifetime inhalant intoxication may be fairly common, especially among youth and in diverse high-risk populations (juvenile and criminal justice, rural, etc.). The same can be assumed for differences in race and gender proportions reported herein.

Laboratory Examination

Random, intermittent evaluation of biologic samples has little value for verifying self-reported abstinence in currently nonintoxicated patients with IUD, because inhalants have a small detection window in the body and tertiary metabolites can be attributed to other sources. However, patients displaying behavioral signs of inhalant intoxication do, in most cases, produce levels of inhalants within detection range in urine and breath. Confirming their presence may later aid in

Telegram: @medical_k

www.konkur.in

clinical and forensic investigations. Currently, the ratio of hippuric acid (a toluene metabolite) to creatinine in urine is one of the most frequently used methods for detecting toluene in the system. It is advised that urine samples be collected in glass chromatography vials containing little or no air space, tightly sealed, and refrigerated until ready for analysis of the ratio of hippuric acid to creatinine (a proxy for toluene concentration). Breath samples can also be collected in specially designed glass traps or in Tedlar (not Mylar) bags designated for solvent containment and should be assessed for the presence of inhalants within a few hours following collection.

Differential Diagnosis

Differentiation from intoxication with other substances, particularly those due to sedative (e.g., ethanol, benzodiazepine, and barbiturate) use, is aided by an identified history of inhalant use, the detection of inhalant odors or paraphernalia (e.g., solvent-soaked rags, bags, etc.), and substance residues on the skin or clothing, perioral or perinasal “glue-sniffer’s rash” from contact with organic solvents, and toxicologic examination of body fluids. Similar to other substances of misuse, polysubstance use is commonly observed among inhalant users, and concurrent intoxication with additional substances may be assessed by history and toxicologic examinations. As noted above, intoxication in persons who test negative on conventional drug screens or who are members of high-risk groups for inhalant use also raises suspicion for inhalant intoxication. In addition, parental, familial, or peer reports of the patient’s prior inhalant use and/or known affiliation with inhalant users increases the likelihood of an inhalant-related intoxication. Despite evidence of inhalant intoxication, in unconscious or comatose patients, other explanations (e.g., closed head injury) must be considered. Dextrose 50% for injection (50 g) and naloxone 2 mg intravenously may help rule out incapacitation or coma originating from diabetes or opioid use, respectively. If delirium develops at any point during intoxication with inhalants, the diagnosis is likely inhalant intoxication delirium, rather than inhalant intoxication. If the patient displays signs of depressed mood, anxiety, or psychosis during inhalant intoxication, and if those symptoms manifest in a manner severe enough to warrant independent clinical attention, the diagnosis should be inhalant-induced depressive disorder, inhalant-induced anxiety disorder, or inhalant-induced psychotic disorder, respectively.

Course and Prognosis

The onset of intoxication is nearly instantaneous following solvent inhalation, given that these compounds are rapidly absorbed across pulmonary membranes in alveolar spaces and are rapidly distributed to the brain and other areas of the body high in lipid content. Inhalants are quickly metabolized and excreted from

Telegram: @medical_k

www.konkur.in

the body through respiration or urine, and inhalant intoxication usually lasts a short duration of a few hours or less, unless the user is intermittently or continuously administering the solvent. Unless trauma, hypoxia, cardiac arrest, chemical burns, or other problems ensue, there are likely to be no lasting or irreversible effects from one or a few intoxication sessions, except that each administration of these drugs produces reinforcing effects, which may increase the likelihood of further use. Prolonged and repeated use may cause persisting harmful effects.

Treatment

Inhalant intoxication, similar to ethanol intoxication, typically requires no medical attention and resolves over a short duration. However, in extreme instances, certain effects resulting from intoxication, such as coma, bronchospasm, laryngospasm, cardiac arrhythmias, trauma, or chemical burns, require medical treatment. Otherwise, caring for an intoxicated individual primarily involves offering reassurance, quiet support, and careful attention to vital signs and level of consciousness. Some evidence suggests that inhalant users who experience physical agitation during episodes of intoxication may be prone to cardiac arrhythmias or arrest. So, surrounding individuals should take care to ensure a calm and reassuring environment when they suspect that someone is under the influence of an inhalant. Sedative drugs (e.g., benzodiazepines), given their similar pharmacologic profile, are contraindicated with inhalant intoxication, since they may potentiate the effects of the inhalant. Given that inhalants have short half-lives, inhalant intoxication usually improves markedly after only 30 minutes of abstinence, unless other potentiating drugs were consumed around the same time as the inhalant. Following resolution of inhalant intoxication, a careful evaluation is necessary with proper intervention or referral for IUD, other SUDs, conduct disorder, antisocial personality disorder, and possible comorbid mood, anxiety, neurocognitive, and other psychiatric conditions.

INHALANT USE DISORDER

In persons showing intermittent changes accordant with substance intoxication, together with smells of organic solvents, inhalation paraphernalia, or the occasionally present perioral or perinasal papular glue-sniffers' rash, a diagnosis of IUD should be considered. The DSM-5 IUD criteria require recipients of the diagnosis to have shown a problematic pattern of use (which implies recurrent use) and to display related clinically significant functional impairments and/or distress. To receive an IUD diagnosis, patients must meet at least 2 of 10 diagnostic criteria. IUD criteria assess whether the patient has used inhalants over a longer period and/or in larger amounts than intended; whether there has

Telegram: @medical_k

www.konkur.in

been an ongoing desire or actual attempts to quit or reduce inhalant use that have proved unsuccessful; and whether there are indications of craving for, tolerance to, or recurrent physically hazardous inhalant use. Other diagnostic criteria assess for inhalant-related social role impairments, use of inhalants despite social, interpersonal, physical, or psychological problems that are caused or worsened by inhalant use, and increased salience of inhalant use reflected in growing amounts of time spent using or recovering from the effects of inhalants. Several specifiers may accompany an IUD diagnosis. Individuals who meet two or three diagnostic criteria are diagnosed with mild IUD, while those meeting four or five criteria receive diagnoses of moderate IUD, and those meeting six or more criteria are diagnosed with severe IUD. Diagnostic specifiers can also be used to indicate whether the person with IUD is in early or sustained remission. If a specific inhalant is identified, this agent should be specified in the diagnosis (e.g., toluene use disorder instead of IUD), but inhalants are often mixtures of psychoactive chemicals, and it is often difficult to identify a specific inhalant. Thus, the diagnosis is often the generic “IUD.”

Although the DSM-5 provides no diagnosis for a characteristic inhalant withdrawal syndrome, and inhalant-related withdrawal signs and symptoms are not included in the diagnostic criteria for IUD, several studies have identified inhalant withdrawal signs/symptoms in some inhalant users; inhalant users with withdrawal signs/symptoms reportedly experience mild restlessness, inattentiveness, anxiety, and other physical symptoms. One national study of persons with a DSM-IV-TR disorder of inhalant dependence found that nearly 48% showed three or more clinically significant inhalant withdrawal symptoms and called for the inclusion of these symptoms in the DSM-5. Thus, despite the absence of a separate inhalant withdrawal diagnosis, patients’ complaints of withdrawal symptoms probably should be counted toward a diagnosis of IUD. ICD-11 uses the category of “volatile solvent dependence” (6C4B.2) to describe a similar disorder. These can be further classified as current use (6C4B.20), early full remission (6C4B.21), sustained partial remission (6C4B.22), sustained full remission (6C4B.23), or unspecified (6C4B.2Z).

Several studies of the DSM-IV-TR inhalant abuse and inhalant dependence diagnostic criteria specifically, and multiple studies of DSM-IV-TR substance abuse and substance dependence disorder criteria, indicated that SUDs were most properly conceptualized as unidimensional disorders of varying levels of severity. Hence, the DSM-5 includes only one “IUD” diagnosis but allows specification of severity based on the number of diagnostic criteria a patient meets.

Laboratory Examination

Telegram: @medical_k

www.konkur.in

Therapy for SUDs often uses repeated tests of biologic samples to confirm patients' reports of abstinence or use. However, with inhalants, such tests may be difficult to interpret. First, these volatile compounds have a brief sojourn in the body and may be detected in urine for only a few hours after use. Second, even if the compounds occur in urine, they may volatilize out of samples during transfer or storage. Third, although hippuric acid, a toluene metabolite, can be detected longer than toluene, hippuric acid also may be produced from foods, raising a question of false-positive findings. Fourth, inhalants may bind to, or pass through, the plastic of urine cups or breath collection bags, reducing concentrations, and making the compounds undetectable. Thus, the most careful monitoring of inhalant use would involve frequent urine samples (e.g., two or three per week) at random times, collected in tightly sealed glass containers with little or no air space, and carefully refrigerated until analysis. Analyses for inhalants usually require gas chromatography, followed by flame ionization, electron capture, or mass spectroscopic procedures. Simultaneous analyses of the ratio of hippuric acid to creatinine may reveal recent toluene use. However, even under ideal conditions, the short half-life of inhalants makes inhalant monitoring much less valuable clinically than monitoring for many other substances. Similarly, breath samples may be collected in specially designed glass traps or in Tedlar (not Mylar) bags. The half-life of inhalants in alveolar air is a matter of minutes, and so breath samples may be useless for monitoring treatment progress in patients who show no current signs of intoxication. Moreover, the authors have examined costs in their region for monitoring tests, as a proportion of the per-patient, per-day reimbursement rates that must cover *all* costs of intensive day treatment. Each urine test for hippuric acid (a metabolite used to test for abuse toluene exposure) uses up about 1.8 days' reimbursement and takes about a week to complete. Thus, frequent biologic monitoring for inhalants is not very practical.

Differential Diagnosis

Several conditions should be considered in the differential diagnosis. First, most adolescents who experiment with inhalants stop spontaneously after one or a few episodes of use and never meet criteria for IUD. Although such use is dangerous and occasionally fatal (often on the first try), the many spontaneous resolutions support recommendations of minimalist, nonalarmist interventions for adolescent users who do not meet criteria for diagnoses of IUD; parents also should be involved. Firm advice to remain abstinent, coupled with education of parents on recognizing future problems, may be sufficient. Second, polysubstance use is common in adolescent patients, and dependence on drugs other than inhalants is proven through history, physical findings, and toxicologic screens. Such disorders may exist in addition to, or instead of, IUD. Third,

Telegram: @medical_k

www.konkur.in

uncontrolled and impulsive behavior during repeated episodes of inhalant intoxication may mimic aspects of, or be comorbid with, conduct disorder or antisocial personality disorder. Antisocial behavior before the initiation of IUD, or during periods of abstinence from inhalants, suggests the presence of these disorders.

The DSM-5 includes the following conditions for consideration in the differential diagnosis of IUD: unintentional (e.g., occupational) exposure to inhalants, intentional inhalant misuse that does not meet IUD criteria, intentional inhalant intoxication in a patient who does not meet IUD criteria, inhalant-induced psychiatric disorder (e.g., inhalant-induced depression) in a patient who does not meet criteria for IUD, and a number of additional substance-related (particularly sedative-related) and medical disorders that may present similarly to inhalant misuse and its consequences.

Course and Prognosis

The high prevalence of inhalant use in high school surveys, and its relatively low prevalence in adulthood, led one expert to state that inhalant use "should be regarded as a passing phase or fad." Most inhalant users do not progress to IUD, but some studies indicate that inhalant use is associated with increased risk of future diagnoses of a broad range of psychiatric disorders including antisocial personality disorder and other SUDs. Among adult substance-dependent patients, a history of inhalant use was associated with significantly enhanced risk of the following: antisocial personality disorder, depression, anxiety disorders including social phobia, polysubstance use, and injection drug use. In fact, those who had been inhalant users within a group of adults with opioid (heroin) use disorder appeared to be a "marginal group with particularly unfavorable developmental conditions and a specific course of addiction."

Most adolescents who progress from inhalant use to IUD eventually shift to use of, and often dependence on, other drugs, but some also continue inhalant use into adulthood. Such chronic patients may use inhalants for extended periods each day for many years; they often show moderate criminal activity, weight loss, significant medical disease, slow and slurred speech, and impaired attention and memory. In a national sample of inhalant users, those with an alcohol use disorder (AUD) and/or mood/anxiety disorder antedating their inhalant use were most likely to transition to IUD, typically within 1 year of inhalant use initiation. With frequent inhalant use, tolerance to the effects occurs as well as potential for mild withdrawal signs symptoms including sleep disturbance, irritability, shakiness, sweating, fleeting illusions, and nausea. One observer reported tachycardia, delusions, and hallucinations during withdrawal.

Medical problems in chronic users may include (1) muscle weakness, sometimes with myoglobinuria and rhabdomyolysis; (2) GI problems, such as

Telegram: @medical_k

www.konkur.in

abdominal pain, nausea, vomiting, or hematemesis; (3) renal dysfunction, often with severe electrolyte imbalance; (4) cardiomyopathy; (5) hepatotoxicity; (6) pulmonary disorders (e.g., pulmonary hypertension, increased airway resistance, and acute respiratory distress); and (7) hematopoietic disorders (including elevated carboxyhemoglobin levels, methemoglobinemia, hemolytic anemia, aplastic anemia, and even acute myelocytic leukemia). Neurologic problems include (1) headache, (2) paresthesias with peripheral neuropathy, (3) reversible cerebellar signs or cerebellar degeneration, (4) radiologic abnormalities of widened sulci and basal cisterns, and (5) dementia (e.g., lead encephalopathy from leaded gasoline or white matter dementia from toluene). There have been significant associations between longer duration of inhalant use and greater likelihood of experiencing tuberculosis, bronchitis, asthma, sinusitis, tinnitus, positive HIV/AIDS status, sexually transmitted disease infections, anxiety, and depression. As reviewed above, maternal inhalant use during gestation has been associated with an FSS similar to fetal alcohol syndrome.

Treatment

A Cochrane Collaboration systematic review published in 2010 showed no randomized or controlled clinical trials of IUD treatments. A systematic review of psychological interventions for inhalant misuse arrived at similar conclusions. Almost all evaluations of psychosocial treatments for IUDs were case series with poor methodologic quality. However, one study of Turkish adolescents assessed a brief cognitive behavioral intervention for inhalant misuse and observed significantly greater rates of continuous abstinence from inhalants at 1-year follow-up for treated youth compared to controls (i.e., 58% vs. 38%).

The lack of evidence-based treatment strategies for IUD is problematic for several reasons. Recent surveys of mental health practitioners show that they do not feel prepared to work with inhalant misusers, although they indicate that this patient group needs particularly intensive and specialized rehabilitative therapy. Moreover, research has documented high incidence rates of health services utilization and many perceived barriers to treatment among inhalant misusers. Some clinicians have called for specialty IUD treatment programs (although there are no data supporting this recommendation) and/or clinics and extended periods of treatment given the myriad psychiatric, neurocognitive, and health disorders shown by many, if not most, persons with an IUD. Given the small prevalence rates of IUDs, the development and implementation of such programs may prove challenging. Specialized programs should target vulnerable communities where IUDs are more common.

Case studies of pharmacologic interventions have assessed the use of drug therapy to reduce craving (e.g., aripiprazole, lamotrigine), inhalant-related withdrawal symptoms (e.g., baclofen), neuropsychiatric symptoms caused by, or

Telegram: @medical_k

www.konkur.in

cooccurring with, inhalant misuse, such as paranoia, psychosis, depression, and anxiety (e.g., carbamazepine, haloperidol, and risperidone), and behavioral symptoms resulting from acute or chronic inhalant misuse such as increased locomotor activity (e.g., vigabatrin, mGluR 2/3 agonist LY 379268). In addition, practitioners may have some success with administering benzodiazepine drugs to patients with acute withdrawal symptoms, given the similarities between inhalants and ethanol (another drug whose acute withdrawal symptoms are often treated with benzodiazepines). Although many of these case studies show potentially promising findings, the literature is simply too sparse and lacking in rigor to support a codified system of treatment guidelines for pharmacologic treatment of persons with inhalant-related disorders.

The scientific literature relating to psychosocial interventions for IUD is equally undeveloped, although holistic, indigenous-led residential treatments, family-based, activity-oriented, and broadly focused biopsychosocial interventions (with aftercare) have been recommended considering the variety and number of impairments typically evidenced by inhalant users. In addition, appropriate medical care is needed for the pathologic sequelae of inhalant use. Given that risk of IUDs is greatest in youth, comprehensive treatment is needed for adolescent patients who progress from experimentation to inhalant-related disorders. Most of these youths have comorbid conduct disorder and are at high risk of serious adverse outcomes. One authority suggests that a comprehensive treatment plan should include eight factors: detoxification; a peer advocate system; assessment of physical, cognitive, and neurologic deficits; building on existing strengths; developing new strengths; therapists trained in inhalant misuse; attention to personal and family issues; and aid in returning to the community.

Many inhalant-using youths are treated in various outpatient, day treatment, and nonhospital residential programs. However, treatment of these youths, many of whom are dependent on multiple substances, is not usually tailored specifically to drug classification (e.g., inhalants), but instead targets substance use and conduct problems more broadly. Referrals are often from social service and juvenile justice agencies, which pay for the treatment. Treatment in these programs begins with a detailed interview, addressing substance use and assessing for SUDs for each drug category in the DSM-5. Most patients meet the criteria for multiple SUDs. Interviews also assess diagnoses of disorders commonly found to be concomitant in this group: conduct disorder, attention deficit hyperactivity disorder (ADHD), major and persistent depressive disorders, and PTSD. Interviews also address experiences of abuse or neglect, which are common in these patients. Group and individual therapies are behaviorally oriented, offering immediate rewards for progress toward actionable goals in treatment and punishments for lapses to earlier behaviors.

Telegram: @medical_k

www.konkur.in

Patients may attend on-site schools with special education teachers, together with planned recreational activities. The patients' parental families, often very chaotic, can be engaged in modifications of structural family therapy or multisystemic therapy, both of which have strong empirical support. Participation in 12-step programs is often needed. Treatment interventions may be coordinated closely with interventions by community social workers and probation officers. Medications are typically not prescribed for IUDs per se, but a psychiatrist often prescribes antidepressants for depression, disulfiram for comorbid AUD, or atomoxetine or bupropion for ADHD (stimulant medications are often avoided in youth with SUDs). Progress is checked with urine and breath samples analyzed for alcohol and other drugs at intake and during treatment. However, frequent monitoring of breath for inhalants, or of urine for hippuric acid, is too expensive for most public treatment programs. Patients who do not abstain in day treatment may be transferred to residential care. Treatment usually lasts 3 to 12 months. Termination is considered successful if the youth has practiced a plan to stay abstinent; is showing fewer antisocial behaviors; has a plan to continue any needed psychiatric treatment (e.g., treatment of comorbid depression); has a plan to live in a supportive, drug-free environment; is interacting with family in a more productive way; shows greater attendance at work or school; and is associating with drug-free, nondelinquent peers. In many cases, of course, these goals are only partially accomplished. As with all other recommended treatments of IUD, controlled studies of long-term outcomes are lacking. Additional therapies may be required for those demonstrating long-term symptoms associated with inhalant-induced damage.

While the long-term damage associated with persistent inhalant use (especially those with chronic encephalopathy) may pose difficulties with treatment interventions, a number of potential preventative and mitigating measures may prove useful in the future. In preclinical models, researchers have realized some success in reversing previous damage or preventing further damage in animals given repeated administrations of toluene. For example, as noted in a previous section, a preclinical study on mice found that apoptotic effects in the mPFC incurred by toluene exposure can be reversed by administering minocycline. Additional evidence suggests that compounds that promote aldehyde dehydrogenase production (e.g., metyrapone) may be useful in reducing the amount of a given aldehyde in the system. In the instance of toluene, benzaldehyde is of particular concern, as this compound, like acetaldehyde in the instance of ethanol consumption, may be responsible for precipitating oxidative stress within the cell. Little research has been done to corroborate this finding in toluene administration at either the preclinical or clinical level. One final method that has also received little attention is the administration of antioxidants in recovering, or even current, inhalant users. Antioxidants may help to restore intracellular levels of GSH and other defense

Telegram: @medical_k

www.konkur.in

systems to aid in the breakdown of superoxide production, which may in turn help to prevent further damage done. The long-term impact of inhalant use results in brain damage for a small, but not insignificant, portion of inhalant users. Development of both effective preventative and mitigative treatment strategies is imperative for clinical practice and will require collaboration with preclinical research.

INHALANT-INDUCED PSYCHIATRIC DISORDERS

Inhalant-Induced Delirium

DSM-5 provides a diagnostic category for inhalant intoxication delirium, which is a disturbance of consciousness and a change in cognition that is a direct physiologic consequence of intoxication with inhalants. Inhalant intoxication delirium should be diagnosed instead of inhalant intoxication if disturbances in attention and other cognitive functions (e.g., memory, language, and perception) predominate in the clinical picture and are severe enough to warrant clinical attention. In DSM-5 and ICD-11, all persons diagnosed with inhalant intoxication delirium must be assessed for a comorbid IUD. Persons with inhalant intoxication delirium are assigned a code of 6C4B.5, which should be associated with a causative condition (6C4B.0, 6C4B.1, 6C4B.2) and may be associated with volatile inhalant intoxication (6C4B.03) or volatile inhalant withdrawal (6C4B.4). The course and treatment of inhalant intoxication delirium are like those of inhalant intoxication, but the additional confusion requires special attention to patient and surrounding individual's safety. If the delirium results in severe behavioral disturbances, short-term treatment with a dopamine receptor antagonist (e.g., haloperidol) may be necessary. Benzodiazepines should be avoided because of the possibility of adding to the patient's respiratory depression.

Inhalant-Induced Psychotic Disorder

The essential features of inhalant-induced psychotic disorder are hallucinations or delusions judged by laboratory tests, history, or physical examination to be due to the direct physiologic effect of inhalant substances. This diagnosis applies to patients who meet criteria for inhalant intoxication but who also have psychotic symptoms in excess of those usually associated with inhalant intoxication. The psychotic symptoms must cause clinically significant functional impairment and/or distress and be severe enough to warrant independent clinical attention. This diagnosis is not made in the presence of inhalant intoxication delirium.

Consistent with DSM-5 and the ICD-11, persons diagnosed with inhalant-induced psychotic disorder are assessed for a comorbid IUD. The diagnosis of

Telegram: @medical_k

www.konkur.in

inhalant-induced psychotic disorder (6C4B.6) should be made with a causative condition (6C4B.0, 6C4B.1, 6C4B.2) and may be associated with volatile inhalant intoxication (6C4B.03) or volatile inhalant withdrawal (6C4B.4).

The course and treatment of inhalant-induced psychotic disorder are like those of inhalant intoxication. The disorder is brief, lasting a few hours to (at most) a very few weeks beyond the intoxication. Clinical evidence suggests that tetraethyl lead is a potent contributor to psychotic symptoms in countries still using leaded gasoline. Vigorous treatment of such life-threatening complications as respiratory or cardiac arrest, together with conservative management of the intoxication itself, is proper. Confusion, panic, and psychosis mandate special attention to patient and surrounding individuals' safety. Severe agitation may require cautious control with haloperidol (5 mg per 70 kg intramuscularly). Sedative drugs, including benzodiazepines, may potentiate and worsen inhalant intoxication.

In a randomized clinical trial, 40 hospitalized psychotic patients with DSM-III-R diagnoses of inhalant dependence and inhalant-induced organic mental disorder volunteered for treatment with either haloperidol (up to 40 mg per day orally) or carbamazepine (up to 1,600 mg per day orally) for up to 5 weeks. Both groups could receive intramuscular haloperidol for acute agitation. The antipsychotic response of the two groups was similar, but there were significantly fewer extrapyramidal reactions in the carbamazepine group. However, without a placebo-control group, these data cannot support either medication being better (or worse) than no medication. One case study of a 25-year-old inhalant-dependent Caucasian man found that 0.5 mg of risperidone daily for 4 weeks, following by a dosage increase to 1 mg daily, was effective in significantly reducing paranoia symptoms and craving for, and use of, inhalants. It was not clear, however, to what extent the psychotic symptoms the patient displayed were due to an independent disorder or inhalant induced. Controversy continues as to whether inhalants produce persisting psychotic states in the absence of delirium or neurocognitive disorder.

Inhalant-Induced Mood Disorder

The essential feature of inhalant-induced mood disorder is a prominent and persistent disturbance in mood characterized by depressed mood and/or anhedonia judged to be due to the direct physiologic effect of inhalant substances. Such mood symptoms sometimes develop during intoxication with inhalants, so this diagnosis applies to patients who meet criteria for inhalant intoxication but who also have depressive symptoms in excess of those usually associated with inhalant intoxication. The depressive symptoms must be severe enough to warrant independent clinical attention and associated with distress, functional impairment, or both. This diagnosis is not made in the presence of

Telegram: @medical_k

www.konkur.in

inhalant intoxication delirium. Per DSM-5 and ICD-11, individuals presenting with inhalant-induced depressive disorder are also assessed for a comorbid IUD. Persons with volatile inhalant-induced mood disorder are coded as 6C4B.70, and this should be made with a causative condition (6C4B.0, 6C4B.1, 6C4B.2) stated and may be associated with volatile inhalant intoxication (6C4B.03) or volatile inhalant withdrawal (6C4B.4).

The course and treatment of inhalant-induced depressive disorder are like those of inhalant intoxication. Inhalant-induced depressive disorder is brief, lasting a few hours to (at most) a very few weeks beyond the intoxication. Although antidepressant drugs are seldom proper for these relatively brief disorders, the risk of suicide requires a careful history and may require psychosocial treatment. Suicide has been implicated in about 40% of both inhalant-related medical examiners' death reports and inhalant-related visits to hospital EDs.

Inhalant-Induced Anxiety Disorder

The essential features of inhalant-induced anxiety disorder are panic attacks or other prominent anxiety symptoms judged to be due to the direct physiologic effect of inhalant substances. Such anxiety symptoms sometimes develop during intoxication with inhalants; thus, this diagnosis applies to patients who meet criteria for inhalant intoxication but who also have anxiety symptoms that predominate in the clinical presentation and that are in excess of those usually associated with inhalant intoxication. The anxiety symptoms must cause distress and/or functional impairments severe enough to warrant independent clinical attention. This diagnosis is not made in the presence of inhalant intoxication delirium. In ICD-11, acute intoxication due to the use of volatile solvents includes patients with marked anxiety symptoms arising during the intoxication.

The DSM-5 and ICD-11 diagnostic protocols require that all patients with inhalant-induced anxiety disorders be assessed for the presence and severity of comorbid IUD. Persons with a volatile inhalant-induced anxiety disorder are coded as 6C4B.71 and should be linked to the causing condition (e.g., 6C4B.0, 6C4B.1 or 6C4B.2) and may also be associated with other codes (6C4B.3 or 6C4B.4). The course and treatment of inhalant-induced anxiety disorder are like those of inhalant intoxication. Sedative and antianxiety drugs are contraindicated since they worsen inhalant intoxication, which precipitates inhalant-induced anxiety disorder.

Inhalant-Induced Major and Mild Neurocognitive Disorder

Before going into great detail, it is worth noting that the DSM-5 diagnostic criteria do not make a distinction between the specific substances of misuse when diagnosing substance-induced major and mild neurocognitive disorder. In

Telegram: @medical_k

www.konkur.in

addition, the diagnosis does not account for the unique effects of each substance outlined in its diagnostic criteria. Studies of inhalant-related neurocognitive disorder are riddled with equivocal findings, beset by numerous methodologic problems, including a narrowed focus on adolescent users with fewer lifetime exposures when the adverse consequences of inhalant use may manifest later in adulthood. Moreover, several investigations of adjudicated adolescent inhalant- and noninhalant-using polysubstance users observed greater deficits in executive function, processing speed, behavior, language, and memory in the inhalant-using group. In a series of studies conducted in Australia, adolescent inhalant users were found to have a variety of neurocognitive impairments relative to control when they were compared to cannabis/other drug users and to community controls. However, these inhalant users did not display interindividual variability among themselves across many measures. Clinical and some research evidence indicate that some inhalant-using adults develop inhalant-induced neurocognitive disorder. For example, in a study mentioned earlier, among toluene users (mean age 29 years) studied with MRI, the neuropsychological impairments correlated strongly with the severity of cerebral white matter abnormalities (e.g., poor white/gray matter distinction), and those abnormalities appear to be caused by inhalants.

The predominant feature of major neurocognitive disorder is a marked decline in level of performance in one or more cognitive domains such that the impacted individual experiences difficulties in the performance of instrumental activities of daily living. The cognitive difficulties can include impaired executive functioning (i.e., planning, organizing, sequencing, and abstracting), deficits in learning and memory, and difficulties with speech, social cognition, and perceptual-motor abilities. The symptoms must represent a noteworthy decrement from earlier functioning, not occur exclusively during delirium, and persist beyond the typical duration of inhalant intoxication. Most impacted persons will meet criteria for a moderate/severe IUD. The ICD-11 category of dementia in other specified diseases classified elsewhere includes inhalant-induced persisting dementia.

Inhalant-induced mild neurocognitive disorder is discerned from inhalant-induced major neurocognitive disorder primarily on the basis that the impairment(s) identified represent(s) a “modest” rather than a “significant” decrement in level of performance of one or more cognitive capacities, and the identified deficits do not interfere with the complex instrumental activities of daily living. In both major and mild inhalant-induced neurocognitive disorder, it is anticipated that abstinence from inhalants (concomitantly with abstinence from other neurotoxic agents) is associated with a stabilization or increment of neurocognitive impairments (i.e., not progressive decline). Both the DSM-5 and ICD-11 require that any patient meeting the criteria for a major or mild inhalant-induced neurocognitive disorder be evaluated for a comorbid IUD. Individuals with an inhalant-induced mild neurocognitive disorder may be identified by the

Telegram: @medical_k

www.konkur.in

code 6C4B.Y which is “other specified disorders due to the use of volatile inhalants” and should be made with a causative condition (6C4B.0, 6C4B.1, 6C4B.2) and may be associated with volatile inhalant intoxication (6C4B.03) or volatile inhalant withdrawal (6C4B.4).

Differential Diagnosis. Almost all patients who meet the criteria for an inhalant-induced neurocognitive disorder have a moderate to severe IUD, and many are alcohol dependent, which can also cause dementia. Many of these patients suffer from other conditions that may by themselves, or in a compounding manner, result in neurocognitive difficulties. These difficulties include a history of head injury and certain drug-induced infections, such as HIV. Such difficulties pose clinical challenges that require careful consideration. Even with clear evidence of prolonged inhalant use, a full evaluation of the myriad causes of neurocognitive dysfunction is required to make a proper diagnosis.

Course and Prognosis. Few of these patients have been studied prospectively. However, a recent 15-year follow-up of 77 previous inhalant users with no chronic encephalopathy showed significant improvements in standard neurologic, cognitive, and oculomotor tests compared to healthy participants. A subset of 17 users who had previously developed chronic encephalopathy demonstrated fewer improvements in the 15-year follow-up. Long-term abstinence may yield promising outcomes. Cessation in use may allow for recovery of brain function in a currently unknown proportion of inhalant users. Given current findings, some inhalant users may develop irreversible neurologic deficits from chronic encephalopathy following prolonged inhalant use. These impairments may cause inhalant users to have difficulties with executive functions (e.g., response inhibition), which may in turn increase the likelihood of relapse, complicating treatment, and each relapse may yield compounding cerebral toxicity. The sooner the user ceases use, the better the outcome and the less likely the user is to develop serious encephalopathy.

Treatment. There is no distinguished treatment of inhalant-induced neurocognitive disorder. Street outreach and comprehensive social service support measures have been offered to severely impacted inhalant-dependent homeless adults. Patients may require extensive support within their families or in foster or domiciliary care.

ADDITIONAL INHALANT CLASSIFICATIONS

Unspecified Inhalant-Related Disorder

Telegram: @medical_k

www.konkur.in

The diagnosis of unspecified inhalant-related disorder is reserved for inhalant-related clinical presentations associated with clinically significant distress and/or functional impairment that do not meet full diagnostic criteria for any specific inhalant-related disorder.

Nitrous Oxide–Related Disorders

The DSM-5 includes nitrous oxide (N_2O)-related disorders among other (or unknown) substance-related disorders because of differences between nitrous oxide and other inhalants in their modes of action and associated problems. Still, many investigations categorize and label nitrous oxide and nitrites as “inhalants,” inconsistent with the DSM-5, and very few studies examine nitrous oxide and nitrites separately from other “inhalants.” Epidemiologic studies suggest that while toluene-containing products may frequently be utilized by adolescents, among adult past-year “inhalant” users, 68% had used nitrous oxide or whippets, making this the most commonly used “inhalant” in that group.

Nitrous oxide was introduced in 1844 by an American Dentist, Dr Horace Wells, for clinical practice, and it is still a widely used inorganic anesthetic gas. Nitrous oxide is also sold in small cartridges (known as “whippets”) as a propellant to dispense whipped cream. These cartridges are easily purchased through internet retailers and, not surprisingly, nitrous oxide misuse seems to appear most commonly among the health care and food service workers who use these preparations. A recent NSDUH estimated that between 90,000 to 122,000, 12- to 17-year-old Americans had inhaled “nitrous oxide” or “whippets’” at least once in their lifetime between 2018 and 2019 unassociated with a medical procedure. In one recent and relatively large study of conduct-disordered youth, nearly 16% reported lifetime nitrous oxide use.

Prior diagnosis with a psychiatric disorder and temperamental fearlessness were significant predictors of nitrous oxide use. Youth who had used volatile solvents and nitrous oxide had significantly greater psychiatric and SUD comorbidity compared to users of volatile solvents alone, nitrous oxide alone, or neither nitrous oxide nor volatile solvents. Nitrous oxide has a rapid onset and offset of action and is mostly excreted in the breath with little or no biotransformation. Nitrous oxide has been shown to reinforce self-administration behavior in animals. Although there is some evidence that nitrous oxide influences opioid systems, the subjective effects of nitrous oxide are not reduced by the opioid antagonist, naloxone.

In studies of persons without SUDs, some prefer inhaling nitrous oxide more than placebo, but others do not. In such studies, the drug produces feelings described as “drunk,” “dreamy,” “coasting or spaced out,” and “pleasant bodily sensations.” Individuals reporting more of these feelings are more likely to choose nitrous oxide over placebo. When compared in the laboratory to oxygen,

Telegram: @medical_k

www.konkur.in

nitrous oxide produces significantly higher ratings of euphoria but no significant increases in subjective sleepiness, distinguishing it from the CNS depressant effects of most inhalants. Nitrous oxide–exposed subjects do as well as oxygen-exposed subjects on tasks of coordination and reaction time but perform significantly worse on some measures such as tasks of logical reasoning and digit symbol substitution, where subjects replace numbers with symbols according to a digit-symbol code.

A recent meta-analysis of 85 studies reported that the most frequent clinical manifestations of nitrous oxide use included paresthesia, unsteady gait, and weakness. Chronic use of nitrous oxide can also produce severe outcomes with neurologic or hematologic disorders reported in almost all published cases, with more than half of the reports occurring in recreational settings. Diffuse polyneuropathy and myelopathy with extensive, although sometimes reversible, neurologic symptoms mimicking those of vitamin B_{12}–related pernicious anemia have been reported. Active vitamin B_{12} requires reduced cobalt, but nitrous oxide irreversibly oxidizes cobalt, suppressing the activity of an important enzyme, methionine synthase. This highlights the need to evaluate whether correcting B_{12} deficiency would prevent nitrous oxide–related toxicity.

A 35-year-old male dentist with no history of other substance use complained of problems with nitrous oxide misuse for 10 years. This use had begun as experimentation with what he had considered a harmless substance. However, his level of use increased over several years, eventually becoming almost daily for months at a time. He felt a craving for nitrous before sessions of use. Then, using the gas while alone in his office, he immediately felt numbness, a change in his temperature and heart rate, and an alleviation of depressed feelings. “Things would go through my mind. Time was erased.” He sometimes fell asleep. Sessions might last a few minutes, or up to 8 hours; they ended when the craving and euphoria ended. He had often tried to stop or cut down, sometimes consulting professionals about the problem.

Cases in the literature strongly suggest that nitrous oxide intoxication, misuse, and dependent use do occur. Considering the drug’s brief duration of action and users’ intermittent inhalation patterns, nitrous oxide appears unlikely to produce a clinically significant withdrawal syndrome. It is not clear, however, whether nitrous oxide produces other substance-related disorders. There are no clinically practical urine or breath tests for the presence of nitrous oxide. Misusers of the drug who develop neurologic symptoms may have low serum concentrations of vitamin B_{12}, and remission of neurologic symptoms has followed combined administration of B_{12} and folate, together with abstinence from nitrous oxide. In

Telegram: @medical_k

www.konkur.in

the absence of controlled studies of treatment of nitrous oxide use disorders, general principles for treating other SUDs should guide the treatment of these patients.

Amyl, Butyl, and Isobutyl Nitrite–Related Disorders

The DSM-5 includes amyl, butyl, and isobutyl nitrite–related disorders among "Other (or Unknown) Substance-Related Disorders." In a 2018 national household survey in the United States, among adult past-year inhalant users, amyl nitrite/poppers/rush were the second most used "inhalant" (>6,000,000) behind nitrous oxide. In comparison, nitrites were the 11th most used "inhalant" among adolescents in that same survey. While prevalence of nitrite use is relatively low in the general population, in some populations (i.e., urban HIV-positive gay and bisexual men), high rates of nitrite/popper use have been shown, and nitrite use has been associated with risky sexual behaviors.

The vapors of the volatile liquid amyl nitrite produce vasodilation and smooth muscle relaxation. Amyl nitrite, once supplied in easily "popped" glass vials, found wide use as acute inhalation therapy for angina pectoris between 1867 and ~1980. Sublingual nitroglycerin tablets have now superseded that use. Amyl nitrite and its close relative butyl nitrite enjoyed a flurry of use as recreational drugs during the 1970s and 1980s. Reports from that time suggest that the use was among adolescents, users of other drugs, and homosexual men. The latter group especially reported using the drugs to enhance orgasm, and these nitrites also were considered to produce a high, a feeling of wild abandon, or an altered state of consciousness. A recent study of antisocial youth found that 83% of nitrite users reported that they experienced intoxication when they inhaled nitrites. Nonmedical users called amyl nitrite vials "*poppers,*" and the availability of those vials declined with their attenuating medical use. Butyl nitrite and related compounds were then increasingly marketed as room deodorizers under suggestive names such as Rush or Locker room. These were intentional ways to skirt laws blocking their abuse like consumption however the target demographic of inhalant abusers remained the same.

In one study of patients who had misused these drugs, most experienced dizziness, light-headedness, cardiac palpitations, blurred vision, and a feeling of warmth immediately after inhalation. Others complained of immediate headache, nasal burning, nausea, cough, dyspnea, or syncope. Nearly half found the experience not at all pleasant; the others rated it only fair to good. Some experts believe the drug does not have primary reinforcing effects mediated in the CNS, but that certain pleasurable sensations associated with peripheral vasodilation lead to its continued use.

A few case reports document severe, but nonfatal, methemoglobinemia after nitrite inhalation by persons genetically deficient in methemoglobin reductase.

Telegram: @medical_k

www.konkur.in

There also are reports of rapidly fatal methemoglobinemia after oral ingestion (not inhalation) of these compounds by genetically normal persons. Some epidemiologic studies further suggested that among homosexual men, nitrite use might increase the risk of HIV infection or of developing Kaposi sarcoma after HIV infection. However, those observations were heavily confounded since nitrite users tended to have more partners and to pursue unsafe sexual practices more frequently.

Considered together, the lack of a compelling instantaneous high, the immediate unpleasant feelings, and the longer-term risks from amyl and butyl nitrite seem to contribute to a low prevalence of use. In 2000 to 2001, among Americans 12 to 17 years of age living in households, 1.5% said that they ever had used "amyl nitrite, 'poppers,' locker room odorizers, or 'Rush.'" Recent MTF survey findings and the results of a large study of conduct-disordered youth also found that less than 2% of 12 to 17 year olds had tried inhaling nitrites.

Some persons with sustained industrial exposures to nitrites experience withdrawal headaches on weekends or vacations, but it seems unlikely that intermittent, brief exposures to these short-acting drugs would produce clinically significant withdrawal in recreational misusers of nitrites. There are no studies for the treatment of amyl or butyl nitrite–related disorders, and so such treatment should follow general principles for the treatment of other substance-related disorders.

FUTURE DIRECTIONS

Although considerable progress has been made in better understanding the pharmacology of inhalants and the epidemiology of inhalant use and IUDs, there are several critical areas that should be the focus of future investigations. First, there is limited empirical research to guide the treatment of adolescents or adults with inhalant-related disorders; such work is vital to clinicians working with such populations. Second, addiction treatment often requires regular objective monitoring for substance use. The currently available methods for monitoring inhalant use are cost prohibitive, are specific to individual inhalants (do not cover the broad spectrum of possible inhalants), generally can only detect very recent use (i.e., testing for specific inhalants), or may lack specificity (i.e., testing for inhalant metabolites such as hippuric acid). Development of sensitive and specific monitoring methods, which are cost-effective, would represent a major contribution. Third, individuals with inhalant-use disorders are very likely to have other mental health problems. Little research thus far has attempted to better understand the reasons underlying that comorbidity (directionality of causality or a common shared risk). Given that inhalant use is common and that a single use may be fatally toxic, it is important to support continued efforts to develop empirically tested, effective inhalant prevention programs that may be broadly

Telegram: @medical_k

www.konkur.in

and cost-effectively implemented. Taxonomic research identifying subtypes of inhalant users could provide data that would facilitate matching of inhalant users to specific treatment interventions. These classifications should focus on sex differences as the reasons for, patterns of, and impacts from inhalant use. Studies of the short- and long-term consequences of inhalant use and longitudinal investigations of the natural history of IUDs are needed. Ethnographic investigations of cultural and subcultural factors relevant to inhalant use could prove informative as to the reasons why and how inhalants are misused among geographic subpopulations. Psychometric research is needed to examine the reliability, validity, and latent structure of DSM-5 inhalant use and inhalant-induced disorders diagnostic criteria in different populations of inhalant users. Health services research is needed to better understand the health care utilization patterns of persons with inhalant-related disorders. Additional investigation of the phenomenology of inhalant intoxication across different inhalants and mixtures of inhalants would provide additional insight into the reinforcing properties of inhalants. Last, exploration of the impact that initial inhalant use has on subsequent drug and psychiatric trajectories is warranted.

11.8 Tobacco-Related Disorders

Smita Das, M.D., Ph.D., M.P.H., Brian Isakson, Ph.D., and Douglas M. Ziedonis, M.D., M.P.H.

Tobacco use disorder (TUD) is the most prevalent, deadly, and costly of substance use disorders (SUDs). The prevalence of addiction to nicotine, the primary psychoactive substance in tobacco, surpasses all other SUDs. Tobacco currently remains unrivaled as the leading cause of premature death and preventable morbidity in the United States and globally with an incidence of one in five deaths in the United States being attributed to cigarette smoking. TUDs are the leading major public health issue and uniquely affect psychiatric patients.

TUD has created tremendous health disparities for patients with mental illness or SUDs, and individuals with multiple adverse childhood events (ACEs) are also at high risk for TUD. The literature on the evidence on why mental health and addiction treatment settings must address tobacco use and TUDs is very clear, including the fact that 44% of all cigarettes in the United States are consumed by smokers with mental illness and SUDs. Among patients in mental health and addiction treatment settings, 50% to 95% are smokers. This is in stark contrast to the general trend of decreasing smoking rates in the United States at large (14% use cigarettes, with an additional 4.5% using e-cigarettes). The most common causes of morbidity and mortality among individuals with a psychiatric disorder or SUD, such as lung cancer, diabetes, and cardiovascular disease, are related to tobacco, and tobacco accounts for the disturbing statistic that people with mental illness die on average 25 years earlier than the general population. In addition to the negative physical health consequences, there is a probable independent association between suicide and current smoking and longer lifetime smoking duration. In a recent analysis, for example, longer lifetime smoking (≥41 vs. ≤10 years) was associated with higher odds of suicide (odds ratio [OR] = 2.26, 95% confidence interval [CI] = 1.30–3.93).

Telegram: @medical_k

www.konkur.in

Unfortunately, TUD has also been one of the most often ignored SUDs in mental health and addiction treatment settings, particularly by psychiatrists; the need to address tobacco in these settings is clear, and clinical practice guidelines delineate expectations to do so. Historically, mental health and addiction treatment settings not only neglected to address tobacco use and TUDs, but there was a minimization and rationalization that supported use. In a survey by the American Association of Medical Colleges (2007) of more than 3,000 physicians, 47% of psychiatrists felt patients had more immediate problems to address and 22% reported that cessation heightens other symptoms. This survey marked a change of improved attitudes for the majority; however, these attitudes of rationalizing and not addressing the topic isolated psychiatrists compared to all other physician specialties surveyed. These assumptions are not supported by the literature.

While psychiatric patients may have a worse tobacco withdrawal experience during the first 2 weeks, their long-term mental status is not worsened and likely improves with their physical health. In fact, accruing evidence demonstrates significant improvement in mental health and quality of life as a result of tobacco cessation. A recent systematic review and meta-analysis conducted by Taylor et al. (2014) assessed 26 smoking cessation studies and found a significant decrease in anxiety, depression, and stress, as well as improvements in overall mood and quality of life among quitters compared to nonquitters (samples not limited to mental health populations). Tobacco cessation also enhances the likelihood of successful abstinence and sobriety from other addictive substances among individuals with an SUD, as continued tobacco use is actually found to hinder recovery from other addictions. While they have worse withdrawal as a result of heavier dependence, people with psychiatric comorbidities are able to quit with overall stable mental health and much better physical health, quality of life, finances, and often lower dosages of psychiatric medication.

Psychiatrists have an opportunity to help improve overall well-being and the lifespans of their patients by evaluating and treating TUD using evidence-based approaches in psychiatric treatment settings, including psychosocial treatments, pharmacotherapies, community resources, and carbon monoxide (CO) monitors. Seven U.S. Food and Drug Administration (FDA)-approved pharmacologic agents are available to help individuals with TUD, including five nicotine replacement therapies

Telegram: @medical_k

www.konkur.in

(NRTs) and two non-NRT pills (bupropion and varenicline). All seven of these medications can be effectively used in psychiatric patients; three NRTs are available over the counter (OTC) or by prescription (patch, gum, lozenge), two NRTs are only by prescription (nicotine inhaler and nasal spray), while the two non-NRTs are by prescription only. The integration of these medications with TUD-specific psychosocial interventions, community resources, and providing guidance and appropriate monitoring can improve quit rates by 50%. Treating TUD will not only help improve a patient's well-being, but these services can be reimbursed by completing "meaningful use" assessments of tobacco, performing CO assessments, and performing TUD treatments. Ultimately, treating TUD in people with mental illness has multiple benefits at the individual, provider, and system levels. There are also evidence-based psychosocial interventions that should be integrated, including through referrals to state quit lines and other community resources that are available by phone, internet, and through in-person meetings.

HISTORY

Tobacco use in the New World dates back to at least 600 AD and was introduced into European culture in the 16th century. Early on, most tobacco use was via pipes, smokeless tobacco, cigars, or in traditional ceremonial activities. The cigarette became popular beginning in the early 1900s with the invention of the cigarette-making machine, the match, and the use of acidifying agents to permit nicotine to enter the lower respiratory tract, where it could be rapidly absorbed into the arterial circulation. Cigarette use grew dramatically in the first half of the 20th century, initially through distribution for free to the military in World War I and II and next with targeting women as well through targeted marketing. The first reports of the association of smoking and disease began in the 1950s and culminated with the 1964 U.S. *Surgeon General's Report on Smoking and Health*. The tobacco industry sought to fight the clear risk of cigarettes by marketing "light" or "low tar" cigarettes, which in reality are no less harmful than other cigarettes and are often just smoked more efficiently. With the tobacco industry's efforts in marketing, tobacco use in the United States did not decline significantly until the 1970s and 1980s owing to tobacco-control activities and taxation. In the 1990s and 2000s, tobacco use in the United States declined a little, and that decline may be

Telegram: @medical_k

www.konkur.in

largely due to environmental smoke laws after the Environmental Protection Agency declared secondhand smoke dangerous as well. Of note, the tobacco industry also tried to suppress these findings. Although tobacco use in many Western nations has declined, use in developing countries is substantially increasing in part due to relaxed policy enforcement and increased marketing practices. Recent attempts by the FDA and the World Health Organization (WHO) to regulate and discourage tobacco use are important but have been only partially successful.

The tobacco industry targeted individuals with mental illness and/or addiction in numerous ways, a likely cause for the high rates of TUD in this population, as described by Prochaska and the evidence documented in The Legacy Tobacco Documents Library (http://legacy.library.ucsf.edu). For example, the tobacco industry attempted to validate the "self-medication hypothesis," that people with schizophrenia needed to smoke to manage their psychiatric symptoms. R.J. Reynolds in a Legacy Library record even specifically studied what they considered the "downscale market profile," people who are homeless or mentally ill, and documents from them note the population is "more impressionable to marketing/advertising … they're more susceptible. They're less formed intellectually … more malleable." Research promoting smoking among those with mental illness was widely distributed in meetings, publications, and through lobbying/policy efforts. Advertising was directed at people with mental illness, implying that tobacco was part of psychiatric illness (i.e., advertisement headline reading, "Schizophrenic. For New Merit, having two sides is just normal behavior"). Also worrisome is the intimate history the tobacco industry had with psychiatric institutions, supplying them with free, low-cost, or tax-free cigarettes. While much of this activity took place from the 1950s to 1970s, even in the 1990s, mental health centers were still communicating with companies like R.J. Reynolds for cigarette donations. Tobacco companies also lobbied to allow for smoking in psychiatric facilities after the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO) mandated smoke-free hospitals.

Beyond the health consequences of tobacco use, the 1988 U.S. Surgeon General's report, *The Health Consequences of Smoking—Nicotine Addiction*, comprehensively reviewed the evidence and concluded that smoking was a form of substance dependence. The most recent reports in 2014 and 2020, "The Health Consequences of Smoking

Telegram: @medical_k

www.konkur.in

—50 Years of Progress" and "Smoking Cessation: A Report of the Surgeon General" outline the dangerous history of tobacco and the strong effects of tobacco control policies in the United States. Nonetheless, tobacco remains the leading preventable cause of death in America.

COMPARATIVE NOSOLOGY AND DIAGNOSTIC FEATURES

Although tobacco dependence prevalence has been high over much of the last century, it was only in the 1980s that the term nicotine dependence was first accepted and included (though not coded) in the *Diagnostic and Statistical Manual of Mental Disorders*, Third Edition (DSM-III-TR) and the ninth edition of the *International Classification of Diseases* (ICD-9) as an SUD. In the 1970s, tobacco corporations sought to influence the American Psychiatric Association (APA) task force revising the DSM; these efforts may have led to the narrow definition of tobacco dependence initially, for example, requiring someone to have seriously tried to quit in order to be diagnosed with TUD. The 1988 U.S. Surgeon General's report, *The Health Consequences of Smoking—Nicotine Addiction* comprehensively reviewed the evidence and concluded that smoking was a form of substance dependence. Also in DSM-III, *abstinence-induced nicotine withdrawal syndrome* was first classified. Nicotine *dependence* and *withdrawal* were the two defined nicotine-related disorders in the revised fourth edition of the DSM-IV-TR, which distinguished nicotine from other substances.

Contrary to other substances, nicotine *abuse* was omitted as a diagnosis in DSM-IV due to the strong propensity for use to transition to what was defined as dependence (when tolerance and withdrawal criteria are met). Nicotine abuse was also confined to significant psychosocial problems but not physical problems, and the former is rare with nicotine use. (Physical problems, however, are present even with nondaily smokers.) The 10th edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) included *harmful use*, a category that is similar to abuse but includes continued use that causes physical problems (which was warranted given the high rates of use despite numerous health consequences). ICD-11, effective as of 2022, also includes harmful patterns of use, nicotine dependence, intoxication,

Telegram: @medical_k

www.konkur.in

and withdrawal among other nicotine-related diagnoses, relying less on tobacco terminology.

May 2013 marked the release of the current DSM-5, which now includes among the 10 substance-related and addictive disorders the classification of tobacco-related disorders. Throughout this chapter, prior DSM-IV *nicotine dependence* terminology has been replaced with the current DSM-5 classification of *TUD*. The DSM-5 diagnostic criteria will be discussed in more detail in this chapter in the assessment section related to establishing a TUD diagnosis.

EPIDEMIOLOGY

In the United States, 14% of the adult population smokes cigarettes, with TUD being the most prevalent of all substance-related and addictive disorders. The prevalence of smoking in the United States has significantly decreased—it was just shy of 50%—over the past five decades. Unfortunately, some groups still disproportionately use tobacco, such as 50% to 85% of those with mental illness/SUDs, with lower income, and with lower education. Females have slightly lower rates of tobacco use (15.2% in women vs. 26.2% in men). Lower tobacco use rates are observed in those older than 65 years of age (11.4%) likely as a result of premature death. Worldwide, 80% of the 1.3 billion tobacco users worldwide live in low- and middle-income countries.

Ninety percent of smokers tried their first cigarette by age 18 and 98% by age 26. Sixty-nine percent of current smokers want to quit smoking completely, and 52.4% of smokers in the United States have made a quit attempt for >1 day in the past year. While 6.2% have sustained cessation, less than half of smokers (48.3%) who saw a health professional in the past year reported receiving advice to quit. In those who try to quit, use of counseling and/or cessation medications was 31.7%.

In terms of the diagnosis of nicotine dependence, approximately 28% of people in the United States develop nicotine dependence at some point in their lives, making it the most prevalent psychiatric disorder. Approximately 50% of current adult daily smokers are nicotine dependent. Nicotine withdrawal occurs in approximately 50% of smokers who try to quit.

Prevalence of Other Traditional and Emerging Tobacco Products

Telegram: @medical_k

www.konkur.in

As a reference to describe other products, a description of a cigarette is warranted. A cigarette is a cylinder of tobacco rolled in thin paper for smoking. Nicotine, a naturally occurring pesticide, is the primary psychoactive and addictive chemical in tobacco, and hence cigarettes. Other chemicals are added to the shredded tobacco mixtures such as humectants (i.e., propylene glycol) to keep the tobacco moist, flavoring products (e.g., menthol), enhancers, sugars, and chemicals, such as ammonia, which boost the addictive properties of cigarettes, especially when burned. A cigarette contains 6 to 11 mg of nicotine, allowing for 1 to 2 mg of absorption, and smoking a pack per day equals 20 to 40 mg of nicotine absorbed per day.

Use of other forms of tobacco products, including older products (e.g., cigars), in addition to new emerging products, such as smokeless tobacco (e.g., snus, hookahs, and dissolvables) and other alternatives, such as electronic nicotine delivery systems (ENDS or e-cigarettes), are gaining popularity today. National estimates based on the 2020 National Health Information Survey (NHIS) reported every day or someday use of the following among adults: Any tobacco product, 20.8%; any combustible product, 16.7%; cigarettes, 14%; cigars/cigarillos/filtered little cigar, 3.6%; regular pipe/water pipe/hookah, 1%; e-cigarettes, 4.5%; smokeless tobacco, 2.4%; and ≥2 tobacco products, 3.9%. Notably, e-cigarette use has been on the rise, and these products are becoming more appealing and accessible among children and adolescents. There are also valid concerns around these products serving as gateways to other tobacco products. Patients should be educated on the addictive nature of emerging forms of tobacco as well as possible misconceptions regarding safety of these products, which are not FDA approved.

Adverse health effects of cigars and cigarillos are comparable to those associated with cigarette use, including cancers (oral, esophageal, and lung) and tobacco-related illnesses that are significantly correlated with level of smoke exposure. Cigars are arguably more harmful than cigarettes as they contain higher concentrations of known carcinogens, toxins, and tar. Whether a cigar user inhales or not, they are still absorbing nicotine; when inhaled, nicotine is delivered more quickly through the lungs, whereas if not inhaled, nicotine is absorbed at a slower rate through the tissue in the mouth. Cigars are offered in a wide range of sizes, thus the amount of nicotine that one might contain can vary largely. Cigars typically contain around 100 to 200 mg of nicotine but can contain

Telegram: @medical_k

www.konkur.in

as much as 444 mg of nicotine. It can be approximated that in proportion to the total nicotine amount and yield of cigarettes, that nicotine exposure from cigars can range anywhere from 9 to 68 mg. The smallest version of cigars is equivalent to the standard size of a cigarette, called a little cigar (containing about 1 g of tobacco—slightly more than the amount in a cigarette). A marginally larger and narrower version is called a cigarillo (containing about 3 g of tobacco).

Electronic cigarettes, also referred to as e-cigarettes or ENDS, have increasingly been linked to marketing statements that promote them as safer alternatives to tobacco, though there is a dearth of clinical research, including nicotine pharmacology studies, in this area to support this claim and meta-analyses indicating an association between use in adolescents and subsequent cigarette use (Khouja, 2021). Electronic cigarettes still contain, in addition to the addictive substance nicotine, toxic chemicals such as propylene glycol (an irritant in antifreeze). As supported by recent clinical studies, the nicotine exposure provided by e-cigarettes, compared to traditional cigarettes, varies according to the experience level of the user, where blood levels of nicotine and its metabolite, cotinine, tend to be similar to that delivered by cigarettes for current e-cigarette smokers and less concentrated for inexperienced users. The amount of nicotine in the e-liquid ranges in strengths of 6 to 24 mg/mL in a cartridge, though there is variation among different e-cigarette brands and brand models in overall nicotine content, as well as in the amount that is actually delivered to the user. The flavored nature of the substance can add appeal to vulnerable populations (youth) and also enhances the addictive potential. In addition, the products are newly regulated by the FDA (in 2016) and the regulation is limited, lending to surges of advertising and widespread availability in convenience stores, vape shops, etc. Emerging research about ENDS is located later in the chapter, including cessation potential and lung injury.

A *water pipe*, also referred to as hookah or shisha, is a device with origins in India. Water pipes date back to the 1700s and are used for smoking tobacco by delivering cooled charcoal tobacco smoke that passes through water before inhaled. Levels of CO, nicotine, tars, and heavy metal exposure from this product can often be even higher than what traditional cigarettes produce, contrary to the common belief that water pipe smoking has less health consequences than cigarette smoking. Variation in nicotine exposure is influenced by a variety of

Telegram: @medical_k

www.konkur.in

determinants, including the temperature at which the tobacco is burned, type of tobacco and water pipe product, and individual patterns of smoking behaviors.

Snus, originally from Sweden, is a form of smokeless tobacco that is encapsulated in a porous pouch that the user stores in between the cheek and the gum; it does not require the need to spit, as is the case with chewing tobacco/dip. Though it has been suggested to be associated with less significant harmful effects than cigarettes if entirely replacing cigarette smoking, it can be a gateway to other tobacco products and may decrease the likelihood of successful smoking cessation attempts. In Sweden, snus use has exceeded smoking, and the country has seen a dramatic decline in lung cancer rates; however, many former smokers are now dependent on snus, and there is evidence of an increased risk of pancreatic cancer.

Chewing tobacco and snuff are fairly similar smokeless products, with the former being a more finely ground form of tobacco and the latter provided in the form of loose leaves. Both are stored in the mouth and then spit out after use. Snuff is encapsulated in a porous pouch, whereas chew or finely ground tobacco is directly placed as a wad between the gum and the cheek, to allow nicotine to be absorbed by the mouth tissue. Typically, the nicotine content of these products can range from 3.6 to 4.5 mg. Compared to the 7 seconds it takes for the brain to respond to nicotine from inhalation of cigarette smoke, the same effect can be delayed to up to 30 minutes for chew or snuff users, though it is continuously delivered for up to 60 minutes after use (whereas nicotine delivery ceases immediately after the last puff of a cigarette). In terms of nicotine content, one dip or pouch of these forms of “spit tobacco” is equivalent to five cigarettes, whereas one can, containing 144 mg of nicotine, equates to smoking 4 packs of cigarettes. Smokeless tobacco users suffer the same systemic adverse effects as smokers due to tars and tobacco additives and have higher rates of oral, prostate, pancreatic, and cervical cancers compared with nonsmokers. Snuff users have a 50-fold increased risk of cancer of the cheek and gum. Smokeless tobacco is associated with numerous dental, periodontal, and oral soft tissue problems, including gingival recession, periodontal attachment loss, tooth staining, halitosis, and leukoplakia (a precursor to oral cancer).

Dissolvables are smokeless products that melt in the mouth, and similar to snus, are promoted as forms of tobacco not subject to prohibited use in

Telegram: @medical_k

www.konkur.in

smoke-free locations. They are provided in forms that mimic candy, such as lozenges, orbs, pellets, strips, or sticks, where the juices are swallowed and are often sweet or minty in flavor. Dissolvables are still addictive in nature and are contributing to poly-nicotine use in individuals who are trying to quit cigarettes (as often these products are marketed as quit aids).

ETIOLOGY

Nicotine and acetylcholine bind to and activate nicotinic acetylcholine receptors. Originally, these receptors were thought to be confined to the ganglia and neuromuscular junction but have now been found in several areas of the CNS. The two types of ligand-gated receptors that appear to be involved in the reinforcing properties of nicotine are the α4/β2 and α7 subtypes. These receptors are unusual in that they quickly desensitize. This phenomenon, plus the fact that repeated use of nicotine increases, not decreases, the number of receptors, suggests that nicotine may actually act as much as an antagonist as an agonist at this receptor. Emerging data indicate that distinct nicotinic receptors including those that contain the β4 subunit are involved in nicotine withdrawal symptoms.

The reinforcing effects of nicotine appear to be modulated by dopamine and glutamate release due to nicotinic receptors on dopamine cells in the ventral tegmental area and the core and shell of the nucleus accumbens, whereas withdrawal symptoms upon nicotine cessation are modulated by glutamate and corticotropin-releasing factor (CRF) release in the habenula-interpeduncular axis. The mesocorticolimbic system neural circuits are now seen as a common pathway for addictive drugs.

There are multiple contributors to tobacco dependence. Nicotine dependence is partly due to its multiple pharmacologic effects and the cigarette delivery device. Nicotine is best absorbed in the oral mucosa, nose, skin, and lung (more so than the stomach due to acidity). It also is able to enter the bloodstream without being processed by the liver (first-pass effects). Nicotine via cigarettes is rapidly absorbed directly into the arterial circulation and reaches the CNS in less than 15 seconds. Peak behavioral and cardiovascular effects occur within a few minutes. Nicotine is metabolized via the liver and has a half-life of 2 hours. The rapid effects of nicotine and the rapid decline lead to withdrawal symptoms that can form rather quickly in smokers.

Telegram: @medical_k

www.konkur.in

Binding of nicotine to receptors leads to the subjective gratifying effects (through modulation of dopamine, glutamate, GABA, norepinephrine, and other systems) in the mesocorticolimbic system. The release of these neurotransmitters (via nicotine receptors) leads to the experience of reinforcing effects of smoking such as pleasure, arousal, and subjective lessening of anxiety. Many people with dependence subjectively feel as though nicotine is required to cope with life demands. Over time, continued use may be to suppress withdrawal. Tolerance also develops (part of dependence), as shown in several studies, and is established quickly and increases over the course of a day. Compared to nonsmokers, smokers often report less of the pleasurable effects of nicotine, such as arousal, vigor, and a subjective experience often referred to as “buzz,” as a result of this tolerance.

Nicotine’s different use patterns related to other drugs of misuse—that is, not striving for intoxication—may also contribute to nicotine dependence. Lack of intoxication allows the smoker to imbibe large amounts of nicotine on a daily basis without producing an obvious behavioral interference in daily activities, which, in turn, increases the chance of physical or psychological dependence. Legal, and relatively inexpensive compared to other drugs, cigarettes can be obtained with few social skills or resources. Being legal, punishment for smoking only occurs from social approbation.

The ideal reinforcer is one that occurs rapidly, frequently, and consistently, with minimal effort, and is unlikely to be punished. Nicotine via cigarettes has all these attributes. Inhalation (smoking) is the most rapid method to deliver a drug to the brain. It is also one of the most, if not the most, frequently reinforced behaviors. Taking 10 puffs per cigarette, times 20 cigarettes per day, times 365 days per year, times 20 years, results in millions of drug self-administrations. Because cigarettes are manufactured, they deliver precise doses of drug. Of course, the tobacco industry has long been invested in making cigarettes more addictive via design changes, paper choice, droplet sizes, additives (such as propylene glycol to keep the tobacco moist, or menthol flavoring), sugars, and chemicals, such as ammonia, which boost the addictive properties of cigarettes, especially when burned. The combination of multiple drug effects, lack of intoxication, and method of delivery makes nicotine users highly susceptible to developing dependence. In addition to the primary reinforcement described above, tobacco is highly subject to secondary

Telegram: @medical_k

www.konkur.in

reinforcement (classical conditioning), where conditioned stimuli (seeing a cigarette, smelling it, or being in situations where one usually smokes) promote the urge to smoke.

Although not widely known, initiation and cessation of tobacco use are as heritable as alcohol dependence or abuse. Some of the genetic effects are shared with alcohol, and some are specific to tobacco. Specific genes may affect responses of the body and the brain to nicotine (metabolism of nicotine, receptor sensitivity, and the levels of neurotransmitters). An example is variants in the *CYP2A6* gene that influence the rate at which a smoker clears nicotine; factors like this also contribute to an individual's susceptibility to tobacco addiction and response to treatments. Similarly, adolescent initiation of smoking can affect the trajectory to dependence (more than 90% of smokers begin as teenagers), social environment, peer modeling, and family environment. In addition, multiple ACEs are highly predictive of tobacco use and are an opportunity for prevention and early intervention.

Children are more likely to start smoking due to ACEs, and as well as those who have a high need to conform, low academic performance, rebelliousness, depressive symptoms, and poor self-esteem. Peer and family influences are paramount. Attention deficit, conduct, and alcohol or drug use disorders increase the risk of initiation and maintenance of smoking. Adolescent initiation of smoking can affect the trajectory to dependence (more than 90% of smokers begin as teenagers), along with social environment, peer modeling, and family environment.

DIAGNOSIS AND CLINICAL FEATURES

Diagnosis in SUDs has evolved to not include abuse versus dependence and rather be framed as levels of severity. To meet diagnostic criteria for SUDs including TUD, at least two of these 11 conditions must occur within a 12-month period in the DSM-5 (these are a blending of abuse and dependence criteria): (1) tobacco use often persists at a higher volume and over a longer duration of time than intended; (2) repeated desire or unsuccessful attempts to quit, cut down, or control tobacco use; (3) a significant amount of time is spent engaging in activities related to acquiring or using tobacco products; (4) craving, or an intense desire, to use tobacco; (5) inability to fulfill major role obligations at work, school, or home due to persistent use; (6) continued use despite continued or

Telegram: @medical_k

www.konkur.in

recurrent problematic social or interpersonal consequences, occasioned or worsened by the effects of tobacco (e.g., arguments with others about tobacco use); (7) important social, recreational, and work-related activities are given up or limited due to tobacco use; (8) tobacco use persists in situations where physically unsafe (e.g., smoking in bed); (9) tobacco use is continued despite knowledge of the probable worsening or contributing effects of tobacco use on persistent or recurrent physical or psychological problems; (10) withdrawal: nicotine associated withdrawal symptoms occur with stopping use; (11) tolerance: an increasingly larger dose of nicotine is needed to obtain the desired effect.

Abstinence threshold is defined as presenting none of the TUD criteria, with the exception of craving, for 3 or more months, with a cutoff of 12 months for early remission, and a threshold of 12 or more months for sustained abstinence. Severity can be assessed by the DSM-5 tobacco-related disorder classification and ICD-11 classification of dependence relies on just mild criteria being met. In DSM-5, mild severity is represented by the presence of two to three symptoms, moderate is four to five symptoms, and severe is six or more symptoms.

Tobacco withdrawal follows use for at least many weeks and either cessation or reduction in use resulting in anxiety; depressed mood; irritability, frustration, or anger; insomnia; difficulty concentrating; restlessness; and increased appetite. To meet withdrawal criteria, at least four of the seven signs or symptoms listed above must apply within 24 hours of abrupt cessation or volume reduction. Contrary to DSM-IV classification of withdrawal, DSM-5 omitted reduced heart rate or weight gain symptoms. In support of this change, research suggests that these variables have no predictive value on smoking cessation outcomes. The insomnia appears to be specific to increased awakenings and intense dreaming. Craving is common, and increased coughing, constipation, mouth ulcers, and decreased performance on vigilance tasks can occur. The syndrome is typically most severe with abstinence from cigarettes, intermediate with abstinence from smokeless tobacco, and least severe with abstinence from nicotine replacement products. Most withdrawal symptoms peak at 1 to 3 days and can last up to 2 to 3 weeks. In addition, craving can persist for 6 months or more.

Tobacco use and TUD are two to three times more prevalent among patients with anxiety, attention deficit, mood, substance use, and other psychiatric disorders. Conversely, these psychiatric disorders are two to

Telegram: @medical_k

www.konkur.in

three times more common among current smokers than among people who have never smoked or are ex-smokers. There are several possible reasons for this association; for example, shared genetic influences on smoking and psychiatric disorders, subjective improvement by nicotine of a psychiatric disorder, modeling other psychiatric patients, and boredom. Depressive symptoms, substance use, and attention deficit predict the likelihood of starting to smoke, the probability of becoming dependent, and the inability to stop smoking. Smokers with a current or past history of most psychiatric disorders are more dependent, have more withdrawal on cessation, and have a lower rate of smoking cessation.

DIFFERENTIAL DIAGNOSIS

Many of the symptoms of tobacco withdrawal can mimic, exacerbate, or mask the symptoms of psychiatric disorders or the adverse effects of psychiatric medications; for example, akathisia, anxiety, depression, irritability, insomnia, and weight gain. Individuals who do quit smoking may have increased psychiatric medication side effects or have caffeine intoxication due to the metabolic changes in the P450 1A2 isoenzyme with stopping smoking. Stopping smoking and maintaining the same caffeine intake will increase the availability of caffeine and its intoxication effects. A differential diagnosis for change in mental status or increased medication side effects should include investigating whether there was a change in smoking status. Nicotine intoxication (rare) causes abdominal pain, dizziness, headaches, nausea, pallor, palpitations, sweating, vomiting, and weakness; treatment is supportive and does not usually involve medications. Children are at risk of nicotine intoxication if they are able to access and consume nicotine medications or other nicotine products, including e-cigarettes.

COURSE AND PROGNOSIS

Twenty percent of all mortality in the United States is due to smoking, making it the leading cause of death in the United States, with a third of those deaths related to cardiovascular/cerebrovascular causes, another third related to cancer, and about a fifth related to respiratory diseases. About 10% of smoking-related deaths are from secondhand smoke exposure in nonsmokers and approximately 45% of smokers die of a

Telegram: @medical_k

www.konkur.in

smoking-related disease. In total, there are more than 480,000 deaths per year in the United States, which includes 41,000 due to secondhand smoke. Smoking is a major risk factor for lung cancer and chronic obstructive pulmonary disease (COPD), accounting for more than 75% of all deaths from these disorders. Other common smoking-related diseases include low–birth weight offspring, perinatal complications, other cancers (e.g., throat, bladder, and pancreas), and ulcers. Additional, less obvious health effects of tobacco demonstrated in research including impaired wound healing, diabetes, impotence, and osteoporosis. Secondhand smoke increases the risk of cancer and heart disease in spouses and the incidence of respiratory and ear problems in children.

With reference to cancer, the 2014 Surgeon General's report, *The Health Consequences of Smoking—50 Years of Progress*, reinforced there is sufficient evidence to infer a causal relationship between smoking and cancers of the lung, larynx, oral cavity, pharynx, esophagus, pancreas, bladder, kidney, cervix, stomach, and acute myeloid leukemia. Cigarette smoke has carcinogens that can act as direct carcinogens, cocarcinogens, or tumor promoters/initiators; smoke, free radicals, and other components can cause irritation, inflammation, cell proliferation/hyperplasia, oxidative stress and damage, and decreased organ function. Lung cancer, the leading cause of cancer deaths in the United States, is predominantly attributable to cigarette smoking, and demonstrates a clear dose response where the risk is associated with the number of cigarettes smoked per day and years smoked—this dose response is evident in other cancers as well.

Aside from cancer, cigarette toxicity in the lungs leads to several other health effects: loss of cilia, hyperplasia, metaplasia, mucus plugging of small airways, destruction of alveoli, and a reduced number of small arteries. Other lung/respiratory sequelae of TUD include COPD (emphysema and chronic bronchitis; the third leading cause of death in the United States, with 90% of cases attributable to cigarette smoking). Unfortunately, COPD is less noticeable in early stages of the disease process since small airways are affected first and are less clinically prominent. This often leads to later notice of effects on the large airways (emphysema) and irreversible progression of the disease. Other respiratory effects include increased risk of respiratory infection, such as pneumonia, in part due to cilia damage and triggering of asthma attacks.

Telegram: @medical_k

www.konkur.in

Heart disease is the leading cause of death in the United States, and 30% of heart disease mortality is caused by smoking, where smokers have two to four times the risk of coronary heart disease, and women are more affected. The end effects of cardiovascular disease include myocardial infarctions, strokes, aortic aneurysm, and the impacts of peripheral vascular disease. Acutely, nicotine causes increases in systolic blood pressure, heart rate, and cardiac output while causing vasoconstriction; another acute effect of smoking is that CO reduces oxygen availability to the heart. Chronically, cigarette smoke increases inflammation, platelet activation/thrombosis, and endothelial dysfunction that can lead to atherosclerosis. Later in the inflammation process, smoking destabilizes plaques and promotes oxidation of low-density lipoproteins; the result is reduced myocardial blood flow, reduced oxygen, and artery occlusion. Nicotine is also arrhythmogenic (it increases serum catecholamines) and this, combined with carboxyhemoglobin lowering the threshold for ventricular fibrillation, can lead to sudden cardiac death, accounting for half of all deaths from coronary heart disease. Quitting smoking reduces the risk of sudden death immediately and in the long term. The risk of myocardial infarction is dose dependent, but as few as one to four cigarettes a day raises the risk of dying from ischemic heart disease. Also, when it comes to quitting smoking and heart disease, the risk is reduced by about half after just the first year of cessation and falls to that of “never-smokers” after 15 years of abstinence.

The course and prognosis of the health effects of TUD are worse with comorbid disorders and exposures. There is an additive effect of environmental carcinogens with smoking that worsens cancer outcomes, for example, with radiation and asbestos exposure. Similarly with oral, laryngeal, and esophageal cancers, alcohol use can worsen cancer outcomes, possibly by chemical interaction; for example, the risk of larynx cancer is 75% higher in people who use tobacco and alcohol versus those exposed to either substance alone. Finally, due to the deleterious effects on the cardiac and respiratory systems, smokers are less able to be physically active. This increases the risk of many other comorbidities.

Environmental tobacco smoke: Secondhand smoke impacts the prognosis of TUDs and the likelihood of quitting when living with other smokers. There are an estimated 7,357 chemical compounds in cigarette smoke, which include respiratory irritants (acrolein and acetaldehyde), cardiovascular damaging chemicals (cyanide, arsenic, and the cresols),

Telegram: @medical_k

www.konkur.in

and carcinogens (other metals, *N*-nitrosamines, and polycyclic aromatic hydrocarbons); over 70 of these chemicals are carcinogenic. Often smokers cohabitate with other smokers, especially in psychiatric group or extended living situations. However, even separating smokers from nonsmokers within the same air space, cleaning the air, opening windows, and ventilating buildings do not eliminate secondhand smoke exposure. Therefore, secondhand smoke is very relevant in psychiatry. Secondhand smoke exposure causes nearly 34,000 heart disease deaths annually among adult nonsmokers in the United States. Secondhand smoke is a cause of cardiovascular disease and lung cancer (increase in risk is 25% to 30%). There is also an association between exposure to secondhand smoke and risk of stroke.

Non-nicotine chemicals in tobacco smoke activate cytochrome P450 liver cytochrome (CYP1A2), thereby decreasing the levels of several medications. As a result, smoking cessation increases the concentrations of these medications. Many of these medications are psychiatric medications, and often the increase can be clinically significant in psychiatric patients; for example, haloperidol, clozapine, and fluvoxamine concentrations increase 30% to 40% with abstinence. Other examples are more antipsychotics (olanzapine and fluphenazine), antidepressants (amitriptyline, nortriptyline, imipramine, clomipramine, and trazodone), benzodiazepines, and caffeine. Therefore, it is important to monitor psychiatric medication doses in smokers where quantity smoked is changing. With a relapse to smoking in a patient on clozapine, for example, clozapine blood levels can be reduced, and psychiatric symptoms may re-emerge and can be life-threatening. Similarly, smoking cessation in someone maintaining steady caffeine consumption can incur caffeine “intoxication,” which will feel like severe nicotine withdrawal, including agitation and restlessness. It is also useful to motivate patients to quit smoking with the potential that they may decrease psychiatric medication doses.

Another special population includes the pregnant smoker: The health of a pregnancy and outcomes in children born to smokers or born to environments with smoke exposure should be addressed. Smoking can even make it harder for a woman to become pregnant and, once pregnant, can increase the risk of preterm (early) delivery, stillbirth (death of the baby before birth), low birth weight, sudden infant death syndrome (SIDS or crib death), ectopic pregnancy, and orofacial clefts in infants.

Telegram: @medical_k

www.konkur.in

There may also be an association that children born to smoking mothers can also have increased risks of mental retardation, learning problems, and ADHD. Fathers are not immune from risks: Smoking can affect sperm and sexual function, which can reduce fertility and also increase risks for birth defects and miscarriage. The use of medications for smoking cessation during pregnancy is debatable. Whether the harm from smoking during pregnancy is due to nicotine, CO, or other chemicals in cigarette smoke is unclear. The concentrations of nicotine from medications are much lower than those from smoking, plus no CO and tar exposure occurs. Often, medications are reserved for pregnant smokers who have failed at cessation without medication.

TREATMENT

Given the widespread evidence base of the harmful effects of TUD, a great deal of research has been done on treatment and allows for the effective use of evidence-based treatments. Several websites and organizations offer information on TUD treatment, including free booklets. There are excellent guidelines for assessing and treating TUDs published in 2008 by the U.S. Public Health Service (USPHS) and for the treatment of SUDs in 2006 by the APA. Also, most state health departments have telephone lines to assist smokers in quitting and have websites with information for providers and patients (Table 11.8–1).

All patients should be assessed for (1) smoking status and (2) motivation to quit (Table 11.8–2). A useful approach to TUD treatment is the 5As model: *Ask, Advise, Assess, Assist,* and *Arrange* follow-up or the minimum standard of AAR: *Ask, Advise,* and *Refer*. Given the overwhelming prevalence and morbidity/mortality of TUD in psychiatric settings, all patients should be *asked* about current and past tobacco use, type of tobacco used, and frequency of use; TUD should be listed in their problem list and treatment plan with strategies for either increasing their motivation or recommendations for how to quit, perhaps including psychosocial treatment, education, community resource referral, and/or medication options and guidance. In addition to asking about tobacco use, assess for DSM-5 criteria. All patients using tobacco should be *advised* to quit with a personalized message, for example, including their specific health risks. With psychiatric patients, it is often important to state one's belief that the patient has the ability to stop. For some, the above advice

Telegram: @medical_k

www.konkur.in

has no immediate effect. However, the cumulative effect of repeating the advice at later visits and the receipt of advice from others can often motivate a quit attempt. Helping smokers who are not ready to quit to reduce the number of cigarettes smoked daily (aided by nicotine replacement medications) can motivate them to try to quit in the near future. The clinician should *assess* for desire to quit. Motivational interviewing/enhancement can be employed even if a patient is not ready to quit. Common motivators to quit are health concerns, effects of smoking on others, and social pressure. Common barriers to cessation are withdrawal, fear of failure, and fear of weight gain. Next, smokers need *assistance*, which can include setting a quit date, preparing for the quit date, need for medication or telephone or in-person therapy, weight gain concerns, high-risk situations, making cigarettes unavailable, discussions with significant others (especially if they too are smokers), and so forth. Finally, the fifth A is for *arranging* follow-up since TUD is an addictive disorder and relapse is likely. Follow-up can include working with the psychiatric provider or using other community resources, such as state quit lines (1-800-QUIT-NOW) (see Table 11.8–1). Because relapse is often rapid, the first follow-up phone call or visit should be 2 to 3 days after the quit date.

- Contact insurance company to ask for help. Some assistance may be free or partially reimbursable, including counseling and NRT medications

Telegram: @medical_k

www.konkur.in

Table 11.8–2.
5 A's Model of Nicotine Cessation Intervention Recommended by the U.S. Public Health Service

Telegram: @medical_k

www.konkur.in

1. **Ask About Tobacco Use:** Systematically screen (and document) current and past nicotine use at every visit
   - Signs of more highly dependent smokers: Smoking within the first 30 minutes after awakening and/or over 20 cigarettes per day
   - Document applicable DSM-5 criteria, withdrawal symptoms, prior quit attempts, types of treatment, social support for quitting, medical conditions
   - Can use a CO meter to assess cigarette use: 15–50 ppm = smoker; 0–5 ppm in 2–3 days of quitting
   - Ask about all forms of nicotine use (including e-cigarettes)
2. Advise to Quit (or reinforce people who have quit) with a clear, strong, and personalized message
   - "Your other health diagnoses, such as asthma, are worsened by smoking and quitting is one of the most important things you can do for your health"
   - "People with psychiatric diagnoses suffer more from smoking-related illnesses and have unique challenges to quitting that we can overcome"
3. Assess for Desire to Quit
   - "How does the idea of quitting smoking sit with you?"
4. Assist Patients

   Strategies for Lower Motivated Patients:
   - For those in precontemplation or contemplation, listen to reasons for not being in preparation
   - Try to increase motivation through CO meter scores, $$ spent, other disorders, increasing freedom, options in relationships, more job opportunities, effect of tobacco smoke on their loved ones (family, friends, pets), longer life, and fewer sick days
   - Do Pros/Cons or "Importance" or "Confidence" ruler
   - Consider the 5 Rs **relevance, risks, rewards, roadblocks,** and **repetition** (revisit the conversation in the future).

   Strategies for Higher Motivated Patients:
   - STAR Quit Plan: Set a quit date, Tell family/friends, Anticipate challenges such as withdrawal and triggers, and Remove nicotine products from environment
   - Discuss specific strategies for common triggers
   - Discuss withdrawal course (worst within 2 weeks)
   - Discuss and plan for slips and relapses

Telegram: @medical_k

www.konkur.in

- Discuss alcohol, stress, weight gain specifically
- When possible, provide prescription for one or combination of 7 FDA medications for TUD (noting that some insurances cover over-the-counter medications when ordered by a physician)
- Encourage some form of counseling support (Quit lines, Nicotine Anonymous, counseling)
- Use shared decision making to increase motivation and buy-in from patient

5. **Arrange Follow-Up**
   - Set a date for a follow-up visit and repeat all of the A's in follow-up
   - Document and integrate into assessment/plan
   - Engagement with state's tobacco quit line (1-800-QUIT-NOW)

Psychosocial Therapies and Community Resources

Psychosocial interventions increase the chance of quitting by 40% to 80% based on a recent Cochrane review analysis and can be varied based on motivational level for quitting. Less-motivated-to-quit individuals can benefit from motivational interviewing/motivational enhancement therapy with personalized feedback. Feedback that has more impact includes CO meter scores, cost of cigarettes per year for them, health problems that they already have that are worsened or caused by ongoing tobacco use, and effect on family and significant others. Educational programs such as learning about healthy living provide information that can help enhance motivation. If patients worry about weight gain with quitting, exercise and nutrition to help them begin to lose weight before quitting can be a helpful strategy.

Behavior therapy, including relapse prevention, is the most widely accepted and well-proven psychological therapy for treating TUDs. Behavior therapy consists of several techniques, three of which are supported by good evidence. *Skills training* and *relapse prevention* identify high-risk situations and plan and practice behavioral or cognitive coping skills for these situations. *Stimulus control* refers to eliminating cues for smoking in the environment. This approach also requires preparation such as removing smoking triggers and working with loved ones to plan for support.

Mindfulness-based interventions are being utilized to help individuals. Mindfulness approaches help individuals stay present in the moment and recognize cravings as temporary thoughts and feelings that will dissipate

Telegram: @medical_k

www.konkur.in

over time and which they can notice and accept without needing to act on those thoughts or feelings. Mindfulness also includes foundational attitudes such as patience, trust, acceptance, gratitude, and openness to new ways, which are all aligned with SUD recovery. Mindful self-compassion adds to mindfulness the concepts of shared humanity (they are not alone, others are trying to quit, and it can be difficult at times) and kindness to self (similarly how they might be kind to others suffering in a similar manner). Mindfulness is also helpful for stress reduction in general.

Twelve-Step Facilitation is a standard evidence-based treatment in most addiction treatment; however, there are no studies of Nicotine Anonymous (NicA) in the literature. The strength of attending meetings can be in the social support and a plan for recovery. There are national phone meetings for easy access for anyone, as well as local meetings, but those are less numerous than Alcoholics Anonymous.

There are increasing studies on incentives or contingency management also helpful for smoking cessation, but implementation in real-world settings is limited by financial and regulatory constraints.

There are an increasing number of other community resources. The most widely used are quit lines that provide individual coaching over the phone and sometimes with free NRT. 1-800-QUIT-NOW works in all states and has moderate certainty evidence in Cochrane reviews. There are online internet websites/apps for those who prefer computer support (i.e., www.becomeanex.org and www.ffsonline.org). Other resources are clinic-run smoking cessation groups, peer specialists, peer websites (www.njchoices.org); a training module for peer specialists (www.Rxforchange.org); and information for club houses (www.genesisclubhouse.org). Other therapies, such as acupuncture, hospitalization, psychedelics, and hypnosis, have been studied, but overall, the results are equivocal and yet to be proven effective on a larger scale. Many of these resources are becoming increasingly more accessible and many are available at no cost. Medicare, Medicaid, and other insurance companies are also now supporting reimbursement of many psychosocial treatments, with more and more options being considered.

Pharmacologic/Interventional Therapies

The USPHS and the APA guidelines recommend that all smokers be offered medication to aid in smoking cessation. Recent reviews and meta-

Telegram: @medical_k

www.konkur.in

analyses suggest that medications may be more effective than psychotherapy approaches alone, and certainly combinations are best. The seven FDA-approved medications include five NRTs, bupropion, and varenicline. NRT patch, gum, and lozenge are available OTC, while NRT inhaler, NRT nasal spray, varenicline, and bupropion are by prescription only in the United States. All the medications approved by the FDA for smoking cessation double the quit rate (similar to results obtained with behavior therapy) and appear equally effective (Table 11.8–3). The one exception may be varenicline, which has been shown superior to some other medications. It can improve quit rates by two to three times compared to treatment as usual. Still though, NRTs can improve quit rates by 50% to 60% compared to placebo. The medications produce few side effects; less than 5% of patients stop medication due to adverse effects (except for nicotine nasal spray). While some medications have prescribing considerations for pregnant women or people with heart conditions, it is certainly the case that continued tobacco use is very harmful for these groups.

History and patient input are essential to choosing medications: cost can be a consideration, as well as previous attempts with a medication, medical comorbidities, severity of dependence/withdrawal, and breakthrough symptoms. Typically, combined patch and another NRT or monotherapy with varenicline are first tried. Combinations of medication have greater efficacy. Updated FDA guidelines on NRTs allow for use while smoking for risk reduction and promote using more than one medication (as shown in practice and research for many years).

Nicotine Replacement Therapies. Because nicotine undergoes first-pass metabolism by the liver, nongastrointestinal routes have had to be used to deliver nicotine. NRTs are effective, presumably because they reduce nicotine withdrawal without the immediate reinforcing effect of rapidly absorbed nicotine in tobacco smoke. Often NRT is used in inpatient or other clean air settings. Most replacement therapies use a short period of maintenance (6 to 12 weeks), often followed by a gradual reduction period (6 to 24 weeks). However, longer-term use may be necessary for some. Most NRTs should be used with caution in cardiovascular patients (specifically those who are 2 weeks postmyocardial infarction, have serious arrhythmias, or have unstable angina). Finally, to optimize oral absorption of nicotine in the gum,

Telegram: @medical_k

www.konkur.in

lozenge, or inhaler, minimize acidic beverage (coffee, juice, soda) consumption 15 minutes prior to and during use.

Nicotine patches (OTC), applied daily to a clean and hairless location, provide long-acting nicotine administration. Typically, patients use a 21-mg patch, although 7- and 14-mg patches can be used for lighter smokers (10 to 15 cigarettes per day). Side effects include local skin reactions (minimized with creams and by rotating patch sites) and insomnia/vivid dreams (minimized by removing the patch prior to bed).

Nicotine gum (OTC) may be used alone or in combination with other medications and is generally utilized hourly in initial phases of cessation. The 2-mg gum is recommended for those smoking less than 25 cigarettes per day, while the 4 mg is generally used for heavier smokers (but dose can vary by preference). Proper usage education is important for efficacy and to decrease adverse effects: patients should “chew” a few crunches until a peppery or tingly flavor emerges and then “park” between the cheek and the gum until the tingle goes away. This will help maximize nicotine absorption (for about 30 minutes) and reduce transfer to the stomach, which can irritate the gastrointestinal tract. The nicotine lozenge (OTC) is easier to take consistently and will achieve 25% to 27% higher plasma concentrations over time compared to the gum (allow the lozenge to dissolve, do not chew it). Patients who smoke their first cigarette within 30 minutes of awakening should use the 4-mg lozenge, while others might consider the 2 mg dose, but again preference should be considered. Both the gum and lozenges provide relief of immediate withdrawal, especially in high-risk situations.

Prescription NRT in the United States includes the inhaler and spray. The inhaler is intended for oral mucosal absorption like the gum and lozenge and provides the smoker with the hand-to-mouth routine of smoking. The nicotine nasal spray provides the fastest absorption of the NRT products and has the highest potential for dependency, as well as more perceived complications of use such as rhinitis.

Non-Nicotine Prescription Medications. Bupropion, which affects dopamine, norepinephrine, and nicotinic–cholinergic receptors, can help decrease cravings and withdrawal symptoms. Dosages of 300 mg per day reliably double quit rates in smokers with and without a history of depression. Combining bupropion and a nicotine medication has greater efficacy. Contraindications to use of bupropion include a seizure disorder

Telegram: @medical_k

www.konkur.in

(the risk of seizures in those appropriately screened is less than 1 in 1,000), current/past bulimia or anorexia nervosa, recent/concurrent monoamine oxidase inhibitor (MAOI) use, or other bupropion use. More common side effects are insomnia and dry mouth. This medication can be started 1 to 2 weeks before a quit date and is often used for up to 6 months postquit.

Varenicline is a partial agonist at the α4β2 neuronal nicotinic acetylcholine receptor; it both relieves craving and withdrawal and, unlike other medications, reduces the reinforcing effects of nicotine by blocking dopaminergic stimulation responsible for smoking reinforcement/reward. While there were concerns about the FDA-issued black box warnings for neuropsychiatric adverse events, more recent research of varenicline in psychiatric patients has found that psychiatric symptoms were not worsened, and there is no evidence of an increased suicide risk. This was especially demonstrated in the 2016 EAGLES trial, which included 8,144 participants across 140 centers in 16 countries; Anthenelli et al. demonstrated no significant increase in neuropsychiatric adverse events attributable to varenicline or bupropion relative to nicotine patch or placebo. Furthermore, the study demonstrated that varenicline was more effective than placebo, nicotine patch, and bupropion in helping smokers achieve abstinence, and bupropion and nicotine patch were more effective than placebo. A subsequent 2016 FDA review did not support the original neuropsychiatric warning which has since been removed.

Table 11.8–3. Pharmacotherapies for Tobacco Use Disorders

FDA-Approved Medications for Tobacco Use Disorders (please consult the Physicians' Desk Reference (PDR) for details)

Product	Initial Prescription	Patient Education Issues	Precautions	Side Effects	Approximate Costs/Day
Nicotine patch (OTC)	If smoking ≥1 pack per day, apply 21-mg patch for 4–6 weeks, then step down to 14-mg and 7-mg patches; start at lower dose for lighter smokers	Rotating the site weekly to reduce irritation from adhesive, apply patch to a clean, dry, hairless location on the skin; if patch falls of due to perspiration, can use medical tape	Caution within 2–6 weeks of heart attack or with severe arrhythmias (applies to all NRTs)	Skin reaction to adhesive which can be treated with hydrocortisone or triamcinolone cream; vivid dreams or sleep disturbances can occur if worn overnight	$1.50–$3.50
Nicotine gum (OTC)	2 mg; 4-mg dose if smoking ≥25 cpd[a]; chew every 1–2 hours as needed for cravings; usual range is 9–16 pieces/day	Chew until a tingling sensation begins and "park" between jaw and cheek once; avoid coffee and other acidic beverages 15 minutes before/during use	Caution in people with dentures and jaw issues	Jaw pain, hiccups, mouth irritation; nausea if swallowing saliva	$2–$5.50 for 9 pieces
Nicotine lozenge (OTC)	2 mg; 4 mg (if smoke within 30 minutes of waking); dissolve (do not chew) by parking between jaw and cheek; use 9–20 pieces/day	Avoid food, coffee, and acidic drinks 15 minutes before/during use	N/A	Hiccups, nausea, heartburn	$3–$4
Bupropion SR with 150 mg/day $90 for 1-month supply; $3 per day; generic forms less expensive	150 mg each morning for 3–7 days, then 150 mg twice a day; also efficacious at 150 mg daily if twice a day dosing not tolerated	Start 1–4 weeks prior quit date to reduce smoking; take second pill in late afternoon to reduce insomnia	Do not use with seizure disorders; do not use in setting of MAOIs, electrolyte abnormalities, or eating disorders; monitor blood pressure	Insomnia (40%), dry mouth, headache, anxiety, rash; side effects reduced with 150-mg daily dosing	<$1 for generic
Varenicline	"Starter" pack (days 1–3, 0.5 mg every morning; days 4–7, 0.5 mg twice a day; weeks 2–12, 1 mg twice a day); continuation pack dosing	Stop smoking when starting 1-mg dose; take with full glass of water and after eating	Adjust dosage for renal impairment; black box warning for cardiovascular adverse events in people with cardiovascular disease	Nausea (take with food); trouble sleeping, abnormal dreams (take second dose earlier in the evening); may also affect the ability to drive or operate heavy machinery	$20 (not yet generic as of 2021)

Information summarized from RxForChange.ucsf.edu
[a]cpd = cigarettes per day.

Transcranial Magnetic Stimulation. The FDA has approved transcranial magnetic stimulation (TMS) for major depressive disorders in 2008, and in 2020 TMS was approved for use in smoking cessation in adults. This is a novel approach with more community-based experience needed to understand how it is being adapted and used in treatment programs.

Combined Psychosocial and Pharmacologic Therapy

Combining medication and behavior therapy increases quit rates over either therapy alone. Also, combination medications have higher efficacy than monotherapy. Combination examples include using nicotine patch and short-acting NRT, bupropion and NRT, and varenicline and bupropion

Telegram: @medical_k

www.konkur.in

or varenicline and NRT. The USPHS Clinical Practice Guidelines recommend, contingent on the absence of medical contraindication, the use of at least one of the seven FDA-approved front-line agents for smoking cessation in conjunction with counseling to increase the likelihood of a successful quit attempt. Patients should be encouraged to use both pharmacologic and psychosocial treatment approaches; however, medications can be effective in the absence of psychosocial therapy; thus, the latter should not be a requirement for the former.

Telegram: @medical_k

www.konkur.in

Ms. H is a 45-year-old patient with schizophrenia who smokes 35 cigarettes per day. She began her cigarette use at approximately 20 years of age during the prodromal stages of her first psychotic break. During the first 20 years of treatment, no psychiatrist or physician advised her to stop smoking, largely because they believed that she could not stop.

At 43 years of age, her primary care physician recommended smoking cessation, especially with her history of asthma and heart disease. The patient attempted to stop on her own, but this lasted only 48 hours, partly because her housemates and friends smoked. During a routine medication check, her psychiatrist *asked* about her smoking history and *advised* that she stop smoking, and the patient described her prior attempts. The psychiatrist *assessed* for motivation, using a 1 to 10 scale of motivation to quit and discussing where Ms. H was on the scale. He also had her breathe into a CO meter to demonstrate decreased oxygen capacity of her lungs and how that affects her asthma and heart disease. The psychiatrist and the patient discussed ways to avoid smokers and had the patient announce her intent to quit and request her friends to try not to smoke around her and to offer encouragement for her attempt to quit. The psychiatrist also noted that Ms. H became irritable, slightly depressed, and restless and had insomnia during prior cessation attempts and thus recommended medications for *assistance*. The patient chose to use nicotine patch plus nicotine gum as needed.

The psychiatrist had the patient call 2 days after her quit attempt as had been *arranged* at the appointment. At this point, the patient stated that the patch and gum were helping. One week later, the patient returned after having relapsed back to smoking. The psychiatrist praised the patient for not smoking for 4 days. After some motivation enhancement, Ms. H was still reluctant to try again immediately.

At the next routine visit 2 months later, the psychiatrist *asked* about smoking again, as it was in the assessment and treatment plan. After *advice* and *assessment*, the psychiatrist and patient listed several activities that the patient could do to avoid being around friends who smoked, phoned the patient's boyfriend to ask him to assist the patient in stopping, asked the nurses of the inpatient ward to call the patient to encourage her, plus they *arranged* for the patient to be in a support group for the next 4 weeks. This time the psychiatrist prescribed the

Telegram: @medical_k

www.konkur.in

medication varenicline. The patient was followed with 15-minute visits for each of the first 3 weeks. She had two “slips” but did not go back to smoking and remained an ex-smoker.

Ms. H’s psychiatrist was correct in using pragmatic plans to help the patient overcome specific problems, in following the patient with short visits or phone calls, and in recommending medication. The total amount of time spent with the patient on smoking was approximately 3 hours, and there was reimbursement; more importantly, the intervention was important to decreasing her morbidity and mortality and was unlikely to be given by other care providers.

Tobacco Use Disorder Treatment of Psychiatric Patients and Other Special Populations

Psychiatric patients who are trying to stop smoking should be encouraged to undertake psychosocial and pharmacologic therapies. These patients experience greater withdrawal symptoms and have a poorer ability to stop as a result of greater smoking levels and more efficient smoking (inhaling more deeply), both resulting in higher levels of nicotine. In addition, these patients should be followed more regularly to detect any possible exacerbation of their psychiatric problem; often the perceived exacerbation results from withdrawal from nicotine and can be managed with NRT. Research demonstrates that smokers with mental illness do not have worsening of clinical symptoms of unipolar depression, bipolar disorder, post-traumatic stress disorder, or schizophrenia with tobacco treatment. Patients on smoke-free psychiatric wards can have withdrawal symptoms that require treatment, and pharmacotherapy is effective for psychiatric populations, including severe mental illness and SUDs. Treating TUDs in psychiatric patients not only reduces illness and lengthens life but can also present other benefits such as more discretionary income, less discrimination, and more options for relationships and employment.

People with SUDs should also be encouraged to quit smoking. Current evidence suggests that, for the large majority of (but not all) patients, stopping smoking does not threaten sobriety. Some newer studies suggest that quitting smoking can increase the likelihood of maintaining sobriety from other drugs.

Telegram: @medical_k

www.konkur.in

Nonabstinence Goals

Given the highly addictive nature of tobacco, some tobacco users may not be able to or want to try to fully quit tobacco. The idea of using less to have less harm or to use an e-cigarette or another nicotine product is raised by some tobacco users. Harm reduction (using less tobacco) has been a method of gradual reduction for lower motivated individuals; however, this strategy often comes with compensatory smoking (i.e., smoking each cigarette more intensely to obtain the necessary nicotine), which appears to minimize any potential benefit of these strategies. Although some have feared that offering or agreeing to the patient's plan for reduction of smoking as a treatment goal would undermine motivation to quit, reduction in tobacco use appears to increase the chance of later quitting and may help motivate some tobacco users initially not willing to quit to try later to quit. Thus, agreeing to monitor a reduction method may not improve health but may lead to cessation by continuing to engage and work with the patient on the ultimate goal of cessation.

SPECIAL POPULATIONS

Expectant Smokers

Smoking and secondhand smoke in pregnancy or in women wanting to get pregnant are associated with multiple increased risks including difficulty becoming pregnant, risks of miscarriage, risk of SIDS, stillbirth, prematurity, low-birth weight, perinatal morbidity such as tissue damage (particularly in the lung and brain), and mortality. Furthermore, children of smoking mothers are twice as likely to become smokers themselves. Addressing smoking in pregnant women and women who wish to be pregnant can have a major impact, as this is often a life event that motivates half of affected smokers to quit. USPHS guidelines recommend that clinicians ask all pregnant women about tobacco use, advise tobacco cessation at all gestational ages, and provide behavioral interventions (motivational interviewing, cognitive behavioral therapy, 5As, quit lines) for those who smoke. The same should be done postdelivery, as over half of women relapse after delivery. The USPHS has concluded that current evidence is insufficient to assess the balance of benefits and harms of nicotine replacement products or other pharmaceuticals for tobacco cessation during pregnancy. The American College of Obstetricians and

Telegram: @medical_k

www.konkur.in

Gynecologists (ACOG) advises that NRT should be considered only after a detailed discussion with the patient of the known risks of continued smoking, the possible risks of nicotine replacement therapy, and need for close supervision. Further, they note that if nicotine replacement therapy is used, it should be with the clear resolve of the patient to quit smoking. A systematic review and meta-analysis to assess the safety of bupropion and varenicline in pregnancy found no evidence that either of these treatments might be harmful in pregnancy and no strong evidence to suggest safety, but available evidence is of poor quality. The ACOG guidelines recommend physicians counsel women about the risks of smoking and the benefits of cessation and discuss the resources available, and if medications are prescribed, a discussion of risks/benefits.

Adolescent Smokers

Adolescents are another vulnerable population. It is proposed that nicotine acts as a gateway drug on the brain via multiple pathways (smoking tobacco, passive tobacco smoke, or e-cigarettes). Earlier use of e-cigarettes is related to initiation of cigarette use. Therefore, adolescence is an important time to screen and treat. The Public Health Service guidelines initially recommend adolescent smokers be provided with counseling interventions to aid them in quitting smoking as this can double quit rates; however, absolute abstinence rates of those who received counseling are low (11.6% quit rate at 6 months). Medications for smoking cessation are not FDA approved for use in children/adolescents. It is noted that although NRT has been shown to be safe for adolescents to use, it is not currently recommended as a component of pediatric tobacco use interventions in the guidelines. More recently the USPHS recommended that primary care clinicians provide interventions, including education or brief counseling, to prevent initiation of tobacco use among school-aged children and adolescents, *but* that the current evidence is insufficient to assess the balance of benefits and harms of primary care-feasible interventions for the cessation of tobacco use among school-aged children and adolescents. As part of routine psychiatry intakes, substance use history, including tobacco and vaping history, is clinically indicated. Vaping is especially important to teens as, since 2014, e-cigarettes have been the most commonly used tobacco among U.S. middle and high school students.

Telegram: @medical_k

www.konkur.in

EMERGING AREAS OF RESEARCH

While cigarettes have existed for decades, there are continued developments in research and health effects, particularly with respect to ENDS.

E-Cigarettes for Smoking Cessation

There is still insufficient evidence for using e-cigarettes as consumer products for smoking cessation. However, there is emerging evidence that, in RCTs, monitored free e-cigarettes as part of a therapeutic intervention may be associated with increased smoking cessation according to a meta-analysis. A separate meta-analysis found that odds of quitting cigarettes were 28% lower in those who used e-cigarettes compared with those who did not use e-cigarettes.

E-Cigarette, or Vaping, Product Use-Associated Lung Injury

E-cigarette, or vaping, product use-associated lung injury, also known as EVALI, was reported in 2,398 people between February 2019 and January 2020. 82% of patients hospitalized with EVALI reported THC use with strong linkage to vitamin E acetate. The Centers for Disease Control and Prevention (CDC) recommended that people not use THC-containing e-cigarette or vaping products, especially those acquired from informal sources such as friends, family members, or from in-person or online dealers, and that vitamin E acetate should not be added to any e-cigarette or vaping products. These cases have reduced and are something we should continue to be mindful of. While vitamin E may have been the cause of these cases, EVALI brings up the concern of using vaping devices with substances other than nicotine. For example, THC vaping more than doubled among adolescents between 2017 and 2019. E-cigarette flavors are also of concern as they can increase both the likelihood of dependence and more adverse health effects.

Emerging Treatment Approaches Using Technology

In addition to traditional methods of cessation assistance described earlier, new technologies beyond just quit lines have emerged. These include text-to-quit programs, apps, and digital therapies. Cochrane Database reviews show promising evidence on text messaging support. Internet-based treatments show moderate efficacy, but aside from

Telegram: @medical_k

www.konkur.in

increasing access, may not be better than other active smoking treatments. Data on real-time video counseling is very limited and more studies need to be done. Unfortunately, there is no strong evidence for use of “apps” currently, as well; however, a number of apps such as the Veteran’s Affair’s Apps are promising. Another interesting area of research is with nicotine vaccines, of which none are currently licensed for public use, but there are a number in development.

PREVENTION AND POLICY INITIATIVES

Policy initiatives to reduce smoking prevalence have focused on tobacco taxation, smoking restrictions, restriction of tobacco advertising, counter advertising via mass media, attacks on the tobacco industry as immoral, restriction of sales to minors, and warnings on cigarette packages. Among these, the effect of taxes is especially large and replicable and influences initiation among youth.

A major policy advancement in many psychiatric settings has to do with tobacco-free public buildings and spaces. In 1993, JCAHO (now called The Joint Commission) banned smoking in hospitals. In addition to reducing access to smoking, thereby compelling a smoker into a quit attempt or at least reduction in cigarettes smoked, environmental tobacco smoke is reduced, and tobacco-related cues are eliminated, as well.

Given that TUDs have their onset typically in adolescence, general school-based tobacco prevention programs have been a logical approach to consider. There may be opportunities to consider high-risk adolescent groups, including those with psychiatric disorders being treated in mental health settings. Tobacco use often precedes mental illness and/or other SUDs. Strategies in school-based settings have focused on preventing the initiation of tobacco or nicotine-related products (such as e-cigarettes) through methods such as education (e.g., about risks of smoking), denormalizing smoking (e.g., correcting overestimates of prevalence of smoking), skills training (e.g., refusal training), and advocacy (e.g., students demonstrate again tobacco industry). Among these, only denormalizing and skills training have good empirical support; however, even with these interventions, the long-term effect of school-based programs is not large.

Policies to Address Nicotine and Health Equity

Telegram: @medical_k

www.konkur.in

It is essential to consider tobacco-related health disparities to understand tobacco use in diverse populations and in implementing tobacco cessation interventions. The CDC (2015) published a document on best practices in health equity in tobacco prevention and control to support health care agencies and government agencies in ensuring equity in their interventions. The CDC defines tobacco-related health disparities as, “Differences that exist among population groups with regard to key tobacco-related indicators, including patterns, prevention, and treatment of tobacco use; the risk, incidence, morbidity, mortality, and burden of tobacco-related illness; and capacity, infrastructure, and access to resources; and secondhand smoke exposure” (CDC, 2014).

Tobacco use has declined significantly, in general, in the United States since the first surgeon general’s report on smoking in 1964. However, specific demographic groups continue to have higher rates of tobacco use and tobacco-related health conditions than the general population. These groups include rural populations, individuals of low socioeconomic status, members of the LGBTQ community, individuals with mental health and substance abuse disorders, American Indian/Native Alaskans, and individuals with high school or lower level of educational attainment.

The same factors that influence health inequity across health conditions influence inequities in tobacco use and cessation, such as access to cessation services in some communities or inequities in health insurance covering cessation services. A lack of cohesive policies that promote healthy communities create disparities for vulnerable populations. In addition, as advertising laws have changed for tobacco products, the tobacco industry has targeted advertising at specific groups where advertising is still allowed (e.g., promotion of sales in convenience stores; sponsoring social and cultural events). Other relevant health inequities in smoking use and cessation include discrimination and a general higher level of stress in groups facing health inequities, such as African Americans.

Considerations for Interventions. Health equity should be a goal of tobacco cessation interventions beyond general health promotion activities. For example, studies have shown that increasing the price of tobacco products reduces use in low-income populations. Health inequities could be reduced by updating advertising policies and laws by reducing exposure to advertising and promotions in convenience stores

Telegram: @medical_k

www.konkur.in

and by enacting stricter laws where people are exposed to secondhand smoke. Policies can be enacted to reduce the density of sale of tobacco products in communities by restricting sale of products in pharmacies, near schools, etc. Finally, increasing access to health insurance and the availability of cessation services covered by health insurance would improve health inequities, particularly in rural and other workforce shortage communities. For example, tobacco screening and cessation interventions should be incorporated into training programs and in all health care services.

When developing and implementing tobacco cessation programs, it is critical to understand cultural factors in use of tobacco and factors that promote or deter cessation. For example, tobacco has been used by many Native American tribes in their ceremonies. However, the use of commercial tobacco is high in Native American populations, and health care providers should understand the cultural relevance of ceremonial use while promoting cessation of commercial products that are much more harmful and addictive. It is important to include community members and cultural experts in developing and implementing cessation interventions to ensure they are culturally relevant to have the greatest impact. These partners can help incorporate language, values, beliefs, health practices, communication styles, and literacy levels of communities when developing culturally relevant interventions. These partners can also help prevent stereotypes or harmful messages that may not be considered by health care providers.

11.9 Opioid Use and Related Disorders: From Neuroscience to Treatment

Sean X. Luo, M.D., Ph.D., and Adam Bisaga, M.D.

The term **opioid** describes a class of psychoactive compounds, both naturally occurring and chemically synthesized, that are related to *opiates*: alkaloid compounds found as natural products in the opium poppy plant, *Papaver somniferum*. Opioids are among the oldest known drugs worldwide: opium poppy use predates recorded history. Opioids can be used medically for pain relief but are also commonly misused by means of nonprescribed use of pharmacologic opioids or illicitly obtained heroin or synthetic opioids such as fentanyl. Opioid use disorders (OUDs) affect a wide range of individuals around the world, and the United Nations Office on Drugs and Crime (UNODC) estimates that around 1.5% of the global population in 2019 had nonmedical use of any opioid-derived compounds, representing an increase from around 0.5% in 2009. In the United States, OUD has dramatically increased in the past few decades and now

Telegram: @medical_k

www.konkur.in

constitutes a large public health problem affecting the young and the old, the affluent and the poor, and professionals and the unemployed. At the same time, there have been significant advances in knowledge about opioids and their effect on the central nervous system (CNS). Practical and effective treatment strategies that target specific brain abnormalities have emerged. There is now a consensus in the medical community that OUD is a chronic, relapsing disorder involving multiple brain circuits and is amenable to pharmacologic and psychosocial interventions.

HISTORICAL BACKGROUND

The Greek word "opos," which means juice, suggests people may have first discovered the liquid from the unripe poppy seed capsule when it is notched. The written record of the early history of opium use and misuse is ambiguous. The preparation described by Homer in *The Odyssey,* given by Helen to Telemachus and his friends to help them forget their grief over Odysseus' absence, was attributed to Homer's imagination by Theophrastus (300 BC). Sumerians cultivated poppies and isolated opium at the end of the third millennium BC Arab traders brought opium to India and China around the 8th century AD, and between the 10th and 13th centuries, opium traveled from Asia Minor to Europe. Thomas Sydenham noted in 1680 that "Among the remedies which it has pleased Almighty God to give man to relieve his sufferings, none is so universal and efficacious as opium." On the other hand, written records of drug misuse and tolerance can be found in Turkey, Egypt, Germany, and England, and the problematic practice of smoking opium reached its apogee in China in the mid-17th century after tobacco smoking was banned. Efforts by the Chinese government to criminalize opium use conflicted with British and French commercial imperatives, leading to the Opium Wars in the 19th century, which greatly influenced the postcolonial era geopolitical landscape.

Sertürner used advanced chemical methods in 1806 to isolate the active ingredient in opium, naming it morphine after Morpheus, the god of dreams. Codeine was isolated from opium a few years later. Over the next century, these purified compounds gradually replaced crude opium for medicinal purposes, although nonmedical use of opium, especially through smoking, still persisted in many parts of the world. The first semisynthetic opium derivative—diacetylmorphine or heroin—was

Telegram: @medical_k

www.konkur.in

introduced into medicine in 1898 and marketed as an effective cough suppressant, and at the time, thought to have very little misuse liability. The first purely synthetic morphine-like opioid, meperidine, was serendipitously discovered in 1939 in a search for atropine replacement. Methadone was discovered in the 1940s and introduced to medical practice in the subsequent decades.

The recognition of opioid withdrawal and addiction by the medical community, especially in the United States, generally began in the 19th century. It was noted at the time that morphine addiction was common among White middle-class women who were given it frequently for numerous medical symptoms such as neurasthenia and cough, as well as in the postpartum period. A variety of remedies were used to treat opioid withdrawal and “cure” morphine addiction. However, these were often more dangerous than untreated withdrawal and were ineffective in preventing relapse. A variety of other opioid-related issues became prominent in the early 20th century: prevalent opium smoking by Chinese immigrants working on railroads, intravenous (IV) use of opioids with the newly introduced hypodermic needle, an increase in illegal activities surrounding drug use, and the importation of opioids from other countries. A variety of medications on the market included opioids components surreptitiously and were mostly unregulated. As drug use was gradually linked to crime, the U.S. Federal Government first passed the Pure Food and Drug Act of 1906, which required accurate labeling of component contents. The subsequent Harrison Narcotics Tax Act of 1914 demarcated a starting point for federal regulation and taxation of the production, importation, and distribution of opiates and Coca products. The Harrison Act had a profound impact on persons exhibiting physical and psychological symptoms of tolerance and withdrawal because it was interpreted by the Treasury Department to exclude the provision of using opioids to treat these symptoms for medical purposes. Clinics that had been established specifically to provide therapeutic morphine to patients with opioid use problems were shut down by the early 1920s. Doctors were urged to avoid treating patients with these symptoms, and some were prosecuted for doing so. Detoxification efforts were plagued by frequent relapses, and many sought alternative access to opioids. As medical prescription of opioids decreased, illicit traffic increased substantially, providing mostly morphine and heroin to individuals with

Telegram: @medical_k

www.konkur.in

addiction. Users were frequently arrested for the possession and sale of opioids and incarcerated.

In the 1930s, the U.S. Public Health Service established two federal hospitals—at Lexington, Kentucky, and Fort Worth, Texas—to deal with the growing number of federal prisoners who were also addicted to opioids. These hospitals provided long-term residential treatment for prisoners and some voluntary patients, and a significant amount of early addiction research was conducted there. Follow-up studies of these prisoners found that relapse rates were high even after long periods of abstinence and treatment. In light of the lack of effective treatment strategies and increasing criminal activities surrounding drug use, worldwide penalties for the illicit use of opioids increased after World War II. The Single Convention on Narcotic Drugs of 1961 established an international treaty to prohibit the production and supply of specific drugs ratified by most member countries. As part of World Health Organization (WHO), the United Nations Commission on Narcotic Drugs was empowered to add, remove, and transfer drugs among the treaty's four schedules of controlled substances. This treaty also required the criminalization of cultivation, production, distribution, possession, and trafficking of scheduled opioids. Governmental regulation of opioids through criminal law became a worldwide phenomenon. In the United States, the Controlled Substance Act of 1970 served as the national implementing legislation for the Single Convention on Narcotic Drugs, and heroin was categorized as a Schedule I drug, the most stringent category of regulation (indicating no valid medical use). Other opioids, such as morphine, oxycodone, and methadone, were designated Schedule II drugs.

Since the 1960s, it has been increasingly recognized that legal regulation is an insufficient intervention both for individuals with problematic opioid use and for the community as a whole. Attention has been shifting toward the development of better treatment programs for opioid-dependent individuals. The Synanon organization was founded in California in 1958 and constituted an early model of a therapeutic community. The 12-step programs, such as Narcotics Anonymous (NA), which grew out of Alcoholics Anonymous (AA), first emerged in Los Angeles in the early 1950s. Since the late 1960s, federal and state agencies have increasingly focused on treatment research. Methadone maintenance began as a research program at Rockefeller University in

Telegram: @medical_k

www.konkur.in

1964. This effective treatment was delivered in the setting of outpatient methadone maintenance clinics, a model that subsequently expanded and became widely adopted throughout the United States and many parts of the world. Problematic opioid use became a condition amenable to medical treatment by physicians and allied health care professionals.

Naltrexone was synthesized in the 1960s and later used to treat opioid addiction; it was approved by the U.S. Food and Drug Administration (FDA) in 1984 as an oral tablet and in 2006 as a long-acting injection. Buprenorphine was initially formulated in the United Kingdom in 1978 as an injection to treat severe pain, and a sublingual formulation was released in 1982, providing a convenient treatment for OUDs introduced in the 1990s. Long-acting preparations of buprenorphine became later available for the treatment of OUD, including an implant released in 2016 and an injection released in 2019. As the availability of residential addiction treatment decreased significantly in the 1990s, the U.S. Congress passed the Drug Abuse Treatment Act of 2000, which permitted physicians with qualifying training to prescribe approved Schedule III, IV, or V medications (such as buprenorphine) for the treatment of addiction or detoxification outside of a methadone clinic setting. Since this law was passed, office-based treatment for OUD with buprenorphine has expanded substantially as the number of individuals presenting for treatment increased with the growing epidemic of misuse of prescription opioids in the United States. Comprehensive Addiction and Recovery Act of 2016 (CARA) increased the treatment limit from 30 cases to 100 cases per year, and SUPPORT for Patients and Communities Act of 2018 (SUPPORT Act) allowed expansion to 275 patients per physician after 1 year of 100 cases. Moreover, the CARA act allowed additional prescribers, qualifying nurse practitioners and physician assistants, to prescribe buprenorphine for the treatment of OUD.

COMPARATIVE NOSOLOGY

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* divides opioid and related disorders into five main diagnoses: OUD, opioid intoxication, opioid withdrawal, other opioid-induced disorders, and unspecified opioid-related disorder.

Opioid use disorder is diagnosed for users of opioids who meet at least 2 of the 11 criteria in the previous 12-month period. These criteria have

Telegram: @medical_k

www.konkur.in

physiologic, behavioral, and cognitive components and have been organized into four categories: impaired control, social impairment, risky use, and pharmacologic changes. This disorder primarily reflects a pattern of compulsive, prolonged self-administration of opioid substances with no legitimate medical purpose or at doses greatly exceeding the amount needed for a medical condition, with continuing use of opioids despite significant substance-related problems. The OUD diagnosis is further specified by a set of additional modifiers: (1) the duration of remission: either *early remission*, where none of the criteria are met for more than 3 months but less than 12 months, or *sustained remission*, where none of the criteria have been met for more than 12 months; (2) whether the individual is *on maintenance therapy*: if the individual is maintained on a medication specifically for the treatment of OUD; and (3) whether the individual is in a *controlled environment*: where access to opioids is restricted. The diagnosis is also coded based on symptom severity. *Mild* OUD denotes the presence of two to three symptoms, *moderate*, four to five symptoms, and *severe*, six or more symptoms.

Opioid intoxication is diagnosed when an individual who recently used an opioid exhibits clinically significant problematic behavioral or psychological changes, such as dysphoria, impaired judgment, or psychomotor agitation or retardation that developed during, or shortly after, opioid use. These individuals also develop symptoms such as drowsiness or coma, slurred speech, and impaired attention and memory. *Opioid withdrawal* is diagnosed when an individual ceases or reduces opioid use or receives an opioid antagonist after a period of opioid use. Three of the nine withdrawal symptoms must develop and cause clinically significant distress for this diagnosis to apply. In addition, DSM-5 also contains unspecified opioid-related disorder to denote clinically significant opioid-related disorders that do not meet any criteria as above, as well as substance/medication-induced depressive disorder, substance/medication-induced psychotic disorder, substance/medication-induced bipolar and related disorder, and substance/medication-induced anxiety disorder, which describe a set of psychotic, depressive, bipolar-related or anxiety-related symptoms that occur soon after exposure or withdrawal from opioids (or other substances).

The DSM-5, released in 2013, represents a significant revision and update of criteria from the DSM-IV-TR and ICD-10 (WHO: International Statistical Classification of Diseases and Related Health Problems 10th

Telegram: @medical_k

www.konkur.in

revision) definitions of opioid-related disorders. Substance use disorder in DSM-5 combines the DSM-IV categories of substance abuse and dependence into a single disorder measured on a continuum from mild to severe, as it has been increasingly observed that these conditions are not dichotomous entities. In DSM-5, each substance is now addressed as a separate use disorder, but the overarching set of criteria is the same. Whereas DSM-IV only requires 1 symptom to diagnose a substance abuse disorder, DSM-5 requires at least 2 symptoms from a list of 11. Drug craving is added to the list, and substance-related legal problems are eliminated because legal contexts differ across cultures and DSM-5 aims to provide a set of criteria that can be applied internationally.

There is a high level of agreement between the DSM-5 and ICD-11 and both have as their central feature an emphasis on the compulsive aspect of drug-using behavior. However, ICD-10 continues to make the distinction between abuse (harmful use category) and dependence. In DSM-5, the code for OUD, mild now corresponds to the ICD-10 definition of harmful use of opioids (F11.10), while the DSM-5 criteria for OUD, moderate and severe, correspond to the ICD-10 code for opioid dependence syndrome (F11.20). It is important to note that within both classification systems, physical dependence, as evidenced by tolerance or withdrawal, is a criterion that is neither necessary nor sufficient for a diagnosis of either OUD or opioid dependence. One of the rationales for the new DSM-5 terminology of OUD, rather than opioid dependence, is to avoid the confusion of symptoms of physical dependence versus the syndrome of drug dependence, as well as avoiding the potentially stigmatizing label of *addiction*, which is commonly used in the lay literature to describe more severe forms of a substance use disorder but also has many other meanings. A more neutral label of a “use disorder” was selected, and the diagnosis of *addiction* does not appear in either DSM-5 or ICD-10, though it remains in the title of the DSM-5 “Substance-Related and Addictive Disorders” chapter.

ICD-10 differs from DSM-5 in that the concept of harmful use is limited to physical and mental health (e.g., hepatitis, overdose, and skin abscess) and specifically excludes social impairments with the reasoning: “Harmful patterns of use are often criticized by others and frequently associated with adverse social consequences of various kinds. The fact that a pattern of use or a particular substance is disapproved of by another person or by

Telegram: @medical_k

www.konkur.in

the culture, or may have led to socially negative consequences such as arrest or marital arguments, is not in itself evidence of harmful use."

EPIDEMIOLOGY

Extensive epidemiologic surveys from both the United States and around the world track trends in opioid use and misuse. In the United States, there are several national and public surveillance systems that provide useful information on different aspects of opioid use and addiction over time: the annual National Survey on Drug Use and Health (NSDUH) estimates the prevalence of substance use, abuse, and dependence within community-dwelling persons aged 12 years and older; the Monitoring the Future (MTF) survey reports on the prevalence of substance use as well as attitudes about drug use among a national sample of 8th-, 10th-, and 12th-grade students, and the Treatment Episode Dataset (TEDS) collects demographic and drug use data from persons of all ages admitted to substance abuse treatment facilities receiving state or federal funding (with some exceptions). Internationally, the World Drug Report provides an annual review of the major developments in drug markets for the various drug categories, from production to consumption. These publicly available data sources, combined with new methods in data mining and visualization, provide an easier way for researchers and public health workers to respond more rapidly to emerging trends in opioid misuse. In this section, heroin and other opioids are discussed separately, as large epidemiologic differences have been observed for these two categories of substances.

Prevalence of Heroin Use and Dependence

In 2019, the NSDUH reported the past-year prevalence of heroin use in the United States among persons aged 12 years or older to be approximately 745,000 people or 0.3% of the population, and the overall diagnosis of OUD affected 438,000 people or 0.2%. A reported decline in the survey was noted from 2015 to 2019, particularly with a decline in young adults aged 18 to 25 years, from 1.5% in 2015 to 0.7% in 2019. It is important to note that a substantial portion of the surveyed participants endorsed symptoms of misuse, such as using medication that is not prescribed or for good drug effect, but only a minority of these individuals receive a diagnosis of OUD. Nevertheless, the prevalence of heroin use

Telegram: @medical_k

www.konkur.in

and opioid misuse, in general, does appear to have peaked between 2011 and 2015 (Fig. 11.9–1A,B). The overall past-year opioid misuse peaked in 2015 at 8.7% and decreased to 5.3% in 2019, and pain reliever misuse constitutes the majority of individuals who use nonprescribed opioids (96.6%). The 2020 to 2021 coronavirus (SARS-CoV-2) pandemic may affect the overall trend of this decrease, and future data will shed light also on changes in the prevalence of high-potency opioids in the general population—something that has not been specifically surveyed so far by NSDUH.

For adolescents (8th, 10th, and 12th grade), the MTF survey showed some stabilization of the prevalence of opioid use. The lifetime prevalence of heroin use in 8th graders was 0.5% in 2020 and 0.3% and 0.4%, respectively, for 10th and 12th graders. For narcotics other than opioids, lifetime prevalence has decreased from 6.8% in 2017 to 5.3% in 2019 and 2020 in 12th graders. Past year reported use also decreased from 4.2% in 2017 to 2.1% in 2020. Extended-release (XR) oxycodone use in the past year was reported to be 0.9% in 8th graders in 2020, 1% in 10th graders, and 2.4% in 12th graders, with prevalence not substantially changed in the past 5 years.

According to a TEDS report (last available for 2017), opioids now constitute the largest fraction of inpatient admissions aged 12 years and older in public substance use disorder treatment settings and have overtaken alcohol and marijuana since 2015. Opioids constituted 34% of all admissions in 2017, with heroin at 26.6%, the largest subgroup. Alcohol constituted 29.5%, and cannabis 12.5%. Importantly, TEDS documented an overall increase in medication-assisted opioid therapy admission for heroin, from 93,108 out of 292,265 (31.8%) in 2007 to 210,853 out of 533,394 (39.4%), but the majority of admissions were still not with planned medication-assisted therapy. There is a predominance of male gender for patients receiving medication-assisted opioid therapy (64.5%), and no ethnic disparity was observed, with White (non-Hispanic) at 60.6% of admissions, Black (non-Hispanic) at 17.5%, and Hispanic of any origin at 14.2% (see Fig. 11.9–1).

Trends in Overdose

According to the Centers for Disease Control (CDC), almost 450,000 people have died in the United States from overdoses involving any opioid, including prescription and illicit opioids, from 1999 to 2019. The

Telegram: @medical_k

www.konkur.in

overdose deaths have been historically associated with three waves: the first wave began with increased prescription opioids, and starting in 2010, there was a rapid increase in overdose death involving heroin. Since 2013, significant increases in overdose deaths involved synthetic and illicitly manufactured high-potency opioids, such as fentanyl. While the overdose stabilized somewhat in 2017 to 2018 (Fig. 11.9–2), more recently there has been a resurgence of overdose associated with these high-potency opioids as well as overdose that involve synthetic opioids combined with methamphetamine or cocaine.

FIGURE 11.9–2. The increase and stabilization of opioid overdose deaths in the United States since 1999. The overdose deaths arrived in three waves, the initial rise in commonly prescribed opioids prior to 2005, then an increase in heroin between 2005 and 2014, and most recently, a rapid rise of newer and higher-potency synthetic opioids since 2013. (See eBook for color images.) (Adapted from CDC/NCHS National Vital Statistics System, Mortality. CDC WONDER, Atlanta, GA: US Department of Health and Human Services, CDC; 2020. https://wonder.cdc.gov/)

Worldwide Trends

The WHO continues to monitor drug use trends worldwide with the World Drug Report, last published in 2020. In 2018, 57.8 million people globally were estimated to have used opioids in the past year, a figure that includes those who had used opiates (30.4 million) and those who had misused pharmaceutical opioids. This corresponds to a past-year

Telegram: @medical_k

www.konkur.in

prevalence of opioid use of 1.2% of the global population aged 15 to 64 years.

Nonmedical use of synthetic opioids continues to fuel a worldwide public health crisis. In West, Central, and North Africa, there has been a large increase in tramadol use, and in North America, the prevalence of fentanyl use has increased. The change of OUD affecting disability-adjusted life years increased dramatically (28%) from 2008 to 2017. The market for opiates in Central Asia and the Russian Federation has changed as well, with the number of people in treatment for opioid-related problems in Russia decreasing sharply. In particular, the worldwide COVID-19 pandemic of 2020 caused drug shortages at the retail level, including reports of heroin shortages in Europe, Southwest Asia, and North America. Pharmacologic opioid painkillers also had significant reported shortages. People with OUD and who use prescription and nonprescription opioids have a high risk of comorbidities such as chronic obstructive pulmonary disease and potentially increased risk for complications and mortality from COVID-19. The overall pattern is that while opioid use is highest in North America, Australia, and New Zealand, much of this opioid use is pharmaceutical painkillers. Heroin and opium use are more common in the Near East and South Asia (see Fig. 11.9–3).

ETIOLOGY AND PATHOGENESIS

OUD is a complex phenomenon that involves multiple etiologic factors at different levels of analysis: genetic and epigenetic influences, synaptic plasticity, alterations in neural circuits, deficits in coping skills, abnormal patterns of thoughts and behavior, and dysfunction in family and social surroundings. The abnormal behavior characteristic of addiction represents the manifestation of a common final pathway and a heterogeneous set of underlying causal factors. These factors influence each other in space and in time in complex and nonlinear ways. For example, peer pressure (a social factor) may commonly precipitate the initiation of heroin use, but differences in neural circuits, likely generated, in part, by differences in genetic variations, eventually yields a difference in drug-related experiences, specifically the balance between positive effects (e.g., euphoric) versus negative effects (e.g., nausea, vomiting) which determine further drug-taking behavior. The interaction between the effects of repeatedly self-administered substance and the resulting

Telegram: @medical_k

www.konkur.in

experiences subsequently causes synaptic plasticity, either reinforcing/strengthening or extinguishing/weakening selected brain circuitries, which in turn affect an individual's behavior—either continuing with a drug-using peer group or a withdrawal from the group.

Initiation of opioid use is dependent on social and cultural context. When opioids are injected or inhaled, the rapid onset of action in the brain induces a *rush* or *flash*, a sudden, brief but intensely pleasurable sensation lasting 1 to 2 minutes. This euphoric sensation subsequently leads individuals to seek repetition of the drug taking (reinforcement). Repeated drug taking and euphoria cause opioid tolerance; changes in neural circuitry make it harder to achieve the same intensity of euphoria with an equal amount of opioids. An abrupt cessation of use by an individual who has been using repeatedly over an extended period produces opioid withdrawal, a set of physical symptoms such as nausea, vomiting, and intense craving signifying the presence of physiologic dependence. The emergence of withdrawal on stopping use and euphoria with continuing use is the basis of a long-term learning process that assigns salience to external and internal cues and experiences associated with positive and negative drug effects (conditioning) and alters the behavioral repertoire of the addicted individual in the form of increased impulsivity or decreased response to social rewards.

Neurobiology of Opioid Use Disorders

Opioids and Opioid Receptors. A variety of opioid compounds exist (Fig. 11.9–4). *Morphine*, *codeine,* and *oxycodone* are commonly prescribed medications for pain relief but can also be diverted for nonmedical use. *Heroin* or diacetylmorphine is the opioid that is most commonly misused by injection; common street names include dope, horse, smack, and tar. Opium extracted from the poppy plant, which is often smoked, is more commonly misused in the Middle East and Asia. More recently, synthetic analogs of fentanyl and nonfentanyl compounds (AH-7921, MT-45, U-47700) with opioidergic activity have become more widely available. Most commonly encountered opioids act at one of the three main opioid receptor systems (mu, kappa, delta). The term *endorphin* refers to a subclass of endogenous opioids, peptides produced naturally by the human body, including dynorphins, enkephalins, endorphins, endomorphins, and nociceptin.

FIGURE 11.9–4. Chemical structures of common medicinal and illicit opioids. They share a three-ring phenanthrene structure as well as a methylamine group. All opioids are chemically related to morphine, the parent compound, and bind to the opioid receptors. Hydromorphone, hydrocodone, oxycodone, and heroin are semisynthetic. These compounds all have analgesic effects and can potentially be substances of abuse, though they have differing pharmacokinetic and pharmacodynamic properties.

Opioid receptors are a group of G protein–coupled receptors (GPCRs) with opioids as ligands and respond to a family of endogenous opioids (endorphins). The opioid receptors are distributed widely in the brain, the spinal cord, and digestive tract. There are four currently known types of opioid receptors: delta (δ), kappa (κ), mu (μ) and nociceptin receptor (NOP). All four types of receptors have seven transmembrane domains (TM1–7). Amino acid residues at the same positions in TM3, TM6, and TM7 interact with ligands to produce downstream effects—the “message” region of the ligands. Another region—the “address” region—produces opioid selectivity and occupies one of two different areas of the binding pocket, depending on the type of opioid (see Fig. 11.9–5).

The downstream activity of opioid receptors results in two known signal transduction pathways: classical and alternative. The classical signal

Telegram: @medical_k

www.konkur.in

transduction relates to the opioid receptor by inducing G proteins to interact with an inward rectifying potassium channel, Kir3. This process causes cellular hyperpolarization and inhibits neural activity. All four opioid receptors also cause a reduction in Ca^{2+} content both intracellularly and in synaptic vesicles and synaptosomes, with compensatory upregulation of vesicular Ca^{2+} content during the development of opiate tolerance. In addition, μ-, δ-, and κ-opioid receptors inhibit adenylyl cyclase activity and inhibit the cAMP-dependent Ca^{2+} influx. More recently, activation of opioid receptors has been shown to induce β-arrestin recruitment and binding in the alternative transduction pathway. Arrestin molecules bind to phosphorylated opioid receptors to regulate their traffic, and this interaction plays a role in the development of tolerance. Phosphorylated arrestin–bound opioid receptor complex also recruits alternate signal transduction cascades, including Mitogen-activated protein (MAP) kinases, inducing numerous other complex downstream molecular events.

Telegram: @medical_k

www.konkur.in

FIGURE 11.9–5. Common structural elements of the opioid receptors. Several features are shared by all four opioid receptor types: seven transmembrane helices (TM1–7), and five shown (*grey cylinders*). ECL2 is a β-hairpin loop region; the arrows represent β-sheets. Ligands are depicted as stick representations inside the binding pocket. The cyan surface indicates the amino acid residues from TM3, TM6, and TM7 that interact with the ligands' "message" regions. The magenta surfaces indicate the residues from TM6 and/or TM7 that interact with the "address" region—responsible for opioid selectivity. (Reprinted with permission from Springer Nature. Filizola M, Devi L. How opioid drugs bind to receptors. *Nature.* 2012;485(7398):314–317. doi: 10.1038/485314a.)

The molecular and cellular mechanisms mediating the development of tolerance to morphine continue to be debated. One hypothesis proposes that tolerance is a result of downregulation of opioid receptors following chronic agonist exposure. More recent *in vivo* studies show that downregulation does not occur consistently with each and every agonist.

Telegram: @medical_k

www.konkur.in

Newer evidence suggests that the receptors may be desensitized and uncoupled from downstream signaling pathways and that chronic exposure changes levels of second messengers, such as cAMP, and upregulation of adenylyl cyclase.

Opioid Receptor Pharmacology. Opioids can interact with opioid receptors in several ways (see Fig. 11.9–5). An opioid *agonist* is a molecule that binds to an opioid receptor and induces downstream signal transduction events. Many opioids produce actions similar to that of morphine (a prototypical μ-opioid receptor agonist), and some bind to various receptor subtypes in a pattern that is distinct from that of morphine, producing a large, diverse array of possible patterns of opioid agonism. Molecules that bind to opioid receptors but initiate no signal transduction action are opioid *antagonists* at those receptors. Naloxone or naltrexone acts as μ-opioid receptor antagonists. When both antagonist and agonist are present, they compete against each other at the binding site. *Partial agonists* such as buprenorphine bind to opioid receptors but only produce a limited effect in intensity or maximal effects compared to a full agonist.

Agonist effect at μ-opioid receptors is the main pharmacologic effect associated with OUDs. The direct physiologic action of μ-agonists include analgesia, respiratory depression, miosis, euphoria, drowsiness, decreased ability to concentrate, changes in endocrine and other functions regulated by the hypothalamus, and increased tone of smooth muscle in the gastrointestinal (GI) tract. Agonists at the κ-opioid receptor often produce dysphoria and analgesia but no significant pupillary change. Heroin, morphine, hydromorphone, oxycodone, and fentanyl are all μ-opioid receptor agonists, and they differ from each other primarily in metabolism, pharmacokinetics, and relative affinities at other opioid receptors, which may produce considerable differences in their subjective effects. For instance, heroin (diacetylmorphine) is more potent and more lipid soluble than morphine, crossing the blood–brain barrier more rapidly and producing a more rapid onset of subjective effects. Patients are often able to discriminate heroin from oxycodone and from fentanyl.

Neural Circuits in Opioid Use Disorders. A variety of animal models have provided a pathway to dissect the neural circuits that mediate the effect of opioid molecules on the opioid receptors to affect animal behavior. The focus of experimental work has been converging on three

Telegram: @medical_k

www.konkur.in

aspects of opioid-associated behavior: self-administration, remodeling occurring with chronic exposure, and adaptation and relapse.

CIRCUITS IN OPIOID SELF-ADMINISTRATION. The μ-opioid receptor mediates the reinforcing effects of heroin and morphine. Blockade of the μ-opioid receptor, but not other opioid receptors, attenuates opiate self-administration. Knockout mice with no μ-opioid receptor expression in the brain do not readily associate contextual cues when these cues are paired with opiate administration (conditioning). Opioid drug conditioning is mediated by neuronal hyperpolarization and neuronal inhibition in multiple structures, including those that provide major afferent input to the ventral tegmental area (VTA); that is, nucleus accumbens (NAc), ventral pallidum, prefrontal cortex (PFC), amygdala, mediodorsal thalamus, and the pedunculopontine tegmental nucleus. This interconnected network is also known as the cortical–pallidal–striatal circuit and is characterized by a high density of opiate receptors with reciprocal connections. Site-specific blockade of μ-opioid receptor in the VTA or NAc attenuates heroin self-administration. Damage to the NAc can abolish opioid self-administration. These findings support the hypothesis that this circuitry mediates the rewarding effects of these agents.

Dopamine appears to play a central role in mediating the rewarding effect of opioids in this circuit as μ-opioid receptor agonists activate VTA dopaminergic neurons and enhance dopamine release in the NAc following heroin self-administration. Electrophysiologic studies support the idea that overlapping and heterogeneous subpopulations of NAc and medial prefrontal cortex (mPFC) neurons are activated during opiate self-administration and mediate its reinforcing effects. There is also evidence that a diverse group of neurons releasing GABA and glutamate, as well as the cannabinoid systems, are involved in mediating the reinforcing effects of opiates.

CIRCUITS INVOLVED IN CHRONIC OPIOID EXPOSURE. Cessation of chronic opioid exposure alters the activity of mesolimbic dopaminergic neurons, and the subsequent decreased dopamine neurotransmission may be related to anhedonia and dysphoria during the early phase of opioid withdrawal. The network level reconfigurations observed in chronic opioid users remain unclear, but dopamine receptor agonists can attenuate some signs of withdrawal in animal models. Chronic opioid use also alters

Telegram: @medical_k

www.konkur.in

the activity of NAc medium spiny neurons that are primary targets of dopamine neurons. These neurons are involved in a diverse number of transmitter release functions, including GABA and the opioid peptides dynorphin and enkephalin, as well as substance P, and project to the ventral pallidum and VTA. Alterations in these output neurons may also contribute to the aversive consequences of opiate withdrawal.

Opioid receptor antagonists, such as naloxone, are hypothesized to function primarily in blocking the μ-opioid receptor in NAc and other regions, including the amygdala, VTA, and locus coeruleus. Selective δ-opioid receptor antagonists can precipitate affective but not somatic components of withdrawal syndrome in animal models. Dynorphin is the endogenous ligand for the κ-opioid receptor, and agonists at these receptors produce dysphoria and negative affect mediated in part by the activation of NAc opioid receptors and inhibition of dopamine release. Increased dynorphin expression after abstinence is related to opiate-induced upregulation of the cAMP pathway and the induction of the gene transcription regulator, cAMP response element-binding protein (CREB). Long-term abstinence from opiates in a previously dependent animal often exhibits a phenomenon of hypersensitivity in dopaminergic neurons—with more dopamine release subsequently with the same dose of drugs. This is possibly related to behavioral sensitization to various drugs of misuse as well as playing a role in the reinstatement of compulsive drug-seeking behavior.

Chronic opioid use also induces circuit reconfiguration in the basolateral amygdala, locus coeruleus, and the bed nucleus of the stria terminalis, involving a variety of neurotransmitters such as glutamate and norepinephrine. Each of these adaptations may be involved in expression of the aversive effects of the opiate-withdrawal syndrome.

CIRCUITS MEDIATING RELAPSE. A large number of diffuse neural circuits appear to be engaged in reinstatement of opioid use in animal models of relapse. Factors involved in relapse in humans, such as stress, renewed contact with the drug, or drug cues and increased drug availability, reliably reinstate drug-seeking behavior in laboratory animals. The mesolimbic dopamine system plays a major role in mediating the priming effects of opiates in drug-seeking behaviors. Intra-NAc infusion of amphetamine, which stimulates dopamine release, can reinstate heroin seeking, while dopamine D2 receptor antagonists block heroin-induced reinstatement of

Telegram: @medical_k

www.konkur.in

drug seeking. Glutamatergic neurons may also be involved in reinstatement. Stress can reliably reinstate heroin seeking in rats, potentially mediated through corticotropin-releasing factor (CRF) releasing neurons, and may result from a distinct neural circuit outside of the mesolimbic dopamine system. Cue-induced relapse has been relatively poorly understood. Dopamine plays a less central role in this phenomenon, and PFC glutamate α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor plasticity is important in cue-induced relapse to heroin seeking.

Human Neuroimaging of Opioid Use Disorders

Key evidence supporting the hypothesis that drug addiction is a chronic disease of the brain comes from brain imaging studies examining a number of critical neural circuits. These studies provide a link between animal models of drug self-administration and human clinical studies. The existing evidence suggests that across all substances, there is a general circuit that is engaged in drug self-administration independent of the specific substance. There are then distinct substance-dependent circuits that mediate reinforcing effects of a specific substance. In opioids, the complex opioid receptor systems throughout the brain interact with the dopamine system in generating and maintaining the complex clinical phenomenon of OUDs. The main brain imaging techniques are structural magnetic resonance imaging (MRI), functional MRI, resting-state MRI, MR spectroscopy (MRS), positron emission tomography (PET), and single photon emission computed tomography (SPECT). Each of these methods can reveal different aspects of brain structure and function.

Converging brain imaging data suggest a distributed neural network of brain regions regulated by the μ-opioid receptor system to mediate pain, reward, motivation, and integration of emotional value. These regions include the anterior cingulate and PFC, the anterior and posterior insular cortex, orbitofrontal cortex, ventral striatum, ventral pallidum, thalamus, hypothalamus, amygdala, periaqueductal gray (PAG), and others. The κ-opioid receptor system is involved in suppressing the antinociceptive actions of opioids at the μ-opioid receptor sites and is the most widely expressed receptor system in the brain. Multiple studies report a push-and-pull antagonism between the μ- and κ-receptor systems. The μ-opioid receptor system is also associated with the positive reinforcing effect of other misused drugs, including cocaine and alcohol, in mediating their

Telegram: @medical_k

www.konkur.in

reward-related behaviors, and increasing binding in μ-opioid receptor is correlated with self-reported craving in cocaine.

PET studies show that dopamine is implicated in OUDs in a number of different ways. As the central neurotransmitter that mediates reward, dopamine D2/3 receptor availability is reduced in subjects with heroin dependence at baseline, which is an effect seen similarly in those dependent on cocaine, alcohol, tobacco, and methamphetamine. Presynaptic dopamine release is also blunted in individuals with heroin dependence (Fig. 11.9–6). There might also be a correlation between dopamine release and the subjective effects of heroin. These results suggest that the dopamine system may be involved in regulating a common underlying circuit in producing a general addiction phenomenon independent of the specific substance of misuse.

Biological psychiatry. *Biologic Psychiatry.* 2012;71(3):192–198. Copyright © 2012, with permission from Society of Biological Psychiatry. doi: 10.1016/j.biopsych.2011.08.024.)

Task-dependent fMRI studies in individuals with opiate dependence suggest that a decreased activity of a cingulofrontoparietal–cerebellar neural circuit may be involved in opioid use, with the region dorsal anterior cingulate cortex (dACC) in particular as being associated with performance deficits on tasks requiring behavioral control and error estimation. MRS suggests reduced concentrations of N-acetyl aspartate (NAA) and glutamate/glutamine within the dACC. Resting-state fMRI shows a significant decline in connectivity of the NAc to a number of

Telegram: @medical_k

www.konkur.in

areas, including laterobasal amygdala, hippocampus, parahippocampus, and the orbital frontal and midcingulate cortices.

While current neuroimaging evidence strongly suggests that there is an underlying circuit-level abnormality that mediates the initiation and maintenance of problematic opioid use, the precise mechanisms, both at the level of network activities of cortical and striatal neurons and their transmitter release, continue to be unclear. There is also no current neuroimaging method for predicting and prognosticating outcomes for OUDs. These important questions represent active areas of research.

Molecular Genetics and Genomics of Opioid Use

The genetic contribution to the development and maintenance of opioid dependence is significant. Twin studies estimate that around 50% to 60% of the liability for heroin addiction is genetic. There is also evidence that genetic vulnerability is made up of common factors that increase the likelihood of developing any drug addiction (16%) and factors that increase the likelihood of developing opioid addiction specifically (38%).

Linkage studies for opioid dependence show clustered linkage on chromosome 17, as well as linkage on a region of chromosome 14 overlying the neurexin 3 gene (*NRXN3*). They also identified a male-specific linkage peak on chromosome 10q and potentially a signal chromosome 4q. Functional polymorphism in *OPRM1* gene (Asn40 Asp), which encodes the μ-opioid receptor, and *OPRD1* (encoding δ-receptor) and *OPRK1* (encoding kappa receptor) have been extensively studied in haplotype-specific case-controlled designs, but results have been inconsistent. A potentially robust positive association between *OPRD1* variants and opioid dependence has been reported but requires replication.

Several genome-wide association studies (GWAS) have now been completed to investigate the genetics of OUD. The largest GWAS of OUD risk so far published (Gelenter et al, 2014) cumulatively included >12,000 subjects from several eastern U.S. recruitment sites and additional subjects accessed via publicly availably (dbGAP application) data from the Study of Addiction: Genetics and Environment (SAGE). The total sample included 6,877 European American and 5,432 African American subjects. The results identified several SNPs that mapped to KCNG2, which encodes a potassium voltage-gated ion channel. Another study isolated association signals of SNPs that mapped to the cornichon family

Telegram: @medical_k

www.konkur.in

AMPA receptor auxiliary protein 3 gene (*CNIH3*), a glutamate receptor–associated regulatory protein encoded on chromosome 1. One study looking at genome-wide SNP data from genotyping microarrays to identify copy number variations (CNVs) that investigated their association with OUD included 5,152 subjects and showed OUD cases had fewer CNVs than the controls, in particular an intergenic region on 18q12.3, which has also been implicated in schizophrenia risk. These studies continue to be of small size by GWAS standards and are constrained by other technical limitations, but taken together, suggest that the molecular genetic basis of OUD arises from the same common underlying genetic loci that affect broad neurodevelopmental phenotypes that affect a distributed cortical expression network.

Psychosocial Factors

Genetic and neural circuits eventually contribute to addiction behavior through their interaction with complex environmental and psychosocial factors. Social attitudes, peer pressure, individual temperament, and drug availability are all determinants of the emergence of problematic opioid use. There is less social stigma associated with prescription opioids relative to heroin, and prescription opioids are believed to be safer in comparison to heroin and are more widely available. As individuals using prescription opioids develop a number of functional impairments, their opioid use often transitions to heroin and the IV route of administration due to lower cost and increasing tolerance for slower-acting agents. The presence of a significant number of opioid users in a neighborhood, town, or city also can create a subculture of opioid experimentation. In the United States, areas in which the prevalence of OUD is high also often have associated high crime rates, unemployment rates, and poorly performing school systems. While correlation does not equal causation, these factors can all be conceptualized as contributing to reduced resistance to opioid use and may worsen the prognosis and treatment efficacy.

Epidemiologic studies show that people who have OUDs place more value on independence and less value on academic achievement. Patients with heroin use disorders have more novelty-seeking, risk-taking, and impulsivity traits and show significant signs of delinquency before their first experimentation with opioids. A significant proportion of heroin users meet the criteria for antisocial personality disorder.

Telegram: @medical_k

www.konkur.in

Most urban residents who use heroin come from single-parent families, and poor parental functioning has been consistently reported as a risk factor for opioid addiction. Family risk factors involve disruption of family structure and disrupted parental relationships. Cross-generational alliances between the individual who uses drugs and one parent against another parental figure are common. Dysfunctional family equilibrium can threaten the recovery process, and an assessment of family dynamics is an important component in the assessment and treatment of someone with OUD.

Integrative Approach

Across different levels of analyses, the etiology of OUD is now conceptualized as a complex interaction of genes, neural circuits, and environment. While the underlying mechanistic details remain subjects of active research, several consensus hypotheses have emerged from a large amount of converging experimental data. First, it appears that there is a large component of risk of developing OUD that derives from genetic influences, and these genetic variations change the pattern of biochemical signaling pathways involved in both opioid receptor and non–opioid receptor systems. These genetic factors of risk interact with environmental risk factors, which derive from sensitization during critical periods, traumatic experiences, and adverse social and economic conditions. The combination of genetic and environmental factors interacting in complex ways eventually leads to a heterogeneous set of neural circuit level abnormalities involving multiple cortical circuits and transmitter systems, likely involving abnormal release and reinforcement of dopamine neurotransmission. These systems subsequently influence both behavior and the rest of the body through their influence on the stress system (pituitary-adrenal system). The initiation of opioid use subsequently induces neuroadaptations in systems regulating reward, motivation and drive, memory, and behavioral control. Changes in other neural systems lead to the development of tolerance and physiologic dependence. As a result, affected individuals develop a range of problematic behavior: not only maintaining drug use but also relapsing following cessation of use. These behaviors lead to criminality, poverty, and a deficit in social support, which in turn strengthens drug-seeking and -using behavior.

This complex, multifactorial etiologic model stipulates that abnormalities in brain function are behind the etiology and maintenance of OUD. It is

Telegram: @medical_k

www.konkur.in

important that patients and their families recognize the significance but also the limitations of this model. OUD is a chronic, relapsing–remitting behavioral brain disorder that is not a character flaw or moral weakness. On the other hand, the central role of neural circuit-level abnormalities does not imply that patients have no control over the choices they make, particularly choices related to their own treatment and recovery. The brain is an incredibly plastic organ, and neural circuits can be remodeled in response to environmental changes, new behaviors, and administration of medications. Effective treatment for opioid addiction should therefore target all of these etiologic factors in a multilevel fashion.

DIAGNOSIS AND CLINICAL FEATURES

Opioid Intoxication and Overdose

The DSM-5 criteria for opioid intoxication are broadly inclusive, and in clinical situations, opioid intoxication symptoms can vary in severity and presentation. Initial euphoria is usually followed by apathy, dysphoria, psychomotor agitation or retardation, and impaired judgment. Pupillary constriction, drowsiness, and slurred speech are common. Other physical signs include cyanosis, cold, clammy skin, and decreased body temperature. There may also be x-ray evidence of pulmonary edema and frothing at the mouth. Blood pressure is decreased but only falls dramatically with severe anoxia. Cardiac arrhythmias have also been reported and may be related to anoxia or to the presence of quinine as an adulterant in the opioid. A marked tolerance usually develops over time to the subjective intoxicating effects of opioids. A summary of sample diagnostic criteria in DSM-5 is included in Table 11.9–1.

On occasion, intoxication is followed by an overdose, a state characterized by unresponsiveness to external stimulation (coma). Signs of opioid overdose include coma with pinpoint but reactive pupils and respiratory depression or apnea. In severe cases, severely depressed respiration can develop, which can lead to anoxia and large, nonreactive pupils. Overdose due to fentanyl can also include respiratory muscle rigidity and laryngospasm (“wooden chest” syndrome). Overdose death can result from hypoxic–ischemic injury to the brain and cardiovascular system, as well as sudden cardiac death from arrhythmia due to electrolyte abnormalities.

Telegram: @medical_k

www.konkur.in

Opioid Tolerance

Tolerance to opioids' intoxicating and hedonic effects is a common reason for escalation of use, seen as an increase in the frequency of use (up to several times per day) and the amount used on each occasion. However, even chronic heroin users experience brief periods of euphoria each time they receive the drug. Ongoing opioid use is, therefore, not solely used to avoid withdrawal. Because of tolerance to physical symptoms of opioids, such as respiratory depression and sedation, opioid effects may not be readily detected in chronic users by even the careful observer, which makes the detection of opioids based on simple observation difficult. High tolerance levels, observed in patients maintained on higher doses of methadone, can be beneficial in minimizing the effects (blocking) of illicit opioids and is one of the mechanisms for the therapeutic effects of methadone and, to a lower extent, buprenorphine.

Table 11.9–1.
Summarized DSM-5 Diagnostic Criteria for Opioid Intoxication

DSM-5 recognizes individuals as experiencing opioid intoxication with the following typical history, signs, and symptoms.

- Behavioral or psychological changes (e.g., euphoria followed by apathy, dysphoria, psychomotor agitation or retardation, impaired judgment).
- Pupillary constriction.
- Drowsiness or coma.
- Slurred speech.
- Impairment in attention or memory.

Opioid Withdrawal

Opioid withdrawal develops after the cessation of or sudden reduction in opioid use that has been heavy and prolonged. The withdrawal syndrome also occurs when an opioid partial agonist such as buprenorphine or an opioid antagonist such as naloxone or naltrexone is administered to a patient who is chronically taking an opioid agonist ("precipitated withdrawal"). Many withdrawal symptoms are the physiologic opposite of intoxication symptoms. Patients undergoing withdrawal complain of anxiety, irritability, restlessness, an "achy feeling" in the legs and back,

Telegram: @medical_k

www.konkur.in

and increased sensitivity to pain. Few objective signs may be present in milder withdrawal. In more severe withdrawal, patients present with nausea or vomiting, abdominal cramps and diarrhea, severe muscle aches, lacrimation and rhinorrhea, yawning, pupillary dilation, and increased sweating and chills. Fever, severe insomnia, confusion, and delirium can occur in severe withdrawal. A summary of sample diagnostic criteria in DSM-5 is included in Table 11.9–2.

Opioid withdrawal can be either *spontaneous* (stopping daily use) or *precipitated* (due to the administration of an opioid antagonist or partial agonist). Spontaneous withdrawal starts 6 to 8 hours after the last use of the short-acting opioids (heroin, morphine, oxycodone, hydrocodone), 24 hours after the last use of longer-acting opioids such as methadone or buprenorphine, and even later in some cases of nonpharmaceutical fentanyl use. Withdrawal severity peaks around 36 to 48 hours and resolves after 5 to 7 days for short-acting agents and after 2 or more weeks in the case of methadone. Administration of an antagonist precipitates opioid withdrawal within minutes after parenteral administration (naloxone) and 2 to 3 hours after oral or injectable administration (naltrexone). Opioid withdrawal precipitated by naltrexone is usually more severe than spontaneous withdrawal but resolves faster, generally within 1 day.

Telegram: @medical_k

www.konkur.in

Table 11.9–2.
Summary DSM-5 Diagnostic Criteria for Opioid Withdrawal

DSM-5 Recognizes individuals as experiencing opioid withdrawal with the following typical history, signs, and symptoms.

History:

- Cessation of (or reduction in) opioid use.
- Administration of an opioid antagonist after a period of opioid use.

Signs and Symptoms:

- Dysphoric mood.
- Nausea or vomiting.
- Muscle aches.
- Lacrimation or rhinorrhea.
- Pupillary dilation, piloerection, or sweating.
- Diarrhea.
- Yawning.
- Fever.
- Insomnia.

A period of continuous receptor activation is required before spontaneous withdrawal is clinically significant, but a precipitated withdrawal can occur even after a few days of taking an opioid. There is considerable variability between individuals in presenting symptoms during opioid withdrawal. The severity of opioid withdrawal also varies across individuals and in time, and depends on the pharmacologic characteristics of the opioid, such as its potency, degree of opioid agonism (e.g., full versus partial agonist), dose, the duration of use, and the rate at which the opioid is removed from the receptors (e.g., a slow taper versus abrupt cessation). In general, the higher the potency, agonist efficacy, and dose, the longer the duration of opioid use, and the faster the removal of opioids from the receptor, the more intense the withdrawal syndrome. Standardized instruments have been developed to quantify the severity of opioid withdrawal symptoms in clinical practice. The Clinical Opiate Withdrawal Scale (COWS) is the most common and utilizes resting pulse rate, sweating, restlessness, pupil size, pain, rhinorrhea, GI symptoms, tremor, yawning, anxiety, and piloerection as anchor points (see Table 11.9–3).

Telegram: @medical_k

www.konkur.in

Opioid withdrawal symptoms can occur after abrupt discontinuation of maintenance treatment with buprenorphine, a partial opioid receptor agonist, but such symptoms are generally less severe than in the case of cessation of a full agonist. Some patients report significant insomnia, irritability, anxiety, and depression. These symptoms tend to resolve within 7 to 10 days. Drug effects from larger doses of buprenorphine (16 to 32 mg or more sublingually) can persist for several days due to its long half-life, and withdrawal symptoms can be delayed for 96 hours or more. This feature of buprenorphine has led to its use on an intermittent basis to prevent withdrawal (e.g., dosing every other day).

Following the resolution of an acute opioid withdrawal syndrome, there also appears to be a period of physiologic abnormality that lasts for weeks to months, referred to as *protracted or postacute withdrawal syndrome*. It is characterized by depressed mood and anhedonia, anxiety, irritability, labile mood, stress intolerance, insomnia, and recurrent craving and urges to use opioids. This protracted syndrome may result from alterations and remodeling of the neural circuitry associated with withdrawal, such as changes in the serotonergic and dopaminergic systems. This syndrome, while not formally included in the DSM-5, is likely a significant contributor to relapse to opioid use.

Opioid-Induced Mental Disorders

DSM-5 specifies a category of substance-induced disorders for a number of different substances that includes a variety of opioid-induced mental disorders (psychotic, bipolar, depressive, anxiety, obsessive-compulsive, sleep, sexual, delirium, and neurocognitive disorders). Chronic opioid use can produce several psychiatric syndromes, and opioid-using patients can also have comorbid psychiatric diagnoses that precede or are independent of opioid use. The important differential considerations, therefore, rely on a detailed history of chronicity and order of emergence for these symptoms. The onset of opioid-induced psychiatric syndromes needs to be temporally connected with the substance use (within 1 month), as opposed to occurring prior to the initiation of substance use or during a prolonged period of abstinence, and opioids need to be capable of producing the specific syndrome. Clinically, it is common to see some degree of depressed mood during and for several weeks after opioid withdrawal. Opioid-induced mood disorder should not be diagnosed during and immediately after opioid withdrawal unless the severity of

Telegram: @medical_k

www.konkur.in

mood disturbance exceeds what is normally encountered or persists for more than a few weeks and is of sufficient intensity to warrant independent clinical attention (e.g., presenting with profound psychomotor retardation or suicidality). Opioid-induced psychotic symptoms are rare, although they have been clinically observed, especially manifesting as derealization and occasionally hallucinations. Opioid-induced sleep disorder and opioid-induced sexual dysfunction are common, and both hypersomnia and insomnia are common complaints of patients who either have OUD or are maintained on opioids for therapeutic purposes. Common sexual dysfunctions for chronic opioid users include erectile dysfunction and orgasmic difficulties. While the presentation and consequences of opioid-induced mental disorders can be identical as in the case of the independent mental disorder, most opioid-induced disorders are likely to improve within days or weeks of abstinence from the abused opioid.

Resting Pulse Rate: (record beats per minute)
Measured after patient is sitting or lying for 1 minute
0 pulse rate 80 or below
1 pulse rate 81–100
2 pulse rate 101–120
4 pulse rate greater than 120

Sweating: *Over past ½ hour not accounted for by room temperature or patient activity*
0 no report of chills or flushing
1 subjective report of chills or flushing
2 flushed or observable moistness on face
3 beads of sweat on brow or face
4 sweat streaming off face

Restlessness: *Observation during assessment*
0 able to sit still
1 reports difficulty sitting still, but is able to do so
3 frequent shifting or extraneous movements of legs/arms
5 Unable to sit still for more than a few seconds

Pupil Size
0 pupils pinned or normal size for room light
1 pupils possibly larger than normal for room light
2 pupils moderately dilated
5 pupils so dilated that only the rim of the iris is visible

Bone or Joint Aches: *If patient was having pain previously, only the additional component attributed to opiates withdrawal is scored*
0 not present
1 mild diffuse discomfort
2 patient reports severe diffuse aching of joints/muscles
4 patient is rubbing joints or muscles and is unable to sit still because of discomfort

Runny Nose or Tearing: *Not accounted for by cold symptoms or allergies*
0 not present
1 nasal stuffiness or unusually moist eyes

Telegram: @medical_k

www.konkur.in

2 nose running or tearing
4 nose constantly running or tears streaming down cheeks

GI Upset: *Over last ½ hour*
0 no GI symptoms
1 stomach cramps
2 nausea or loose stool
3 vomiting or diarrhea
5 Multiple episodes of diarrhea or vomiting

Tremor: *Observation of outstretched hands*
0 No tremor
1 tremor can be felt, but not observed
2 slight tremor observable
4 gross tremor or muscle twitching

Yawning: *Observation during assessment*
0 no yawning
1 yawning once or twice during assessment
2 yawning three or more times during assessment
4 yawning several times/minute

Anxiety or Irritability
0 none
1 patient reports increasing irritability or anxiousness
2 patient obviously irritable anxious
4 patient so irritable or anxious that participation in the assessment is difficult

Gooseflesh Skin
0 skin is smooth
3 piloerrection of skin can be felt or hairs standing up on arms
5 prominent piloerrection

Score:
5–12 = **mild;**
13–24 = **moderate;**
25–36 = **moderately severe;**
more than 36 = **severe withdrawal**

From Wesson DR, Ling W. The Clinical Opiate Withdrawal Scale (COWS). *J Psychoactive Drugs.* 2003;35(2):253–259, reprinted with permission of Taylor & Francis Ltd, http://www.tandfonline.com. doi: 10.1080/02791072.2003.10400007.

Opioid Use Disorder

DSM-5 OUD diagnosis spans a spectrum of signs, symptoms, and problematic behaviors (Table 11.9–4). These include problems related to opioid use (social/interpersonal, neglect in major roles, physical and psychological problems), abnormal behavior (inability to control the amount or to stop use, spending a lot of time on use at the expense of other recreational activities), physiologic changes (tolerance and withdrawal), and craving. Two or more criteria are set as a threshold for the diagnosis, and three levels of severity are specified (mild, moderate, and severe). The diagnostic criteria are primarily assessed during a detailed clinical interview, while repeated toxicology tests (e.g., urine or saliva) can be used as corroborating evidence of chronic use. No single criterion is given special weight: the presence of tolerance and withdrawal are neither necessary nor sufficient for the diagnosis. The broad emphasis for these criteria is to specify the degree of impairment in social and occupational function due to a pattern of problematic opioid use rather than on the timing, quantity, type, or route of use.

Pathology and Laboratory Examination

There is currently no biomarker for the diagnosis of OUDs. The most commonly used urine toxicology tests can detect recent opioid use. Urination is a major route for drug elimination, and urine testing is a convenient alternative to testing blood. Drug metabolites are first detectable in urine 3 to 6 hours after use. Morphine, heroin, codeine, and hydrocodone can be detected in urine for 1 to 3 days after use. Heroin metabolite (6-acetylmorphine) can be detected in urine for up to 8 hours after use, after which heroin can be detected as morphine (its metabolite). The ingestion of modest amounts of poppy seeds (of the type and amount used in baking), which contain opium alkaloids, may also produce positive results on tests with high sensitivity. Synthetic and semisynthetic opioids such as methadone, fentanyl, buprenorphine, tramadol, and oxycodone require specific tests as these do not share metabolites with natural opioids (morphine and codeine). Methadone can be detected in urine for up to 4 days after a single-use episode and for longer with repeated use.

Telegram: @medical_k

www.konkur.in

Table 11.9–4.
Summarized DSM-5 Criteria for Opioid Use Disorder

DSM-5 recognizes opioid use disorder as a pattern of problematic opioid use leading to significant clinical impairment within a 12-month period, with at least 2 of the following elements in history, symptoms, and signs:

- Opioids taken in larger amounts or over a longer period.
- Persistent desire to cut down.
- A great deal of time is spent to obtain, use or recover from opiates.
- Craving.
- Failure to fulfill major role obligations at work, school, or home.
- Persistent or recurrent social or interpersonal problems
- Important social, occupational, or recreational activities.
- Opioid use that is physically hazardous.
- Continued opioid use despite physical or psychological problems.
- Tolerance.
- Withdrawal.

Other toxicology methods involve testing saliva or hair. Samples of oral fluids can detect recent opioid use with approximately the same sensitivity as urine testing, though they may have a shorter detection window, especially with fat-soluble drugs such as THC. Moreover, drugs can be detected in saliva immediately after smoking or injecting and within 1 to 2 hours after swallowing. The main advantage of saliva testing is that sample collection can be fully observed, which minimizes the risk of sample adulteration (substitution, dilution, and additives) encountered with unobserved urine testing. Analysis of hair clippings can provide information and offers an average measure of use over the preceding 2 to 3 months. Hair testing is a better indicator of chronic use than urine, but drug use within the previous week will not be detected in hair.

Patients with a history of IV opioid use should also be tested for hepatitis (B and C) and human immunodeficiency virus (HIV) infections. Sharing straws for intranasal (IN) opioid use is a risk factor for hepatitis C. At the time of initial evaluation, it is also important to assess liver functions, complete blood count, and basic metabolic panel, as opioid-using patients tend to have poor nutritional status, and acute opioid intoxication can cause metabolic abnormalities and leukocytosis. Chest x-

Telegram: @medical_k

www.konkur.in

rays may show evidence of tuberculosis or pulmonary fibrosis in persons using injection materials contaminated with microcrystalline talc or cotton particulates. Methadone may prolong the QT interval on EKG; therefore EKG can be useful in detecting individuals with prolonged QT.

Physical examination is often normal though signs of intoxication or withdrawal may be present. IN use of heroin may cause nasal irritation and necrosis. IV use can lead to needle marks throughout the body because injection sites are concealed (e.g., soles of the feet). Infections (e.g., thrombophlebitis, skin abscess), lymphatic obstruction, and edemas are not uncommon. Subcutaneous and muscle tissue hardening can result from repeated intramuscular (IM) injections of meperidine (seen among health professionals). Skin lesions consisting of scars, skin atrophy, and hyperpigmentation suggest chronic use. Endocarditis may produce fever and heart murmurs. Signs of liver abnormalities, such as stigmata and ascites, should also be documented. Mental status examinations often show abnormalities in mood, affect, and cognition.

Differential Diagnosis

Diagnosing is usually straightforward in clinical situations when an individual requests treatment and is open about the duration and frequency of use and the nature of associated problems. However, in earlier stages of the disease, collateral information from family and peers confirmed with toxicology results is necessary, as individuals tend to underrecognize or diminish the existence and impact of drug-related problems. Patients with a long history of addiction who relapsed may try to hide the history of illness when trying to obtain opioids in the medical setting—engaging the family or reaching out to previous medical providers is important for an accurate diagnosis and an adequate treatment plan.

OUD can be misdiagnosed in patients with chronic pain or intermittent acute pain syndromes (e.g., sickle cell disease) who exhibit a range of problematic behavior such as arguing with medical staff, requesting higher doses and more potent opioids, and seeking medications from multiple doctors. Ongoing and poorly controlled pain may elicit these behaviors, a phenomenon sometimes referred to as *pseudoaddiction*. Careful longitudinal observation, outside informants, and urine toxicology testing, alongside continued appropriate attempts at pain relief and treatment of co-occurring medical and psychiatric problems, are required in generating the differential diagnosis. An empathic, compassionate, and

Telegram: @medical_k

www.konkur.in

nonargumentative approach to working with such patients is essential, and a physician–patient contract specifying the treatment plan and procedures to follow is helpful.

In most cases, *opioid withdrawal* is easy to diagnose, as its physiologic signs are very typical. Diagnosing withdrawal in the early phases, when patients mostly report subjective symptoms of various aches, pains, and anxiety, may be more difficult, and further monitoring may be necessary. Poor response to treatment of withdrawal with opioid agonists such as methadone suggests withdrawal from other substances. Administering buprenorphine to an opioid-dependent individual who does not have clear signs of opioid withdrawal can worsen the withdrawal (precipitated withdrawal). The presence of severe withdrawal (autonomic instability, confusion, or seizures) without classic opioid-withdrawal signs (e.g., yawning, vomiting, diarrhea) raises the strong possibility of withdrawal from other substances such as alcohol or sedative–hypnotics. Toxicology evaluation, which includes assays for synthetic opioids, is essential in all cases presenting with drug-withdrawal symptoms.

Similarly, *opioid intoxication* must be differentiated from mixed intoxications in which opioids only play a minor role. In general, a failure to respond to repeated doses of naloxone suggests that intoxication is caused by a nonopioid. Older adult patients may respond to opioids with dysphoria and confusion in *atypical opioid intoxications* rather than opioid-induced delirium or opioid-induced psychotic disorders, which are rare.

COURSE AND PROGNOSIS

The clinical course for OUDs is highly variable. Some persons apparently can use opioids occasionally (e.g., several times a month) over periods of months or years without meeting the criteria for an OUD. This is the more common course for patients who use prescription opioids but is also seen in those using heroin. Data from national surveys suggest that approximately one-third of recreational users develop moderate to severe OUD in their lifetimes, and the rates are lower in people who use prescription opioids recreationally. Even though most recreational users do not go on to develop a use disorder, there is no reliable way to predict among first-time users on an individual level who will progress to OUD. The presence of a co-occurring psychiatric or substance use disorder and IV use of heroin are major risk factors. Patients who meet criteria for an

Telegram: @medical_k

www.konkur.in

OUD at some point in their lives can achieve significant periods of abstinence, often without formal treatment. Most commonly, affected individuals will experience a chronic and recurring course of illness.

Patterns of Use and Relapses and a Long-Term Prognosis

OUD typically has a chronic course, though the progress and remission through this course in a particular individual is highly variable. Opioid use commonly begins with single doses used intermittently (e.g., weekend use) with longer periods of abstinence, either self-imposed or involuntary in the form of imprisonment or hospitalization, lasting from a few weeks to years. Gradually, there is a transition to daily use and an increase in the frequency and, later, the quantity of use episodes. Multiple uses of short-acting opioids throughout the day are common, often with a first dose in the morning preceding all other daily activities to eliminate or avoid early withdrawal symptoms.

Periods of self-detoxification and voluntarily imposed abstinence are typical but often followed by a relapse, especially under stress. Stress, depression, and life crises (especially arguments and interpersonal losses) are commonly associated with relapse. Some persons can maintain a lower level of use early on following relapse, but more commonly, the frequency of use, tolerance, physiologic dependence, and drug-related problems rapidly escalate, usually at a faster pace than during early periods of the disorder. The most common reasons for seeking abstinence are accumulating occupational, family, financial, and legal problems, feelings of fatigue and exhaustion with activities needed to maintain daily use, and inevitable periods of withdrawal. For others, emergence of severe depression or a legal mandate is the primary reason they want to stop using and seek out treatment.

Treatment allows individuals to initiate and maintain long-term abstinence. One of the major goals of treatment is to avoid accidental overdose and favorably modify the course of the disorder by minimizing the impact of risk factors on relapse (relapse prevention). In most cases, more than one treatment episode is necessary to achieve long-term remission, however, among individuals who have a good treatment response, multiple treatment attempts can have a cumulative effect, and the duration of each drug-using episode tends to shorten. Many patients who have had a positive experience in treatment will be able to recognize high-risk situations and protect themselves from relapse or will be able to

Telegram: @medical_k

www.konkur.in

return to treatment after the first few episodes of drug use (lapse) and minimize the risk that lapse would progress to a full-blown relapse.

Repeated relapse, although common, is not an inevitable course of OUD. Cohort studies show that 10% to 40% of interviewed opioid users are abstinent at long-term follow-up. Treatment research conducted throughout the past four decades shows that a reasonable proportion of opioid users enter long-term remission. Sustaining ongoing treatment and monitoring, longer lengths of stay in treatment, and self-motivation have been identified as the most important reasons for long-term recovery. Other protective factors include practicing religion, spirituality, employment, and family involvement. Positive outcomes, such as greater participation in prosocial activities, including employment and improved mental health, are both causes and effects of long-term recovery. Many patients who develop an OUD do not enter treatment and tend to have a less severe form and course of the disorder and fewer co-existing medical and psychiatric problems as compared to those seen in treatment programs.

For a large proportion of patients, OUD is a life-long condition with severe health and social consequences. A longitudinal study of 581 patients with moderate to severe OUD who were placed under the California Civil Commitment Program in the early 1960s showed that during the 33-year follow-up period, 49% died, a death rate more than 50 times greater than age-matched controls. Most of the deaths involved drug-related causes or violence. Among the survivors, many had serious medical and psychiatric problems and were involved in the criminal justice system. At the time of the follow-up interview, 20% were using heroin, 10% refused testing, 4% were incarcerated, and 56% were currently abstinent, but 40% had used heroin within the past year. More than 60% of subjects reported long periods of abstinence (>1 year). A review of long-term follow-up studies found abstinence rates between 10% and 20% for both drug-free and methadone maintenance treatment. In more recent studies, such as the AIDS Linked to the Intravenous Experience (ALIVE) Study, conducted over the 12-year study period, four patterns were noted in patients with a pattern of injection drug use: 29% of participants remained persistent drug injectors, 20% ceased injection, 14% relapsed once, and 37% had multiple transitions.

Legitimate work, lack of criminal activity or other drug use, solid family relationships, and good psychological adjustment are favorable indicators

Telegram: @medical_k

www.konkur.in

for good long-term prognosis. Severity of comorbid psychiatric conditions at the beginning of treatment usually conveys a bad prognosis. Over shorter follow-up periods, methadone maintenance, therapeutic communities, and drug-free programs were significantly superior to detoxification-only programs.

Opioids and Crime

The relationship between drug use and crime is complex. Heroin use correlates with increased levels of criminal activity, especially income-generating crime. In outpatient opioid maintenance treatment, crime reduction is often one of the main outcomes of interest. Observational studies have shown that methadone maintenance treatment reduces crime in persons using heroin. Retention in treatment is consistently shown to be an important factor in mediating this reduction. Patients in continuous treatment had the greatest reductions in criminal activity, while those who drop out after several treatment episodes have the highest rates of criminal convictions. On the other hand, there is a smaller association between crime and illicit use of other opioids and other causal factors of crime, such as poverty, lack of social services, and discrimination.

Morbidity and Mortality

Chronic use of pure opioids, including methadone and buprenorphine, in nontoxic doses, has relatively few known side effects as tolerance develops to most of the acute effects. The cognitive impairment seen with long-term alcohol and sedative use is not generally found with long-term use of opioids. The only organ toxicity appears to be endocrinopathy with lower levels of testosterone and other sex hormones and resulting physiologic changes (loss of libido, impotence, amenorrhea). Occasionally, patients report chronic constipation and sleep disturbances. There is, however, toxicity associated with frequently found contaminants in the heroin supply, especially found in individuals who inject opioids.

Despite the relative safety of chronic opioids, the life expectancy of those with OUD, especially those using heroin, is markedly reduced. Death occurs at a young age, with an average of 44 years of potential life lost for each fatality. The rate of mortality among those with OUD is 6.5 times the rate expected in the general population, with a higher rate for younger persons. The overall standardized morality rate in the United

Telegram: @medical_k

www.konkur.in

States is about 1.0% to 1.5% per person per year, 0.8% to 1.2% in a cohort of people treated for opioid dependence in Australia, and 2% to 3% in British clinics providing unadulterated injectable drugs to younger patients. Overdose is the most frequent cause of death, followed by unintentional injuries (accidents and violence) and suicide. Recent reports suggest that ongoing medication treatment with buprenorphine is associated with lower all-cause mortality, emergency room admissions, and inpatient hospitalizations. Death related to liver disease, particularly viral hepatitis, is very common, while HIV-related mortality has been steadily decreasing thanks to HIV prevention efforts and harm reduction programs such as needle exchange.

Overdose. Even though overdose is the most common cause of death in individuals with OUD, most overdoses are nonlethal. Only 1 out of 25 to 50 overdoses results in death; however, harm associated with nonlethal overdoses can be significant because even brief periods of complete anoxia can irreversibly damage CNS, and there is an accumulating effect of multiple overdoses. Most cases of overdose occur in older, long-term users, many of them using via injection, and many of those individuals have one or more nonlethal overdoses before a lethal one. It is not well understood why some individuals are at increased risk of overdose. A majority of overdoses involve multiple CNS depressants, most commonly alcohol and benzodiazepines, but also other opioids such as methadone. The risk of overdose appears to be much higher in those using potent synthetic opioids such as fentanyl analogs as compared to those using heroin or prescription opioids.

Medical Comorbidity. Most of the medical complications seen in chronic users of opioids, particularly users of heroin, are due not to heroin but to medical complications related to exposure to other substances used concurrently (e.g., impurities and adulterants in heroin and acetaminophen in prescription painkillers), harmful drug administration practices (e.g., nonsterile injecting), and high-risk behaviors associated with life experiences (e.g., violence or unprotected sex). Infections of the skin and subcutaneous tissue (abscesses, cellulitis), thrombophlebitis, endocarditis, pneumonia, and hepatitis are frequently seen medical complications. Acute infections are the major reason for inpatient admission of people who inject drugs.

Telegram: @medical_k

www.konkur.in

Viral hepatitis, particularly hepatitis C (HCV), is the leading infectious cause of death in the United States and the leading cause of liver transplantation and liver cancer. In the United States, up to 80% of HCV cases are seen among persons who inject drugs, as are half of all new cases of infection. Abnormal liver function is seen in two-thirds of those who use heroin, and it may persist after the cessation of injections. High-risk sexual and drug-use behaviors are the most common mode of transmission of hepatitis and HIV. Despite education efforts and other prevention measures, the frequency of these behaviors remains high in the population of those who inject drugs. All patients who are in treatment should be offered vaccination for hepatitis B.

Acquired immune deficiency syndrome (AIDS) remains an important factor in mortality among IV opioid-using patients. HIV seroprevalence has a wide geographic variability and is lower among those who have continuously been in drug treatment. The incidence of tuberculosis is also higher among heroin users than in the general population and has been linked to the compromised immune system of these individuals regardless of whether or not they have HIV. Persons who inject drugs should have access to measures that reduce the spread of hepatitis and HIV, such as clean injecting equipment, condoms, and access to medical care.

Other infections related to IV substance use and sharing of needles include malaria, tetanus, osteomyelitis, and syphilis. Endocarditis related to staphylococcus but also pseudomonas or candida may result in serious complications. Endocarditis can cause abscesses in the brain or spinal cord, meningitis, diffuse vasculitis, and subarachnoid hemorrhage from rupture of an infected aneurysm. Various contaminants (e.g., talc) entering the bloodstream can cause pulmonary emboli, which can eventually result in angiothrombotic pulmonary hypertension and right ventricular failure. Staphylococcal pneumonitis may also be related to septic emboli. Poor IV injecting technique can cause chronic edema of extremities. Subcutaneous or intracutaneous injection (known as “skin popping”) may cause widespread ulceration and disfigurement.

Patients surviving overdose may experience long-term sequelae of anoxic brain injury, such as transverse myelitis, amblyopia, plexitis, peripheral neuropathy, parkinsonian syndrome, movement disorder, intellectual impairment, and personality changes. Pathologic changes in muscles and degeneration of peripheral nerves have also been seen. Synthetic opioids can affect cardiac conduction by lengthening the QT

Telegram: @medical_k

www.konkur.in

interval, which can cause serious arrhythmias, such as torsade des points. Methadone has a lower margin of safety as compared to buprenorphine, with prolonged QT interval (≥500 msec) seen in approximately 2% of patients treated with methadone.

Chronic pain is commonly seen within the opioid-dependent population. Pain is often cited as the reason for initiating use of prescription opioids and heroin, and chronic and usually post-traumatic pain is often reported by patients who use opioids.

Psychiatric Comorbidity. Comorbid psychiatric conditions are the rule rather than the exception in OUD. The type and severity of additional psychiatric diagnoses can influence the course of the disorder and treatment. The first and second waves of the U.S.-based National Epidemiologic Survey on Alcohol and Related Conditions (NESARC), collected between 2001 and 2006, found that 69% of men and 74% of women with OUD in their lifetimes met criteria for an additional mood, anxiety, or another substance use disorder at some point in their lives. Some of the most common diagnoses included mood disorders, antisocial personality disorder, anxiety disorders, and alcohol use disorder (see Table 11.9–5). Findings from the Australian Treatment Outcome Study (ATOS) also show a high prevalence of mental disorders among opioid users, among those both who are in treatment and those who are not. In the ATOS, the most prevalent comorbid psychiatric conditions were major depression, post-traumatic stress disorder (PTSD), and antisocial personality.

Among the NESARC cohort, women were twice as likely as men to have a lifetime mood or anxiety disorder. Women were twice as likely as men to have paranoid personality disorder but half as likely as men to have antisocial personality disorder. Women were less likely than men to meet criteria for abuse of cocaine and marijuana and less likely than men to be dependent on alcohol. Women in the ATOS cohort also were more likely to have depression or PTSD.

The long-term outcome for OUD among persons with additional major psychiatric disorders, such as schizophrenia or bipolar I disorder, is not generally known. However, a study that specifically examined the efficacy of additional psychiatric care for dual-diagnosis subjects in an outpatient specialty clinic found that, although they initially had significantly more frequent illicit opioid use than patients without comorbid psychiatric

Telegram: @medical_k

www.konkur.in

conditions, they had higher retention rates in treatment and, after 6 months of treatment had comparable success rates to the single-diagnosis group.

TREATMENT

The most effective treatment for OUD involves a combination of medication to normalize brain functioning, psychosocial interventions aiming to develop new skills and reduce the risk of relapse, and community-based supportive interventions to integrate the patient with their community. The primary goals of treatment include (1) reduction or cessation of illicit opioid use to initiate abstinence, (2) prevention of relapse to regular use in abstinent individuals, (3) minimizing the medical, psychiatric, and social complications of drug use, especially the risk of overdose and death, and (4) improving the medical, psychological, and social function and the quality of life. Specific treatment goals should be individualized for each patient and include their input throughout the treatment episode.

FIGURE 11.9–7. Schematic of pharmacologic action of different classes of agents affecting μ-opioid receptors. A full agonist, such as heroin, induces all of the capacity for intrinsic activity of the opioid receptor. A partial agonist, such as buprenorphine, only allows for half of the activity to proceed, blocking other full agonists from achieving the full biologic effect. Antagonists, such as naloxone and naltrexone, eliminate the potential for any other agent to bind to the receptor and activate the receptor.

Clinical Pharmacology of Medications Used in Treatment of Opioid Use Disorders

The primary pharmacologic treatment strategy, broadly known as medications for opioid use disorder (MOUD) treatment, aims at engaging the μ-opioid receptor. The three classes of medications used in treatment are full agonists, partial agonists, and antagonists, each of which exerts a different pharmacologic effect at the receptor (Fig. 11.9–7). Opioid full agonists, which include methadone, morphine, heroin, and oxycodone, bind to the receptor and activate it to the maximum capacity, with the pharmacologic and clinical effect that is directly correlated with the dose. Methadone is used for detoxification and as a maintenance agent.

Telegram: @medical_k

www.konkur.in

The opioid partial agonist buprenorphine strongly binds to the receptor but activates it only partially; at most, the effect is approximately 50% of the maximum effect produced by the full agonist. The agonist effect of buprenorphine is directly correlated with the dose at the lower range of doses, but as the dose increases, the pharmacologic and clinical effect increases very little, and it reaches a ceiling level beyond which no further increase in agonist effect is possible. Functionally, buprenorphine acts primarily as an agonist (producing receptor activation). However, buprenorphine has a high affinity (binding strength) to the receptor, and therefore it can function as an antagonist (blocker), preventing agonists with lower receptor affinity from activating the receptor (i.e., can block the effects of heroin as a therapeutic mechanism). Buprenorphine can also act as a functional antagonist if given to individuals who are physically dependent, with agonists occupying receptor sites. In such a situation, buprenorphine will abruptly displace the agonist from the receptor, but since it will have only a partial effect at the receptor, it will cause a sudden drop in the level of agonist effect (decreased receptor activation), resulting in a precipitated withdrawal. Buprenorphine is used to assist detoxification and as a maintenance agent.

Opioid antagonists (e.g., naloxone, nalmefene, and naltrexone) bind to the receptor but do not exert any activity. These medications function as antagonists—they compete for binding at the receptor with agonists and partial agonists, thereby preventing the agonist from binding to the receptor and exerting any effect (receptor blocking effect as a therapeutic mechanism). In an individual physically dependent on opioids, antagonists given in sufficient doses will displace the remaining agonist from the receptor, suddenly decreasing receptor activation, which leads to precipitation of opioid withdrawal. Naloxone is used in the treatment of overdose; it can rapidly reverse opioid receptor activation, such as following a large dose of heroin or fentanyl. However, higher doses of naloxone can precipitate opioid withdrawal. Naltrexone is a long-acting agent used following detoxification as a strategy to prevent relapse and re-establishment of physiologic dependence.

The last group of medications used in the treatment of OUD includes medications that target various signs and symptoms emerging during acute and protracted opioid withdrawal (e.g., clonidine, lofexidine).

Treatment of Opioid Overdose

Telegram: @medical_k

www.konkur.in

Opioid overdose or overdose on mixed opioid–sedatives generally presents with unconsciousness and respiratory depression and constitutes a medical emergency. As most overdoses that come to medical attention are nonlethal, immediate treatment is essential to minimize the impact of anoxia and prevent irreversible injury to the CNS and other organs. Immediate interventions include airway protection and support of breathing in case of very low respiratory rate and use of supplemental oxygen attached to a bag-valve mask. Naloxone, an opioid antagonist, should be administered parenterally as soon as possible to reverse opioid overdose, preferably via the IV or the IM route.

Naloxone is given at the dose of 0.2 to 0.4 mg to a patient in a coma to aid in the maintenance of respiration. Higher initial doses (1 to 2 mg) should be given to patients with apnea or in cardiorespiratory arrest. Naloxone has a relatively short half-life (60 to 90 minutes) and must be repeatedly administered or given as an IV infusion in patients who have overdosed on an opioid with a longer half-life (e.g., XR oxycodone); otherwise, the patient can fall back into a coma after the effect of naloxone wears off. To minimize the risk of precipitated withdrawal, naloxone should be titrated gradually, and its fast elimination allows very accurate dosing without the risk of an unnecessarily prolonged effect.

Naloxone can also be administered subcutaneously or intramuscularly if it is difficult to establish IV access. IN administration can also be used as it is a popular form of naloxone available in take-home programs, acceptable to lay-people responders, but the IN dose has a slightly slower onset of action, and the dose might need to be higher to provide response comparable to the IM doses. Signs of improvement—increase in respiratory rate and pupillary dilation—should occur within 2 to 3 minutes following IV administration. If no response is seen during this time, higher (1 to 2 mg) repeated doses should be given at 2- to 3-minute intervals while ventilation and oxygenation are maintained. There is limited evidence suggesting that overdose following fentanyl administration may require higher doses of naloxone administered much sooner to successfully reverse overdose as compared to heroin overdose.

The primary goal of naloxone administration is to restore adequate ventilation (above 10 respirations/minute) and oxygenation (above 92%) rather than full alertness. Administering higher doses of naloxone can precipitate opioid withdrawal and may cause difficulties with controlling agitation. An acute lung injury (with hypoxia, rales, and mouth frothing)

Telegram: @medical_k

www.konkur.in

can be seen in rapid overdose reversals in patients with marked hypoventilation. If there is no improvement after 10 mg of naloxone is given, alternative diagnoses must be considered. Most overdoses include other sedatives such as alcohol and benzodiazepines, and therefore strategies aimed at managing toxicity from other substances should also be considered if the response to naloxone is insufficient.

The most important strategy to reduce frequency of overdoes is the medication-based treatment of OUD. Most individuals who overdose on heroin are not in treatment at the time of overdose. Those who enter treatment significantly reduce the use of opioids and other CNS depressants and have a significantly lower risk of overdose.

Treatment of Opioid Withdrawal (Detoxification)

Opioid withdrawal is usually treated in the setting of detoxification, which continues to be a major medical treatment modality used in working with opioid-dependent individuals. The primary goals of detoxification are (1) to provide safe removal of the opioid and the physiologic dependence from the organism and prevent life-threatening complications that might happen if opioid withdrawal is left untreated, (2) to address and stabilize the patient's physical and psychological health, and (3) to provide psychoeducation about long-term treatment approaches and offer a pathway to access and initiate such treatment.

It is important to note that detoxification by itself is never a sufficient treatment modality. Detoxification that is not followed by a relapse-prevention treatment has a very high rate of early relapse, as much as 90%, and the risk of opioid overdose is much greater in individuals who were detoxified as the detoxification also removes the physiologic tolerance to opioids which protects against overdose. Therefore, "detoxification" has no clinical utility in the absence of a plan for medication-based maintenance treatment and has no evidence for improving outcomes unless serving as a bridge to long-term treatment with medications. Detoxification is necessary before starting relapse-prevention treatment with the opioid antagonist naltrexone, but it is not needed before starting maintenance treatment with the opioid agonist methadone and is needed only partially before starting maintenance treatment with buprenorphine (transition from full to partial opioid receptor activation).

Telegram: @medical_k

www.konkur.in

Improved detoxification methods have evolved over the past 150 years, reflecting a more humanitarian view of addicted individuals and a better understanding of addiction as a medical disorder. Medication-assisted detoxification usually occurs under medical supervision in an inpatient or outpatient treatment setting. The inpatient setting is reserved for patients with a history of severe or complicated withdrawal, those expected to have severe withdrawal based on the baseline pattern of substance use (e.g., patients with mixed opioid and sedative–hypnotic withdrawal), and those presenting with co-existing medical and psychiatric problems that will require close monitoring and stabilization. For many individuals, inpatient detoxification may not be a realistic option because of occupational or domestic responsibilities and lack of adequate medical insurance to pay for intensive hospital treatment, whereas outpatient detoxification and relapse prevention treatment initiation allow more individuals to benefit from treatment.

FIGURE 11.9–8. Trajectory of opioid withdrawal symptom severity under different treatment strategies. Patients who are untreated (*orange*) initially experience prolonged and intense withdrawal symptoms. Symptomatic treatment can improve these early withdrawal symptoms. Agonist-assisted treatment can significantly attenuate early withdrawal symptoms but may induce a prolonged state of mild withdrawal after several weeks. Antagonist-assisted withdrawal with symptomatic treatment will shorten the duration of withdrawal though the initial withdrawal severity may be greater. (See eBook for color images.)

Telegram: @medical_k

www.konkur.in

Three main detoxification strategies are currently in clinical use: (1) symptomatic treatment only with nonopioid medication, (2) agonist-assisted detoxification, and (3) antagonist-assisted detoxification with symptomatic treatment. Each of these regimens is expected to produce a different dynamic of the onset, severity, and duration of withdrawal symptoms (Fig. 11.9–8). The main difference is that in agonist-assisted detoxification, withdrawal symptoms tend to be more severe toward the later phase of treatment when the agonist is tapered off and may continue after treatment completion, while in symptomatic treatment only and antagonist-assisted detoxification, withdrawal symptoms are more severe early in treatment and are usually minimal later in treatment.

Symptomatic Treatment of Opioid Withdrawal. Opioid withdrawal is characterized by a wide range of signs and symptoms affecting multiple organ systems. The severity of withdrawal can be significantly alleviated with medications directed at each component of withdrawal. This so-called "symptomatic treatment" or treatment with ancillary (adjunctive) medications is frequently utilized, particularly in situations where opioids are not used in detoxification because of legal restrictions or concerns about medication diversion. Ancillary medications are also a mainstay of treatment during antagonist-assisted detoxification and can also be used during agonist-assisted detoxification to alleviate residual withdrawal symptoms after the agonist is tapered off. Similarly, symptomatic treatment can be offered to individuals attempting initiation of treatment with buprenorphine to help with withdrawal emerging during the initial agonist-washout period.

The following classes of medications are used to target specific syndromes emerging during opioid withdrawal:

1. Autonomic (sympathetic) arousal can be decreased using α-2 adrenergic agonists. Clonidine is the most widely used symptomatic-treatment medication, effective in relieving a wide range of autonomic withdrawal symptoms (sweating, restlessness, tremor, rhinorrhea). Sedation is a particularly welcomed effect of clonidine; however, other aspects of withdrawal (such as muscle/bone pain and insomnia) are not helped by clonidine. Clonidine is given orally, starting at doses of 0.1 to 0.3 mg three to four times a day or given as a 0.1 to 0.2 mg/day patch. In outpatient settings, doses tend to be lower due to the potential for postural hypotension that is more difficult to monitor.

Telegram: @medical_k

www.konkur.in

Hypotensive risks of clonidine are most pertinent in the situation of fluid loss (vomiting/diarrhea). Maintaining aggressive oral hydration with electrolyte fluids, best used as a preventive intervention, is helpful in increasing the tolerability of clonidine. Lofexidine is another FDA-approved adrenergic agent with an effectiveness profile similar to clonidine, with a risk of hypotension that appears to be lower compared to clonidine.

2. Anxiety and restlessness are particularly troublesome aspects of opioid withdrawal and often the reason why some patients prematurely withdraw from treatment. Clonidine may only partially help with anxiety, and therefore anxiolytic/sedating agents that work through a different mechanism may be very helpful, especially when given in combination with clonidine. Benzodiazepines are the most commonly used anxiolytics because they have a wide margin of safety and are available as several agents with varying duration of action, allowing great flexibility in use. Clonazepam (0.5 to 1.0 mg), chlordiazepoxide (25 to 50 mg), or oxazepam (15 to 30 mg) can be given two to four times per day to prevent and alleviate anxiety/agitation. Benzodiazepines are especially suited for use in the inpatient setting as there is concern about the potential for benzodiazepines to be misused or unsafe (if taken in combination with an opioid or alcohol) during outpatient detoxification. Other classes of sedative agents that can be used include antihistamines such as diphenhydramine or hydroxyzine.
3. Insomnia, which at times can be severe, is seen in most patients undergoing opioid withdrawal, and targeting insomnia can greatly improve the tolerability of detoxification though rarely can it be completely treated. Specific hypnotic agents used include zolpidem (5 to 10 mg) or zopiclone (7.5 to 15 mg), but sedating antidepressants (e.g., trazodone 50 to 150 mg) or atypical neuroleptics (e.g., quetiapine 50 to 200 mg) can also be used.
4. Other symptoms of withdrawal can also be treated symptomatically. Musculoskeletal pain can be alleviated using nonsteroidal anti-inflammatory drugs (ibuprofen or ketorolac) or antispasmodic agents (cyclobenzaprine or methocarbamol). GI distress responds well to antiemetic agents (prochlorperazine, ondansetron), and diarrhea can be treated with loperamide, or octreotide in severe cases.

Agonist-Assisted Detoxification. Two agonist medications are approved in the United States for use in the treatment of opioid

Telegram: @medical_k

www.konkur.in

withdrawal: methadone and buprenorphine. Both methadone and buprenorphine are effective in treating signs and symptoms of opioid withdrawal and have a long elimination half-life that makes them good candidates for detoxification. Agonist-assisted detoxification involves the substitution of the short-acting agonist at the receptor site (usually heroin or oxycodone) with a long-acting agonist, followed by a gradual reduction in the dose of the agonist to minimize the severity of associated withdrawal. The severity of associated withdrawal is directly proportional to the rapidity of dose reduction; however, it tends to be relatively greater in the final stages of agonist discontinuation, especially during methadone taper (necessitating extended taper), and persists after the last dose is given.

Methadone is a full opioid agonist and can be given immediately after the cessation of opioids to preclude withdrawal. However, buprenorphine is a partial opioid agonist, and it will precipitate withdrawal if given to a physically dependent patient who does not show signs of withdrawal; thus, a waiting period to allow for the spontaneous withdrawal to emerge is necessary before the first buprenorphine dose can be given. Therefore, it may be more difficult for patients to initiate detoxification with buprenorphine as compared to methadone. On the other hand, the use of buprenorphine has fewer restrictions, a better safety profile, and a lower severity of terminal withdrawal after administration of the final dose, making it a more appropriate agent in most treatment settings.

METHADONE. For patients who have been using heroin or illicit prescription opioids, the initial dosage of methadone is usually up to 30 mg orally. If objective signs of withdrawal persist after the first dose of methadone, additional doses can be given after approximately 2 to 4 hours. As a general rule, initial stabilization does not require more than 40 mg of methadone during the first 24 hours, but it can be higher in the inpatient setting if clear signs of moderate or severe withdrawal are present after the initial 6 to 10 hours of the observation period. For example, individuals with easy access to large doses of high-potency opioids, such as health care providers, may require higher initial doses. After 24 to 48 hours of dose stabilization, the patient's methadone dose can be gradually reduced by 10% to 20% or by 5 mg per day. Inpatient detoxification with methadone is usually completed within 1 week.

Telegram: @medical_k

www.konkur.in

In case of detoxification in an outpatient setting, the first-day dose should not exceed 40 mg. Over the next few days, the dose may be raised (generally by no more than 10-mg increments every 2 to 3 days) until the patient has no discernible withdrawal symptoms. In most cases, the dose of 40 to 60 mg per day is sufficient to prevent any opioid withdrawal; however, this dose may not be adequate to eliminate craving. In case of continuing opioid use, the dose of methadone needs to be increased further, and the attempt at detoxification needs to be postponed with the goal changed to stabilization (no withdrawal symptoms, craving, or opioid use). In general, a period of dose stabilization, at minimum 4 weeks in duration, is necessary prior to a slow dose reduction schedule. Studies of outpatient methadone withdrawal show that gradual dose reductions (e.g., 3% per week) have a greater likelihood of success versus more rapid dose reductions (e.g., 10% per week). Dose reductions are generally well tolerated, but as the dose is reduced to below 20 to 30 mg per day, there is often increasing withdrawal distress with each dose change and increased risk of illicit opioid use. Another factor that interferes with the final discontinuation is the negative expectancy effect, where the patient expects an increase in withdrawal symptoms as the medication is stopped and experiences significant distress. Conducting single-blind detoxification, where the patient agrees to be blinded to the actual dose and rate of taper, can improve tolerability and success. Outpatient detoxification using an opioid agonist can usually be accomplished in 1 to 2 months, but slower reductions, with periods of stable dose before subsequent dose tapers, can be more effective in patients who have difficulty tolerating the process.

BUPRENORPHINE. While methadone has been safely and effectively used for detoxification for almost 50 years, buprenorphine has become an alternative option following FDA approval of sublingual buprenorphine products indicated for the treatment of opioid withdrawal. The sublingual buprenorphine is marketed in two formulations: a *monotherapy product* containing buprenorphine alone and a *combination therapy product* that contains buprenorphine and naloxone. The monotherapy product is usually used during buprenorphine-assisted detoxification, though a combination product can also be used.

Detoxification using buprenorphine can be safely accomplished in the inpatient setting under direct monitoring. The first dose of buprenorphine

Telegram: @medical_k

www.konkur.in

should be given after a period of agonist washout when the patient experiences at least moderate severity of withdrawal. It may take 12 to 24 hours, or even longer, for the withdrawal syndrome to emerge, and it is preferred that objective signs are present (yawning, rhinorrhea, mydriasis, chills). Some patients are unable to tolerate the initial agonist washout and may benefit from medications providing symptomatic relief (e.g., clonidine, hypnotics) or transition to treatment with methadone.

The first dose of buprenorphine typically given is 1 to 2 mg to minimize the risk of worsening withdrawal, though it may be greater (4 mg) in case of severe withdrawal. Subsequent 2 mg doses are given every 2 to 4 hours until most withdrawal symptoms are eliminated. Usually, the total dose needed to effectively suppress withdrawal on the first day is 8 to 10 mg. Buprenorphine taper is usually started on the second day, with the daily dose decreased by 2 mg every day, followed by 1 mg decreases during the last 2 days of taper. The complete taper can usually be accomplished in 5 to 7 days, and the long elimination half-life of buprenorphine (31 to 35 hours) is very useful in extending and gradually reducing the medication effect after it is discontinued.

Buprenorphine-assisted detoxification can also be accomplished in the outpatient setting, and the strategy is generally similar to methadone-assisted detoxification. Ideally, the first day's dosing should occur under medical supervision to minimize the risk of buprenorphine-precipitated withdrawal. Patients are instructed to arrive in withdrawal, which typically starts 12 hours after the last dose of a short-acting opioid or 24 hours or more after a long-acting opioid like methadone. The first dose of buprenorphine is usually 1 to 2 mg, and if no precipitated withdrawal is observed, subsequent 2-mg doses are given at the clinic every 2 hours, with additional doses given to take at home until the withdrawal symptoms are eliminated. If withdrawal worsens after the first buprenorphine dose, it is best to wait for 4 to 6 hours before giving the next buprenorphine dose, while the precipitated withdrawal can be treated symptomatically with medications such as clonidine. The total daily dose needed on the first day is usually 8 to 12 mg. Subsequent daily dose increases of 2 to 4 mg are recommended if needed to relieve opioid withdrawal and craving and initiate opioid abstinence. Once a period of stabilization is established, slow dose reductions can begin, usually in 2-mg dose increments. Because of the prolonged elimination half-life of buprenorphine, dose reductions are best introduced at weekly intervals, as the patient may not

Telegram: @medical_k

www.konkur.in

experience the effect of dose reduction until several days later. As is the case with methadone, slower dosage reduction schedules are usually better tolerated and less likely to prompt relapse. There appear to be less severe withdrawal symptoms after completion of buprenorphine taper versus methadone taper, and buprenorphine-assisted detoxification becomes a more widely used intervention, especially since the use of buprenorphine for that purpose does not require a special license that is needed for methadone.

Antagonist-Assisted Detoxification. Although agonist taper and symptomatic treatment can effectively minimize the distress of detoxification, these strategies do not shorten and may extend the duration of detoxification to 7 to 10 days, and many individuals drop out of treatment before completion. Several methods have been developed to shorten the duration of detoxification and to use it as a starting point for antagonist-based treatment to prevent postdetoxification relapse, the procedure known as “naltrexone induction.” To accomplish it, opioid antagonist such as naltrexone is introduced during detoxification, and the emerging withdrawal symptoms are treated symptomatically (e.g., clonidine and clonazepam combination). To minimize the severity of naltrexone-precipitated withdrawal, naltrexone is introduced 2 to 3 days after the last dose of opioid agonist in low-dosage (e.g., 1 to 3 mg) and quickly titrated upward over the ensuing 2 to 4 days up to the full blocking dose of naltrexone (25 to 50 mg oral tablet or an injection of XR preparation). As a variant to this procedure, 1 day of buprenorphine (4 to 8 mg) can be used as a step-down from a full agonist before the initiation of naltrexone.

Precipitated withdrawal can be quite severe if the initial dose of naltrexone is large and given too early (before completing detoxification), and it could be dangerous due to severe fluid loss, hypotension, or delirium. Therefore, early naltrexone initiation requires close monitoring, preferably on an inpatient basis, and is best used in patients without medical problems that may worsen during withdrawal (e.g., asthma, diabetes, heart disease).

Detoxification under heavy sedation or general anesthesia, so-called ultrarapid procedures, has been advocated in an effort to initiate naltrexone immediately after cessation of opioids and to shorten the duration of the procedure (resolution of physiologic dependence) to 1 to 2

Telegram: @medical_k

www.konkur.in

days. While these methods may increase the likelihood of successful induction onto naltrexone compared to more gradual and longer procedures, these methods require a highly experienced anesthesiology team and are expensive. Moreover, these methods can produce life-threatening, though rare, adverse events, including aspiration pneumonia, pulmonary edema, renal failure, and ketoacidosis, complications that are never seen in the course of traditional detoxification methods. Therefore, ultrarapid methods should not be suggested as an alternative to other methods of detoxification; however, in highly selected cases, there might be a benefit to using these methods to initiate relapse-prevention treatment with long-acting opioid antagonists.

Relapse After Detoxification. Extensive evidence shows that detoxification—resolution of opioid withdrawal after the cessation of opioid use—is by itself not adequate to treat OUD. In the absence of relapse-prevention treatment, most patients will relapse within the first few months, and such relapse can be very dangerous, as detoxified individuals do not have physiologic tolerance to protect them from acute opioid toxicity. Therefore, detoxification can only be seen as the first step of engagement in treatment, while the primary treatment goal is the prevention of relapse to illicit opioid use.

Relapse-prevention treatment strategies that can be implemented after the cessation of opioid use generally include a combination of pharmacologic treatment with antagonist or agonist agents and psychosocial interventions. The outcomes of treatment that includes only psychosocial approaches, even if delivered in a high-quality and optimized manner, are inferior to treatments that include pharmacologic support. The exception might be a long-term residential treatment (e.g., therapeutic community) where individuals have no ready access to opioids while undergoing intensive treatment and rehabilitation and are monitored for protracted withdrawal symptoms (e.g., insomnia, low energy, anxiety, and drug craving), emerging during early abstinence. Nevertheless, the strongest evidence points to the benefits of added pharmacologic support to minimize the risk of relapse during the initial abstinence from opioids.

Treatment of Opioid Use Disorder

The ultimate goals of treatment vary not only for patients but also for providers. There are several perspectives as to what constitutes the

Telegram: @medical_k

www.konkur.in

primary goal of treatment for OUD, ranging from sustained, life-long abstinence from all psychoactive substances to the minimization of harm to the individual that continues using opioids. For the medical community, treatment goals usually include protection against overdose and death, as well as the reduction in symptoms of the disorder, more specifically, cessation of illicit opioid use and the elimination of craving and withdrawal with resulting improvement in physical and psychological health. Often, complete abstinence early in treatment is an unattainable goal, and more realistic immediate goals are treatment engagement, reduction of use amount or frequency, and the elimination of particularly risky drug-use practices. For others, the primary goal of treatment is the achievement of recovery, often defined as living in abstinence from all psychoactive substances, including psychoactive medications, supported by changes in many aspects of life (social, recreational, and vocational). Unfortunately, sometimes the goal of recovery is seen as incompatible with the use of medications, particularly opioid agonists. However, these two approaches do not have to be exclusionary and can be complementary on a time continuum, with more immediate medical goals as a first step leading to long-term lifestyle changes.

Psychosocial Interventions. A broad range of psychosocial interventions has been used and evaluated as treatment strategies for opioid dependence. Psychological interventions commonly include unstructured, supportive psychotherapy and drug counseling but may also include various psychological techniques such as cognitive behavioral therapy (CBT) or contingency management (CM). Social interventions include assistance with daily needs (food, clothing, housing), employment counseling, assistance with access to health care, and engagement in social support networks.

CBT is a particularly valuable approach to the treatment of OUD with strong evidence for its effectiveness. CBT is a structured and goal-oriented approach based on the assumption that drug taking is a learned behavior. During treatment, patients are introduced to and practice (learn) new skills and cognitive strategies to replace the dysfunctional behaviors and cognitions and, through these changes, support abstinence. Clinical trials evaluating psychosocial interventions have shown that regular counseling reduces illicit drug use, and the quality of counseling and rapport between patient and counselor significantly impact outcome

Telegram: @medical_k

www.konkur.in

measures. In patients with higher levels of psychiatric symptoms like depression, CBT or supportive psychotherapy produced superior results compared to drug counseling alone. CBT can also be effective in reducing HIV risk behaviors associated with IV drug use.

A CM approach is often used as a part of treatment that focuses on promoting new behaviors that are competing with drug use. CM involves giving patients tangible rewards to reinforce positive behaviors such as abstinence, treatment attendance, and compliance with medication. Monitored urine collection and testing with immediate consequences are necessary for CM effectiveness. Patients do not receive cash payments for abstinence, but rather they receive vouchers to purchase goods and services consistent with their treatment goals. Toxicology also provides an objective index of treatment progress, and test results can be discussed in therapy sessions in order to promote better understanding of situations that lead to continued drug use. Both CBT and CM can work in synergy with medication treatment as these can be focused on medication adherence.

NA is a self-help group of abstinent drug abusers modeled on the 12-step principles of AA. This approach emphasizes two strategies to maintain abstinence: spirituality (faith and hope for recovery) and pragmatism (belief in doing “whatever works” to avoid using drugs again). Such groups now exist in most large cities and online, providing useful group support. Although the evidence supporting the usefulness of such groups has been very limited, observational studies show their effectiveness, and therefore, patients receiving medications should be encouraged to participate in the self-help groups. Because 12-step groups emphasize abstinence from all psychoactive substances, patients treated with opioid agonists may find themselves being ostracized in traditional NA groups. Alternative approaches were developed for patients on agonist medications, including Methadone Anonymous (MA), a variant of a 12-step program specifically for patients treated with methadone. Additional approaches, such as family and network therapy, can improve compliance with medication and can enhance outcomes in opioid addiction treatment.

Pharmacologic Interventions. In the United States, four medications are currently approved by the U.S. FDA for the treatment of OUD (MOUD); methadone (used since the mid-1960s and approved in 1972),

Telegram: @medical_k

www.konkur.in

oral naltrexone (used since the 1970s and approved in 1984), buprenorphine (approved in 2002), injectable, long-acting naltrexone (approved in 2010), and several newer XR buprenorphine formulations (2017/2021). LAAM (levacetylmethadol), a long-acting agent similar to methadone that was in use since its approval in 1993 but was discontinued in Europe and the United States in the early 2000s due to limited uptake (in the United States), and cardiac toxicity concerns (in Europe) (Table 11.9–6).

Several large, multisite, pragmatic randomized clinical trials have now been completed by the National Drug Treatment Clinical Trials Network (NIDA-CTN), consistently demonstrating the effectiveness and treatment response characteristics of pharmacologic interventions. Patients assigned to buprenorphine and methadone had a comparable rate of treatment success (avoiding relapse) in an outpatient setting, between 10% and 30% at 12 weeks. Patients who presented with prescription OUD rather than heroin use disorder also substantially benefitted from buprenorphine maintenance treatment, compared with a detoxification and taper program. Patients assigned to treatment with daily buprenorphine versus monthly XR-naltrexone have shown higher rates of inpatient induction onto buprenorphine. However, patients discharged to outpatient care on buprenorphine or XR-naltrexone had comparable rates of success (avoiding relapse), between 44% and 48%, at 24 weeks.

METHADONE. In the United States, there are over 400,000 patients in outpatient treatment programs receiving methadone (as of 2021). The original approach pioneered in the 1960s emphasized using methadone dosage sufficient to suppress opioid drug craving and producing a cross-tolerance blockade of other opioids. Doses of methadone were in the 80 to 120 mg per day range, and patients were encouraged to remain on methadone indefinitely, working toward recovery. Subsequent treatment programs used lower doses of methadone (less than 50 mg per day) with fewer ancillary services as the methadone maintenance treatment in support of recovery was seen not as a goal in itself but rather a transitional stage before the eventual detoxification. Lower doses of methadone were often adequate for eliminating withdrawal and retaining patients in treatment, but often these doses only partially suppressed craving and drug-seeking behavior and did not produce adequate cross-tolerance to block large doses of heroin. Empirically, patients maintained

Telegram: @medical_k

www.konkur.in

on lower doses of methadone are far more likely to discontinue treatment, and those who do so are unlikely to maintain abstinence from illicit opioids.

Table 11.9–6.
Medications for Opioid Use Disorder (MOUD)

Medication	Class	Route of Administration	Dosing and Formulations	Side Effects and Monitoring
Methadone	Full agonist	Oral	Start 20–30 mg Increase by 10 mg per day	Sedation Constipation Sexual side effects Increased QT interval Monitor liver enzymes
Buprenorphine/ naloxone	Partial agonist	Sublingual	Start 12 mg/3 mg, increase by 2 mg daily to max of 24 mg	Sedation Constipation Urinary retention Sexual side effects Monitor liver enzymes
Buprenorphine	Partial agonist	Sublingual	Start 12 mg, increase by 2 mg daily to max of 24 mg	Similar to buprenorphine/naloxone
Extended-release naltrexone	Full antagonist	Intramuscular (IM) injection	380 mg IM every 4 weeks	Opioid withdrawal symptoms: insomnia, anxiety, sweats, appetite changes Monitor liver enzymes
Extended-release buprenorphine	Partial agonist	Subcutaneous injection	Start at 300 mg every 4 weeks for 2 months, then 100 mg every 4 weeks	Sedation Constipation Sexual side effects Monitor liver enzymes

Meta-analytical studies show methadone's clear superiority over treatments without medication with regard to improving treatment retention and reducing heroin use. The majority of patients treated in methadone programs also show decreased nonopioid drug use, criminal behavior, symptoms of depression, and increased gainful employment. The effectiveness of opioid maintenance treatment is influenced by the dose and the quality of the additional services provided. The optimal dose is generally in the 80 to 120 mg/day range, with some patients requiring higher doses to achieve an optimal clinical response. Effective individual drug counseling can significantly augment treatment outcomes in terms of decreasing illicit opioid and cocaine use, decreasing needle sharing and crime, and increasing psychological well-being.

Among patients who initiate methadone maintenance, there is an increase in mortality due to respiratory depression (due to ongoing illicit opioid use); however, after that time, there is a reduction in mortality that remains as long as the patient is maintained on the medication. The risk of overdose is again increased after patients stop taking methadone. Methadone is relatively safe as a long-term maintenance agent. The main safety concern is the risk of excessive sedation with a rapid dose

Telegram: @medical_k

www.konkur.in

escalation and where other sedating agents, prescribed or illicit, are used in combination with methadone.

Among the most common side effects with methadone are constipation, excessive sweating, decreased libido, and sexual dysfunction. Opioids can reduce plasma levels of testosterone and follicle-stimulating hormone (FSH). Sleep abnormalities (insomnia and nightmares) and altered electroencephalogram (EEG) sleep patterns are frequently found during the first months of methadone treatment and return to baseline, but complaints of sleep abnormalities may persist.

Clinicians should be aware that a variety of medications could cause a change in plasma levels of methadone by inducing or inhibiting hepatic enzymes that metabolize methadone (CYP3A4). For example, adding rifampin, phenytoin, carbamazepine, darunavir, or efavirenz to the methadone regimen may cause a decrease in methadone levels with resulting opioid withdrawal, while adding fluconazole/ketoconazole, fluvoxamine, erythromycin, or delavirdine may produce an increase in methadone levels, causing excessive sedation. Methadone appears to increase the QTc interval in some patients, an effect that can increase the risk of a cardiac conduction abnormality (torsade de pointes). This effect is dose related and is more commonly seen with very high doses of methadone. However, other risk factors for QTc prolongation may increase the risk for cardiac complications in patients treated with methadone, including coadministration with other medications increasing QT interval, such as amifampridine, metronidazole, thioridazine, or ziprasidone.

In the United States, methadone can be dispensed only at an outpatient opioid treatment program (OTP) certified by the Substance Abuse and Mental Health Services Administration (SAMHSA) and registered with the Drug Enforcement Administration (DEA) or to a hospitalized patient who is admitted for a medical or psychiatric reason other than to treat OUD. SAMHSA-certified OTP facilities provide daily doses of methadone under direct supervision until the patient is deemed stable enough to receive take-home doses. The decision to dispense methadone from the OTP, and to be taken unsupervised at home, should balance the benefits of reduced frequency of clinic visits in stable patients with the risks of misuse (e.g., injection) and diversion of methadone to the illicit drug market.

www.konkur.in

BUPRENORPHINE. Buprenorphine is a high-affinity partial μ-opioid receptor agonist, κ-receptor antagonist, and ORL-1 agonist. At lower doses of up to 16 mg, buprenorphine has a dose-dependent opiate-like effect, but at higher doses, there is progressively less increase in opiate-like effects up to a point where a maximum effect is reached. This ceiling to the μ-opioid agonist effects of buprenorphine limits adverse effects such as respiratory depression, which improves its safety profile. Buprenorphine has poor oral bioavailability, and therefore it is usually administered transmucosally (sublingually as a tablet or film and as a buccal film). To decrease the potential for misuse of buprenorphine as an outpatient maintenance agent, pharmaceutical formulations contain buprenorphine mixed with naloxone in a four-to-one dose ratio. Because naloxone has poor sublingual bioavailability, it exerts minimal effect when a medication is taken sublingually as prescribed. However, if a buprenorphine–naloxone product is dissolved and injected by a person physically dependent on opioids such as heroin, naloxone exerts a maximal effect, blocking some of the effects of buprenorphine and, in certain cases, precipitating withdrawal.

Buprenorphine is highly lipid soluble and has a long elimination half-life (24 to 48 hours), allowing for once-daily dosing and even less frequent dosing with higher doses. Agonist effects of buprenorphine prevent withdrawal symptoms from emerging. Because buprenorphine has a higher receptor affinity than most other opioids, it effectively blocks the effects of agonists by a direct occupation of the receptor sites (unlike methadone, which produces a blocking effect primarily via the mechanism of cross-tolerance, i.e., maintaining high levels of tolerance). Buprenorphine has been shown to be effective in the treatment of opioid dependence in an office-based setting, and buprenorphine 12 mg is equally effective in promoting treatment retention and suppression of heroin use as 50 to 60 mg of methadone. There is preliminary evidence that buprenorphine doses above 16 mg per day may be more effective than lower doses.

To avoid precipitation of opioid withdrawal during initiation of buprenorphine, patients should present with at least mild severity withdrawal symptoms with gradual buprenorphine dose titration during the first day, similarly to the protocol used for buprenorphine-assisted detoxification (see above). Unlike methadone, there is little concern about overdose during treatment initiation with buprenorphine. However,

Telegram: @medical_k

www.konkur.in

combining buprenorphine with benzodiazepines or other sedative–hypnotics can produce excessive sedation, and there are case reports of fatalities associated with parenteral misuse of buprenorphine along with a benzodiazepine. Common side effects of buprenorphine include constipation, nausea, headache, upset stomach, excessive sweating, somnolence, and decreased interest in sex. Most of these side effects are mild in severity and decrease over time.

Similarly to methadone, buprenorphine is primarily metabolized by the CYP3A4, and medications that block this enzyme, such as atazanavir/ritonavir, may produce excessive sleepiness while enzyme inducers, such as rifampin, may precipitate opiate withdrawal. The clinical impact of pharmacokinetic interactions with buprenorphine is generally less significant than with methadone; however, dose adjustment may be necessary to achieve optimal clinical response and minimize risks for adverse effects. There is no evidence that buprenorphine produces significant cognitive impairment or electrocardiogram (ECG) QTc prolongation.

In the United States, treatment providers can treat OUD using buprenorphine in a manner similar to treatment with other controlled substances (unlike methadone which cannot be prescribed for that purpose, it can only be dispensed in the OTP setting). The law passed in 2000 (the Drug Addiction Treatment Act) allowed office-based opioid treatment (OBOT) of opioid dependence with schedule III, IV, or V medications that were approved for an opioid dependence indication, with buprenorphine being the only opioid meeting these criteria. In order to prescribe buprenorphine, physicians must apply for permission (known as an X-waiver) granted by the DEA. As of 2021, waivered physicians are qualified to treat up to 30 patients in the first year of their waiver. Providers who wish to treat a larger number of patients need to complete a training course and attest to the provision of psychosocial treatment, after which they can request permission to increase the patient cap to 100, and even up to 275, provided they meet additional criteria. Buprenorphine can also be dispensed in a manner similar to methadone in the OTP without the DEA waiver or restriction on the number of patients treated by a prescribing physician.

Several formularies of XR buprenorphine have been approved by the U.S. FDA. In 2016, FDA approved a polymeric rod implant of buprenorphine that slowly releases low doses of buprenorphine over the

Telegram: @medical_k

www.konkur.in

course of 6 months before needing replacement. However, the product was discontinued due to difficulties in commercialization as the product was indicated for stable patients treated with low-dose buprenorphine, implant insertion and removal required a small in-office incisional procedure, which was burdensome, and the storage and management of controlled substance were also difficult for many providers. In 2017, the FDA approved a once-monthly subcutaneous injection formulation of buprenorphine, which achieves a constant, therapeutic blood concentration of buprenorphine.

Buprenorphine sustained release injection (Sublocade) is usually initiated after the patient is stabilized on the daily doses of sublingual buprenorphine preparation. The initial 300-mg dose of SC buprenorphine is followed by another 300-mg dose given a month later. After that maintenance dose of 100 mg is administered monthly with the buprenorphine blood level produced by this regimen roughly corresponding to 24 mg of daily sublingual buprenorphine (approximately 3 ng/mL). The maintenance can continue with monthly doses of 300 mg, which produces higher blood levels and appears to be more beneficial for patients who inject opioids.

NALTREXONE. The use of opioid antagonists to treat opioid dependence is based on the idea that after detoxification, relapse can be prevented using an opioid receptor antagonist, which directly blocks heroin from exerting euphoric effects. Individuals who resume opioid use while maintained on the antagonist usually stop using after a few attempts, and with continuing abstinence, drug-seeking behavior gradually stops (behavioral extinction mechanism). In addition to providing blockade of opioid effects in case of use, patients taking naltrexone experience less craving in the presence of opioid-related cues and are more likely to maintain full abstinence. The effectiveness of antagonist-based treatment is contingent on full adherence to the medication regimen.

Naltrexone is a high-affinity and long-acting μ-opioid receptor antagonist that provides a dose-dependent blockade of heroin and synthetic opioids effects. Naltrexone may be an attractive treatment option to some patients, as in contrast to methadone or buprenorphine, it is not a controlled substance, so it can be prescribed without a special license, it has no misuse or diversion potential, and there is no withdrawal distress

Telegram: @medical_k

www.konkur.in

on missing the dose or stopping treatment as patients treated with naltrexone are not physiologically dependent on opioids.

Naltrexone can be useful in selected patients such as (1) those who had limited or no treatment success with agonists (e.g., continued to experience craving, frequently used illicit opioids, or had intolerable side effects), (2) patients with high motivation for abstinence from all opioids such as those very active in an NA 12-step program, and (3) patients who have been successful in agonist therapy and wish to discontinue it but would like to be protected against relapse with medication. However, naltrexone remains a less popular treatment option in countries where agonists are widely available due to the need to be fully detoxified before treatment can be started, poor medication adherence in many patients, and protracted withdrawal symptoms that may persist in the first few weeks of treatment with naltrexone.

Naltrexone is available as an oral 50-mg tablet that can be taken daily or three times a week (e.g., 100 mg on Mondays and Wednesdays and 150 mg on Fridays) to provide stable blood levels to block substantial doses of heroin. Naltrexone is also available in XR preparations that can maintain sufficient blocking serum levels of naltrexone. One such XR preparation available and approved by the FDA is a monthly IM injection (Vivitrol). There are also implantable preparations of naltrexone with a much longer duration of action (3 to 6 months) available in other countries; however, only one of these implants has full regulatory approval of the national drug monitoring agencies (an implant approved in Russia).

The effectiveness of treatment with injectable XR-naltrexone has more than double the success rate of treatment with oral naltrexone, and it became a first-line treatment when available. Oral treatment can still be effective in the context of involving a family member or a professional to provide ongoing support and monitoring of medication administration, which is critical at the beginning of treatment. Alternatively, adherence with oral naltrexone may be improved by incorporating a CM behavioral approach into the treatment.

Naltrexone can be readily initiated in patients who have undergone opioid withdrawal in the inpatient and residential setting for more than a week after completing the opioid taper. Initiating naltrexone maintenance is more challenging in an outpatient setting because of the need for an extended opioid-free period during which patients continue to experience mild severity opioid withdrawal. To determine that a therapeutic dose of

Telegram: @medical_k

www.konkur.in

naltrexone can be administered without precipitating withdrawal, a urine drug test negative for all opioids is necessary to confirm opioid abstinence. In addition, a test dose of an antagonist (challenge), either with naloxone (0.8 to 1.2 mg IM) or low-dose naltrexone (6 to 12.5 mg), can be administered to determine that there is no residual physiologic dependence and to confirm that the patient will not experience protracted withdrawal following the administration of the full dose (380 mg of XR-naltrexone or 50 mg oral naltrexone).

Because naltrexone is not metabolized by the P450 cytochromes, interactions with other medications are not of clinical concern. Naltrexone is contraindicated in patients taking any opioids, including partial and mixed agonists such as buprenorphine and nalbuphine, as it will precipitate severe withdrawal in such patients.

OTHER MEDICATION-BASED APPROACHES. There are a considerable number of patients who are unable to benefit from treatment with methadone, buprenorphine, or naltrexone, and alternative approaches to provide these individuals with effective treatment have been explored. This includes a maintenance treatment with slow-release oral morphine and with a medically prescribed pharmaceutical-grade heroin.

Oral morphine has been used in individuals who are unable to tolerate or do not find the effects of methadone useful as being different from the effects of heroin. In those patients, morphine can have positive effects on mood and sleep and eliminate craving for heroin in contrast to methadone. It may also minimize the use of other medications (e.g., sedatives) often seen when such patients are treated with methadone. Maintenance treatment with a once-daily slow-release preparation of morphine is available in several European countries. However, because of the short duration of action, many such patients continue to need methadone to prevent withdrawal symptoms overnight, and the use of morphine in a treatment setting is complicated by the difficulties in assessing heroin use to measure outcomes. At the present time, there is not a sufficient number of experimental studies to draw generalizable conclusions.

Prescription heroin as a treatment strategy for heroin dependence has been available in the United Kingdom since 1926, and in the past 30 years, this approach has been piloted and researched in other European countries and Canada. Heroin maintenance is usually offered as a “last

Telegram: @medical_k

www.konkur.in

resort" treatment, and there is a broad consensus that it should be offered to only a very selective group of patients with chronic illness who were offered and failed other approaches, including a high-dose methadone maintenance treatment. Recent studies focused on the effectiveness of supervised prescription injectable heroin in participants that failed treatment with methadone and where prescribed heroin was used in combination with oral methadone. In such studies, patients treated with heroin have better treatment retention and reduced use of illicit drugs as compared to patients treated with methadone, but heroin-treated patients had a greater risk for adverse events. At the present time, there is an insufficient number of experimental studies to draw conclusions about the practice of heroin treatment in the community.

Treatment of Special Populations

There is a complex relationship between the criminal justice system, patients with substance abuse disorders, and drug-dependence treatment systems. Treatment of patients involved with the criminal justice system includes efforts directed at persons who are incarcerated, and interventions are designed for persons under legal restraints but still residing in the community. Specialized interventions have been developed for this patient population. Drug courts, which now operate within each state in the United States, combine close criminal justice supervision with long-term drug abuse treatment that typically requires drug testing of parolees.

Illicit opioid use during pregnancy is associated with adverse effects for both the pregnant woman and the fetus though it is not associated with any specific teratogenic effects. There is a higher risk for infections, preeclampsia, miscarriage, premature rupture of membranes, and premature labor, as well as stillbirths, premature infants, and infants with low birth weight and neonatal opioid withdrawal (also called neonatal abstinence syndrome). Infants who survive may be infected with HIV and other diseases as a result of maternal high-risk behavior and are at risk for sudden infant death syndrome (SIDS). Most of these risks can be substantially reduced with methadone or buprenorphine maintenance treatment, with fewer data available studying the impact of treatment with naltrexone.

Health professionals often come to treatment when their drug use is discovered by colleagues or by drug enforcement agencies. Under

Telegram: @medical_k

www.konkur.in

supervision, most (as much as 85%) of these patients recover and are able to return to practice. Returning to specialties with easy access to opioids can pose a serious hazard to continued abstinence. Treatment with XR naltrexone, which is easy to supervise, may be particularly useful in those patients.

CONCLUSION

OUD is a chronic, relapsing–remitting illness that has grown to become a sustained, global public health challenge. In the past decade, it has affected every demographic and socioeconomic group and caused significant morbidity and mortality through overdose and other medical consequences. There are three approved medication treatments for OUD: methadone, buprenorphine (both oral and XR injection formulations), and XR naltrexone. All three medications have been shown to be effective for reducing relapse and medical consequences. Patients also benefit from psychotherapy that targets behavioral change and motivational enhancement. In those who are engaged with treatment, sustained recovery can be achieved.

11.10 Sedative-, Hypnotic-, or Anxiolytic-Related Disorders

JOHN J. MARIANI, M.D.

DEFINITION

This chapter will discuss the epidemiology, neurophysiology, clinical characteristics, and management of sedative-, hypnotic-, and anxiolytic-related disorders. Sedative, hypnotic, and anxiolytic medications constitute a broad group of agents that are classified by their clinical effects, with most medications in this grouping having γ-aminobutyric acid (GABA) agonist or GABAergic transmission facilitation effects. In this chapter, these medications will be collectively referred to as "sedative–hypnotics," with the understanding that within this class of medications, distinctions as to clinical effects are, to some degree, artificial. From both a public health and clinical management perspective, the benzodiazepines are the most important sedative–hypnotic agents because of their common use and wide availability, both by prescription and from nonprescription sources. Benzodiazepines and other sedative–hypnotic agents are widely prescribed because of their efficacy in the treatment of anxiety, insomnia, and other therapeutic indications. Like other prescribed controlled substances, most individuals will be able to use sedative–hypnotic agents without developing a pattern of problematic or compulsive use. However, for a minority of individuals exposed to sedative–hypnotic agents, a pattern of use meeting criteria for a substance use disorder may develop. These individuals need specialized assessment and care to avoid the potential behavioral and medical consequences of sedative–hypnotic use disorder.

Studies of sedative, hypnotic, or anxiolytic use disorders are limited by the operational definition of substance use disorders set forth in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (5th ed. Text rev.; DSM-5 TR). Sedative–hypnotic agents, and related anxiolytic medications, have the potential to induce

tolerance, and with regular use, individuals may be at risk of a discontinuation syndrome or frank withdrawal state. However, drug addiction is a sociobehavioral phenomenon, albeit with significant pharmacologic origins and medical consequences. There is a tendency to conflate the neuroadaptive changes that develop in response to chronic sedative–hypnotic administration (physiologic dependence) with the concept of a substance use disorder or addiction. Many individuals who have difficulty tapering or discontinuing prescribed sedative–hypnotic agents because of neuroadaptive changes may be considered “addicted” by themselves or clinicians but do not meet full criteria for a substance use disorder unless other symptoms are present.

The addictive potential of a substance is usually inferred from data on illicit trafficking; population surveys of nonprescription use; audits of prescribing practices; postmarketing studies; monitoring of diversion from physician’s offices, pharmacies, or manufacturing sites; emergency room treatment; and overdose deaths. Pharmacologic characteristics also predict misuse liability: Drug-induced euphoria and the development of tolerance, an abstinence syndrome, or cross-tolerance with known addictive substances may all predict the risk of misuse or addictive potential. Finally, a number of laboratory methods for determining drug preferences in human and animal models have been developed to determine misuse liability. Sedative–hypnotic medications that have general GABAergic effects tend to have the potential for misuse and addiction. In general, because of their risk of misuse and addiction, sedative–hypnotic medications are classified as controlled substances. This risk is related to, but distinct from, the tendency for GABAergic medications to induce pharmacologic tolerance and be predisposed to developing withdrawal. An individual who developed tolerance and withdrawal while prescribed a sedative–hypnotic agent in the context of legitimate medical treatment, and displayed no other symptoms, would not meet criteria for a substance use disorder.
