Arthritides are common clinical presentations (or manifestations) of several viral diseases, such as hepatitis B, hepatitis C, parvovirus B19 infection, and rubella, and occasionally accompany infection due to adenovirids, enteroviruses, herpesvirids, mumps virus, or HIV-1/HIV-2. Arthropod-borne alphaviruses are also common causes of arthritides—usually acute febrile syndromes with joint involvement often accompanied by a maculopapular rash. Rheumatic involvement includes arthralgia with or without typical inflammatory signs, including periarticular redness, swelling (less commonly, joint effusions), and immobility. Most alphavirus infections are less severe and have fewer articular manifestations in children than in adults. In temperate climates, these ailments are summer diseases. The most significant alphavirus causes of arthritides are chikungunya virus disease, Ross River disease, Barmah Forest virus infection, and Sindbis virus infection. ZIKV infections may also be associated with joint manifestations. Less significant but historically notable are viruses that caused isolated cases or epidemics. A large (>2 million cases), albeit isolated, epidemic was caused by o'nyong-nyong virus from 1959 to 1962 (o'nyong-nyong fever). Mayaro virus, Semliki Forest virus, and Una virus caused isolated cases or limited and infrequent outbreaks (30 to several hundred cases per year). Symptoms and signs of infections with these viruses often are similar to those observed with chikungunya virus disease. Two orthobunyaviruses—Gan Gan virus and Trubanaman virus—and the orthoflavivirus Kokobera virus have been associated with single cases of polyarthritic disease. Except for a vaccine to prevent chikungunya virus disease, no specific therapies or licensed vaccines exist.

Chikungunya Virus Disease Historically, chikungunya virus (CHIKV) was considered endemic in rural areas of Africa, with intermittent outbreaks occurring in towns and cities of both Africa and Asia. In 2004, a large epidemic began in the Indian Ocean region (specifically on the islands of Réunion and Mauritius) and was most likely spread by travelers. YF mosquitoes and Asian tiger mosquitoes are the major CHIKV vectors. All regions with established populations of these two vectors have now documented local mosquito-borne transmission, and the virus has now been identified across Africa, Asia, Europe, and the Americas, including in the continental United States, where suitable vector mosquitoes are present in southern states and local transmission has been documented. From December 2013 to June 2023, >3.6 million cases were reported from 50 countries or territories in the Americas.

The disease is more common in adults. After an incubation period of 2–10 days, the abrupt onset of fever (often severe, with a saddleback pattern) and severe arthralgia are accompanied by constitutional symptoms and signs, including chills, abdominal pain, anorexia, conjunctival injection, headache, nausea, and photophobia. Migratory polyarthritis mainly affects the small joints of the ankles, feet, hands, and wrists, but the larger joints may be involved. Rash may appear at the outset or several days into the illness; its development often coincides with defervescence around day 2 or 3 of clinical illness. The rash is most intense on the trunk and limbs and may desquamate. In hospitalized patients with severe acute disease, uncommon but reported manifestations include cardiorespiratory, neurologic, renal, neurologic, and ocular complications; deaths have been reported, typically in the context of large outbreaks. Young children develop less prominent symptoms and signs and are therefore less frequently hospitalized. Children also often develop a bullous rather than a maculopapular/petechial rash. Although pregnant women are not at risk of more severe disease, there is a high risk of maternal–fetal transmission, particularly during the intrapartum period, that, in some cases, has led to fetal death. Recovery may require weeks, and a significant portion of middle-aged to older patients develop chronic arthritis or arthralgia syndromes (typically involving the same joints) that may be disabling. The risk of chronic musculoskeletal syndromes is increased in patients with preexisting osteoarthritis or severe acute disease who test positive for the human leukocyte antigen B27 subtype (HLA-B27) and may be associated with cryoglobulins. Although petechiae and epistaxis are occasionally seen, CHIKV should not be considered as a cause of VHF. Laboratory abnormalities may include transient lymphopenia and mild thrombocytopenia, as well as elevated activities of AST and concentrations of C-reactive protein (CRP). Treatment of chikungunya virus disease relies on acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs). For patients with refractory arthritis, glucocorticoids or disease-modifying antirheumatic drugs (DMARDs) may be considered. A live-attenuated vaccine to prevent chikungunya virus disease has been approved by the U.S. Food and Drug Administration (FDA) and is undergoing postmarketing evaluation. Other vaccine and therapeutic candidates in preclinical development may benefit from the designation of CHIKV as the representative pathogen for arthritic alphaviruses.

Ross River Disease and Barmah Forest Virus Infection Ross River virus (RRV) and Barmah Forest virus (BFV) cause diseases that are clinically indistinguishable (hence the previously common disease designation of "epidemic polyarthritis" for both infections). RRV has caused epidemics in Australia, Papua New Guinea, and the South Pacific since the beginning of the 20th century. In 1979 and 1980, the virus swept through the Pacific Islands, causing >500,000 infections. From 1991 to 2011, the virus caused 92,559 infections in rural and suburban areas of Australia. From 2014 to 2015, >10,000 cases were recorded in Australia. RRV is predominantly transmitted by *Aedes normanensis*, *Aedes vigilax*, and *Culex annulirostris* mosquitoes. Marsupials (e.g., kangaroos, wallabies, and koalas) and rodents are probably the main vertebrate hosts, but infection also occurs in horses and other livestock. BFV infections have been increasingly documented since the early 1990s. For instance, from 1991 to 2011, 21,815 cases were recorded in Australia, and new data indicate that the disease also occurs in Papua New Guinea. BFV is transmitted by both *Aedes* and *Culex* mosquitoes and has been isolated from biting midges. The vertebrate hosts remain to be determined, but serologic studies implicate horses and possums.

Of the human RRV and BFV infections surveyed, 55–75% were asymptomatic; however, clinical illness can be debilitating when it occurs. After a typical incubation period of 3–9 days, patients develop the sudden onset of symmetric joint pain predominantly involving the peripheral extremities. Generally, a nonitchy, diffuse, maculopapular rash (more common in BFV infection) develops coincidentally or follows shortly; but, in some patients, rash can precede joint pain by several days. Constitutional symptoms (e.g., low-grade fever, asthenia, headache, myalgia, and nausea) are not prominent or are absent in many cases. Most patients are incapacitated for considerable periods (6 months or more) by joint involvement that interferes with grasping, sleeping, and walking. Ankle, interphalangeal, knee, metacarpophalangeal, and wrist joints are most often involved, although elbows, shoulders, and toes may also be affected. Periarticular swelling and tenosynovitis are common, and one third of patients have true arthritis (more common in Ross River disease). Myalgia and nuchal stiffness may accompany joint pain. Only half of all patients with arthritis can resume normal activities within 4 weeks, and 10% continue to limit their activities after 3 months. Occasionally, patients are symptomatic for >1 year but without progressive arthropathy.

In the diagnosis of either infection, clinical laboratory values are normal or variable. Tests for rheumatoid factor and antinuclear antibodies are negative, and the erythrocyte sedimentation rate is acutely elevated. Joint fluid contains 1000–60,000 monocytes per microliter, and viral antigen can usually be detected in macrophages. Serologic demonstration of rising antibody titers is the cornerstone of diagnosis, though it should be noted that virus-specific IgM antibodies may persist for month to years. Isolation of the virus from blood after mosquito inoculation or growth of the virus in cell culture is possible early in the illness. Because of the great economic impact of annual epidemics in Australia, an inactivated RRV vaccine has been under advanced development; phase 3 trials were completed in 2015 with promising results, but the candidate vaccine has not yet been developed for the market. Analgesics or NSAIDS are used for symptomatic treatment.

Sindbis Virus Infection Sindbis virus is typically transmitted to birds primarily by infected *Culex* and *Culiseta* mosquitoes that also vector human transmission over a range that includes Africa, Asia, Europe, and Australia. Infections with northern European or southern African variants are particularly likely in rural environments. Although infections may be subclinical, rash and arthralgia typically develop after an incubation period of <1 week. Constitutional clinical signs are not marked, and fever is modest or absent. The rash, which lasts ≈1 week, begins on the trunk, spreads to the extremities, and evolves from macules to papules that often vesiculate. The arthritis is polyarticular, migratory, and incapacitating, with resolution of the acute phase in a few days. The ankles, elbows, knees, phalangeal joints, wrists, and—to a much lesser extent—proximal and axial joints are involved. Persistence of joint pain and occasionally arthritis may continue for months or even years despite lack of deformities.

ENCEPHALITIS

The major encephalitis viruses are found in the families *Flaviviridae, Peribunyaviridae, Rhabdoviridae,* and *Togaviridae*. However, individual agents of other families, including Dhori virus and Thogoto virus (*Orthomyxoviridae*) and Banna virus (*Sedoreoviridae*), have caused isolated cases of encephalitis. Arboviral encephalitides are seasonal diseases, commonly occurring in the warmer months. Their incidence varies markedly with time and place, depending on ecologic factors that determine vector activity and human exposure. The causative viruses differ substantially in terms of the ratio of clinical to subclinical infections, case-fatality rate (CFR), and postacute sequelae. Humans are not considered important amplifiers of these viruses.

All the viral encephalitides discussed in this section share a similar pathogenesis. An infected arthropod ingests blood from a human and, through this contact, initiates infection. Initial viremia, thought to originate from the lymphoid system, leads to multifocal entry into the CNS, presumably via infection of olfactory neuroepithelium and subsequent passage through the cribriform plate via infected macrophages or infection of brain capillary endothelial cells. During the viremic phase, there may be little or no recognizable disease except in tick-borne orthoflavivirus encephalitides, which have clearly delineated phases of fever and systemic illness.

CNS dysfunction or damage and associated clinical symptoms/signs arise partly from direct neuronal infection and subsequent damage and partly from edema, inflammation, and other indirect effects of the host response. The usual pathologic features of arboviral encephalitides are focal necroses of neurons, inflammatory glial nodules, and perivascular lymphoid cuffing. Involved areas display the "luxury perfusion" phenomenon, with normal or increased total blood flow and low oxygen extraction. The typical patient presents with a prodrome of nonspecific constitutional symptoms and signs, including fever, abdominal pain, sore throat, and respiratory signs. Headache, meningeal signs, photophobia, and vomiting quickly follow. The severity of human infection widely varies from an absence of symptoms/signs to febrile headache, aseptic meningitis, and full-blown encephalitis. The proportions and severity of these manifestations vary with the infecting virus and with known (e.g., age) and mostly unknown host immunogenetic determinants. Encephalitic involvement of deeper brain structures may be signaled by lethargy, somnolence, and cognitive deficit detected by mental status examination. More severely affected patients are obviously disoriented and may become comatose. Tremors, loss of abdominal reflexes, cranial nerve palsies, hemiparesis, monoparesis, difficulty swallowing, limb-girdle syndrome, and frontal lobe signs are common. Spinal and motor neuron diseases have been documented after WNV and Japanese encephalitis virus infections. Seizures and focal signs may be evident early or may appear during the disease. Some patients present with an abrupt onset of fever, convulsions, and other signs of CNS involvement. Encephalitis usually lasts a few days to several weeks and may be fatal, or recovery may be slow (with weeks or months before the return of maximal recoverable function) or incomplete (with persisting long-term deficits). Difficulty concentrating, fatigability, tremors, and personality changes are common during recovery.

The diagnosis of arboviral encephalitides depends on careful history-taking (travel/exposures), physical examination (in particular, of a febrile patient with signs of CNS dysfunction), and virus-specific or serology-specific laboratory testing. Clinicians should (1) consider empirical acyclovir treatment for herpesvirus meningoencephalitis and antibiotic treatment for bacterial meningitis until test results are received; (2) exclude intoxination and metabolic or oncologic causes, including paraneoplastic syndromes, hyperammonemia, liver failure, and anti-*N*-methyl-D-aspartate (NMDA) receptor encephalitis; and (3) rule out a brain abscess or a cerebrovascular event. Leptospirosis, neurosyphilis, Lyme disease, cat-scratch disease, opportunistic infections in immunocompromised patients, and more recently described viral encephalitides (e.g., Nipah virus infection), among others, should be considered in the differential diagnosis if epidemiologically relevant. CSF examination usually shows a modest increase in white blood cell (WBC) counts—in the tens or hundreds or perhaps a few thousand. In early phases of disease, a significant proportion of CSF WBCs may be polymorphonuclear leukocytes (PMNs), but monocytes later predominate. CSF glucose concentrations are generally normal. There are exceptions to this pattern of findings. In eastern equine encephalitis, for example, PMNs may predominate during the first 72 h of disease, and hypoglycorrhachia may be detected. In lymphocytic choriomeningitis, lymphocyte counts may be in the thousands, and glucose concentrations may be diminished. A humoral immune response is usually detectable at or near the onset of disease. Both serum (sampled in the acute or convalescent phase) and CSF should be examined for IgM antibodies, and plaque-reduction neutralization testing and/or RT-PCR should be conducted to detect viruses. Viruses generally cannot be isolated from blood or CSF, although Japanese encephalitis virus has been recovered from CSF of patients with severe disease. RT-PCR analysis of CSF may yield positive results but cannot exclude diagnoses. Metagenomic/high-throughput sequencing of CSF may support diagnosis of arboviral encephalitides. Viral antigen is present in brain tissue, although its distribution may be focal. Electroencephalography usually shows diffuse abnormalities and thus is not directly helpful.

Experience with medical imaging is still evolving but is generally nonspecific, as most patients do not present with pathognomonic abnormalities; however, imaging may be useful to rule out other suspected causes of disease. Both computed tomography (CT) and magnetic resonance imaging (MRI) scans may show normal results except for evidence of preexisting conditions or occasional diffuse edema. Notably, images acquired early may be normal and imaging abnormalities may only be detected later as the disease evolves. Although not pathognomonic, characteristic imaging abnormalities for some arboviral encephalitides have been reported, such as with eastern equine encephalitis (focal abnormalities) and severe Japanese encephalitis (hemorrhagic bilateral thalamic abnormalities).

Supportive care for severely ill patients may require management of elevated intracranial pressure, the syndrome of inappropriate secretion of antidiuretic hormone, respiratory failure, or seizures. Specific therapies for these viral encephalitides are not available. The only practical preventive measures are vector management and personal protective measures against the arthropod transmitting the virus. Direct human-to-human transmission has not been confirmed. For Japanese or Central European/Far Eastern tick-borne encephalitides, vaccination should be considered in specific circumstances (see relevant sections that follow).

Flavivirids The most significant orthoflavivirus encephalitides are Central European/Far Eastern tick-borne encephalitides, Japanese encephalitis, St. Louis encephalitis, and WNV infection. Murray Valley encephalitis and Rocio virus infection resemble Japanese encephalitis but are documented only occasionally in Australia and Brazil. Powassan virus has caused ≈400 cases of often-severe disease (CFR ≈8%), frequently occurring among children in eastern Canada and the United States. Usutu virus causes sporadic human infections (e.g., 105 cases from 2012 to 2021 in Europe), but such infections may be underdiagnosed.

CENTRAL EUROPEAN/FAR EASTERN TICK-BORNE ENCEPHALITIDES Tick-borne encephalitis virus (TBEV) is currently subdivided into four groups: the western/European subtype (previously called Central European encephalitis virus), the (Ural-)Siberian subtype (previously called Russian spring–summer encephalitis virus), the Far Eastern subtype, and the louping ill subtype (previously called louping ill virus, or, in Japan, Negishi virus). Small mammals, grouse, deer, and sheep are the vertebrate amplifiers for these viruses, which are transmitted by ticks. The risk of infection varies by geographic area and can be highly localized. Human infections usually follow outdoor activities during which tick bites occur or consumption of raw (unpasteurized) milk or cheese from infected goats or, less commonly, infected cows or sheep. Milk seems to represent the main transmission route for louping ill subtype viruses, which cause disease very rarely. Several thousand infections with TBEV are recorded each year among people of all ages. Tick-borne encephalitis occurs between April and October, with a peak in June and July.

Western/European viruses classically caused bimodal disease. After an incubation period of 7–14 days, the illness begins with an influenza-like febrile prodrome (fever, arthralgia/myalgia, headaches, and nausea and/or vomiting) that lasts for 2–4 days and is thought to correlate with viremia. A subsequent remission for several days is followed by the recurrence of fever and the onset of neurologic signs. The neuroinvasive phase (7–10 days before onset of improvement) varies from mild aseptic meningitis (more common among younger patients) to severe (meningo)encephalitis with coma, seizures, tremors, and motor signs. Spinal and medullary involvement can lead to typical limb-girdle paralysis and respiratory paralysis. Most patients with western/European virus infections recover (CFR ≈1–2%), and only a minority of patients have significant residual deficits. However, patients with (Ural-)Siberian virus infections have worse outcomes (CFR ≈7–8%) and are more likely to experience prolonged infections and develop chronic disability.

Infections with Far Eastern viruses generally run a more abrupt and severe course. The encephalitic syndrome caused by these viruses sometimes begins without a remission from the fever-myalgia phase and has more severe manifestations than the western/European syndrome. CFR is high (≈20–40%), and major sequelae—most notably, lower motor neuron paralyses of the proximal muscles of the extremities, trunk, and neck—are common, developing in approximately half of patients. Thrombocytopenia may occur during the initial febrile illness, resembling the early hemorrhagic phase of some other tick-borne orthoflavivirus infections, such as Kyasanur Forest disease. In the early stage of the illness, virus may be detected by PCR or isolated from the blood; however, after the onset of CNS manifestations, virus cannot typically be detected in or isolated from the CSF, and diagnosis requires detection of IgM antibodies in serum and/or CSF.

Diagnosis of Central European/Far Eastern tick-borne encephalitides primarily relies on serology and detection of viral genomes by RT-PCR. There is no specific therapy for infection. However, effective alum-adjuvanted, formalin-inactivated virus vaccines (FSME-IMMUN and Encepur) are produced in Austria, Germany, and Russia in chicken embryo cells. Two doses of the Austrian vaccine separated by an interval of 1–3 months appear to be effective in the field, though antibody responses are similar when vaccine doses are given 2 weeks apart. Because rare cases of postvaccination Guillain-Barré syndrome have been reported, vaccination should be reserved for people likely to experience rural exposure in an endemic area during the season of transmission. Cross-neutralization for the western/European and Far Eastern variants has been established, but there are no published field studies on cross-protection among formalin-inactivated vaccines.

Because up to 4% of ticks in endemic areas may be infected, the use of immunoglobulin prophylaxis of Central European/Far Eastern tick-borne encephalitides has increased in some regions. Prompt administration of high-titer-specific immunoglobulin is routine in some areas (e.g., Russia) but has been discontinued in many European countries because of concerns for antibody-mediated enhancement of infections and/or disease.

JAPANESE ENCEPHALITIS Japanese encephalitis is the most significant viral encephalitis in Asia. Each year, ≈68,000 cases and ≈13,600–20,400 deaths are reported. Japanese encephalitis virus is found throughout Asia—including in the Russian Far East, Japan, China, India, Pakistan, and Southeastern Asia—and causes occasional epidemics on western Pacific Islands. The virus has previously been considered endemic in Australia's Torres Strait Islands; from 2021 to 2022, 45 cases causing seven deaths were identified across a broad region of eastern and southern Australia. The virus is particularly common in areas where irrigated rice fields attract the natural avian vertebrate hosts and provide abundant breeding sites for *Culex tritaeniorhynchus* mosquitoes, which transmit the virus to humans. Amplification by pigs, which subsequently abort pregnancies, and horses, which develop encephalitis, may be significant, as well. Vaccination of domestic pigs and horses may reduce the transmission of the virus. After an incubation period of 5–15 days, clinical signs of Japanese encephalitis range from nonspecific febrile illness (nausea, vomiting, diarrhea, and/or cough) to aseptic meningitis, meningoencephalitis, acute flaccid paralysis, and severe encephalitis. Common findings are cerebellar signs, cranial nerve palsies, and cognitive and speech impairments. A Parkinsonian presentation and seizures are typical in severe cases. Patients may present with neuropsychiatric manifestations, including abnormal behavior and acute psychosis. MRI detection of thalamic abnormalities is specific but insensitive. CFR in hospitalized patients is high (≈20–30%) and long-term neurologic dysfunction and disability are common in survivors. However, most long-term residents of endemic areas eventually seroconvert after natural environmental exposures and develop protective immunity. Effective vaccines are available and indicated for naïve individuals who are relocating or traveling frequently or over extended periods to endemic rural areas. Usually, two intramuscular doses of the vaccine are given 28 days apart, with the second dose administered at least 1 week prior to travel.

ST. LOUIS ENCEPHALITIS St. Louis encephalitis virus is transmitted among birds by mosquitoes. This virus causes a low-level endemic infection among rural residents of the central and western United States,

where *Culex tarsalis* mosquitoes serve as vectors. Urban mosquitoes (*Culex pipiens* and *Culex quinquefasciatus*) have been responsible for epidemics, resulting in hundreds or even thousands of cases in cities of the central and eastern United States. Most cases occur in June through October in the United States, but sporadic cases of the disease have been noted throughout the year in Latin/Central America and the Caribbean. The urban mosquitoes breed in accumulations of stagnant water and sewage with high organic content. The elimination of open sewers and trash-filled drainage systems is expensive and may not be possible. However, installation of screens on windows and vents of houses and implementation of personal protective measures may be effective in preventing infection. Mosquitoes are most active outdoors at dusk; bites can be avoided by modifying activities and using repellents.

Most St. Louis encephalitis virus infections are subclinical; susceptibility to severe disease increases with age. Infections that result in aseptic meningitis or mild encephalitis are concentrated among children and young adults, whereas severe and/or fatal cases primarily affect the elderly. Infection rates are similar in all age groups; a pathophysiologic explanation for higher risk of severe disease in older individuals is unclear. After an incubation period of 4–21 days, patients typically present with a nonspecific prodrome (fever, malaise, myalgia, and/or headache), followed by rapid-onset CNS manifestations with neurologic abnormalities that commonly include nuchal rigidity, hypotonia, hyperreflexia, myoclonus, and tremors. Severe cases can include cranial nerve palsies, hemiparesis, and seizures. Of interest, during and after the prodrome, patients often report dysuria and may have viral antigenuria and pyuria. Overall CFR is ≈7% but may be increased up to ≈20% among patients >60 years of age. Recovery is slow, and emotional lability, difficulty concentrating, memory issues, asthenia, and tremors are commonly prolonged in older convalescent patients. The CSF of patients with St. Louis encephalitis usually contains tens to hundreds of WBCs, with a lymphocytic predominance and a left shift. The CSF glucose concentration is normal in these patients.

WEST NILE VIRUS INFECTION WNV is now the primary cause of arboviral encephalitis in the United States. From 1999 to 2022, 28,684 cases of neuroinvasive disease (e.g., meningitis, encephalitis, and acute flaccid paralysis), with 2641 deaths, and 26,891 cases of nonneuroinvasive infection, with 135 deaths, were reported. WNV was initially described as being transmitted among wild birds by *Culex* mosquitoes in Africa, Asia, and southern Europe. In addition, the virus has been implicated in severe and fatal hepatic necrosis in Africa. WNV was introduced into New York City via diseased birds in 1999 and subsequently spread to other areas of the northeastern United States, causing die-offs among crows, exotic zoo birds, and other birds. The virus has continued to spread and is now found in all states (of the United States) as well as in Canada, Mexico, South America, and the Caribbean islands. *C. pipiens* mosquitoes remain the major vectors in the northeastern United States, but mosquitoes of several other *Culex* species and Asian tiger mosquitoes are also involved. Jays compete with crows and other corvids as amplifiers elsewhere in the United States.

The majority of WNV infections are subclinical. After an incubation period of 3–14 days, 20% of those infected develop typical F&M syndrome (without CNS involvement); <1% develop aseptic meningitis and severe encephalitis, particularly among the elderly. The febrile syndrome associated with WNV infection is notable for the frequent—rather than occasional—appearance of a maculopapular rash concentrated on the trunk (especially in children) and the development of lymphadenopathy. Back pain, fatigue, headache, myalgia, retroorbital pain, sore throat, nausea and vomiting, and arthralgia (but not arthritis) are common symptoms. Most patients fully recover, though asthenia may persist for several weeks. Patients who develop neuroinvasive disease typically have meningitis, encephalitis, or acute flaccid paralysis syndromes, often with some overlap. The risk of encephalitis, neurologic sequelae, and death is increased in male, elderly, diabetic, and hypertensive patients and in patients with previous CNS disease, but the pathophysiologic determinants of such a wide spectrum of disease phenotype and severity have otherwise been unexplained. Host genetic risk factors for neuroinvasive disease and death may include chemokine receptor CCR5 deficiency. Recent identification of a high prevalence (≈35%) of preexisting autoantibodies against type I interferons in patients with encephalitis (vs patients with subclinical WNV infection, in whom the prevalence approximated the general population) suggests this predisposition may underlie 40% of cases of WNV encephalitis. In addition to the more severe motor and cognitive sequelae, milder neurologic findings may include cranial nerve palsies, tremor, slight abnormalities in motor skills, and loss of executive functions. Given the burden of disease, intense clinical interest, and widely available diagnostics, more unusual features are increasingly described (including chorioretinitis, myocarditis, myositis and rhabdomyolysis, orchitis, flaccid paralysis with histologic lesions resembling poliomyelitis, and initial presentation with fever and focal neurologic deficits in the absence of diffuse encephalitis). Immunosuppressed patients may have fulminant courses or may develop persistent CNS infection. Postacute neurologic sequelae are common, especially in patients with severe neuroinvasive disease syndromes, and thus far have persisted in some patients for >5 years. Virus transmission through both transplantation and blood transfusion has necessitated screening of blood and organ donors by nucleic acid–based tests. A low but non-zero risk of maternal-to-fetal/neonatal transmission has been reported. Diagnosis rests upon detection of IgM antibodies in serum or CSF. In patients with potential prior exposures to sero-cross-reactive flaviviruses, plaque-reduction neutralization testing for specific neutralizing antibodies or molecular testing (PCR) may aid in specific diagnosis. Treatment is supportive only, and ventilatory support may be required for severe neuroinvasive disease. Although an equine vaccine is available, prevention of WNV infection in humans relies on avoidance of mosquito bites, vector control, and safe handling of potentially infected carcasses.

Peribunyavirids • **CALIFORNIA ENCEPHALITIS** California encephalitis virus has been implicated in only a very few cases of encephalitis (California encephalitis *sensu stricto*), whereas its close relative, La Crosse virus (LACV), is the major cause of this disease (historically ≈80–100 cases per year in the United States, although prevalence has been lower in recent years). La Crosse encephalitis is most reported in the upper midwestern United States but is also found in other areas of the central and southeastern parts of the country, such as West Virginia, Tennessee, North Carolina, and Georgia. Inkoo, Jamestown Canyon, Lumbo, snowshoe hare, and Ťahyňa viruses are close relatives of LACV that also cause human disease (California encephalitis *sensu lato*, including La Crosse encephalitis). Transovarial infection is a strong component of transmission of these viruses in *Aedes* and *Ochlerotatus* mosquitoes. The vector of LACV is the *Ochlerotatus triseriatus* mosquito. These mosquitoes are infected by transovarial transmission, venereal transmission, and feeding on viremic chipmunks and other mammals. *O. triseriatus* mosquitoes breed in standing water in locations such as tree holes and abandoned tires; they bite during daylight hours. Risk factors for human cases include recreation in forested areas, residence at a forest's edge, and nearby standing water. Intensive environmental modification based on these findings has reduced the incidence of disease in a highly endemic area in the midwestern United States.

Most humans are infected from July through September. Asian tiger mosquitoes efficiently transmit LACV to mice and have transmitted it transovarially in the laboratory. This aggressive anthropophilic mosquito has the capacity to urbanize, and its possible transmission of virus to humans is of concern. The prevalence of antibody to LACV in humans is 20% or higher in endemic areas, indicating that infection is common but most often asymptomatic or subclinical.

Neuroinvasive disease after LACV infection varies from aseptic meningitis accompanied by confusion to severe and occasionally fatal encephalitis (CFR <0.5%). CNS disease has been recognized primarily in children <15 years of age. After an incubation period of ≈3–7 days, a usual nonspecific febrile prodrome is followed by the sudden onset of CNS manifestations, including headache and lethargy, often with nausea, vomiting, convulsions (in half of patients), and coma (in

one-third of patients). Focal seizures, hemiparesis, tremor, aphasia, chorea, Babinski signs, and other evidence of significant neurologic dysfunction are common during acute neuroinvasive disease. Most patients recover completely, but ≈10% develop postacute sequelae, including recurrent seizures, focal neurologic deficits, and cognitive and behavioral problems that may affect learning abilities.

The WBC count is commonly elevated and left-shifted in patients with LACV infection, sometimes reaching 20,000/μL. CSF leukocyte counts are typically 30–500/μL, usually with a monocyte predominance (although 25–90% of cells are PMNs in some patients). The blood protein concentration is normal or slightly increased, and the glucose concentration is normal. Specific virologic diagnosis based on IgM-capture assays of serum and CSF is efficient. The only human anatomic site from which virus has been isolated is the brain.

Treatment is supportive over a 1- to 2-week acute phase and focused on the prevention and management of status epilepticus, cerebral edema, and the syndrome of inappropriate secretion of antidiuretic hormone. A phase 2B clinical trial of IV ribavirin in children with LACV infection was discontinued during dose escalation because of adverse effects.

Jamestown Canyon virus has been implicated in several cases of encephalitis in adults (≈10–40 cases per year since 2011), usually with a significant respiratory illness at onset. Human infection with this virus has been documented in Northern America (in the United States in at least 10 states and in Canada), where the vector mosquito (*Aedes stimulans*) feeds on its main host, the white-tailed deer (*Odocoileus virginianus*). Ťahyňa virus can be found in Africa, China, Central Europe, and Russia. The virus is a prominent cause of undifferentiated febrile disease but can also cause pharyngitis, pulmonary syndromes, aseptic meningitis, or meningoencephalitis.

Rhabdovirids • **CHANDIPURA VIRUS INFECTION** Chandipura virus is an emerging and increasingly significant human virus in India, where it is transmitted among hedgehogs by mosquitoes and sandflies. In humans, the disease begins as a rapid-onset influenza-like illness, with fever, headache, abdominal pain, nausea, and vomiting. These manifestations are followed by infection-related or autoimmune-mediated encephalitis that may cause altered mental status and seizures. Notably, neither the virus nor abnormal cells are detected in CSF; the brain has not been examined histopathologically, but limited cerebral imaging data query whether CNS disease is more likely related to cerebrovascular events (vasospasm/vasculitis) than to infectious encephalitis. Several hundred cases of Chandipura virus infection are recorded in India every year in children, with a CFR ≈45–80%. Infections with other arthropod-borne rhabdovirids (Isfahan, Piry, vesicular stomatitis Indiana, and vesicular stomatitis New Jersey viruses) may imitate the early febrile stage of Chandipura virus infection.

Togavirids • **EASTERN EQUINE ENCEPHALITIS** This disease is encountered primarily in swampy foci along the east coast and, more recently and specifically, the southeastern coast of the United States, with a few inland foci as far removed from the coastlines as Michigan, Wisconsin, Arkansas, and Montana (≈4–40 cases/year). Humans are mostly infected from June through October. During this period, *Culiseta* mosquitoes infect birds and virus spills over into other vectors, such as *Aedes sollicitans* or *Aedes vexans* mosquitoes, which are more likely to feed on mammals. Especially with spread to the southeastern coast, there is concern over the amplifying role of introduced Asian tiger mosquitoes, which have been found to be infected with eastern equine encephalitis virus and are an effective experimental vector in the laboratory. Horses are a common target for the virus. Contact with unvaccinated horses may be associated with human disease, but horses probably do not play a significant role in amplification of the virus.

Most infections are subclinical. After an incubation period of ≈5–10 days, symptomatic individuals develop a nonspecific febrile prodrome, after which a small proportion (2% of adults, 6% of children) develop sudden and rapidly progressive neuroinvasive disease with (meningo)encephalitis syndromes associated with focal neurologic deficits, seizures, profoundly altered mental status, and coma. Neuroinvasive disease is highly fatal (CFR ≥30–50%) and >50% survivors have residual postacute sequelae. Acute PMN CSF pleocytosis, often occurring during the first 1–3 days of disease, is another indication of severity, and it parallels peripheral leukocytosis with a left shift. Extensive necrotic lesions and PMN infiltrates are found at postmortem examination of the brain. Specific treatment is not available, although the therapeutic role of IV immunoglobulin (IVIG) remains under query. A formalin-inactivated vaccine has been used to protect laboratory workers but is not generally available or applicable.

VENEZUELAN EQUINE ENCEPHALITIS VEEV is separated into epizootic viruses (subtypes IA/B and IC) and enzootic viruses (subtypes ID, IE, and IF). Closely related enzootic viruses are Everglades virus, Mucambo virus, and Tonate virus. Enzootic viruses are found primarily in humid tropical-forest habitats and are maintained between culicoid mosquitoes and rodents. These viruses cause acute febrile syndromes in humans but are not pathogenic for horses and do not cause epizootics. Everglades virus has caused sporadic cases of encephalitis in humans in Florida. Extrapolation from the rate of genetic change suggests that Everglades virus may have been introduced into Florida <200 years ago. Everglades virus is most closely related to the ID-subtype viruses that appear to have given evolutionary rise to the epizootic variants active in South America.

Epizootic viruses have an unknown natural cycle but periodically cause extensive epizootics/epidemics in equids and humans in the Americas. These epizootics/epidemics are the result of high-level viremia in horses and mules, which transmit the infection to several types of mosquitoes, which in turn infect humans. Humans also have high-level viremia, but their role in virus transmission is unclear. Relatively restricted epizootics of Venezuelan equine encephalitis (VEE) occurred repeatedly in South America in <10-year intervals from the 1930s until 1969, when a massive epizootic, including tens of thousands of equine and human infections, spread throughout Central America and Mexico, reaching southern Texas in 1971. Genetic sequencing suggested that the virus from that outbreak originated from residual "un-inactivated" IA/B-subtype virus in veterinary vaccines. The outbreak was terminated in Texas with a live-attenuated vaccine (TC-83), originally developed for human use by the U.S. Army; the epizootic virus was then used for further production of inactivated veterinary vaccines. No further major outbreaks occurred until 1995 and 1996, when large epizootics of VEE occurred in Colombia/Venezuela and Mexico, respectively. Of the >85,000 clinical cases, 4% (more children than adults) had neurologic symptoms/signs, resulting in 300 deaths. The viruses involved in these epizootics, as well as previously epizootic IC viruses, are close phylogenetic relatives of known enzootic ID viruses. This finding suggests that active virus evolution and selection of epizootic viruses are underway in South America.

During epizootics, extensive human infection is typical, with clinical disease occurring in 10–60% of infected individuals. Most infections result in notable acute febrile syndromes, whereas relatively few (5–15%) result in neurologic disease. A low rate of CNS invasion is supported by the absence of encephalitis after the many infections (from exposure to aerosols) that have occurred in the laboratory setting. Small-molecule and monoclonal antibody-based antiviral therapeutics are in preclinical development but not yet approved. These (and vaccine; see below) efforts may benefit from the designation of VEEV as a representative pathogen for the encephalitic alphaviruses.

The prevention of epizootic VEE depends on vaccination of horses with the attenuated TC-83 vaccine or with an inactivated vaccine prepared from that variant. Enzootic viruses are genetically and antigenically different from epizootic viruses, and protection against the former with vaccines prepared from the latter is relatively ineffective. Humans can be protected by immunization with similar vaccines prepared from Everglades virus, Mucambo virus, and VEEV, but the use of the vaccines is restricted to laboratory personnel because of reactogenicity, possible fetal pathogenicity, and limited availability.

WESTERN EQUINE ENCEPHALITIS The primary maintenance cycle of western equine encephalitis virus in the western United States and Canada involves *Aedes*, *C. tarsalis*, and *Culiseta* mosquitoes and

birds (principally sparrows and finches). Equids and humans become infected, and both suffer encephalitis without amplifying the virus. St. Louis encephalitis virus is transmitted via a similar cycle in the same regions harboring western equine encephalitis virus; disease caused by the former occurs about a month earlier than that caused by the latter (July through October). Large epidemics of western equine encephalitis occurred in the western and central United States and Canada from the 1930s through the 1950s but have been uncommon since then. From 1964 through 2010, only 640 cases were reported in the United States. This decline in incidence may reflect, in part, the integrated approach to mosquito management employed in irrigation projects and, in part, the increasing use of agricultural pesticides. The decreased incidence of western equine encephalitis almost certainly reflects the increased tendency for humans to be indoors behind closed or screened windows at dusk—the peak biting period of the major vector.

Most infections are subclinical or mild. After an incubation period of ≈5–10 days, most symptomatic patients develop a nonspecific febrile prodrome with spontaneous recovery. The small minority of patients who develop neuroinvasive disease present with a typical viral meningoencephalitis syndrome (headache, vomiting, neck and back stiffness, and/or altered mental status). The frequency and morbidity of severe neurologic disease are increased among infants and very young children; in addition, CFR is high in this and in very elderly populations (3–7% overall). One-third of individuals who have convulsions during the acute illness have subsequent seizure activity. Infants <1 year of age—particularly those in the first months of life—are at serious risk of persistent motor and cognitive deficits. Of those 5–9 years of age, twice as many males as females develop clinical encephalitis; the contribution of biological versus behavioral factors (increased outdoor exposure to the vector) to incidence differences is uncertain. Specific treatment is not available. A formalin-inactivated vaccine has been used to protect laboratory workers but is not generally available.

PULMONARY DISEASE

Hantavirus pulmonary syndrome (HPS) was first described in 1993, but retrospective identification of cases by immunohistochemistry (1978) and serology (1959) supports the idea that HPS is a recently discovered disease rather than a truly new one. The causative agents are orthohantaviruses of a distinct phylogenetic lineage that is associated with the cricetid rodent subfamily Sigmodontinae. Sin Nombre virus, which chronically infects western deermice (*Peromyscus sonoriensis*), is the most important agent of HPS in the United States. Several other related viruses (Anajatuba, Andes, Araraquara, Araucária, bayou, Bermejo, Black Creek Canal, Blue River, Caño Delgadito, Castelo dos Sonhos, Catacamas, Choclo, Juquitiba, Laguna Negra, Lechiguanas, Maciel, Maripa, Monongahela, New York, Orán, Paranoá, Pergamino, Rio Mamoré, and Tunari viruses) cause the disease in Northern and South America. Andes virus is unusual in that it has been implicated in human-to-human transmission. HPS particularly affects rural residents living in dwellings permeable to rodent entry or workers in occupations that risk rodent exposure. Each type of rodent has particular habits; in the case of deermice, these behaviors include living in and around human habitation.

After a typical incubation period of 2–3 weeks, HPS begins with a nonspecific prodrome of ≈3–4 days (range 1–11 days) comprising fever, malaise, myalgia, and—in many cases—gastrointestinal disturbances (e.g., abdominal pain, nausea, and vomiting). Dizziness is common, and vertigo is occasional. Severe prodromal symptoms/signs may bring some patients to medical attention, but most cases are recognized as the pulmonary phase begins, with typical signs of slightly lowered blood pressure, tachycardia, tachypnea, mild hypoxemia, thrombocytopenia, and early radiographic signs of pulmonary edema. Physical findings in the chest are often surprisingly scant. The conjunctival and cutaneous signs of vascular involvement seen in orthohantavirus VHFs (see "Viral Hemorrhagic Fever," below) are uncommon but may be more frequent with HPS outside Northern America. Early recognition and triage of patients at this stage are critical because, shortly after onset, hypotension and noncardiogenic edema progress rapidly to hypoxemic respiratory failure.

The differential diagnosis of HPS includes undifferentiated sepsis syndromes and severe acute respiratory infections and should be informed by local epidemiology. Considerations include severe atypical pneumonia (*Legionella*, *Mycoplasma*, and Q fever), influenza, rickettsial disease, meningococcemia, septicemic plague, tularemia, leptospirosis, dengue, and YF. Fever with severe abdominal pain and tenderness merits consideration of the causes of a "surgical" abdomen and pyelonephritis. A specific diagnosis is best made when antigen-specific IgM, present in most symptomatic patients, is detected in acute-phase serum. Sin Nombre virus antigen testing detects antibodies to the related HPS-causing orthohantaviruses. Occasionally, heterotypic viruses will cross-react (only to the IgG ELISA), but the very low seroprevalence of these viruses in normal populations queries this laboratory finding. Orthohantaviral RNA is cleared quickly, although RT-PCR may be useful to detect virus in tissue biopsies, thrombus, or at autopsy. RT-PCR and DNA sequencing may be needed in specifically identifying the infecting virus in areas outside the home range of deermice, in atypical cases, and for molecular epidemiology.

During the prodrome, differentiating HPS from other causes is difficult, but diagnostically helpful features emerge at or soon after initial presentation. A new dry cough, usually absent at disease onset, may signal the pulmonary phase. Early in disease, interstitial edema may be evident radiographically; with progression, bilateral alveolar infiltrates in a central pattern and with a normal-sized heart signal the development of noncardiogenic edema. Pleural effusions are often seen. Coincident thrombocytopenia, circulating atypical lymphocytes (lymphoblasts), and a left shift (often with marked leukocytosis) are considered almost diagnostic in experienced centers. Hemoconcentration, hypoalbuminemia, and proteinuria also aid in diagnosis. Although thrombocytopenia and partial thromboplastin time (PTT) prolongation are usually found, clinical evidence of coagulopathy or laboratory indications of DIC are found in only a minority of severely ill patients. Patients with severe illness also have acidosis and elevated serum lactate concentrations. Oliguria and mildly increased values in serum creatinine concentrations are common, but patients with severe HPS often have markedly decreased glomerular filtration. Some American orthohantaviruses other than Sin Nombre virus (e.g., Andes virus) have been associated with more severe renal dysfunction, but few such cases have been studied.

After recognition, early triage-based monitoring and management of hemodynamic, respiratory, and renal dysfunction during the first few hours are critical to improved outcomes. During this period, hypotension and hemoconcentration suggest intravascular volume depletion; however, aggressive IV fluid therapy is not advised in the setting of widespread capillary leak, frequently depressed cardiac output, and oliguria. Mild hypoxemia may be managed by oxygen administration alone, but mechanical ventilatory support of respiratory failure and shock is often needed. Pulmonary artery catheterization enables pulmonary capillary wedge pressure–guided inotropic and vasopressor support and cautious intravascular volume replacement. The most critically ill patients with a low cardiac index or refractory hypoxemia despite this support may benefit from extracorporeal membrane oxygenation, ideally before the onset of shock. CFR is high (≈30–40%), even with appropriate management, but most patients surviving the first 48 h of hospitalization are extubated and discharged within a few days with no apparent long-term sequelae. Although ribavirin inhibits orthohantaviruses in vitro and has been effectively used in patients with HFRS due to Hantaan virus, an underpowered randomized clinical trial of ribavirin for HPS failed to show efficacy. Preclinical development of novel small-molecule– and monoclonal antibody-based therapeutics for HPS is ongoing.

VIRAL HEMORRHAGIC FEVER

VHF syndrome encompasses a small number of acute viral infections that cause severe disease and multisystem organ dysfunction sharing a mutual pathophysiologic disruption to vascular function, stability, and integrity. In practice, viral infections classified as VHFs vary widely across a spectrum of clinical phenotypes and severity; indeed, hemorrhagic manifestations are typically not the most prominent nor severe

features of disease. Nonetheless, the VHF designation largely captures a useful common theme: hemorrhagic manifestations are a sign of widespread vascular dysfunction or damage that plays a central role in local, organ-specific, and systemic expression of disease. Direct or indirect damage to the microvasculature leads to increased permeability and (particularly when platelet function is decreased) to actual disruption and local hemorrhage most evident in the skin and mucous membranes. Cutaneous flushing and conjunctival suffusion are examples of common observable abnormalities due to dysfunction of local circulation. Similarly, affected microvasculature may be fragile to trauma and external forces, such as the application of a blood pressure cuff causing a positive tourniquet sign. Although overt hemorrhage occurs infrequently, subtle local hemorrhagic signs (e.g., bleeding of the gums or at IV catheter sites) are often present on careful examination. Circulatory dysfunction may also contribute to specific organ dysfunction or damage that may be particularly prominent in some VHF cases; for instance, the kidneys are primary targets in HFRS, and the liver is a primary target in YF. Regarding severe systemic manifestations, hypotension and shock are not usually a direct result of life-threatening blood loss but rather an indication of generalized circulatory dysfunction contributing to hemodynamic instability. Despite this common theme, the pathogenesis of VHF is poorly understood and varies among the viruses regularly implicated in the syndrome. In some viral infections, direct damage to the vascular system or even to parenchymal cells of target organs is an important factor; in other viral infections, soluble mediators are thought to play a major role in the development of hemorrhage or hemodynamic derangement.

Symptom initiation in the acute phase in most VHF syndromes is associated with ongoing virus replication and viremia, typically with nonspecific fever and arthralgia/myalgia, usually of abrupt onset (mammarenavirus infections are exceptions, as they often develop gradually). Within a few days, patients present for medical attention with severe fatigue and prostration that is often accompanied by anorexia, severe headache, sore throat, chest pain, gastrointestinal symptoms (abdominal pain, nausea, vomiting, and/or diarrhea), dizziness, hyperesthesia, and photophobia. Initial examination often reveals only an acutely ill febrile patient with asthenia, conjunctival suffusion, tenderness to palpation of muscles or abdomen, and borderline hypotension or postural hypotension (perhaps with tachycardia). Petechiae (often best visualized in the axillae), flushing of the head and thorax, periorbital edema, and proteinuria are common. AST activities are usually elevated at presentation or within a day or two thereafter. Hemoconcentration from vascular leakage is usually evident and is most marked in HFRS and in severe dengue. Seriously ill patients develop more severe clinical signs, including initial organ dysfunction typical of the causative virus; continued high viral loads coupled with ineffective and dysregulated immune responses lead to progressive multiorgan dysfunction characterized by shock, acute kidney injury, CNS injury (encephalopathy, coma, seizures), severe hemorrhagic manifestations, and death.

One of the major diagnostic clues is travel to an endemic or active outbreak area within the incubation period for a given syndrome. Except in infections with Seoul virus, DENV-1–4, and yellow fever virus (YFV), which have urban hosts/vectors, rural travel exposures are more commonly associated with a VHF. In addition, several travel-associated diseases—falciparum malaria, shigellosis, typhoid fever, leptospirosis, relapsing fever, and rickettsial diseases—should also be considered in the differential diagnosis, as they are treatable despite being potentially fatal.

Early recognition of VHF is crucial for timely initiation of appropriate supportive clinical care and virus-specific therapy (if available). Key components of clinical care include prompt isolation and hospitalization even in absence of clinical signs; rapid triage and ongoing monitoring of vital signs; the prevention and management of dehydration, hypovolemia, and hemodynamic instability (with closely monitored IV fluids and vasopressors); the prevention and management of acute kidney injury and electrolyte abnormalities; empiric or specific treatment of common concurrent or secondary bacterial or parasitic infections; replacement of blood products (packed red blood cells, clotting factors, and platelets as indicated); and the usual precautionary measures used in the treatment of patients with hemorrhagic diatheses. DIC should be treated only with clear laboratory evidence and if laboratory monitoring of therapy is feasible; there is no proven benefit of such therapy. Of note, VHF patients are commonly hypovolemic from insensible fluid and gastrointestinal losses and require intravascular fluids to maintain blood pressure and glomerular filtration; however, VHF patients may also have decreased cardiac output, capillary leak syndromes, and oliguria that require judicious fluid management and inotropic/vasopressor support. Specific therapy is available for several of the VHFs. Strict barrier nursing and other precautions against infection of medical staff and visitors are indicated when VHFs are encountered, except when the illness is due to DENV-1–4, orthohantaviruses, RVFV, or YFV.

Novel VHF-causing agents are still being discovered. Some of these viruses have recently emerged and continue to cause disease (e.g., severe fever with thrombocytopenia syndrome virus [SFTSV]). Others have caused isolated VHF-like cases without recurrence, including viruses for whom Koch's postulates are yet to be fulfilled (e.g., Bas-Congo virus).

Bunyaviricetes The most significant VHF-causing bunyaviricetes are arenavirids (Junín, Lassa, and Machupo viruses), hantavirids, nairovirids (Crimean-Congo hemorrhagic fever virus), and phenuivirids (RVFV and SFTSV). Other bunyaviricetes—e.g., the Garissa variant of Ngari virus and Ilesha virus (both orthobunyaviruses) or Chapare, Guanarito, Lujo, and Sabiá viruses (all mammarenaviruses)—have caused sporadic VHF outbreaks.

ARGENTINIAN AND BOLIVIAN HEMORRHAGIC FEVERS These severe diseases (with CFR reaching >50% in individual outbreaks) are caused by Junín virus and Machupo virus, respectively. Clinical presentations of both diseases are similar, but epidemiology differs because of the distribution and behavior of the distinct rodent reservoirs. Argentinian hemorrhagic fever has been recorded only in rural areas of Argentina, whereas Bolivian hemorrhagic fever seems to be confined to rural Bolivia. Unusually for arboviruses, infection with the causative agents almost always results in disease, and all ages and both sexes are affected. Person-to-person or nosocomial transmission is rare but has occurred. The transmission of Junín virus from male survivors to their partners suggests the need to avoid intimate contact in early convalescence (and counseling in this regard for all patients with mammarenavirus hemorrhagic fevers). In contrast to LF (see below), thrombocytopenia—often marked—is the rule, mucosal hemorrhage is common, and CNS dysfunction (e.g., marked confusion, tremors of the upper extremities and tongue, and cerebellar signs) is much more common in disease caused by Junín virus and Machupo virus (20–30%). Some cases follow a predominantly neurologic course, with a poor prognosis. Convalescence is protracted and frequently associated with sequelae such as hearing loss.

Typical clinical laboratory findings (thrombocytopenia, leukopenia, and proteinuria) support the diagnosis. Argentinian and Bolivian hemorrhagic fevers are readily treated with convalescent plasma given within the first 8 days of illness; however, the use of convalescent plasma may be associated with neurologic sequelae. In the absence of passive antibody therapy, (off-label) IV ribavirin in the dose recommended for LF is likely to be effective in all South American VHFs caused by mammarenaviruses. A safe, effective, live-attenuated vaccine exists for Argentinian hemorrhagic fever. After vaccination of >250,000 high-risk people in the endemic area, the incidence of this VHF decreased markedly. In experimental animals, this vaccine is cross-protective against Bolivian hemorrhagic fever. Other mammarenaviruses have caused isolated or sporadic VHF in South America, including Guanarito virus (Venezuelan hemorrhagic fever) and Chapare and Sabiá viruses. Multivalent vaccine approaches against all five VHF-causing mammarenaviruses in this region are in preclinical development.

LASSA FEVER Lassa virus (LASV) is known to cause endemic and epidemic disease in Nigeria, Sierra Leone, Guinea, and Liberia, although it is probably more widely distributed in Western Africa. In Western Africa alone, probably tens to hundreds of thousands of LASV

infections occur annually, and ≈20% of these develop LF, which can be a prominent cause of febrile disease. For example, in one hospital in Sierra Leone, laboratory-confirmed LF is consistently responsible for one-fifth of admissions to the medical wards. LASV can be transmitted by close person-to-person contact. Nosocomial spread has occurred but is uncommon if appropriate infection prevention and control practices are followed. All ages and both sexes are affected; the incidence of disease is highest in the dry season, but transmission occurs year-round.

The majority of LASV infections are subclinical or mild. After a highly variable incubation period of 1–3 weeks, symptomatic patients have the gradual onset of a nonspecific febrile prodrome (among the VHF agents, only mammarenaviruses are typically associated with a gradual onset of illness). Progression in the second week of illness includes sore throat, cough, retrosternal chest and back pain, and gastrointestinal symptoms (abdominal pain, vomiting, and/or diarrhea). A maculopapular rash may be noted in light-skinned patients. Further disease progression includes conjunctival infection, head and neck edema, and respiratory (pneumonia and/or pleural effusions) and cardiac (pericarditis and/or pericardial effusions) manifestations. In late stages, multisystem organ dysfunction occurs with acute kidney injury, CNS manifestations (encephalopathy, coma, and/or seizures), shock, and hemorrhage (seen in only ≈15–30% of LF patients overall). Laboratory abnormalities may include leukocytosis, thrombocytopenia, elevated serum creatinine levels, hyperkalemia, hypoalbuminemia, elevated AST and ALT activities, and proteinuria. Viral load, age, pregnancy status, clinical signs (CNS features, face and neck swelling, hypotension, hemorrhage, and/or jaundice), and laboratory abnormalities (high serum creatinine levels, AST activity, leukocytosis, and/or thrombocytopenia) have been associated with fatal outcome. Pregnancy is associated with higher case fatality, especially during the last trimester, when fetal death is 90%. Interruption of pregnancy via medical abortion may increase survival rates, but data on LF and pregnancy outcomes remain sparse. In survivors, a high rate (≈30%) of sensorineural deafness (onset during the acute illness or in convalescence, usually bilateral) occurs; other postacute sequelae of LF are poorly defined but include neurologic and mental health issues. The virus is detected in the urine during convalescence and has been detected in seminal fluid early in recovery. Reinfection may occur but has not been associated with severe disease.

Aggressive supportive and critical care, including renal replacement therapy when available, is required to improve outcomes. Regarding LASV-specific therapy, observational studies in the 1980s informed the current practice of treating patients with (off-label) ribavirin (IV route preferred). Historically, ribavirin appeared to be partially effective in reducing fatality from that documented among retrospective controls. However, possible side effects, such as reversible anemia (which usually does not require transfusion), dependent hemolytic anemia, and bone marrow suppression, need to be kept in mind. When used, ribavirin should be given by slow IV infusion in a dose of 32 mg/kg; this dose should be followed by 16 mg/kg every 6 h for 4 days and then by 8 mg/kg every 8 h for 6 days. Small-molecule and monoclonal antibody therapeutics are in advanced preclinical development, and research networks in Western Africa are preparing for randomized clinical trials that will be critical to inform best specific therapeutic approaches. Inactivated LASV vaccines failed in preclinical studies, but several promising vaccine platforms are under experimental evaluation.

HEMORRHAGIC FEVER WITH RENAL SYNDROME HFRS is the most significant VHF today, with >100,000 cases of severe disease in Asia annually and thousands of mild infections in Europe. The disease is widely distributed in Eurasia. The major causative viruses are Puumala virus (Europe), Dobrava virus (the Balkans), and Hantaan virus (Eastern Asia). Amur, gōu, Kurkino, Muju, Saaremaa, Sochi, and Tula viruses also cause HFRS but much less frequently and in more geographically confined areas that are determined by the distribution of reservoir hosts. Seoul virus is an exception; because it is associated with brown rats (*Rattus norvegicus*), which migrate on ships, the virus has a worldwide distribution. Despite the wide distribution of Seoul virus, only mild or moderate HFRS occurs in Asia; human disease has been difficult to identify in many areas of the world, although an outbreak in North America has been described. Most cases of HFRS occur in rural residents or vacationers; again, the exception is Seoul virus infection, which may be acquired in an urban, rural, or laboratory setting. Classic Hantaan virus infection in Korea and in rural China is most common in the spring and fall and is related to rodent density and agricultural practices. Human infection is acquired primarily through aerosols of rodent urine, although virus is also present in rodent saliva and feces. Patients with HFRS are not infectious.

Most patients with hantavirus infections do not develop severe disease. Classic features of HFRS include fever, hypotension, hemorrhage, and acute kidney injury, with severe disease expressed in four identifiable stages after a typical 1- to 2-week incubation period:

1. The *febrile* stage lasts 3 or 4 days and is identified by the abrupt onset of fever, headache, severe myalgia, thirst, anorexia, and often nausea and vomiting. Photophobia, retroorbital pain, and pain on ocular movement are common, and the vision may become blurred with ciliary body inflammation. Flushing over the face, the anterior neck, and back is characteristic, as are pharyngeal injection, periorbital edema, and conjunctival suffusion. Petechiae often develop in areas of pressure, the conjunctivae, and the axillae. Back pain and tenderness to percussion at the costovertebral angle reflect massive retroperitoneal edema. Thrombocytopenia and mild to moderate DIC is present, and hemorrhagic manifestations may occur. Other early laboratory findings include proteinuria and an active urinary sediment.
2. During the *hypotensive* stage (lasting from a few hours to 48 h), the blood pressure falls (sometimes with shock) with a compensatory tachycardia (vs the relative bradycardia typical of the febrile phase). Kinin activation and capillary leak are marked, leading to hemoconcentration. Leukocytosis with a left shift develops, and thrombocytopenia persists. Atypical lymphocytes—which, in fact, are activated $CD8^+$ and, to a lesser extent, $CD4^+$ T cells—circulate. Renal perfusion is compromised from local and systemic circulatory changes resulting in necrosis of tubules, particularly at the corticomedullary junction, and oliguria. Consequent inability to concentrate the urine develops, and the urine's specific gravity falls to 1.010. Proteinuria is marked. Diffuse hemorrhage may appear, including hematemesis, hemoptysis, and melena.
3. During the *oliguric* stage, hemorrhagic tendencies continue, probably in large part because of uremic bleeding defects. Oliguria persists for 3–10 days before the return of renal function marks the onset of the polyuric stage.
4. During the *polyuric* stage (diuresis with hyposthenuria), the inability to concentrate the urine may lead to volume depletion and electrolyte abnormalities.

Mild cases of HFRS may be much less stereotypical, presenting only with fever, gastrointestinal abnormalities, and transient oliguria followed by hyposthenuria. Infections with Puumala virus, the most common cause of HFRS in Europe ("nephropathia epidemica"), result in a similar general but much-attenuated presentation. Bleeding manifestations are found in only 10% of patients, hypotension rather than shock is usually documented, and oliguria is present in only about half of patients. The dominant features may be fever, abdominal pain, proteinuria, mild oliguria, and sometimes blurred vision or glaucoma, followed by polyuria and hyposthenuria in recovery. CFR is <1%.

HFRS should be suspected in patients with exposure in an endemic (typically rural) area. Prompt recognition of the disease permits rapid hospitalization and expectant management of shock and renal failure. Clinical laboratory parameters include leukocytosis (which may be leukemoid and with a left shift), thrombocytopenia, elevated serum creatinine level, proteinuria, and hematuria. HFRS is readily diagnosed by an IgM-capture ELISA that is positive at admission or within 24–48 h thereafter. The isolation of orthohantaviruses is difficult, but RT-PCR of renal biopsy, thrombus (collected early in the clinical course), or postmortem tissues may yield molecular diagnosis and should be used if definitive identification of the infecting virus is required.

Mainstays of therapy are management of shock with vasopressor support and modest crystalloid infusion, IV human serum albumin administration, timely renal replacement therapy to prevent volume overload that may result in pulmonary edema, and control of hypertension to prevent intracranial hemorrhage. Use of IV ribavirin has reduced CFR and morbidity in severe cases, provided treatment is begun within the first 4 days of illness. CFR approaches 15% but should be lower than 5% with adequate supportive and critical care. Generally, surviving patients make a full recovery, even of glomerular function, and postacute sequelae have not been identified.

CRIMEAN-CONGO HEMORRHAGIC FEVER (CCHF) CCHFV causes severe VHF over a wide endemic area (Africa, Asia, and Europe), determined primarily by the distribution of ixodid *Hyalomma* ticks. Incidence has been increasing in known endemic areas (particularly in Western Asia), and recent autochthonous infections in nonendemic areas, such as Spain, suggest that the at-risk geography is expanding. Because of the propensity of CCHFV-transmitting ticks to feed on domestic livestock and some wild mammals, veterinary serosurveys are the most effective mechanism for the monitoring of virus circulation. Human infections are acquired via tick bites, during the crushing of infected ticks, and contact with blood or body fluids of infected animals or humans (including nosocomial and vertical transmission). Domestic animals do not become ill but do develop viremia. Thus, risk of acquiring CCHFV occurs during sheep shearing, animal slaughter, or contact with infected hides or carcasses from recently slaughtered infected animals. Nosocomial outbreaks are common and are usually related to extensive blood exposure or needlesticks.

The majority of infections are subclinical. After an incubation period that varies by exposure to a tick bite (1–3 days) or blood or body fluids (3–7 days, perhaps shorter after nosocomial exposures to highly viremic patients), patients develop a sudden-onset nonspecific febrile prodrome typical to VHF. Severe illness is also typical, with the possible exceptions of a profound and dysregulated inflammatory component, more severe hemorrhagic manifestations (including extended ecchymoses and/or retinal and pulmonary hemorrhage), and more severe liver injury, resulting in jaundice in some patients. Recovery (for most patients; sequelae are not identified) or rapid progression to fatal disease occurs in the second week of illness with multiorgan (renal and respiratory) dysfunction, shock, and profound coagulopathy leading to massive bleeding. Clinical laboratory findings indicate coagulopathy as well as markers of liver (elevations in activities of AST/ALT and bilirubin concentrations) and muscle (elevations in creatine phosphokinase levels) injury. Predictors of fatal outcome include clinical features (hematemesis, melena, and/or altered mental status), laboratory biomarkers (viral load, thrombocytopenia, elevated AST/ALT levels, and/or obvious DIC), and delayed CCHFV-specific IgM and IgG responses. The mainstay of treatment is supportive and critical care, including extracorporeal support of organ dysfunction. The pathophysiology argues for combined virus-specific and disease-modifying immunomodulatory approaches. The benefit of IV ribavirin, suggested in observational studies that were likely confounded, has not been borne out in randomized trials. Small-molecule antivirals (favipiravir and molnupiravir), monoclonal antibodies, and the use of convalescent plasma are in preclinical evaluation, but clinical studies are needed. The routine use of steroids and/or IVIG is not currently recommended. No human or veterinary vaccines are recommended.

RIFT VALLEY FEVER The natural range of RVFV was previously confined to sub-Saharan Africa, with circulation of the virus markedly enhanced by substantial rainfall. The El Niño Southern Oscillation phenomenon of 1997 facilitated subsequent spread of Rift Valley fever (RVF) to the Arabian Peninsula, with epidemic disease in 2000. The virus has also been found in Madagascar and Egypt, where it caused major epidemics in 1977–1979, 1993, and thereafter. RVFV is maintained by transovarial transmission in floodwater *Aedes* mosquitoes and presumably also via a vertebrate amplifier. Increased transmission during particularly heavy rains leads to epizootics characterized by high-level viremia in cattle, goats, or sheep. Numerous types of mosquitoes feed on these animals and become infected, thereby increasing the possibility of human infections. Remote sensing via satellite can detect the ecologic changes associated with high rainfall that predict the likelihood of RVFV transmission. High-resolution satellites can also detect the special depressions in floodwaters from which the mosquitoes emerge. The virus can be transmitted to humans by mosquitoes but most commonly by contact with blood or aerosols from domestic animals. Therefore, transmission risk is high during birthing, and both abortuses and placentas need to be handled with caution. Risk is also high during animal slaughter but decreases thereafter as anaerobic glycolysis in postmortem tissues results in an acidic environment that rapidly inactivates bunyaviricetes in carcasses. Neither person-to-person nor nosocomial transmission of RVFV has been documented.

RVFV is unusual in that it causes several clinical syndromes. Most infections are either subclinical or produce a typical F&M syndrome after an incubation period of 2–6 days. A much smaller proportion (<1%) of patients develop typical VHF notable for prominent liver involvement (jaundice) and an extremely rapid course with high case fatality (50%, within 3–6 days), often with renal failure and DIC/hemorrhagic manifestations. Further, <1% of patients develop a late onset (1–4 weeks) meningoencephalitis syndrome that is not usually fatal but does lead to severe neurologic sequelae. Perhaps 10% of otherwise mild infections develop a late-onset (1–3 weeks) retinal vasculitis causing blurred or loss of vision. Funduscopic examination reveals edema, hemorrhages, and infarction of the retina as well as optic nerve degeneration. In a small proportion of patients (<1 in 200), retinal vasculitis is followed by viral encephalitis. Of interest, the late onset of both retinal disease and meningoencephalitis—after serum neutralizing antibody has developed—suggests (so far, undefined) immunopathology.

No proven therapy exists for RVF. Epidemic disease is best prevented by vaccination of livestock. The ability of this virus to propagate after introduction into Egypt suggests that other potentially receptive areas, including the United States, should develop response plans. RVF, like VEE, is likely to be controlled only with adequate stocks of an effective live-attenuated vaccine, but global stocks are unavailable. A formalin-inactivated vaccine confers immunity in humans; however, quantities are limited, and three injections are required. This vaccine is recommended for potentially exposed laboratory workers and for veterinarians working in sub-Saharan Africa. A new live-attenuated vaccine, MP-12, is being tested in humans (phase 2 trials have been completed). The vaccine is safe and licensed for use in sheep and cattle. A modified replication-incompetent chimpanzee adenovirus (ChAdOx1) vectored vaccine has recently been shown to be safe and immunogenic in phase 1 trials. In addition, several vaccines are being developed specifically for use in animals.

SEVERE FEVER WITH THROMBOCYTOPENIA SYNDROME This tick-borne disease is caused by SFTSV. The primary tick vector, the Asian long-horned tick (*Haemaphysalis longicornis*), is endemic in areas of southeast Asia and Oceania, and geographic distribution has been increasing, likely via migratory birds (in Asia) or by importation of pets or livestock (in the United States, where the vector is now widespread and considered invasive). Numerous human infections have been reported during the past few years from China, and cases have also been detected in Japan, the Republic of Korea, Vietnam, and Thailand. Seroprevalence in endemic areas of China approaches 5%. The clinical presentation ranges from mild nonspecific febrile syndromes to severe VHF with high CFR (>12%) particularly in older individuals. After a 1- to 2-week incubation period, patients develop a nonspecific febrile prodrome that may include abdominal pain, vomiting, and diarrhea. Common laboratory abnormalities include prominent thrombocytopenia, leukopenia (often with atypical lymphocytes), markers of hepatocyte injury, and elevated ferritin levels. Most patients recover spontaneously; however, in the second week of illness, some patients develop severe disease with multiorgan dysfunction that can include acute renal injury, myocarditis, meningoencephalitis, DIC with hemorrhage, and hemophagocytic lymphohistiocytosis. Diagnosis requires RT-PCR, as serologic tests are not available. No vaccines or approved

therapeutics are available (though ribavirin and favipiravir have been used in patients) and treatment relies on supportive care.

Flasuviricetes The most significant orthoflaviviruses that cause VHF are the mosquito-borne DENV-1–4 and YFV. These viruses are widely distributed and cause tens to hundreds of thousands of infections each year. Alkhurma hemorrhagic fever virus (>600 cases since discovery in 1995), Kyasanur Forest disease virus (≈10,000 cases over 60 years), and Omsk hemorrhagic fever virus (isolated infections every year with intermittent larger outbreaks) are geographically very restricted but prevalent tick-borne orthoflaviviruses that cause VHF, sometimes with subsequent viral encephalitis. Tick-borne encephalitis virus has caused VHF in a few patients. There is currently no therapy for infection with these VHFs, but an inactivated vaccine has been used in India to prevent Kyasanur Forest disease (and there is a vaccine to prevent tick-borne encephalitis; see above).

SEVERE DENGUE Although most individuals infected with DENV-1–4 have either subclinical infection or F&M syndrome (the febrile phase), some of these patients enter a critical (or plasma leakage) phase—often as fever declines—and develop the criteria for severe dengue: a definite or presumptive diagnosis of dengue infection plus either (1) plasma leakage severe enough to cause shock or respiratory distress, or (2) severe bleeding, or (3) severe organ dysfunction. Early recognition and action long before this critical period are crucial to initiate appropriate supportive care. Indeed, all patients with a presumptive diagnosis of dengue (of any severity) should be initially assessed for designated warning signs (dengue with warning signs, directing inpatient management) as well as for the criteria for severe dengue (i.e., a provisional diagnosis of severe dengue should be made clinically).

The complex determinants of risk for this progression to severe dengue include host and viral factors but center most notably around the potential for immune-mediated enhancement of disease. Several weeks after convalescence from infection with DENV-1–4, the transient protection conferred by that infection against reinfection with a heterotypic DENV usually wanes. Heterotypic reinfection may result in classic dengue without/with warning signs or, less commonly, in severe dengue. In the past 20 years, YF mosquitoes have progressively reinvaded Latin America and other areas, and frequent travel by infected individuals has introduced multiple variants of DENV-1–4 from many geographic areas. Thus, the pattern of hyperendemic transmission of multiple DENV serotypes established in the Americas and the Caribbean has led to the emergence of severe dengue as a major problem. Among the millions of DENV-1–4 infections, ≈500,000 cases of severe dengue occur annually, with a CFR of ≈2.5%. The induction of vascular permeability and shock depends on multiple factors, such as the presence or absence of enhancing and nonneutralizing antibodies, age (susceptibility to severe dengue drops considerably after 12 years of age), sex (females are more often affected than males), race (white people are more often affected than black people), nutritional status, and the timing and sequence of infections (e.g., DENV-1 infection followed by DENV-2 infection seems to be more severe than DENV-4 infection followed by DENV-2 infection). The presence of neutralizing antibodies is associated with decreased viremia on subsequent infection. In addition, considerable heterogeneity exists among variants in each DENV population. For instance, Southeastern Asian DENV-2 variants have more potential to cause severe dengue than do other variants. Recent evidence points to a key role for the DENV NS1 protein in the vascular leak phenomenon associated with severe dengue.

In milder cases of severe dengue, restlessness, lethargy, thrombocytopenia (<100,000/μL), and hemoconcentration are detected 2–5 days after the onset of typical dengue, usually at the time of defervescence. The maculopapular rash that often develops in dengue (without/with warning signs) may also appear in severe dengue. However, severe dengue is most notoriously identified as the consequence of a vascular leak syndrome leading to intravascular volume depletion, hypoalbuminemia, serosal effusions (pleural, ascitic), and, in severe cases, circulatory collapse (i.e., shock, typically lasting 2–3 days), often with an accompanying narrowed pulse pressure, hepatomegaly, and cyanosis. Bleeding tendencies (evidenced by a positive tourniquet test and petechiae) or overt bleeding in the absence of underlying causes (e.g., preexisting gastrointestinal lesions) may be detected but are less common in children. Organ involvement may include mild hepatic injury, CNS abnormalities (e.g., altered mental status, seizures), cardiac abnormalities (e.g., arrhythmias), renal disturbances (e.g., acute kidney injury), and ocular dysfunction.

A virologic diagnosis of severe dengue can be made by the usual means (nucleic acid amplification or antigen detection) in the first 5 days of infection, after which diagnosis relies on serologic testing. Combination testing—point-of-care rapid tests for NS1 antigen and IgM antibody assays—is increasingly used in the clinical setting. The early detection of IgG (starting at 4 days after illness onset, rapidly rising) suggests a secondary rather than primary infection, in which IgG is detected later and at much lower titers. However, serologic cross-reactivity after infection with (or vaccination for) antigenically similar orthoflaviviruses (e.g., YFV, ZIKV, and Japanese encephalitis virus) confounds diagnosis.

As above, patients with severe dengue should be hospitalized and rapidly triaged (and then closely monitored) for hemodynamic instability and bleeding. In general, appropriate IV fluids should be administered as early as possible, preferably before shock develops. Based on clinical parameters (vital signs, urine output, hematocrit, bleeding, and signs of volume overload), algorithmic approaches have been developed to standardize appropriate fluid management (crystalloid vs colloid vs blood rate) and monitoring of patients with and without shock and/or bleeding. CFR varies greatly depending on early recognition and quality of treatment. However, most patients with severe dengue respond well to supportive therapy, and the overall CFR at experienced clinical centers in the tropics is probably as low as 1%. When patients enter the convalescent phase, significant fluid reabsorption (of extravascular fluid and effusions) occurs as the plasma leak resolves, blood pressure improves, and diuresis occurs. Notably, a patchy erythematous pruritic rash may develop and desquamate during recovery. Significant postacute sequelae include prolonged fatigue and depression.

The key to control of both dengue (without/with warning signs) and severe dengue is the control of YF mosquitoes, which also reduces the risk of urban YF and CHIKV circulation. Control efforts have been handicapped by the presence of nondegradable tires and long-lived plastic containers in trash repositories—creating perfect mosquito breeding grounds upon filling with water during rainfall—and by insecticide resistance. Urban poverty and an inability of the public health community to mobilize the human population to respond to the need to eliminate mosquito breeding sites are also factors in lack of mosquito control. New approaches that may be considered in the future of vector control include the release of *Aedes* mosquitoes infected with *Wolbachia* or carrying dominant lethal genetic mutations that will be passed on to offspring. A tetravalent live-attenuated dengue vaccine based on the attenuated YFV 17D platform (CYD-TDV, or Dengvaxia) was licensed in 2015 and registered in 20 countries for individuals 9–45 years of age. However, retrospective analysis of phase 3 trials in Latin America and Asia suggested protection from severe dengue only in previously seropositive individuals; indeed, the risk of severe dengue was actually increased in seronegative vaccine recipients over that in nonvaccinated seronegative individuals, suggesting that a "first serologic hit" from the vaccine predisposes naïve recipients to more severe primary dengue infection. Strategic revision to avoid vaccine-enhanced disease pivoted to include prevaccination serologic screening aimed to avoid vaccination of seropositive individuals; however, the requirement for prevaccine testing and decision-making is challenging. Recently, live-attenuated candidate vaccines based on modified recombinant DENVs have been or are being evaluated, with these learnings in mind. Qdenga (TAK-3), given in two doses 3 month apart, has shown overall efficacy against infection and hospitalization in seropositive and seronegative children, although not against DENV-3 (in fact, a very small signal of potentially increased risk of hospitalization after DENV-3 infection was observed), and the trial did not include DENV-4 infections. This vaccine has been approved for use in several European countries. Recommendations globally are currently for introduction in settings with high transmission intensity for maximal

public health impact while reducing potential risk in seronegative individuals. Further postmarket evaluation is ongoing. More recently, a phase 3 trial of Butantan-DV, a single-dose tetravalent vaccine, was shown to prevent symptomatic DENV-1 and DENV-2 infection; in the absence of DENV-3 and DENV-4 infections during the trial, efficacy against these serotypes is unknown. TVOO3, a single-dose vaccine designed to balance DENV serotype-specific components, is currently undergoing phase 3 clinical evaluation; similar concerns about safety are being addressed.

YELLOW FEVER YFV had caused major epidemics in Africa and Europe before its transmission by YF mosquitoes was discovered in 1900. Urban YF became established in the Americas because of colonization with YF mosquitoes—originally an African mosquito. Subsequently, different types of mosquitoes and nonhuman primates were found to maintain YFV in Africa and in Central and South American rain forests. Transmission to humans is incidental, occurring via bites from mosquitoes that have fed on viremic monkeys. After the identification of *Ae. aegypti* as the vector of YF, containment strategies were aimed at increased mosquito control. Today, urban YFV transmission occurs only in some African cities, but the threat exists in the cities of South America, where reinfestation by YF mosquitoes has taken place, and DENV-1–4 transmission by these mosquitoes is common. Despite the existence of a highly effective and safe vaccine, several hundred jungle cases of YF occur annually in South America, and 84,000–170,000 severe jungle and urban cases (resulting in 29,000–60,000 fatal outcomes) occurred in Africa in 2013 alone. In 2016, a large urban outbreak (Luanda, Angola) spilled over to generate local transmission in large cities in neighboring countries (e.g., Kinshasa, Democratic Republic of the Congo) as well as travel-related cases in China; the signal of a global threat that included exportation to Asia stimulated ongoing efforts to identify and vaccinate highest-risk populations in 40 targeted countries in Africa and South America, to reactively vaccinate people in outbreak settings, and to increase measures to prevent exportation.

YF is a typical VHF notable for prominent hepatic necrosis. After an incubation period of 3–6 days, patients present with a nonspecific febrile illness (fatigue, myalgia, backache, headaches, photophobia, anorexia, nausea or vomiting) associated with viremia typically lasting 3–4 days. After defervescence, 10–15% of patients develop recrudescent fever and "intoxication" characterized by severe dysfunction of the liver and other organs. Hepatic failure leads to the characteristic jaundice, bleeding (gastrointestinal tract, nasopharyngeal mucosa), abdominal pain with nausea and vomiting, and hyperammonemic encephalopathy; acute kidney injury leads to oliguria, azotemia, and marked albuminuria; and myocardial injury and encephalitis have been described. Abnormalities in liver function tests range from modest elevations of hepatic aminotransferase activities in mild cases to severe liver injury, hyperbilirubinemia, and the synthetic dysfunction of acute hepatic failure. After early leukopenia, leukocytosis occurs as disease progresses, and coagulation abnormalities are common. Treatment is supportive only. Although most infections are subclinical, 50% of patients who enter the toxic phase die in the next 7–10 days.

Urban YF can be prevented by the control of YF mosquitoes. The continuing sylvatic cycles require vaccination of all visitors to areas of potential transmission with live-attenuated variant 17D vaccine virus, which cannot be transmitted by mosquitoes. With few exceptions, reactions to the vaccine are minimal; immunity is provided within 10 days and lasts for at least 25–35 years. Recent meta-analytic review of 39 clinical studies suggests seroprotection is high (>90%) and perhaps lifelong after one vaccine dose in adults from nonendemic areas, raising questions about the utility of further boosting in this population. An egg allergy mandates caution in vaccine administration. Although fetal harm has not been documented, pregnant women should be immunized only if they are at risk of exposure to YFV. Because vaccination has been associated with several cases of encephalitis in children <6 months of age, it is contraindicated in this age group and not recommended for infants 6–8 months of age unless the risk of exposure is very high. Rare, serious, multisystemic adverse reactions (occasionally fatal), including vaccine-associated "viscerotropic" YF, have been reported, particularly affecting the elderly and those with congenital (mutations affecting interferon α [IFNα] signaling) or acquired (autoantibodies to IFNα, thymoma) impairment affecting viral control. The risk-to-benefit ratio should be weighed before vaccine administration to individuals ≥60 years of age. Nevertheless, the number of deaths of unvaccinated travelers with YF exceeds the number of deaths from vaccination, and a liberal vaccination policy for travelers to involved areas should be pursued. Timely information on changes in YF distribution and YF vaccine requirements can be obtained from the U.S. Centers for Disease Control and Prevention (*https://wwwnc.cdc.gov/travel/yellowbook/2024/preparing/yellow-fever-vaccine-malaria-prevention-by-country*).

216 Filovirids: Orthoebolavirus and Orthomarburgvirus Infections

Jens H. Kuhn, Ian Crozier

Several viruses in the family *Filoviridae* cause severe infections in humans that are often fatal. Introduction of filovirids into human populations is an extremely rare event that most likely occurs by direct or indirect contact with reservoir hosts (known and unknown) or by contact with sick or deceased filovirid-infected mammals. Filovirids are highly infectious but not exceptionally contagious. Human-to-human transmission occurs through direct person-to-person contact or exposure to infected bodily fluids or tissues; there is no evidence of aerosol or respiratory droplet transmission in natural outbreak settings. Infections manifest initially with a nonspecific influenza-like febrile illness that rapidly progresses to commonly include gastrointestinal manifestations and, in severe illness, coagulopathy, multiple-organ dysfunction syndrome, shock, and death. Although the prevalence and source remain controversial, serologic footprints of subclinical

acute filovirid infections have been identified since the first descriptions of filovirid disease outbreaks. Filovirid disease survivors may be persistently infected in immune-privileged tissue compartments, commonly in the male reproductive tract, but also in the central nervous system (CNS), and in intraocular tissues and fluids; notably, filoviral persistence has been rarely associated with the re-ignition of outbreaks. Historically, the prevention of filovirid infections has consisted primarily of tried-and-true epidemiologic approaches (e.g., isolation of cases, contact tracing, effective infection prevention and control, and safe burial practices). Treatment of disease traditionally consisted only of limited supportive clinical care (often constrained by in-field capacity); indeed, filovirid-specific vaccines or therapeutic agents had not been rigorously evaluated in humans prior to the 2013–2016/2021 outbreaks of Ebola virus disease (EVD) that occurred in Western Africa. Building on the knowledge gained in Western Africa and during the 2018–2020 EVD outbreak in the Democratic Republic of the Congo, prevention and treatment strategies now include the widespread deployment of an effective vaccine specific to Ebola virus (EBOV); the use of effective therapeutics based on virus-specific monoclonal antibodies (mAbs), which were identified in a first-of-its-kind randomized controlled trial; and the delivery of improved supportive care. Although these advances have essentially become new standards for prevention and treatment of EVD, the same cannot yet be said for other filovirid diseases.

Filovirids are categorized as World Health Organization (WHO) Risk Group 4 pathogens. Consequently, all work with material potentially containing replicating filovirids should be conducted in maximum containment (biosafety level 4) laboratories, or the viruses should be inactivated prior to activities in biosafety level 2/3 laboratories. These viruses must be handled by experienced personnel wearing appropriate personal protective equipment (PPE; see "Control and Prevention," below) and following rigorous standard operating procedures. In addition, when filovirid disease outbreaks are suspected or confirmed, the appropriate national authorities and WHO reference laboratories should be contacted immediately.

ETIOLOGY

The family *Filoviridae* includes nine official genera **(Figs. 216-1 and 216-2)**. Human pathogens are found in two of these genera, *Orthoebolavirus* and *Orthomarburgvirus*. Collectively, these pathogens cause "filovirid" ("filovirus") disease (FVD; International Classification of Diseases, Eleventh Revision [ICD-11], code 1D60). FVD is subdivided into "Ebola disease" (EBOD; ICD-11, code 1D60.0), caused by four of six classified orthoebolaviruses (Bundibugyo virus [BDBV], EBOV, Sudan virus [SUDV], and Taï Forest virus [TAFV]), and "Marburg disease" (MARD; ICD-11, code 1D60.1), caused by the two orthomarburgviruses, Marburg virus and Ravn virus. Accordingly, specific diseases are optimally named with the virus-specific cause such that, for example, "EVD" is distinguished from "Sudan virus disease (SVD)."

Mammalian filovirids have linear, nonsegmented, negative-sense RNA genomes that are ≈19 kb in length. These genomes contain seven genes that encode seven structural proteins: a nucleoprotein (NP), a polymerase cofactor (VP35), a matrix protein (VP40), a glycoprotein ($GP_{1,2}$), a transcriptional activator (VP30), a ribonucleoprotein complex-associated protein (VP24), and a large (L) protein that contains an RNA-directed RNA polymerase domain. Orthoebolaviruses, but not orthomarburgviruses, additionally encode three nonstructural proteins of unknown functions (sGP, ssGP, and Δ-peptide). Filovirions are unique among human virus particles in that they are predominantly pleomorphic filaments but also assume torus-like or 6-like shapes (width ≈91–98 nm; average length <1 μm). These enveloped virions contain helical ribonucleoprotein capsids and are covered with $GP_{1,2}$ spikes **(Fig. 216-3)**.

EPIDEMIOLOGY

The majority of recorded FVD outbreaks, including the 2013–2016 EVD outbreak, can be traced back to single index patients who transmitted the infection to others. Although small outbreaks may not have been recorded historically, the epidemiology of EVD transmission chains suggests that only ≈50 natural host-to-human spillover events have occurred since the discovery of filovirids in 1967. However, outbreaks associated with reignition of human-to-human transmission from a persistently infected survivor of a previous outbreak have more recently been described. Outbreak frequency, size, and overall

Philadelphia, Wolters Kluwer/Lippincott Williams & Wilkins, 2020, pp 449–503. Analysis courtesy of Nicholas Di Paola, PhD, USAMRIID, Fort Detrick, MD, USA. Figure courtesy of Jiro Wada, NIH/NIAID/DCR/IRF-Frederick, Fort Detrick, MD, USA.)*

case-fatality rate are likely the result of complex interactions of the specific filovirid, the reservoir hosts (known and unknown), the susceptible human population (e.g., varying with age, unknown genetic determinants of susceptibility and disease severity, and risk behavior), and the geographic setting (e.g., local public health capacity, socioeconomic conditions, and cultural practices).

As of November 13, 2024, 35,608 cases of human filovirid disease and 15,886 deaths had been recorded **(Fig. 216-4)**. These numbers emphasize both the high case-fatality rate (number of deaths per number of sick people; 44.6%) and the overall low mortality (reflecting the impact on the healthy population) related to filovirid diseases. Of these totals, 28,652 cases and 11,325 deaths occurred during the 2013–2016 EVD outbreak in Western Africa; this was the largest of all recorded FVD outbreaks. Natural FVD outbreaks had not been considered a global threat until regional and then global spread during this outbreak challenged that tenet. Filovirids that are pathogenic in humans appear to be exclusively endemic to equatorial (Western, Middle, and Eastern) Africa **(Fig. 216-5)**, although this distribution may change if natural or artificial environmental alterations lead to filovirid host migration and increased contacts between nonhuman hosts and humans.

Outbreaks have been contained when high-risk activities (e.g., ritual washing as part of burial practices) have been limited or been made safer with appropriate infection prevention and control. Of particular importance is accessibility to health care centers with staff trained and equipped (e.g., with PPE) for adequate infection prevention and control, to limit both community spread and nosocomial amplification. The incidence of FVD may have increased over the past two decades (Fig. 216-4 and Fig. 216-5), but debate continues as to whether this increase is due to increased filovirid activity, more frequent human interaction with filovirid hosts, or improvement in surveillance capabilities.

FVD outbreaks are associated with distinct meteorologic and geographic conditions and are probably associated with distinct hosts or reservoirs. The four orthoebolaviruses that cause disease in humans appear to be endemic in humid rainforests. EVD outbreaks in particular have often been associated with hunting in forests or contact with bushmeat (i.e., meat from apes, other nonhuman primates, duikers, or bush pigs). Ecologic studies suggest that EBOV may play a role in extensive and often-fatal epizootics among wild ape populations. However, only one orthoebolavirus, TAFV, has been isolated from nonhuman primates in the wild. Orthomarburgviruses, on the other hand, seem to infect hosts inhabiting arid woodlands, and associated outbreaks have almost always been epidemiologically linked to individuals visiting or working in natural or engineered caves or mines. The cave-dwelling Egyptian rousette (*Rousettus aegyptiacus* (Geoffroy, 1810)), a pteropodid (fruit) bat, serves as a natural and subclinically infected reservoir for both Marburg virus and Ravn virus. Although bats are suspected hosts for orthoebolaviruses as

well, definitive proof is lacking. To date, the nonpathogenic Bombali virus is the only orthoebolavirus for which coding-complete genome nucleic acid has been detected in bats. EBOV and Reston virus have been loosely connected to frugivorous and insectivorous bats by means of antibody or genome fragment detection, whereas the hosts of BDBV, SUDV, and TAFV are enigmatic.

PATHOGENESIS

Human infections typically occur through direct exposure of skin lesions or mucosal surfaces to contaminated body fluids or material or by parenteral inoculation (e.g., via accidental needlesticks or reuse of needles in poorly equipped hospitals). Numerous studies, both in vitro and in vivo (in several animal models of human disease), have illuminated aspects of FVD pathogenesis (Fig. 216-6). The $GP_{1,2}$ spikes on the surface of filovirions determine their cell and tissue tropism by engaging cell-surface molecules and the intracellular filovirid receptor NPC intracellular cholesterol transporter 1 (NPC1).

One of the hallmarks of filovirid pathogenesis is a pronounced modulation and dysregulation of immune responses. The first targets of filovirions are local macrophages, monocytes, and dendritic cells. Several structural proteins of filovirions (i.e., VP35, VP40, and/or VP24) then suppress intrinsic and innate immune responses by, for example, inhibiting the type I interferon antiviral pathways. This immunomodulation ultimately enables a productive filovirid infection, resulting in very high viral titers (>10^6 PFU/mL of serum in humans) with dissemination to most tissues. In tissues, filovirions infect additional

phagocytic cells, including other macrophages (alveolar, peritoneal, and pleural macrophages; Kupffer cells in the liver; and microglia in the CNS), epithelial cells (e.g., adrenal cortical cells and hepatocytes), stromal cells (fibroblasts), and endothelial cells. Infection is cytolytic in some—but not all—infected cells; e.g., hepatocyte necrosis likely contributes to elevated aminotransferase activities, and hepatic synthetic dysfunction contributes to coagulopathy. Infection leads to the secretion of soluble signaling molecules (varying with the cell type) that likely contribute to forward dysregulation of immune responses and ultimately to multiorgan dysfunction syndromes. For instance, infected macrophages secrete proinflammatory cytokines, leading to further recruitment of monocyte-derived macrophages to the site of infection. In contrast, infected dendritic cells are not activated to secrete cytokines, and the expression of major histocompatibility class II antigens is partially suppressed, with consequently deficient antigen presentation. Immunosuppression also occurs in part by massive lymphoid depletion in lymph nodes, spleen, and thymus in the absence of effective humoral and cell-mediated immune responses, especially in severe or fatal disease. Results from animal studies suggest that depletion is a direct consequence of considerable lymphocyte death; this explanation would also account for the severe lymphopenia that develops in patients. In addition to potential florid filovirid dissemination, another consequence of lymphocyte depletion may be susceptibility to secondary bacterial and fungal infections.

Other pathogenic hallmarks of filovirid infections include coagulopathy and endothelial dysfunction. Along with hepatic synthetic dysfunction, disseminated intravascular coagulation may contribute though this remains controversial. Thrombocytopenia, increased concentrations of tissue factor, consumption of clotting factors, increased concentrations of fibrin degradation products (D-dimers), and declining concentrations of protein C are typical features of severe disease. Consequently, fibrin deposition and microthrombotic small-vessel occlusion and necrotic/hypoxic infarction may occur in some tissues, particularly in the gonads and, less often, in the kidneys and spleen. In addition, petechiae, ecchymoses, extensive visceral effusions, and other hemorrhagic signs are observed in internal organs, mucous membranes, and skin. However, actual severe blood loss is a rare event (although it frequently occurs during or after childbirth). Most likely,

aberrance in cytokines or other factors, such as nitric oxide, and direct infection and activation of endothelial cells are responsible for upregulated permeability of blood-vessel endothelia. This upregulation leads to fluid redistribution and interstitial tissue edema and hypovolemic or septic shock are common features of severe disease.

Despite this long list of pathogenetic hallmarks, increasing evidence from clinical settings suggests that effective filovirid-specific adaptive immune responses do develop, coinciding with control and clearance of viremia and subsequent clinical improvement in surviving patients. However, depending on the severity of illness (including organ dysfunction and late complications), clinical illness may be protracted and recovery incomplete.

CLINICAL MANIFESTATIONS

Diseases caused by orthoebolaviruses and orthomarburgviruses present very similar clinical phenotypes that cannot be distinguished at the bedside and, for all practical purposes, may be considered the same disease; this approach may change as higher-resolution characterization of human FVD accrues. The prevalence and character of clinical signs do not differ significantly in disease caused by disparate filovirids (except for the possibly apathogenic Reston virus), although, with the exception of the 2013–2016 EVD outbreak, the numbers of deeply characterized clinical observations are very low. The incubation period is 2–25 days (most commonly 7–10 days), after which infected people develop a nonspecific influenza-like syndrome characterized by sudden onset of fever and chills, severe headaches, cough, myalgia, pharyngitis, arthralgia of the larger joints, development of a maculopapular rash, and other symptoms/signs. A subsequent second phase (≈5–7 days after disease onset and thereafter) involves the gastrointestinal (nausea and vomiting and/or diarrhea, sometimes with abdominal pain), respiratory (chest pain, cough, and/or dyspnea), cardiovascular (hypotension and/or edema), and central nervous (confusion, headache, and/or coma) systems. Common hemorrhagic manifestations include subconjunctival injection, petechial rash, gingival bleeding, and bleeding at injection sites; epistaxis, hematemesis, hematuria, and melena occur but are less common. Patients usually succumb to acute disease 4–14 days after infection, often with severe multiorgan dysfunction that commonly includes shock and acute renal or respiratory failure.

Typical laboratory findings are leukopenia (with cell counts as low as 1000/μL) with a left shift prior to leukocytosis, thrombocytopenia (with counts as low as 50,000/μL), increased activities of liver enzymes (aspartate aminotransferase > alanine aminotransferase, γ-glutamyltransferase), increased creatinine and urea concentrations with proteinuria, electrolyte derangement (hypokalemia or hyperkalemia, hyponatremia, and/or hypocalcemia), hypoglycemia, hypoalbuminemia, prolonged prothrombin and partial thromboplastin times, and elevated creatine phosphokinase activities. Nonspecific markers of systemic inflammation (e.g., C-reactive protein concentrations) may be markedly elevated in severely ill patients.

DIAGNOSIS

Filovirid disease cannot be diagnosed based on clinical presentation alone. Numerous diseases common in equatorial Africa need to be considered in the differential diagnosis of a febrile patient. Almost all of these occur at a much higher incidence than FVD and are much more likely diagnoses in non-outbreak settings; however, during outbreaks and in peri-outbreak periods, timely and accurate laboratory diagnosis to rule in or rule out filovirid infection is critical. The most important infectious disease mimics of FVD are falciparum malaria and typhoid fever; also important are enterohemorrhagic *Escherichia coli* enteritis, gram-negative septicemia (including shigellosis), meningococcal septicemia, rickettsial infections, fulminant viral hepatitis, leptospirosis, measles, and other high-consequence viral infections (in particular, Lassa fever and yellow fever). Rarer noninfectious possibilities, including venomous snakebites, warfarin intoxication, and the many causes of acquired or inherited coagulopathy, also must be considered in the bleeding patient. An exposure history—including exposure to caves or mines; direct contact with bats, nonhuman primates, or "bushmeat"; direct contact with severely ill local residents; or admission to rural hospitals with patient-to-patient or patient-to-health-care-worker clusters of illness—should raise the index of suspicion.

If FVD is suspected based on epidemiologic and/or clinical manifestations, infectious disease specialists and the proper public health authorities should be notified immediately. Laboratory diagnosis of FVD is relatively straightforward but ideally requires the capacity for maximum containment, which usually is not available in filovirid-endemic countries. Increasingly, laboratory diagnosis is performed with patient samples inactivated in mobile field "glove boxes" by on-site personnel trained in the safe use of diagnostic assays adapted for field use in lower-containment settings. Consequently, diagnostic samples should be collected and processed with great caution and with the use of appropriate PPE and strict barrier techniques. With adherence to established biosafety precautionary measures, samples should be sent in suitable transport media to national or international reference laboratories. Acute-phase blood/serum is the preferred diagnostic specimen because it usually contains high titers of filovirions.

The current assay of choice for the diagnosis of filovirid infection is reverse-transcription polymerase chain reaction (RT-PCR) targeting one or more filovirid genes; a typical detection limit is 1000–5000 PFU/mL of serum, depending on the assay. When available, safe, rapid-turnaround, and standardized in-field PCR-based approaches (e.g., the Cepheid GeneXpert platform) are now standardly deployed during outbreaks. Antigen-capture enzyme-linked immunosorbent assays (ELISAs) or immunochromatographic assays for the detection of filovirion proteins are in development and may be useful as point-of-care rapid diagnostic tests (RDTs) in the future; sensitivity limitations of EBOV-specific antigen-based RDTs restrict current use to diagnosis of postmortem samples only. Direct immunoglobulin M (IgM) capture, direct IgG capture, or IgM-capture ELISAs (including multiplex approaches) are used for the detection of filovirion-targeting antibodies from patients in the later stages of disease (i.e., those who have been able to mount a detectable antibody response), including survivors. All of these assays can be conducted on samples treated with guanidinium isothiocyanate (for RT-PCR), cobalt-60 irradiation (for ELISA), or other effective measures (heat or irradiation treatment) that render filovirids noninfectious. Virus isolation in cell culture and plaque assays for quantification or diagnostic confirmation are relatively simple but must be performed in maximum-containment laboratories. If available, electron microscopic examination of inactivated samples or cultures for the unique filamentous structures of filovirions can further support diagnosis (Fig. 216-3). Formalin-fixed skin biopsy samples and possibly skin swabs can be useful for safe postmortem diagnoses. In-field (or near in-field) rapid genome sequencing was first deployed to inform classic epidemiology in Western Africa during the 2013–2016 EVD outbreak and has become a mainstay of outbreak control and response, even in endemic settings.

TREATMENT

Filovirid Disease

Clinical management of patients with suspected or confirmed filovirid disease should be conducted by health care workers who have been well-trained in the complex care of FVD patients and who are using appropriate PPE in care environments with appropriate infection prevention and control measures (see "Control and Prevention," below). Historically, management of FVD had been entirely supportive (and even that limited by resource constraints) because the efficacy and safety of specific antiviral countermeasures had not been rigorously studied outside of animal models of disease. The 2013–2016 EVD outbreak in Western Africa highlighted the need to conduct rigorous, feasible, and ethical clinical research during outbreaks. Building on challenges and lessons learned in that setting, the first-of-its-kind Pamoja Tulinde

Maisha (PALM) randomized clinical trial was conducted during the 2018–2020/2021 EVD outbreak in the Democratic Republic of the Congo and identified two therapeutics based on mAbs specific to EBOV to improve survival rates. mAb114 (ansuvimab-zykl) and REG-EB3 (atoltivimab, maftivimab, and odesivimab-ebgn) were subsequently approved for the treatment of EVD in PCR-confirmed adults (including pregnant women) and children. Both are administered via carefully monitored single-dose infusions initiated as soon as possible after diagnosis. In addition, efforts during this outbreak demonstrated the will and capacity to deliver more advanced supportive and critical care accompanying specific therapeutics in the African outbreak setting. Although evidence is lacking, consensus treatment strategies include those generally recommended for severe septicemia/sepsis/shock **(Chap. 315)** and should be applied with an emphasis on standard approaches—i.e., monitoring and response to respiratory dysfunction (e.g., oxygen), circulatory dysfunction (e.g., intravascular fluid repletion and vasopressor support), and CNS dysfunction (e.g., ruling out of reversible causes, notably hypoglycemia)—as well as the detection and management of acute kidney injury, hemorrhage, electrolyte derangements, and nutritional status and the prevention and treatment of secondary or co-infections. Pain management and administration of antipyretics, antiemetics, and antidiarrheal agents may be considered. Crucial strategies to improve outcomes in the most severely ill FVD patients include preventing organ dysfunction and providing safe and effective temporary organ support (e.g., mechanical ventilation and renal replacement) to expand the window for administration of medical countermeasures and development of effective endogenous immune responses.

COMPLICATIONS

Even in patients who have initial virologic or clinical improvement, complications in the second or third week of illness may include secondary infections; persistent renal dysfunction and electrolyte abnormalities; respiratory insufficiency; neurologic compromise (e.g., EBOV-related meningoencephalitis, cerebrovascular events, and seizures); cardiac dysfunction (e.g., myocarditis and pericarditis); and venous thrombosis. Pregnancy and labor are historically associated with severe complications and poor outcomes in filovirid disease due to clotting factor consumption, fetal loss, and/or severe blood loss during birth; in the era of EBOV-specific therapeutics and optimized supportive care, maternal and fetal outcomes are improved.

A number of sequelae have been self-reported or historically described in survivors of FVD, including prolonged and sometimes incapacitating arthralgia and myalgia, asthenia, alopecia, visual problems (including uveitis), hearing loss, memory loss and neurocognitive dysfunction, mental health conditions (anxiety, depression, and posttraumatic stress disorder), and reproductive problems. Well-controlled observational studies of EVD survivors were first conducted in the aftermath of the 2013–2016 Western Africa EVD outbreak. Compared with their close-contact controls, Liberian EVD survivors had an increased incidence of headache, arthralgia and myalgia, memory loss, fatigue, and urinary frequency as well as abnormal results in abdominal, chest, neurologic, musculoskeletal, and ocular exams. Of individual and public health significance is the potential for persistence of filovirids in immune-privileged tissue compartments (and their associated fluids) in FVD survivors, most commonly in the semen of male survivors (with the rare but documented potential for sexual transmission) and rarely in the CNS (causing recrudescent meningoencephalitis), the eye (causing recrudescent uveitis), and the placenta (causing transmission or placental insufficiency). True relapses that resemble the course of primary FVD are extremely rare but have been described. The risk of the remote reignition of outbreaks from persistently infected FVD survivors is apparently rare but obviously consequential. Notably, these events have only been detected after the two largest EVD outbreaks, suggesting a likely limitation, with the caveat that available samples and genomic tools to determine outbreak relatedness have historically not been available. EVD outbreaks in the Democratic Republic of the Congo in 2021 were genomically linked to the previous 2018–2020 outbreak. After a 5- to 7-year interim, an EVD outbreak in Guinea in 2021 was genomically linked to the 2013–2016 Western African outbreak; this event remains enigmatic as corroborating epidemiologic links have not been found.

PROGNOSIS

Among the most severe of acute viral diseases in humans, FVD generally has a poor prognosis, although with much greater heterogeneity than was historically assumed; i.e., the 70–90% case-fatality rate ascribed for many decades to EVD has required revision. With an incomplete evidence base, the outcome probably depends on factors that include the particular filovirid causing the infection (Fig. 216-4), host factors (age, immune status, coinfections, and unknown host genetic factors), virus exposure route and dose, viral load, the presence and severity of organ dysfunction, and—critically—the availability of filovirid-specific countermeasures and requisite supportive care. Despite the receipt of effective EBOV-specific therapeutics, outcomes in severe EVD patients with high viral loads and complex organ dysfunction remain suboptimal and will require future research to evaluate and advance virus-targeted (e.g., combination therapeutic), disease-targeted (e.g., immunomodulatory), and optimized supportive care strategies. After resolution of acute disease, the long-term health and survival outcomes for FVD survivors are unknown. It is uncertain how increased access to filovirid-specific therapeutics and life-saving support will impact filovirid persistence in survivors; short- and long-term surveillance will be necessary to avoid individual consequences (e.g., relapse and/or recrudescent inflammatory syndromes) and public health consequences (e.g., reignition of outbreak transmission chains in the peri-outbreak or post-outbreak period).

Although remarkable progress in understanding and improving outcomes in EVD has occurred in recent years, the same cannot yet be said for disease caused by filovirids other than EBOV, either in acute disease or in convalescence.

CONTROL AND PREVENTION

Prevention of viral exposure in nature is challenged by an incomplete understanding of filovirid ecology. To prevent orthomarburgvirus infection, people entering or living in areas where Egyptian rousettes can be found should avoid direct or indirect contact with these animals. Prevention in nature is more difficult in the case of pathogenic orthoebolaviruses, largely because ecologic reservoirs have not yet definitively been identified. EVD outbreaks have been associated with hunting or consumption of nonhuman primates more than exposure to bats. Indeed, the mechanism of introduction of orthoebolaviruses into nonhuman primate populations, if it occurs at all, is unclear. (Only one pathogenic orthoebolavirus, TAFV, has unequivocally been detected in wild nonhuman primates.) Therefore, to prevent orthoebolavirus infection, the only evidenced advice that can be offered to travelers and locals is to avoid contact with "bushmeat," nonhuman primates, and bats. In any setting, the local involvement of medical anthropologists and careful community engagement is strongly advised to ensure preventive risk communication is not received as threatening or patronizing.

Biomedical prevention strategies have historically been limited to tried-and-true pillars of outbreak control, centering on the identification and isolation of cases, contact tracing, ensuring that health care workers and other response personnel have appropriate training and capacity in infection prevention and control, and preventing high-risk transmission events. Measures aimed at preventing and controlling infection, including relatively simple barrier nursing techniques, vigilant use of appropriate PPE, quarantine, and contact tracing, usually effectively terminate or at least contain FVD outbreaks. Isolation of infected people and their contacts and avoidance of direct person-to-person contact without appropriate PPE usually prevent further spread, as the virions are not transmitted through droplets or aerosols under natural conditions. Typical protective gear sufficient to prevent filovirid infections consists of disposable gloves, gowns, and shoe

covers and a face shield and/or goggles. If available, N-95 or N-100 respirators may be used to further limit infection risk. Positive-air-pressure respirators should be considered for high-risk medical procedures, such as intubation or suctioning. Medical equipment used in the care of an infected patient, such as gloves or syringes, should never be reused. Because filovirions are enveloped, disinfecting with detergents (e.g., 1% sodium deoxycholate, diethyl ether, or phenolic compounds) is relatively straightforward. Bleach solutions are recommended at 1:100 for surface disinfection and 1:10 for application to excreta or corpses. Whenever possible, potentially contaminated materials should be autoclaved, irradiated, or destroyed.

Emerging from research conducted during the 2013–2016 EVD outbreak in Western Africa, a vaccine based on a recombinant vesicular stomatitis Indiana virus expressing EBOV $GP_{1,2}$ (rVSV-ZEBOV/Ervebo) was the first filovirid vaccine approved for use in the United States and the European Union (EU). It is now widely deployed in both a reactive-ring vaccination strategy, targeting close contacts and their contacts in EVD outbreak settings, and for the preexposure vaccination of health care workers in at-risk regions. More recently, a heterologous dose vaccine candidate incorporating EBOV $GP_{1,2}$ into an adenovirus vector (Ad26.ZEBOV-GP/Zabdeno) followed by a vaccinia virus vector incorporating multiple filovirid antigens (MVA-BN-filo/Mvabea) has been shown to be safe and immunogenic in humans. Though evaluation of efficacy in a clinical trial has not been possible, immunobridging data gained during nonhuman primate experimentation led to regulatory authorization in the EU under "exceptional circumstances"; the two-dose requirement likely limits current use to proactive preexposure prevention in "peri-outbreak" settings rather than reactive "in-outbreak" reactive strategies. Development and evaluation of this and other vaccine candidates continue toward complementary preventive approaches for non-outbreak or peri-outbreak settings, with emphasis on the durability of immune responses and increases in preventive breadth toward other filovirids.

Even in the absence of high-level evidence, expert consensus informs the targeted use of EBOV-specific vaccine or postexposure prophylaxis (PEP) to prevent infection or disease in health care workers considered to have had a high-risk EBOV exposure (e.g., after needlestick injury). Evidence is needed to inform the use of PEP in high-risk contacts in the field outbreak setting. For male survivors, abstinence from sexual activity with a partner for at least 12 months after disappearance of clinical signs is recommended, unless testing proves semen to be free of filovirid RNA. (The use of condoms is generally recommended for all sexual activities.) Reproductive tract and CNS tissues, including ocular tissues and fluids from survivors, should be handled with appropriate precautions until demonstrated to be filovirid-RNA free. The role of filovirid-specific therapeutics in the prevention or treatment of filoviral persistence is unclear.

217 Pathogenesis, Diagnosis, and Treatment of Fungal Infections

Michail S. Lionakis, John E. Edwards, Jr.

DEFINITION AND ETIOLOGY

In recent decades, human fungal infections have dramatically increased worldwide as a result of the AIDS pandemic, the widespread use of antibacterial agents, and the introduction of cytotoxic agents and precision medicine biologics for the treatment of autoimmune and neoplastic diseases and for use in patients undergoing solid organ transplantation or hematopoietic stem cell transplantation. Moreover, of great concern has been the recent rise in fungal infections caused by drug-resistant species, such as azole- and/or echinocandin-resistant *Candida glabrata* and *Candida auris* and azole-resistant *Aspergillus fumigatus*. Among the ~5 million fungal species, only a few cause human infections **(Table 217-1)**.

Fungal infections are classified as *mucocutaneous* and *deep organ* infections on the basis of anatomic location and as *endemic* and *opportunistic* infections on the basis of epidemiology. Mucocutaneous infections can cause serious morbidity but are rarely fatal. Deep organ infections cause severe illness and often carry a high mortality rate. The endemic mycoses are caused by fungi that are not part of the normal human microbiota but are environmentally acquired. The opportunistic mycoses are caused by fungi (*Candida, Aspergillus*) that often are components of the human microbiota and whose ubiquity in nature renders them easily acquired by immunosuppressed hosts (Table 217-1). Opportunistic fungi cause serious infections when impaired host immune responses allow the organisms to transition from commensals to invasive pathogens. Endemic fungi typically cause self-limited disease in immunocompetent hosts but severe illness in immunosuppressed patients.

Fungi are morphologically classified as *yeast*, *mold*, and *dimorphic*. Yeasts are seen as round single cells or budding organisms. Molds grow as filamentous forms called *hyphae* both at room temperature and in tissue. *Aspergillus*, Mucorales, and dermatophytes that infect skin and nails are mold fungi. Variations exist within this classification system. For instance, when *Candida* infects tissue, both yeasts and filamentous forms (pseudohyphae) may be present (except in the cases of *C. glabrata* and *C. auris*, which form only yeasts in tissue); in contrast, *Cryptococcus* exists only in yeast form. *Dimorphic* is the term used to describe fungi that have two forms; they grow as yeasts or large spherical structures in tissue but as filamentous forms at room temperature in the environment (Table 217-1).

Patients acquire deep organ infection by molds and endemic dimorphic fungi via inhalation. Skin dermatophytes are primarily environmentally acquired, but human-to-human transmission may also occur. The commensal *Candida* invades deep tissues from sites of mucocutaneous colonization, usually in the gastrointestinal tract or the skin in the case of *C. auris*.

In this chapter, we outline general principles of immunology, diagnosis, and treatment related to the most common human fungal infections.

PATHOGENESIS

In the past decade, our understanding of fungal recognition pathways and of tissue-specific innate and adaptive antifungal host defense mechanisms has markedly expanded. A major breakthrough has been the discovery and functional characterization of the C-type lectin receptor/spleen tyrosine kinase/caspase recruitment domain–containing protein 9 (CLR/SYK/CARD9) signaling pathway, which mediates fungal polysaccharide recognition and orchestrates proinflammatory mediator production, leukocyte recruitment, inflammasome

TABLE 217-1 Major Fungal Infections, Associated At-Risk Patient Populations, and Diagnostic Tests

INFECTION (MOST COMMON FUNGAL GENERA AND SPECIES)	CLINICAL SYNDROME(S)	RISK FACTOR(S)	DIAGNOSTIC TEST(S)
Mold (Filamentous) Fungi			
Aspergillosis (*Aspergillus fumigatus, A. terreus, A. flavus, A. niger, A. nidulans*[a])	Pneumonia or disseminated infection ABPA Keratitis	Neutropenia, glucocorticoids, HSCT, post-influenza or COVID-19, BTK inhibition Atopic individuals Direct inoculation	*Culture* of BAL fluid: low sensitivity, nonspecific (colonization, contamination) *Histologic examination* of tissue[b]: acute-angle septate hyphae *Biomarkers:* GM (BAL > serum); serum BDG (nonspecific)
Mucormycosis (*Rhizopus, Rhizomucor, Mucor, Cunninghamella*, and *Lichtheimia* spp.)	Sinopulmonary infection Rhinocerebral infection Necrotizing skin infection	Neutropenia, HSCT Diabetic ketoacidosis Direct inoculation (e.g., tornado victims)	*Culture* of BAL fluid or sinus tissue: very low sensitivity *Histologic examination* of tissue: ribbon-like aseptate hyphae *Biomarkers:* Negative
Fusariosis (*Fusarium solani, F. oxysporum*)	Pneumonia or disseminated infection Keratitis	Neutropenia Direct inoculation	*Culture* of tissue or blood: one of the few molds recovered from blood *Histologic examination* of tissue: acute-angle septate hyphae *Biomarkers:* GM can be positive; BDG (nonspecific)
Scedosporiosis (*Scedosporium apiospermum*)	Pneumonia or disseminated infection	Neutropenia, glucocorticoids, HSCT	*Culture* of BAL: low sensitivity, nonspecific (colonization, contamination) *Histologic examination* of tissue: acute-angle septate hyphae *Biomarkers:* BDG can be positive
Phaeohyphomycosis (*Cladophialophora, Alternaria, Phialophora, Rhinocladiella, Exophiala*, and *Exserohilum* spp.)	Sinopulmonary, CNS, or disseminated infection Skin infection Allergic sinusitis	HSCT, neutropenia, glucocorticoids, healthy individuals (for CNS), TNF-α inhibition Direct inoculation Atopic individuals	*Culture* of ordinarily sterile site *Histologic examination* of tissue: cell walls may appear dark brown or golden on H&E; Fontana-Masson may stain fungal melanin
Dermatophytosis (*Trichophyton, Microsporum*, and *Epidermophyton* spp.)	Skin and nail infections	Healthy individuals	*Culture* or *microscopic examination* of scrapings or clippings: chains of arthrospores (diagnostic)
Eumycetoma (*Madurella mycetomatis*)	Skin and subcutaneous infections	Healthy individuals	*Culture* and *macroscopic and histologic examination* of grains harvested from biopsy or aspiration
Yeast Fungi			
Mucosal candidiasis[c] (*Candida albicans, C. glabrata*)	Oropharyngeal or esophageal candidiasis Vulvovaginal candidiasis	AIDS, glucocorticoids Antibiotic use	*Culture* of mucosal surfaces *Histologic examination* of esophageal tissue or wet preparation (10% KOH) of vaginal discharge: yeast and/or pseudohyphae
Invasive candidiasis[c] (*C. albicans, C. glabrata, C. parapsilosis, C. tropicalis, C. auris*)	Candidemia Disseminated infection (spleen, liver, kidney, eye, heart, CNS)	Critical illness (ICU) Neutropenia, glucocorticoids	*Culture* of blood: low sensitivity *Histologic examination* of tissue: yeast and/or pseudohyphae *Biomarkers/other tests:* BDG (nonspecific); T2 magnetic resonance in whole blood
Cryptococcosis (*Cryptococcus neoformans, C. gattii*)	Pneumonia Osteomyelitis Meningoencephalitis	AIDS, glucocorticoids Sarcoidosis AIDS, AAbs to IFN-γ or GM-CSF, BTK or JAK inhibition	*Culture* of CSF, BAL fluid, blood *Microscopic examination* of tissue or CSF: encapsulated yeast (GMS, India ink, mucicarmine stain) *Biomarkers: Cryptococcus* Ag (serum, CSF) is sensitive and specific
Trichosporonosis[d] (*Trichosporon asahii, T. mucoides, T. asteroides*)	Superficial skin infection (white piedra) Disseminated infection (skin, eye)	Healthy individuals Neutropenia, glucocorticoids, HSCT, SOT	*Culture* of tissue or blood *Histologic examination* of tissue: yeasts, hyphae, and arthroconidia *Biomarkers:* BDG can be positive
Endemic Dimorphic Fungi			
Histoplasmosis (*Histoplasma capsulatum, H. duboisii* [in Africa])	Self-limited pneumonia Disseminated infection (liver, bone, bone marrow) Fibrosing mediastinitis	Healthy individuals AIDS, SOT, glucocorticoids, AAbs to IFN-γ, JAK or TNF-α inhibition	*Culture* of blood or tissue: low sensitivity; weeks needed for growth *Histologic examination* of tissue: yeast with narrow-based budding *Other tests: Histoplasma* Ag (urine > serum > BAL); BDG can be positive; serology (CF) can be useful in non-AIDS patients
Blastomycosis (*Blastomyces dermatitidis, B. gilchristii*)	Pneumonia Disseminated infection (skin, bone, mucosal surfaces, genitourinary tract)	Healthy individuals AIDS, glucocorticoids, TNF-α inhibition	*Culture* of BAL or tissue: low sensitivity; weeks needed for growth *Histologic examination* of tissue: yeast with broad-based budding *Other tests:* serology (CF, ID) has low sensitivity; *Blastomyces* Ag test cross-reacts with other endemic fungi; GM can be positive
Coccidioidomycosis (*Coccidioides immitis, C. posadasii*)	Self-limited pneumonia Disseminated infection (CNS, bone)	Healthy individuals AIDS, glucocorticoids, TNF-α inhibition	*Culture* is diagnostic[e] *Histologic examination:* spherules *Other tests:* serology (CF, ID); *Coccidioides* Ag test can be useful in CNS infection; BDG can be positive
Paracoccidioidomycosis (*Paracoccidioides brasiliensis, P. lutzii*)	Pneumonia Disseminated infection (skin, bone, mucosal surfaces)	Healthy individuals AIDS, glucocorticoids	*Culture* of tissue: active disease; several weeks needed for growth *Histologic examination* of KOH preparations or tissue: yeast with budding in steering-wheel pattern *Other tests:* serology (ID, CF); *Paracoccidioides* Ag test

(*Continued*)

TABLE 217-1 Major Fungal Infections, Associated At-Risk Patient Populations, and Diagnostic Tests (Continued)

INFECTION (MOST COMMON FUNGAL GENERA AND SPECIES)	CLINICAL SYNDROME(S)	RISK FACTOR(S)	DIAGNOSTIC TEST(S)
Sporotrichosis (*Sporothrix schenckii*)	Lymphocutaneous infection (ascending lymphangitis) Disseminated infection	Direct inoculation AIDS, glucocorticoids	*Culture* of tissue (diagnostic) *Histologic examination*: cigar-shaped yeast, often with surrounding asteroid body
Talaromycosis (*Talaromyces marneffei*)	Pneumonia Disseminated infection (skin, bone, mucosal surfaces)	Healthy individuals AIDS, glucocorticoids, AAbs to IFN-γ	*Culture* of tissue (diagnostic) *Histologic examination* of tissue: yeasts with transverse septa *Biomarkers:* GM is often positive
Adiaspiromycosis (*Emmonsia crescens, E. parva*)	Pneumonia	Occupational dust exposure	*Culture:* nonculturable *Histologic examination*: thick-walled adiaspore within granuloma
Emergomycosis (*Emergomyces africanus, E. pasteurianus*)	Disseminated infection (lungs, skin)	AIDS, SOT	*Culture* of infected tissue *Histologic examination* of tissue: yeast with narrow-based budding *Biomarkers: Histoplasma* Ag can be positive
Chromoblastomycosis (*Fonsecaea pedrosoi, F. monophora*)	Skin and subcutaneous tissue infections	Healthy individuals	*Culture* of infected tissue *Histologic examination* of scrapings (KOH) or tissue (GMS): sclerotic bodies (pathognomonic)
Other Fungi			
Pneumocystosis[f] (*Pneumocystis jirovecii*)	Pneumonia Disseminated infection (eye, CNS, skin, gastrointestinal tract)	AIDS, glucocorticoids, BTK inhibition AIDS	*Culture:* nonculturable *Histologic examination* (gold standard): special (GMS, Diff-Quik) or immunofluorescence stains *Biomarkers/other tests:* BDG (nonspecific); BAL fluid PCR (sensitive; can be positive in colonized individuals)

[a]*A. nidulans* is seen almost exclusively in chronic granulomatous disease. [b]GMS or PAS stains. [c]Some *Candida* species form pseudohyphae. [d]*Trichosporon* species are yeast-like fungi that also generate septate hyphae and arthroconidia. [e]*Coccidioides* is a laboratory hazard. It is important to notify the microbiology laboratory if this infection is suspected. [f]*Pneumocystis* is present in cyst and trophozoite forms.

Abbreviations: AAbs, autoantibodies; ABPA, allergic bronchopulmonary aspergillosis; Ag, antigen; BAL, bronchoalveolar lavage; BDG, β-D-glucan; BTK, Bruton's tyrosine kinase; CF, complement fixation; CNS, central nervous system; CSF, cerebrospinal fluid; GM, galactomannan; GM-CSF, granulocyte-macrophage colony-stimulating factor; GMS, Gomori methenamine silver; H&E, hematoxylin and eosin; HSCT, hematopoietic stem cell transplantation; ICU, intensive care unit; ID, immunodiffusion; IFN-γ, interferon γ; JAK, Janus kinase; KOH, potassium hydroxide; PAS, periodic acid–Schiff; PCR, polymerase chain reaction; SOT, solid organ transplantation; TNF-α, tumor necrosis factor α.

activation, and Th17 cell differentiation upon fungal invasion. Human inherited CARD9 deficiency causes severe mucocutaneous and invasive fungal disease and is the only known primary immunodeficiency to feature fungus-specific infection susceptibility without a predisposition to other infections, autoimmunity, allergy, or cancer. Notably, CARD9-deficient patients develop infections by certain fungi in certain tissues, including (1) chronic mucocutaneous candidiasis linked to defective interleukin (IL) 17 responses; (2) infections of the central nervous system (CNS) caused by *Candida* (but also by *Aspergillus* and phaeohyphomycetes) linked to impaired microglial-neutrophilic responses; and (3) deep dermatophytosis. Thus, the clinical use of SYK inhibitors for autoimmunity and cancer may cause opportunistic fungal disease. Human inherited deficiency of Toll-like receptor (TLR) signaling does not lead to spontaneous fungal disease, yet polymorphisms in TLR pathway molecules may increase the risk of fungal disease in critically ill or immunosuppressed persons, and TLR stimulation may boost protective CLR immunity, as has been shown with the TLR7 agonist imiquimod in chromoblastomycosis.

The development of clinically relevant animal models of mycoses and the phenotypic characterization of fungal infections that develop in patients with primary immunodeficiencies and in recipients of immune pathway-targeting biologics have led to the delineation of fungus-, cell-, and tissue-specific requirements for antifungal host defense **(Fig. 217-1)**.

At the mucosal interface, IL-17-producing lymphoid cells play a critical role in protection by driving epithelial cell production of antimicrobial peptides that restrict mucosal *Candida* invasion. Indeed, AIDS patients are at risk for mucosal—but not invasive—candidiasis. Concordantly, inherited deficiency of IL-17 signaling caused by mutations in *IL17F*, *IL17RA*, *IL17RC*, or *TRAF3IP2* (encoding the IL-17 receptor adaptor ACT1) or pharmacologic inhibition of IL-17 signaling by biologics that target IL-12p40, IL-23p19, IL-17A, IL-17A/IL-17F, or IL-17RA cause mucosal—but not invasive—candidiasis. Other conditions that underlie a predisposition to chronic mucocutaneous candidiasis include primary immunodeficiencies due to mutations in *STAT3*, *STAT1*, *DOCK8*, *JNK1*, *IRF8*, *RORC*, and *CARD9*, all of which impair Th17 cells, as well as thymoma and autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED), which feature autoantibodies to IL-17A, IL-17F, and IL-22. In APECED, exacerbated T cell–derived interferon γ (IFN-γ)/STAT1 responses disrupt the integrity of the oral epithelial barrier, thereby promoting mucosal fungal invasion and infection; remission of candidiasis can be achieved with JAK inhibition in APECED and STAT1 gain of function (GOF). Of note, vaginal candidiasis (unlike oropharyngeal and esophageal candidiasis) develops in the setting of antibiotic treatment, not AIDS or IL-17–targeted biologics; this observation underscores the role of the microbiota in fungal control at the vaginal—but not the oral—mucosa.

On the other hand, neutrophils—but not lymphocytes—are critical for control of invasive infections caused by *Aspergillus* (and other inhaled molds) and *Candida* (Fig. 217-1). Indeed, patients with chemotherapy-induced neutropenia and patients undergoing allogeneic hematopoietic stem cell transplantation are at risk for invasive aspergillosis and candidiasis. Both oxidative and nonoxidative burst–dependent effector mechanisms are operational within neutrophils for fungal killing. Inherited deficiency in neutrophil superoxide generation due to mutations in the six subunits of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex causes chronic granulomatous disease, a prototypic primary immunodeficiency that carries a lifetime risk for invasive aspergillosis of ~40%; infrequently (i.e., in <5% of cases, mostly infants), chronic granulomatous disease predisposes to invasive candidiasis. The unexpected development of invasive mold infections in recipients of Bruton's tyrosine kinase (BTK) inhibitors has recently uncovered the critical role of BTK in promoting myeloid phagocyte-dependent antifungal effector functions.

Host defenses against fungi that reside within macrophages, such as *Cryptococcus*, *Pneumocystis*, and endemic dimorphic fungi, depend on the interplay of IFN-γ–producing lymphoid cells and IL-12–producing macrophages that enable intramacrophagic fungal killing (Fig. 217-1).

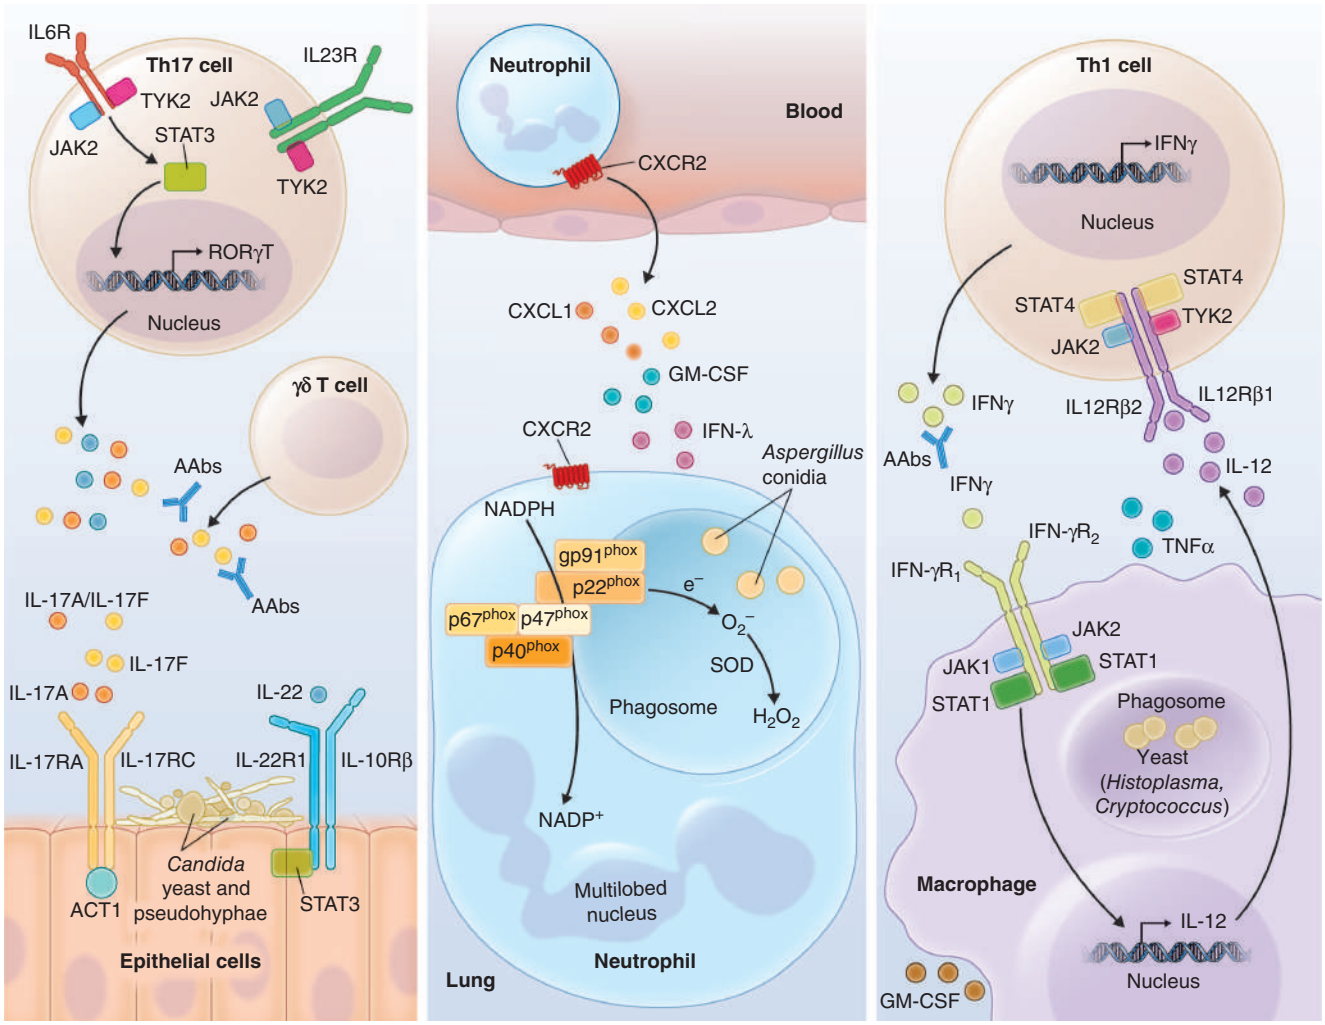

FIGURE 217-1 Host defense against fungi. ***Left:*** Production of IL-17A, IL-17F, and IL-22 by Th17 cells, Tc17 cells, γδ T cells, and innate lymphoid cells confers protection from mucosal *Candida* invasion. STAT3 promotes Th17 differentiation via RORγt induction. IL-17A and IL-17F bind to IL-17RA and IL-17RC on epithelial cells and signal via ACT1 to produce antimicrobial peptides that inhibit fungal growth. IL-22 binds to its receptor on epithelial cells and activates STAT3 to mediate epithelial proliferation and repair. ***Middle:*** Activation of $CXCR2^+$ neutrophils recruited from blood in the *Aspergillus*-infected lung enables assembly of the six subunits of NADPH oxidase and superoxide generation that promotes fungal killing. Production of reactive oxygen species by neutrophils is facilitated by recruited monocyte-derived and plasmacytoid dendritic cells via type I and type III IFNs and GM-CSF. ***Right:*** The interaction of Th1 cells with macrophages is protective against intramacrophagic endemic dimorphic fungi, *Pneumocystis*, and *Cryptococcus*. Upon fungal uptake, macrophages produce IL-12 that binds to its receptor on T cells and activates STAT4, with consequent release of IFN-γ. IFN-γ binds to its receptor on macrophages and activates STAT1, thereby enabling fungal killing. TNF-α and GM-CSF are also critical for macrophage activation. AAbs, autoantibodies; IL, interleukin; IFN, interferon; JAK, Janus kinase; GM-CSF, granulocyte-macrophage colony-stimulating factor; NADPH, nicotinamide adenine dinucleotide phosphate; RORγt; RAR-related orphan receptor γ; SOD, superoxide dismutase; STAT, signal transducer and activator of transcription; TNF, tumor necrosis factor; TYK2, tyrosine kinase 2.

Indeed, AIDS patients and those receiving glucocorticoids, which affect lymphocytes and macrophages both quantitatively and qualitatively, are at risk for severe infections by these fungi. Accordingly, inherited impairment of the IL-12/IFN-γ signaling axis caused by mutations in *IL12RB1*, *IFNGR1*, *IFNGR2*, *STAT1*, *IRF8*, or *GATA2* underlies susceptibility to severe infection by intramacrophagic fungi (and other intramacrophagic pathogens, such as mycobacteria and salmonellae). In addition, the IFN-γ–targeting monoclonal antibody emapalumab, JAK inhibitors that block IFN-γ–dependent cellular responses, and autoantibodies to IFN-γ predispose to infection with intramacrophagic fungi, as do biologics targeting tumor necrosis factor α (TNF-α) and autoantibodies to granulocyte-macrophage colony-stimulating factor (GM-CSF). The latter predisposing factors reveal the central role of these two Th1-associated cytokines—TNF-α and GM-CSF—in macrophage activation.

Taken together, these observations show that the cellular and molecular factors that drive protective antifungal immune responses vary greatly with the anatomic site of the infection, the offending fungus, and the patient population (Table 217-1). The growing body of data on human immunologic responses to fungi promises to inform precision medicine strategies for risk assessment, prophylaxis, immunotherapy, and vaccination of vulnerable patients.

DIAGNOSIS

The diagnostic modalities used for various fungal infections are outlined in Table 217-1 and are detailed in the chapters on specific mycoses that follow in this section. Definitive diagnosis of a fungal infection requires histopathologic identification of the fungus invading tissue with parallel culture of the fungus from the specimen. Certain fungi have distinctive morphologic features that facilitate diagnosis (Table 217-1). The stains most often used to identify fungi are periodic acid–Schiff (PAS) and Gomori methenamine silver (GMS). *Candida*, unlike other fungi, is visible on Gram-stained tissue smears. Hematoxylin and eosin stains define accompanying histologic features of fungal disease (granuloma formation, angioinvasion, necrosis) but are insufficient to reliably identify fungi in tissue. A positive India ink stain of cerebrospinal fluid (CSF) is diagnostic for cryptococcosis. Most laboratories use calcofluor white staining coupled with fluorescence microscopy to identify fungi in fluid specimens. A positive fungal culture of blood or tissue may signify either patient colonization or lab contamination instead of true infection, with the most likely scenario depending on the fungus and the anatomic site. In blood, *Candida* can be detected with any of the widely used automated blood culture systems, but the lysis-centrifugation technique increases the sensitivity of blood cultures for

both *Candida* and other less common fungi (e.g., *Histoplasma*). Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) is now used extensively for detection and speciation of fungi recovered from culture.

The several available fungal-antigen and serologic tests vary in sensitivity and specificity. The most reliable of these tests are the antibody to *Coccidioides*, *Histoplasma* antigen, and cryptococcal polysaccharide antigen. Serologic tests are also available for other endemic dimorphic fungi (Table 217-1). The galactomannan test—especially in the bronchoalveolar lavage fluid—is useful for the diagnosis of aspergillosis; however, false-negative results are common, particularly in patients receiving antifungal prophylaxis, and false-positive results may occur with other fungal infections. The β-glucan test has a high negative predictive value for invasive candidiasis but lacks specificity. T2 magnetic resonance is now approved by the U.S. Food and Drug Administration (FDA) for detection of *Candida* in blood. Several polymerase chain reaction and nucleic acid hybridization assays exist for fungal detection but are not standardized and are not widely used in the clinic.

ANTIFUNGAL DRUGS

This section provides a brief overview of available agents for the treatment of fungal infections. Drug regimens and schedules are detailed in the chapters on specific mycoses that follow in this section. Since fungal organisms, like human cells, are eukaryotic, the identification of drugs that selectively kill or inhibit fungi but that are not toxic to human cells poses challenges. Indeed, far fewer antifungal than antibacterial agents have been introduced into clinical medicine.

Early initiation of appropriate antifungal therapy is a critical determinant of favorable outcome, as has been shown for candidemia, aspergillosis, and mucormycosis. In addition, source control of the infection is important—e.g., with removal of the central venous catheter in candidemia, drainage of abdominal abscesses in intraabdominal candidiasis, and surgical debridement of sinus tissue in mucormycosis. Moreover, an essential factor in a favorable prognosis in patients with opportunistic mycoses is the achievement of immune reconstitution—e.g., with neutrophil recovery, tapering of glucocorticoids or other immunosuppressive drugs, or initiation of combination antiretroviral therapy in AIDS.

AMPHOTERICIN B

The advent of amphotericin B (AmB) in the 1950s revolutionized the treatment of deep-seated mycoses. Before the availability of AmB, cryptococcal meningitis and other disseminated fungal infections were nearly always fatal. AmB remains the broadest-spectrum antifungal agent. Its fungicidal mechanism of action involves forming extramembranous sponge-like aggregates that extract fungal ergosterol from lipid bilayers. AmB remains the preferred antifungal agent for the treatment of mucormycosis and fusariosis and for induction therapy for cryptococcal meningitis and disseminated infections caused by endemic dimorphic fungi. However, AmB has several limitations, including lack of a licensed oral formulation and significant toxicity from the intravenous preparations, primarily renal and infusion-related (fever, chills, thrombosis). The introduction of lipid AmB formulations has ameliorated these toxicities, and the lipid formulations have largely replaced the original deoxycholate formulation in resource-rich settings. In developing countries, AmB deoxycholate is still widely used because of the high cost of the lipid formulations. The two lipid formulations commonly used in the clinic are liposomal AmB and AmB lipid complex, which exhibit comparable efficacy, toxicity, and tissue penetration profiles.

AZOLES

Azoles offer important advantages over AmB, such as the availability of oral and IV formulations and a lack of renal toxicity. The mechanism of action of azoles involves inhibition of lanosterol 14α-demethylase and ergosterol synthesis in the fungal cell membrane, with a consequent accumulation of toxic sterol intermediates and growth arrest. Unlike AmB, azoles are considered fungistatic.

Fluconazole Fluconazole plays an important role in the treatment of several fungal infections. Its major advantages are the availability of oral and IV formulations, a long half-life, penetration into most body fluids (ocular fluid, CSF, urine), and minimal toxicity. This drug rarely causes liver toxicity; high doses may result in alopecia, dry mouth, and a metallic taste. Notably, the administration of even low doses of fluconazole to pregnant women for the treatment of vaginal candidiasis was recently linked to miscarriage and stillbirth. Fluconazole has no activity against molds and most endemic dimorphic fungi and is less active than the newer azoles against *C. glabrata* and *C. krusei.*

Fluconazole is the preferred agent for the treatment of coccidioidal meningitis, although relapses may occur despite therapy. Fluconazole is also used as consolidation and maintenance therapy for cryptococcal meningitis and for the treatment of mucosal candidiasis. It is used for treating candidemia in patients who are not critically ill or immunosuppressed; in these patients, fluconazole was found to be as efficacious as AmB. Because of increasing rates of azole-resistant *Candida* strains, echinocandin treatment is preferred, which is then replaced by fluconazole once a susceptible *Candida* species is recovered. Fluconazole is effective as prophylaxis in recipients of high-risk liver and allogeneic bone marrow transplants, although many centers now use posaconazole in neutropenic patients, given its added activity against molds. Fluconazole prophylaxis in leukemic patients, in AIDS patients with low CD4+ T-cell counts, and in patients on surgical intensive care units is controversial.

Itraconazole Itraconazole is available in oral (capsule, suspension) and IV formulations and has broader antifungal activity—i.e., against molds and endemic dimorphic fungi—than fluconazole. Itraconazole is the drug of choice for mild to moderate histoplasmosis and blastomycosis and has also been used to treat chronic coccidioidomycosis, phaeohyphomycosis, sporotrichosis, and mucocutaneous mycoses such as oropharyngeal candidiasis, tinea versicolor, tinea capitis, and onychomycosis. Although it is approved by the FDA for use in febrile neutropenic patients, most centers now use newer azoles in such patients. Disadvantages of itraconazole include its poor CSF penetration, the use of cyclodextrin in its oral suspension and IV formulation, and its variable level of absorption in the capsule form, which requires monitoring of blood levels in patients receiving capsules for disseminated mycoses. A new formulation of itraconazole, called SUBA-itraconazole (for "super-bioavailability"), which results in improved absorption and less variable plasma levels, has recently been approved by the FDA. Itraconazole is a potent CYP3A4 inhibitor; this characteristic leads to significant drug interactions. The drug causes hepatotoxicity and cardiac toxicity that may manifest as congestive heart failure.

Voriconazole Voriconazole is also available in oral and IV formulations, has far broader antifungal activity than fluconazole (including *C. glabrata*, *C. krusei*, *Aspergillus*, *Scedosporium*, and endemic dimorphic fungi—but not Mucorales), and penetrates into most body fluids (ocular fluid, CSF). It is the preferred agent for the treatment of aspergillosis and also has been used to treat scedosporiosis and as step-down (but not primary) therapy for coccidioidomycosis, blastomycosis, and histoplasmosis. Voriconazole is considerably more expensive than fluconazole, and as with itraconazole, its use is associated with numerous interactions with drugs typically used in patients at risk for fungal infections. Hepatotoxicity, visual disturbances, and skin rashes (including photosensitivity) are relatively common, and long-term use requires skin cancer surveillance. A unique toxicity of voriconazole among azoles is fluorosis-associated periostitis. It is crucial to monitor drug levels because (1) voriconazole is metabolized in the liver by CYP2C9, CYP3A4, and CYP2C19; and (2) human genetic variation in CYP2C19 activity exists and can lead to significant interpatient variability in drug levels. Dosages should be reduced in patients with hepatic, but not renal, failure; however, because the IV formulation is prepared in cyclodextrin, it should be given with caution to patients with severe renal failure.

Posaconazole Posaconazole has broader activity than voriconazole, including activity against Mucorales. Both oral (suspension, tablet) and IV formulations are available. Posaconazole is approved by the FDA for antifungal prophylaxis in neutropenic leukemic patients and allogeneic hematopoietic stem cell transplant recipients as well as for treatment of oropharyngeal candidiasis, including infections refractory

to fluconazole or itraconazole. Posaconazole has been reported to be effective salvage therapy for aspergillosis, mucormycosis, fusariosis, cryptococcosis, histoplasmosis, and coccidioidomycosis, although controlled clinical trials are lacking. The tablet formulation is not hampered by the suboptimal absorption that occurs with the suspension; the tablet also results in higher and more reliable blood levels of the drug. Posaconazole is less hepatotoxic than voriconazole and does not cause the skin, visual, or bone toxicity that occurs with voriconazole. However, the use of posaconazole is linked to significant P450-related drug interactions and can lead to pseudohyperaldosteronism, which may manifest with hypokalemia, edema, and/or hypertension.

Isavuconazole Isavuconazole is available in oral and IV formulations and has broad antifungal activity similar to that of posaconazole. Isavuconazole is approved by the FDA for treatment of aspergillosis (on the basis of a randomized controlled trial that found it noninferior to voriconazole) and mucormycosis (on the basis of an open-label, noncomparative trial of 37 patients). Isavuconazole appears to be less hepatotoxic than voriconazole; it does not cause skin, bone, or visual toxicity, and it causes fewer P450-associated drug interactions than voriconazole.

Oteseconazole The newest azole—a tetrazole—oteseconazole, is approved by the FDA for the treatment of recurrent vulvovaginal candidiasis. It has potent activity against *Candida* (including azole-resistant strains) species and endemic dimorphic fungi. Its long half-life allows for once-weekly dosing following induction. Oteseconazole does not appear to cause hepatotoxicity or P450-associated drug interactions, but it is contraindicated in women of reproductive potential as it may cause fetal ocular toxicity.

ECHINOCANDINS

The echinocandins include the FDA-approved drugs caspofungin, anidulafungin, micafungin, and rezafungin, which are available solely as an IV formulation and inhibit β-1,3-glucan synthase, an enzyme that is crucial for fungal cell-wall synthesis but is not a constituent of human cells. Rezafungin, a new generation echinocandin, has a prolonged half-life that allows for weekly dosing with front-loading. The different echinocandins have comparable efficacy, toxicity, and tissue penetration profiles; are fungicidal for *Candida* and fungistatic for *Aspergillus*; and have no activity against other molds, *Cryptococcus*, or endemic dimorphic fungi. Their most common use to date is in candidal infections. These drugs offer three major advantages: minimal toxicity, minimal drug interactions, and activity against all *Candida* species. The minimal inhibitory concentrations (MICs) of echinocandins are higher against *Candida parapsilosis* than against other *Candida* species, but the higher MICs do not translate into less clinical efficacy against this species.

In controlled trials, caspofungin was as efficacious as AmB against candidemia and invasive candidiasis and as efficacious as fluconazole against candidal esophagitis. Caspofungin has also been efficacious as salvage therapy for aspergillosis. Anidulafungin is approved by the FDA as therapy for candidemia in nonneutropenic patients and for *Candida* esophagitis, abdominal infection, and peritonitis. In controlled trials, anidulafungin was noninferior and possibly superior to fluconazole against candidemia and invasive candidiasis and was as efficacious as fluconazole against candidal esophagitis. Micafungin is approved by the FDA for the treatment of candidal esophagitis and candidemia and for antifungal prophylaxis in hematopoietic stem cell transplantation. Moreover, micafungin yielded favorable results when used for the treatment of invasive aspergillosis and candidiasis in open-label trials. Rezafungin was recently approved by the FDA for the treatment of candidemia and invasive candidiasis.

IBREXAFUNGERP

Ibrexafungerp is an oral antifungal agent that belongs to a new class of glucan synthase inhibitors called triterpenoids and has potent activity against *Candida* species. Ibrexafungerp has been approved by the FDA for the treatment of vulvovaginal candidiasis and recurrent vulvovaginal candidiasis as it maintains its antifungal efficacy at low pH that is often observed in the vaginal mucosa. Its use is contraindicated in pregnant and lactating women.

FLUCYTOSINE (5-FLUOROCYTOSINE)

Flucytosine use has diminished as newer antifungal drugs have been developed. Its mechanism of action involves intrafungal conversion to 5-fluorouracil, which inhibits fungal DNA synthesis. The use of flucytosine in combination with AmB as induction therapy for cryptococcal meningitis is based on the drugs' synergistic interaction and favorable flucytosine CSF penetration that promotes a rapid decline of the cryptococcal burden in the CSF. Flucytosine is also used in combination with AmB for the treatment of candidal meningitis and endocarditis, although comparative trials with AmB monotherapy are lacking. Flucytosine monotherapy is not recommended as it is associated with the development of resistance. Flucytosine can cause bone marrow suppression and liver toxicity, which are intensified when the drug is used with AmB.

TERBINAFINE

Terbinafine inhibits squalene epoxidase and ergosterol synthesis, is used for onychomycosis and ringworm infection, and is as effective as itraconazole in both conditions. Although active against other fungi, terbinafine penetrates poorly into tissues beyond the skin and nails and therefore is not preferred for systemic mycoses. Terbinafine carries a risk for hepatotoxicity.

TOPICAL ANTIFUNGAL AGENTS

A detailed discussion of topical agents for mucocutaneous mycoses is beyond the scope of this chapter; the reader is referred to **Chap. 225** and the dermatology literature. Azoles such as clotrimazole, miconazole, and ketoconazole are often used topically to treat common cutaneous mycoses as well as oropharyngeal and vaginal candidiasis. In vaginal candidiasis, oral fluconazole given once has the advantage of not requiring repeated intravaginal application. The polyenes nystatin and AmB have also been used topically for oropharyngeal and vaginal candidiasis. Agents from other classes that are used to treat these conditions include ciclopirox, haloprogin, terbinafine, naftifine, tolnaftate, and undecylenic acid.

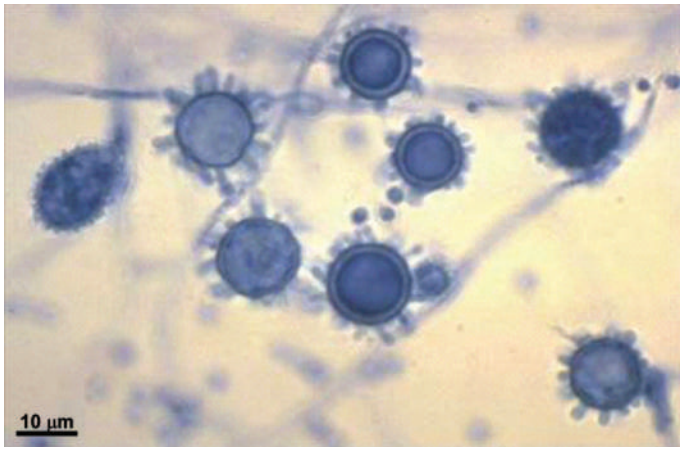
218 Histoplasmosis

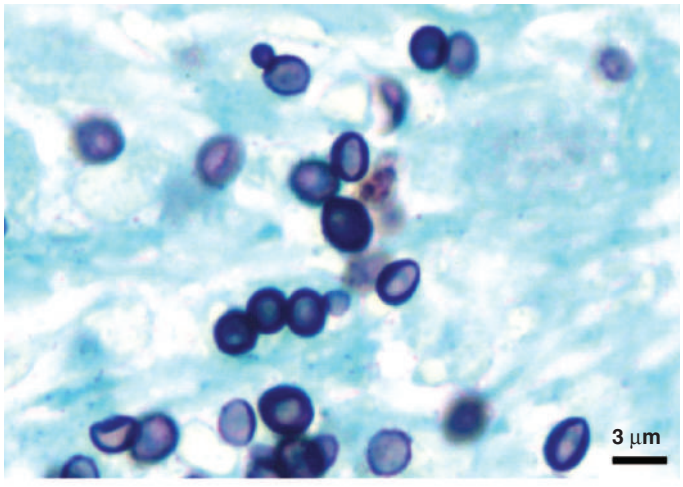
Chadi A. Hage, L. Joseph Wheat

ETIOLOGY

Histoplasma capsulatum, a thermal dimorphic fungus, is the etiologic agent of histoplasmosis. In most endemic areas in North America, *H. capsulatum* var. *capsulatum* is the causative agent. In Central and South America, histoplasmosis is common and is caused by genetically different clades of *H. capsulatum* var. *capsulatum*. In Africa, *H. capsulatum* var. *duboisii* is also found. Yeasts of var. *duboisii* are larger than those of var. *capsulatum*.

Mycelia—the naturally infectious form of *Histoplasma*—have a characteristic appearance, with microconidial and macroconidial forms **(Fig. 218-1)**. Microconidia are oval and are small enough





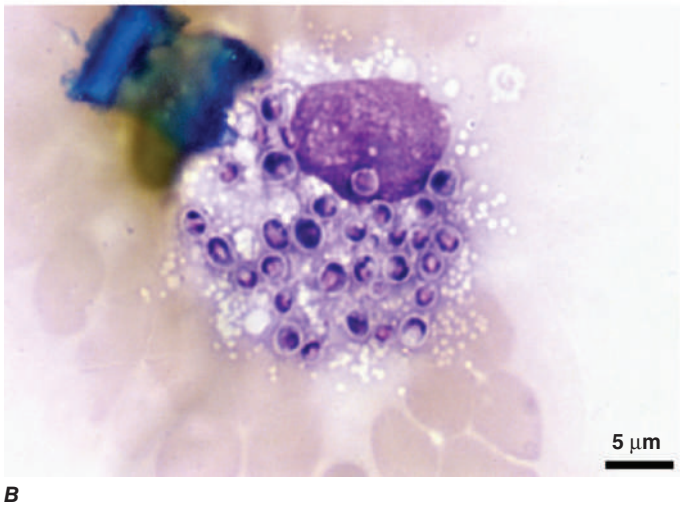


FIGURE 218-1 Spiked spherical conidia of *H. capsulatum* (lacto-phenol cotton blue stain) grown in the laboratory at room temperature.

(2–4 µm) to reach the terminal bronchioles and alveoli. Shortly after infecting the host, mycelia transform into the yeasts that are found inside macrophages and other phagocytes. The yeast forms are characteristically small (2–5 µm), with occasional narrow budding (Fig. 218-2). In the laboratory, mycelia are best grown at room temperature, whereas yeasts are grown at 37°C on enriched media.

B

FIGURE 218-2 ***A.*** Small (2–5 µm) narrow budding yeasts of *H. capsulatum* from bronchoalveolar lavage fluid (Grocott's methenamine silver stain). ***B.*** Intracellular yeasts of *H. capsulatum* within an alveolar macrophage from a patient with AIDS and disseminated histoplasmosis (Giemsa stain).

EPIDEMIOLOGY

Histoplasmosis is the most prevalent endemic mycosis in North America. Although this fungal disease has been reported throughout the world, its endemicity is particularly notable in the Ohio and Mississippi river valleys of North America and in certain parts of Mexico, Central and South America (Brazil), Africa, and Asia. Histoplasmosis is increasingly reported outside of the traditionally known endemic areas. The geographic distribution of histoplasmosis is related to the humid and acidic nature of the soil in the endemic areas. Soil enriched with bird or bat droppings promotes the growth and sporulation of *Histoplasma.* Disruption of soil containing the organism leads to aerosolization of the microconidia and exposure of humans nearby. Activities associated with high-level exposure and high infection attack rate include spelunking, excavation, cleaning of chicken coops, demolition and remodeling of old buildings, and cutting of dead trees. Most cases seen outside of highly endemic areas represent imported disease, e.g., in Europe, histoplasmosis is diagnosed fairly often, mostly in emigrants from or travelers to endemic areas on other continents. The epidemiology of histoplasmosis is changing as a result of global climate changes and with the continued expansion of at-risk populations and the acceleration of intercontinental and international travel that brings this infection to areas of the world that are not known to be endemic. The population at risk for histoplasmosis continues to grow as a result of increasing numbers of patients receiving immunosuppressive therapies for autoimmune disorders, cancers, and organ transplants.

PATHOGENESIS AND PATHOLOGY

Infection follows inhalation of microconidia (Fig. 218-1). Once they reach the alveolar spaces, microconidia are rapidly recognized and engulfed by alveolar macrophages, where they transform into yeasts (Fig. 218-2), a process that is integral to the pathogenesis of histoplasmosis and is dependent on the availability of calcium and iron inside the phagocytes. The yeasts are capable of evading the immune system and multiplying inside resting macrophages. Neutrophils and then lymphocytes are attracted to the site of infection. Before the development of cellular immunity, yeasts use the phagosomes as a vehicle for translocation to local draining lymph nodes, whence they spread hematogenously throughout the reticuloendothelial system. Effective cellular immunity develops ~2 weeks after infection. T cells produce interferon-γ to assist the macrophages in killing the organism and controlling the progression of disease. Interleukin 12 and tumor necrosis factor α (TNF-α) play an essential role in cellular immunity to *H. capsulatum*. In the immunocompetent host, macrophages, lymphocytes, and epithelial cells eventually organize and form granulomas that contain the organisms. These granulomas typically fibrose and calcify; calcified lung nodules, mediastinal lymph nodes, and hepatosplenic calcifications are frequently found in healthy individuals from endemic areas. In immunocompetent hosts, infection with *H. capsulatum* confers protective immunity to reinfection. In patients with impaired cellular immunity, the infection is not properly contained and can disseminate throughout the reticuloendothelial system. Progressive disseminated histoplasmosis (PDH) can involve multiple organs, most commonly the lungs, bone marrow, spleen, liver (Fig. 218-3), adrenal glands, and mucocutaneous membranes. Unlike latent tuberculosis, inactive histoplasmosis does not reactivate. In patients with mildly impaired immune systems, active infection may smolder and eventually worsen with further decline in immunity.

Structural lung disease (e.g., emphysema) impairs the clearance of pulmonary histoplasmosis leading to the development of chronic pulmonary disease. This chronic process is characterized by progressive inflammation, tissue necrosis, and fibrosis mimicking cavitary tuberculosis.

CLINICAL MANIFESTATIONS

The clinical spectrum of histoplasmosis ranges from asymptomatic infection to life-threatening illness. The attack rate and the extent and severity of the disease depend on the intensity of exposure, the immune status of the exposed individual, and the underlying lung architecture of the host.

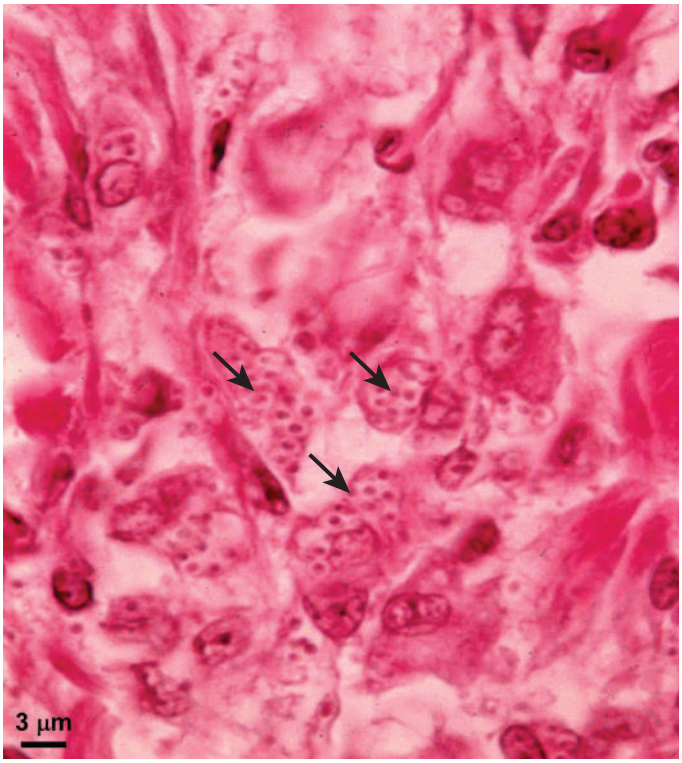

FIGURE 218-3 Intracellular yeasts (*arrows*) of *H. capsulatum* in a liver biopsy specimen (hematoxylin and eosin stain) from a patient who developed progressive disseminated histoplasmosis while receiving anti–tumor necrosis factor therapy for rheumatoid arthritis.

In immunocompetent individuals with low-level exposure, most *Histoplasma* infections are either asymptomatic or mild and self-limited. Of adults residing in endemic areas, up to 75% have immunologic and/or radiographic evidence of previous infection without clinical manifestations. Asymptomatic lung nodules representing controlled histoplasmosis are frequently found on chest computed tomography (CT) scans obtained during screening for lung cancer in smokers from endemic areas. When symptoms of acute histoplasmosis develop, they usually appear 1–4 weeks after exposure. Heavy exposure leads to a flulike illness with fever, chills, sweats, headache, myalgia, anorexia, dry cough, dyspnea, and chest pain. Chest radiographs usually show signs of pneumonitis with prominent hilar or mediastinal adenopathy. Pulmonary infiltrates may be focal with light exposure or diffuse with heavy exposure. Rheumatologic symptoms of arthralgia or arthritis, often associated with erythema nodosum, occur in 5–10% of patients with acute histoplasmosis. Pericarditis may also develop. These manifestations represent inflammatory responses to the acute pulmonary infection rather than extrapulmonary spread. Affected hilar or mediastinal lymph nodes may undergo necrosis and coalesce to form large mediastinal masses that can cause compression of great vessels, proximal airways, and the esophagus. These necrotic lymph nodes may also rupture and create fistulas between mediastinal structures (e.g., bronchoesophageal fistulae).

PDH is typically seen in immunocompromised individuals, who account for ~70% of cases. Common risk factors include AIDS (CD4+ T-cell count, <200/μL), extremes of age, the administration of immunosuppressive medications to prevent or treat rejection following transplantation (e.g., prednisone, mycophenolate, calcineurin inhibitors), and the use of methotrexate, anti-TNF-α agents, and other biologic response modifiers for autoimmune disorders. PDH may also occur in healthy individuals, some of whom may have rare undiagnosed genetic immunodeficiencies of the relevant immune pathways (IFN-γ and TNF-α). Workup for these conditions should be considered in healthy subjects with PDH.

The clinical spectrum of PDH ranges from an acute, rapidly fatal course—with diffuse interstitial or reticulonodular lung infiltrates causing respiratory failure, shock, coagulopathy, and multiorgan failure—to a subacute or chronic course with a focal organ distribution. Common manifestations include fever, weight loss, hepatosplenomegaly, and thrombocytopenia. Other findings may include meningitis or focal brain lesions, ulcerations of the oral mucosa, gastrointestinal ulcerations and bleeding, and adrenal insufficiency. Prompt recognition of this devastating illness is of paramount importance in patients with severe manifestations or with underlying immunosuppression, especially those due to AIDS **(Chap. 208)** or anti-TNF therapy.

Chronic cavitary histoplasmosis is seen in smokers who have structural lung disease (e.g., bullous emphysema). This chronic illness is characterized by productive cough, dyspnea, low-grade fever, night sweats, and weight loss. Chest radiographs usually show upper-lobe infiltrates, cavitation, and pleural thickening—findings resembling those of tuberculosis. Without treatment, the course is slowly progressive.

Fibrosing mediastinitis is an uncommon but serious complication of histoplasmosis. In certain patients, acute infection is followed for unknown reasons by progressive fibrosis around the hilar and mediastinal lymph nodes, encasing mediastinal structures with potentially devastating consequences. Major manifestations include superior vena cava syndrome, obstruction of pulmonary vessels, and airway obstruction. Patients may experience recurrent pneumonia, hemoptysis, or respiratory failure. Fibrosing mediastinitis is fatal in up to one-third of cases.

In healed histoplasmosis, calcified mediastinal nodes or lung parenchymal nodules may erode through the walls of the airways and cause hemoptysis and expectoration of calcified material. This condition is called *broncholithiasis*.

The clinical features and management of histoplasmosis caused by the genetically different clades in Central and South America are similar to those of the disease in North America. African histoplasmosis caused by var. *duboisii* is clinically distinct and is characterized by frequent skin and bone involvement.

DIAGNOSIS

Recommendations for the diagnosis and treatment of histoplasmosis are summarized in **Table 218-1**. Once suspected, the diagnosis of histoplasmosis is usually straightforward as many diagnostic tools are now available in the United States. This is not the case in resource-limited endemic regions of Central America, South America, and Africa, where the diagnosis is often delayed, with consequently poor outcomes.

Fungal culture remains the gold standard diagnostic test for histoplasmosis. However, culture results may not be known for up to 1 month, and cultures are often negative in less severe cases. Cultures are positive in ~75% of patients with PDH and chronic pulmonary histoplasmosis. Cultures of bronchoalveolar lavage (BAL) fluid are positive in about half of patients with acute pulmonary histoplasmosis causing diffuse infiltrates and hypoxemia. In PDH, the culture yield is highest for BAL fluid, bone marrow aspirate, and blood. Cultures of sputum or bronchial washings are usually positive in chronic pulmonary histoplasmosis. Cultures are typically negative, however, in other forms of histoplasmosis.

Fungal stains of cytopathology or biopsy materials showing structures resembling *Histoplasma* yeasts are helpful in the diagnosis of PDH, yielding positive results in about half of cases. Yeasts can be seen in BAL fluid (Fig. 218-2) from patients with diffuse pulmonary infiltrates, in bone marrow biopsy samples, and in biopsy specimens of other involved organs (e.g., liver, adrenal glands). Occasionally, yeasts are seen within circulating phagocytes on blood smears from patients with severe PDH. However, staining artifacts and other fungal elements sometimes stain positively and may be misidentified as *Histoplasma* yeasts. Culture and pathology are no longer performed in most patients because diagnosis is more often established by antigen detection and/or serology, more rapidly and without subjecting the patient to invasive procedures.

The detection of *Histoplasma* antigen in body fluids is extremely useful in the diagnosis of PDH and acute diffuse pulmonary histoplasmosis.

TABLE 218-1 Recommendations for the Diagnosis and Treatment of Histoplasmosis

TYPE OF HISTOPLASMOSIS	DIAGNOSTIC TESTS	TREATMENT RECOMMENDATIONS	COMMENTS
Acute pulmonary, mild to moderate with no improvement by the time of diagnosis	*Histoplasma* antigen (BAL fluid, serum, urine) Cytopathology and fungal culture of BAL fluid *Histoplasma* serology (ID and CF), (EIA): IgG and IgM	Itraconazole (200 mg bid) for 6–12 weeks. Monitor renal and hepatic function.	Patients with mild cases usually recover without therapy, but itraconazole should be considered if the patient's condition is not already improving by the time the diagnosis is established.
Acute pulmonary, severe illness, respiratory failure (ARDS)	*Histoplasma* antigen (BAL fluid, serum, urine) Cytopathology and fungal culture of BAL fluid *Histoplasma* serology (ID and CF), (EIA): IgG and IgM	Lipid AmB (3–5 mg/kg per day) ± glucocorticoids for 1–2 weeks; then itraconazole (200 mg bid) for 6–12 weeks. Monitor renal and hepatic function.	Adjust itraconazole dose to achieve blood levels of 2–5 μg/mL.
Chronic/cavitary pulmonary	*Histoplasma* serology (ID and CF), (EIA): IgG and IgM Fungal culture of sputum or BAL fluid	Itraconazole (200 mg bid) Adjust dose to achieve blood levels of 2–5 μg/mL for at least 12 months. Monitor hepatic function.	Continue treatment until radiographic findings show no further improvement. Monitor for relapse after treatment is stopped.
Progressive disseminated	*Histoplasma* antigen (BAL fluid, serum, urine) *Histoplasma* serology (ID and CF), (EIA): IgG and IgM Fungal culture of blood or bone marrow aspirate Cytopathology on biopsy of affected organ	Lipid AmB (3–5 mg/kg per day) for 1–2 weeks; then itraconazole (200 mg bid); adjust dose to achieve blood levels of 2–5 μg/mL for at least 12 months. Monitor renal and hepatic function.	Liposomal AmB is preferred, but the AmB lipid complex may be used because of cost. Chronic antifungal maintenance therapy may be necessary if the degree of immunosuppression cannot be substantially reduced. Monitor antigen levels in urine and serum during treatment to ensure proper response.
Central nervous system	*Histoplasma* antigen CSF *Histoplasma* serology (ID and CF), (EIA): IgG and IgM Fungal culture of CSF	Liposomal AmB (5 mg/kg per day) for 4–6 weeks; then itraconazole (200 mg bid) Adjust dose to achieve blood levels of 2–5 μg/mL for at least 12 months. Monitor renal and hepatic function.	A longer course of lipid AmB is recommended because of the high risk of relapse. Itraconazole should be continued until CSF or MRI abnormalities clear.

Abbreviations: AmB, amphotericin B; BAL, bronchoalveolar lavage; CF, complement fixation; CSF, cerebrospinal fluid; EIA, enzyme immunoassay; ID, immunodiffusion; MRI, magnetic resonance imaging.

The sensitivity of this method is >95% in patients with PDH and >80% in patients with severe acute pulmonary histoplasmosis resulting from heavy exposure, if both urine and serum are tested. Antigen levels correlate with severity of illness in PDH and can be used to follow disease progression, as levels predictably decrease with effective therapy. Increasing antigen levels also predict relapse. *Histoplasma* antigen can be detected in cerebrospinal fluid from patients with *Histoplasma* meningitis and in BAL fluid from those with pulmonary histoplasmosis. Lateral flow antigen detection allows the diagnosis of histoplasmosis at the bedside as a point-of-care testing method, which might offer access to rapid testing in resource-limited areas of the world where traditional antigen testing might not be available. Cross-reactivity occurs with African histoplasmosis, blastomycosis, coccidioidomycosis, paracoccidioidomycosis, talaromycosis, and rarely aspergillosis.

Serologic tests, including immunodiffusion (ID), complement fixation (CF), and IgG and IgM enzyme immunoassay (EIA), are useful for the diagnosis of histoplasmosis, especially in immunocompetent patients. One month may be required for the detection of antibodies after the onset of infection by ID or CF, but antibodies may be detected earlier by more sensitive methods (EIA). IgM appears first then declines, and IgG appears later and increases during the infection. EIA for IgG and IgM antibodies provides a more accurate method for monitoring changes and antibody levels. Serologic tests are especially useful for the diagnosis of chronic pulmonary histoplasmosis. Limitations of ID and CF, however, include insensitivity early in the course of infection and reduced sensitivity in immunosuppressed patients, especially those receiving immunosuppression for organ transplantation. Also, antibodies may persist for several years after infection. Positive results from past infection may lead to a misdiagnosis of active histoplasmosis in a patient with another disease process.

TREATMENT

Histoplasmosis

Treatment is indicated for all patients with PDH or chronic pulmonary histoplasmosis as well as for most symptomatic patients with acute pulmonary histoplasmosis who have not improved by the time the diagnosis is established, especially in those with diffuse infiltrates and difficulty breathing. In most other cases of pulmonary histoplasmosis, treatment is not recommended, especially if the immune system of the host is intact and the degree of exposure is not heavy. The symptoms usually are mild, subacute, and not progressive, and the illness resolves without therapy. Treatment should be considered if the symptoms are not improving within a month.

The preferred treatments for histoplasmosis (Table 218-1) include the lipid formulations of amphotericin B in severe cases and itraconazole in others. Liposomal amphotericin B is more effective and better tolerated than the deoxycholate formulation and is more effective in patients with AIDS and PDH. The deoxycholate formulation of amphotericin B is an alternative to a lipid formulation for patients at low risk for nephrotoxicity and if liposomal amphotericin B is not available. Posaconazole and isavuconazole are alternatives for patients who cannot take itraconazole. *Histoplasma* may develop resistance to fluconazole and voriconazole, and they are not the preferred alternative to itraconazole, especially in immunocompromised patients.

In severe cases requiring hospitalization, a lipid formulation of amphotericin B is used first for 2 weeks, followed by itraconazole. In patients with meningitis, a lipid formulation of amphotericin B should be given for 4–6 weeks before switching to itraconazole. In immunosuppressed patients, the degree of immunosuppression should be reduced if possible, although immune reconstitution inflammatory syndrome (IRIS) may ensue. Antiretroviral treatment improves the outcome of PDH in patients with AIDS and is recommended; however, whether antiretroviral treatment should be delayed to avoid IRIS is unknown.

Blood levels of itraconazole should be monitored to ensure adequate drug exposure, with target concentrations of the parent drug and its hydroxy metabolites measuring 2–5 μg/mL. Drug interactions should be carefully assessed; itraconazole not only is cleared by cytochrome P450 metabolism but also inhibits cytochrome P450. This profile causes interactions with many other medications used routinely in organ transplant recipients.

The duration of treatment for acute pulmonary histoplasmosis is 6–12 weeks, while that for PDH and chronic pulmonary histoplasmosis is at least 1 year. Antigen levels in urine and serum should be monitored during and for at least 1 year after therapy

for PDH. Stable or rising antigen levels suggest treatment failure or relapse and should raise concerns regarding proper intake of itraconazole (capsule formulation with food), adherence to treatment, drug absorption, itraconazole serum concentrations, and drug interactions.

Lifelong itraconazole maintenance therapy is recommended for patients with persistently suppressed immunity but not for those with immune recovery—e.g., patients with AIDS who complete at least 1 year of itraconazole and show no signs of active infection including *Histoplasma* antigen levels <2 ng/mL, CD4+ T-cell count recovery to at least 150/μL (preferably >250/μL), and HIV suppression with viral load <50 copies/mL on antiretroviral therapy. Similarly, maintenance therapy may not be necessary in other immunocompromised patients if the clinical findings have cleared, antigen levels are <2 ng/mL, and immunosuppression is substantially reduced.

Fibrosing mediastinitis, which represents a chronic fibrotic reaction to past mediastinal histoplasmosis rather than an active infection, does not respond to antifungal therapy. Often patients with mediastinal granuloma have chronic or progressive courses and receive treatment with itraconazole and corticosteroids to reduce disease progression.

219 Coccidioidomycosis

Neil M. Ampel

DEFINITION AND ETIOLOGY

Coccidioidomycosis, commonly known as Valley fever (see "Epidemiology," below), is caused by dimorphic soil-dwelling fungi of the genus *Coccidioides*. Genetic analysis has demonstrated the existence of at least two species, *C. immitis* and *C. posadasii*. These species are indistinguishable with regard to the clinical disease they cause and their appearance on routine laboratory media, although *C. posadasii* may grow more quickly at higher temperatures. Thus, the organisms will be referred to simply as *Coccidioides* for the remainder of this chapter.

EPIDEMIOLOGY

Coccidioidomycosis is confined to the Western Hemisphere between the latitudes of 40°N and 40°S. In the United States, areas of high endemicity include the southern San Joaquin Valley of California (hence the sobriquet "Valley fever") and the south-central region of Arizona. However, infection may be acquired in other areas of the southwestern United States, including the other southern counties in California, southern Nevada, southwestern Utah, southern New Mexico, and western Texas. Cases acquired well outside the recognized endemic areas, including in eastern Washington state and in northeastern Utah, have also been described, and a recent climate model suggests that the endemic range may expand further east and north over time. Outside the United States, coccidioidomycosis is endemic to northern Mexico as well as to localized regions of Central America. In South America, there are endemic foci in Colombia, Venezuela, northeastern Brazil, Paraguay, Bolivia, and north-central Argentina.

The fungus is known to inhabit the native soils within the endemic regions. Because of the difficulty in isolating *Coccidioides* from environmental sites, the precise characteristics of potentially infectious soil are not known, but alluvial alkaline deposits in regions of relative aridity with moderate temperature ranges are most closely associated with endemicity. In the United States, several outbreaks of coccidioidomycosis have been associated with soil from archeologic excavations of Amerindian sites both within and outside of the recognized endemic region. When isolated from the soil, *Coccidioides* is found no more than 2–20 cm below the surface, nor is it usually isolated from cultivated soil. In addition to its saphrophytic soil phase, *Coccidioides* appears to have an endozoan life cycle, likely infecting burrowing rodents. This would suggest that the organisms are concentrated in these rodents and their burrows rather than extant in the soil.

In endemic areas, most cases of human coccidioidomycosis occur without obvious soil or dust exposure. Climatic factors may increase the risk of infection. Periods of aridity following rainy seasons are associated with increases in the number of symptomatic infections. The number of reported cases of coccidioidomycosis has been steadily increasing over the past two decades. In 2019, a total of 20,003 cases were reported. The majority of these were either from Arizona or California, in approximately equal numbers, with Nevada, New Mexico, and Utah reporting a small fraction of cases. The factors associated with these increases have not been elucidated but likely include an influx of older individuals without prior coccidioidal infection into endemic areas, construction activity, increased reporting, and changing climate.

PATHOGENESIS, PATHOLOGY, AND IMMUNE RESPONSE

The life cycle of *Coccidioides* is depicted in **Fig. 219-1**. On agar media and in the environment, *Coccidioides* organisms exist as filamentous molds or mycelia. Individual filaments (*hyphae*) elongate and branch, some growing upward. Portions of these aerial hyphae thicken and septate, and alternating cells then degenerate by autolysis, leaving barrel-shaped viable spores called *arthroconidia*. Measuring approximately 2 μm by 5 μm, individual arthroconidia can easily dislodge from the hypha and become airborne. These may persist in the air for prolonged periods. When arthroconidia are inhaled by a susceptible host, their small size allows them to evade initial mechanical mucosal defenses and reach deep into the bronchial tree, where infection is initiated.

Once within a susceptible host, the individual arthroconidia enlarge, become rounded, and develop internal septations. The resulting structures, called *spherules*, may attain sizes up to 200 μm and are unique to *Coccidioides*. The septations encompass uninuclear elements called *endospores*. Spherules may rupture and release packets of endospores that can themselves develop into new spherules, thus propagating infection locally. If returned to artificial media or the soil, the fungus reverts to its mycelial stage.

Clinical observations and data from animal studies strongly support the critical role of a robust cellular immune response in the host's control of coccidioidomycosis. Necrotizing granulomas containing spherules are typically identified in patients with resolved pulmonary infection. In disseminated disease in which infection is not controlled, granulomas are generally poorly formed or do not develop at all, and a polymorphonuclear leukocyte response is frequently seen. In patients who are asymptomatic or in whom the initial pulmonary infection has resolved, delayed-type hypersensitivity to coccidioidal skin antigens has been routinely documented and T-cell activation has been observed in peripheral blood stimulated with coccidioidal antigens. In persons who have developed protective cellular immunity, spherules exist in the lungs for prolonged periods, possibly lifelong, in a latent

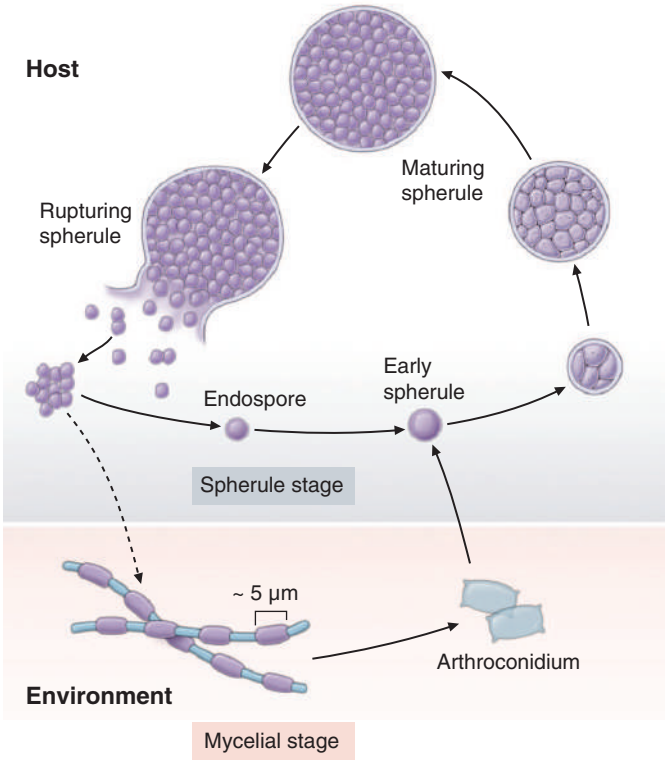

FIGURE 219-1 Life cycle of *Coccidioides*, including the mycelial phase in the environment and the spherule phase in the host.

state. This results in the persistence of protective immunity but also places those infected at risk of recurrent active disease if that immunity should wane.

CLINICAL AND LABORATORY MANIFESTATIONS

After infection, 60% of individuals are completely asymptomatic. The other 40% have symptoms that are related primarily to pulmonary infection, including fever, cough, and pleuritic chest pain. Symptoms generally occur from several days to up to 3 weeks after inhalation of arthroconidia. The risk of symptomatic illness increases with age.

In addition to these local symptoms indicative of infection, there are several manifestations of primary pulmonary coccidioidomycosis that are due to an immunologic response. Most prominent among these are cutaneous reactions. A diffuse, erythematous maculopapular rash, known as toxic erythema, has been noted in some cases. In addition, erythema nodosum **(see Fig. A1-39)**—typically over the lower extremities—and erythema multiforme **(see Fig. A1-24)**—usually in a necklace distribution—may occur. Lesions consistent with Sweet syndrome have also been reported **(Chap. 21)**. Cutaneous manifestations are especially common in women. Symmetrical arthralgias ("desert rheumatism"), often involving the ankles, knees, and hips, may also occur with or without cutaneous manifestations.

Primary pulmonary coccidioidomycosis is often misdiagnosed as a community-acquired bacterial pneumonia. However, the diagnosis of primary pulmonary coccidioidomycosis is strongly suggested by the findings of rash or symmetrical arthralgias in a patient with an appropriate exposure history. The finding of any of the following is also strongly suggestive of coccidioidomycosis: a history of night sweats, marked fatigue, peripheral-blood eosinophilia, failure to improve with antibacterial therapy, and an upper lobe infiltrate or hilar or mediastinal lymphadenopathy on chest imaging.

In most patients, primary pulmonary coccidioidomycosis resolves without sequelae over several weeks. However, several pneumonic complications may arise. Pulmonary nodules are residua of the primary pneumonia. Generally single, frequently located in the upper lobes, and usually ≤4 cm in diameter, nodules are often discovered on routine chest radiograph in asymptomatic patients. Calcification is uncommon. Coccidioidal pulmonary nodules can be difficult to distinguish radiographically from pulmonary malignancies. Like malignancies, coccidioidal nodules often enhance on positron emission tomography. However, unlike malignancies, routine computed tomography (CT) imaging often demonstrates multiple nodules and there may be microsatellite lesions, scattered smaller nodules surrounding the larger one. These findings are not specific, and biopsy may be required to distinguish between these two entities.

Pulmonary cavities occur when a nodule extrudes its contents into the bronchial tree, resulting in a thin-walled shell. Frequently asymptomatic, these cavities may on occasion be associated with persistent cough, hemoptysis, and pleuritic chest pain. They may also become secondarily infected with bacterial oral flora, environmental fungi such as *Aspergillus* species, or even with *Coccidioides* growing from the cavity wall. Rarely, a cavity may rupture into the pleural space, causing pyopneumothorax. In such cases, patients present with acute dyspnea, and the chest radiograph reveals a collapsed lung with a pleural air-fluid level. Chronic or persistent pulmonary coccidioidomycosis manifests with prolonged fever, cough, and weight loss and is radiographically associated with pulmonary scarring, fibrosis, and cavities. It is most common in patients who already have chronic lung disease due to other etiologies.

In some cases, primary pneumonia presents as a diffuse reticulonodular pulmonary process in association with dyspnea and fever. This manifestation of pulmonary coccidioidomycosis may occur in settings of intense environmental exposure or in those with profoundly suppressed cellular immunity, such as persons with untreated HIV-1 infection and markedly depressed peripheral blood CD4 cell count. In the latter case, this picture is associated with unrestrained fungal growth and is frequently associated with fungemia.

Clinical dissemination occurs in approximately 1% of infected individuals and is defined as finding the fungus outside the thoracic cavity. Dissemination is more likely to occur in male patients, particularly those of African and perhaps Filipino ancestry, and in persons with depressed cellular immunity, including patients with HIV-1 infection and peripheral blood CD4 counts of <250/µL, those receiving chronic glucocorticoid therapy, those with allogeneic solid-organ transplants, and those being treated with tumor necrosis factor-α antagonists or other biological response modifiers. Women who acquire new coccidioidal infection during the second or third trimester of pregnancy or postpartum also are at significant risk for disseminated disease. Common sites for dissemination include the skin, bones, joints, soft tissues, and meninges. Dissemination may follow symptomatic or asymptomatic pulmonary infection and may involve only one site or multiple anatomic foci. When it occurs, clinical dissemination is usually evident within the first 6 months after primary pulmonary infection and is generally associated with a lack of cellular immunity to *Coccidioides*.

Of the disseminated syndromes, coccidioidal meningitis is the most dire and is uniformly fatal if untreated. Patients usually present with a persistent dull headache, often accompanied by lethargy, and confusion. Nuchal rigidity, if present, is not severe. Examination of cerebrospinal fluid (CSF) demonstrates lymphocytic pleocytosis with profound hypoglycorrhachia and elevated protein levels. CSF eosinophilia is occasionally observed. The diagnosis is usually established by finding coccidioidal complement-fixing antibody (see below) in the CSF in association with the CSF inflammatory pattern described above. The fungus is isolated from the CSF in fewer than one-third of cases. Magnetic resonance imaging with gadolinium frequently demonstrates enhancement in the basilar meninges. With or without appropriate therapy, patients may develop hydrocephalus, usually communicating, which presents clinically as a marked decline in mental status, often with gait disturbances. An elevated opening CSF pressure on lumbar puncture and dilated ventricles on brain imaging are hallmarks of this condition.

DIAGNOSIS

Serology is the most common method to establish the diagnosis of coccidioidomycosis. Several techniques are available, including the traditional tube-precipitin (TP) and complement-fixation (CF) assays, immunodiffusion TP and CF (IDTP and IDCF), and enzyme

immunoassay (EIA) to detect IgM and IgG antibodies. TP and IgM antibodies are found in serum soon after infection and persist for weeks to months. They are not useful for gauging severity of disease. The CF and IgG antibodies occur later in the course of the disease and persist longer than TP and IgM antibodies. Rising CF titers are a reflection of fungal growth and are associated with clinical progression, and the presence of CF antibody in CSF is indicative of coccidioidal meningitis. Antibodies disappear over time in persons whose clinical illness resolves and the presence of coccidioidal antibodies in the serum does not indicate immunity or control of coccidioidomycosis.

Because of its commercial availability, relatively rapid turnaround time, and higher sensitivity than other tests, EIAs for IgM and IgG are recommended for the initial diagnosis of coccidioidomycosis. Both tests, but particularly the IgM EIA, are occasionally falsely positive, and results should be interpreted cautiously when used for screening purposes in asymptomatic individuals. If either the IgM or IgG EIA serology is positive, immunodiffusion tests (IDTP and IDCF) or traditional TP and CF assays should be performed for confirmation. If the IDCF or traditional CF assays are qualitatively positive, a CF titer should be requested. The optical density obtained from the EIA IgG does not correlate with the serologic titer of either the IDCF or traditional CF assay and should not be used as a surrogate for a titer. The CF titer is an important prognostic tool. High titers, for example, those ≥1:32, suggest unrestrained fungal growth, predict disease activity, and suggest the possibility of extrathoracic dissemination.

Coccidioides grows within 3–7 days at 37°C on a variety of artificial media, including blood agar. Therefore, it is always useful to obtain samples of sputum or other respiratory fluids and tissue for culture in suspected cases of coccidioidomycosis. The clinical laboratory should always be alerted to the possibility of this diagnosis, since *Coccidioides* poses a significant laboratory hazard if it is inadvertently inhaled. The organism can also be identified directly. While treatment of samples with potassium hydroxide is rarely fruitful, examination of sputum or other respiratory fluids after Papanicolaou, Gomori methenamine silver, or calcofluor white staining may reveal spherules in a significant proportion of patients with pulmonary coccidioidomycosis. For fixed tissues (e.g., those obtained from biopsy specimens), spherules with surrounding inflammation can be demonstrated with hematoxylin-eosin or Gomori methenamine silver staining.

A commercially available test for coccidioidal antigenuria and antigenemia has been developed and appears to be useful in immunosuppressed patients with severe or disseminated disease. It is also useful when the CSF is assayed in cases of suspected coccidioidal meningitis. False-positive results may occur in cases of histoplasmosis or blastomycosis. Some laboratories offer genomic detection by polymerase chain reaction; this assay does not appear to be more sensitive than culture but can be more rapid.

TABLE 219-1 Clinical Presentations of Coccidioidomycosis, Their Frequency, and Recommended Initial Therapy for the Immunocompetent Host

CLINICAL PRESENTATION	FREQUENCY, %	RECOMMENDED THERAPY
Asymptomatic infection	60	None
Primary pneumonia (focal)	40	In most cases, none[a]
Diffuse pneumonia	<1	Amphotericin B followed by prolonged oral triazole therapy
Pulmonary sequelae	5	
Nodule		None
Cavity		In most cases, none[b]
Chronic pneumonia		Prolonged triazole therapy
Disseminated disease	≤1	
Skin, bone, joint, soft tissue disease		Prolonged triazole therapy[c]
Meningitis		Lifelong triazole therapy[d]

[a]Treatment is indicated for hosts with depressed cellular immunity as well as for those with prolonged symptoms and signs of increased severity, including night sweats for >3 weeks, weight loss of >10%, a complement-fixation titer of >1:16, and extensive pulmonary involvement on chest radiography. [b]Treatment (usually with the oral triazoles fluconazole and itraconazole) is recommended for persistent symptoms. [c]In severe cases, some clinicians would use amphotericin B as initial therapy. [d]Intraventricular or intrathecal amphotericin B is recommended in cases of triazole failure. Hydrocephalus may occur, requiring a cerebrospinal fluid shunt.

Note: See text for dosages and durations.

TREATMENT

Coccidioidomycosis

Currently, two classes of antifungal agents are useful for the treatment of coccidioidomycosis (Table 219-1). While once prescribed routinely, amphotericin B in all its formulations is now reserved for only the most severe cases of dissemination and for intrathecal or intraventricular administration in patients with coccidioidal meningitis in whom other antifungal therapy has failed. The original formulation of amphotericin B, which is dispersed with deoxycholate, is usually administered intravenously in doses of 0.7–1.0 mg/kg either daily or three times per week. The newer lipid-based formulations are associated with less renal toxicity, but there are no studies indicating whether they lead to better improvement than the deoxycholate formulation in coccidioidomycosis. The lipid dispersions are administered intravenously at doses of 3–5 mg/kg daily or three times per week.

Triazole antifungals are currently the principal drugs used to treat most cases of coccidioidomycosis. Clinical trials have demonstrated the usefulness of both fluconazole and itraconazole as initial agents. Fluconazole has been the triazole of choice for the treatment of coccidioidomycosis in the past because of availability, cost, predictable oral absorption, and perceived lack of severe adverse events. However, there are no studies demonstrating its superiority over other triazole antifungals, and evidence indicates that itraconazole is more effective against bone and joint disease and may be more effective for other forms of coccidioidomycosis. For both drugs, a minimal oral adult dosage of 400 mg/d should be used. The maximum dose of itraconazole is 200 mg three times daily, but higher doses of fluconazole may be given and 800 mg is frequently prescribed for coccidioidal meningitis. The newer triazole antifungals, voriconazole and posaconazole, are useful for all types of clinical disease, including meningitis, and should be considered in cases where fluconazole or itraconazole therapy has failed. To date, isavuconazole has been used in limited circumstances in coccidioidomycosis but also appears to be effective, including for meningitis. High-dose triazole therapy may be teratogenic during the first trimester of pregnancy, and triazole therapy should be avoided in pregnant women during this period.

There are several new antifungal agents that are promising for the treatment of coccidioidomycosis in the future. These include olorofim, oteseconazole, ibrexafungerp, fosmanogepix, and oral liquid nanocrystal amphotericin B. At this time, only olorofim has been studied in human coccidioidomycosis, and none are currently approved for use in coccidioidomycosis. However, olorofim has been studied in human coccidioidomycosis and has received U.S. Food and Drug Administration breakthrough therapy designation for difficult-to-treat Coccidioides meningitis.

Most patients with focal primary pulmonary coccidioidomycosis do not require antifungal therapy. Patients for whom antifungal therapy should be considered include those with underlying cellular immunodeficiencies and those with prolonged symptoms and signs of extensive disease. Specific criteria include symptoms persisting for ≥2 months, night sweats occurring for >3 weeks, weight loss of >10%, a serum CF antibody titer of >1:16, and extensive pulmonary involvement apparent on chest radiography. When antifungal therapy is used, either fluconazole or itraconazole at 400 mg daily anywhere from 6 weeks to 6 months is considered appropriate.

Diffuse pulmonary coccidioidomycosis represents a special situation. Because most patients with this form of disease are

profoundly hypoxemic and critically ill, many clinicians favor beginning therapy with an amphotericin B formulation combined with an oral triazole antifungal. The triazole antifungal therapy is continued alone once clinical improvement occurs and should be continued for 6 months to 1 year.

The nodules that may occur after primary pulmonary coccidioidomycosis do not require treatment. As noted above, these nodules are not easily distinguished from pulmonary malignancies by means of radiographic imaging. Close clinical follow-up and biopsy may be required to separate these two entities. Most pulmonary cavities do not require therapy. Antifungal treatment should be considered in patients with persistent cough, pleuritic chest pain, and hemoptysis. Occasionally, pulmonary coccidioidal cavities become secondarily infected (see above). This development is often manifested by an air-fluid level within the cavity. Bacterial oral flora or *Aspergillus* species are commonly involved, and therapy directed at these organisms should be considered. Surgical removal of the cavity may be required in cases of persistent productive cough and hemoptysis or in those cases of a persistently growing cavity. In addition, cavities >4 cm in diameter are unlikely to resolve spontaneously, and surgical extirpation should be considered. Surgery is always required in cases of pyopneumothorax. For chronic pulmonary coccidioidomycosis, prolonged antifungal therapy—lasting for at least 1 year—is usually required, with monitoring of symptoms, radiographic changes, sputum cultures, and serologic titers.

Most cases of disseminated coccidioidomycosis require prolonged antifungal therapy. The duration of treatment is based on clinical improvement in conjunction with a significant decline in serum CF antibody titer. Such therapy routinely is continued for at least several years. Relapse occurs in 15–30% of individuals once therapy is discontinued and it is important to continue to monitor such patients on a regular basis (e.g., every 3–4 months) after antifungal therapy is discontinued.

Coccidioidal meningitis poses a special challenge. While most patients with this form of disease respond to treatment with oral triazoles, 80% experience relapse when therapy is stopped. Therefore, lifelong therapy is recommended. In cases of triazole failure, intrathecal or intraventricular amphotericin B may be used. Installation requires considerable expertise and should be undertaken only by an experienced health care provider. Shunting of CSF in addition to appropriate antifungal therapy is required in cases of meningitis complicated by hydrocephalus. It is prudent to obtain expert consultation in all cases of coccidioidal meningitis.

PREVENTION

There are no proven methods to reduce the risk of acquiring coccidioidomycosis among residents of an endemic region, but avoidance of inhalation of uncultivated soil or dust is a reasonable measure. For individuals with suppressed cellular immunity, the risk of developing symptomatic coccidioidomycosis is greater than that in the general population. Among those about to undergo allogeneic solid-organ transplantation, antifungal therapy is appropriate prior to transplantation when there is evidence of active or recent coccidioidomycosis. Several transplant centers in the endemic region provide universal antifungal prophylaxis for 6 months to 1 year after solid-organ and allogeneic stem cell transplantation, and lifelong universal prophylaxis has been advocated after lung transplantation to prevent the development of coccidioidomycosis after transplantation.

Cases of donor-transmitted coccidioidomycosis have been reported. Donors who are living or have lived in a coccidioidal endemic region should be screened serologically for coccidioidomycosis before transplantation and organ donation deferred if there is evidence of active infection.

Data on the use of antifungal agents for prophylaxis in other situations are limited. The administration of prophylactic antifungals is not recommended for HIV-1-infected persons who live in an endemic region. Most experts would administer a triazole antifungal to patients with a history of active coccidioidomycosis or a positive coccidioidal serology in whom therapy with tumor necrosis factor-α antagonists or other biological response modifiers is being considered.

There are recent efforts to develop a vaccine for coccidioidomycosis, and a live avirulent product has demonstrated promising results in a canine model. Future studies will determine if this is a viable strategy for preventing or ameliorating coccidioidal infection in humans.

220 Blastomycosis

Gregory M. Gauthier, Bruce S. Klein

DEFINITION

Blastomycosis is a pyogranulomatous disease that follows the inhalation of *Blastomyces* conidia or hyphal fragments. Typically, *Blastomyces* causes pulmonary infection; however, a subset of patients will have disseminated disease that involves organs such as the skin, bone, brain, or genitourinary system. Blastomycosis is considered a primary fungal infection because it affects persons with either intact or impaired immune systems. A delay in diagnosis is common because blastomycosis mimics other diseases such as bacterial pneumonia, tuberculosis, and malignancy. Diagnosis involves culture- and nonculture-based tests. Amphotericin B formulations and triazoles are the drugs of choice for treatment.

ETIOLOGY

Blastomyces is a species complex comprising *B. dermatitidis*, *B. gilchristii*, *B. helicus*, *B. percursus*, *B. emzantsi*, *B. silverae*, and *B. parvus*. *B. silverae* and *B. parvus* are not known to commonly infect humans. *Blastomyces* species exhibit thermal dimorphism, which involves the ability to convert between hyphal and yeast morphologies in response to temperature. In the soil (22–25°C), *Blastomyces* grows as septate hyphae that produce infectious conidia. Among the *Blastomyces* species, *B. helicus* is unique because its hyphae grow in a coiled pattern and it does not sporulate under in vitro growth conditions. In organs and tissues (37°C), *Blastomyces* grows as a pathogenic yeast **(Fig. 220-1)** that elicits pyogranulomatous inflammation. The yeast form of all *Blastomyces* species grows as broad-based budding yeast cells, with subtle differences in size among the different species (4–29 μm).

EPIDEMIOLOGY

Although the majority of *Blastomyces* infections occur in North America, blastomycosis is a systemic fungal infection of global importance, with infections also occurring in Africa and Asia. In the United States, the traditional geographic range for *Blastomyces* includes the Mississippi

FIGURE 220-1 *Blastomyces* yeast at 37°C, with broad-based budding between mother and daughter cells (*arrow*). Bar = 10 µm. *(Gregory M. Gauthier, MD, MS.)*

and Ohio River basins, the St. Lawrence River basin, states bordering the Great Lakes, and southeastern states. In Canada, the traditional geographic range includes the provinces of Saskatchewan, Manitoba, Ontario, and Quebec. In North America, *B. dermatitidis* is located throughout the traditional geographic range. *B. gilchristii* is geographically restricted to Minnesota, Wisconsin, Canada, and areas along the St. Lawrence River. *B. dermatitidis* and *B. gilchristii* are thought to have diverged 1.9 million years ago during the Pleistocene epoch, with *B. gilchristii* restricted to formerly glaciated areas. *B. dermatitidis* is found in glaciated and nonglaciated areas. In the environment, *B. dermatitidis* and *B. gilchristii* are not uniformly distributed; rather, they grow in ecologic niches often referred to as *microfoci*, which are characterized by acidic, sandy soils that are found near water and that contain decaying organic matter such as vegetation or wood. In upstate New York State, blastomycosis is an emerging pathogen in the Capitol District and upper Susquehanna River Subbasin with *B. dermatitidis* (88.4%) more common than *B. gilchristii* (11.6%). In Canada, blastomycosis is an emerging pathogen in the province of Saskatchewan. *B. helicus* infections have been reported in the western United States (California, Montana, Idaho, Colorado, Nebraska, Texas) and Canada (Saskatchewan, Alberta); their ecologic niche has yet to be defined. The geographic range and ecologic niche for *B. parvus* and *B. silverae* are unknown.

Outside of North America, blastomycosis has been reported in Africa (>100 cases), India (<10 cases), and Israel. On the basis of morphologic analysis, nearly all clinical isolates of *Blastomyces* in Africa were originally thought to be *B. dermatitidis*. However, molecular phylogenetic analysis of human clinical isolates has demonstrated that multiple *Blastomyces* species exist in Africa, including *B. dermatitidis*, *B. gilchristii*, *B. percursus*, and *B. emzantsi*. A combination of internal transcribed spacer (ITS) sequencing, multilocus sequence typing (MLST), and whole genome sequencing was used to identify a new species, *B. emzantsi*, and to differentiate *B. percursus* from other *Blastomyces* species. MLST has identified a *B. dermatitidis* isolate from Rwanda and *B. gilchristii* from Zimbabwe and South Africa. Analysis of 20 isolates from South Africa collected over a 40-year period identified them as either *B. emzantsi* or *B. percursus*. The geographic distribution and ecologic niche of the four *Blastomyces* species in Africa are unknown. In India, there have been fewer than 10 autochthonous cases of blastomycosis, with the majority identified by morphologic analysis. One autochthonous case (caused by *B. percursus*) with molecular confirmation has been reported from Israel.

Epidemiologic information about blastomycosis derives primarily from passive laboratory surveillance, retrospective studies, and outbreak investigations. The lack of sensitive skin testing and serologic testing, along with difficulty in isolating *Blastomyces* from the environment by culture or molecular methods, has limited an in-depth epidemiologic understanding of blastomycosis. In North America, blastomycosis is reportable in five U.S. states (Minnesota, Wisconsin, Michigan, Arkansas, and Louisiana) and two Canadian provinces (Manitoba, Ontario). The annual incidence of blastomycosis in the traditional endemic area ranges from 0.11 to 2.17 cases/100,000 persons. In older persons (Medicare beneficiaries, 1999–2008), the nationwide annual incidence of blastomycosis was 0.7/100,000, with the highest rates in the midwestern and southern regions of the United States. Analysis of Healthcare Cost and Utilization Project (HCUP) data estimated that 11,776 persons were hospitalized for blastomycosis in the United States from 2010 through 2020, with the majority of patients from midwestern (58.8%) and southern (31.4%) states. In certain places, such as Vilas County, Wisconsin, and Kenora, Ontario, blastomycosis is hyperendemic, with annual incidence rates ranging from 40 to 117 cases/100,000 persons. Incidence data likely underestimate the true burden of infection because they are limited to persons with clinically apparent infection. Patients with asymptomatic or subclinical infections are undercounted.

Most *Blastomyces* infections are sporadic and can occur in either rural or urban areas. There have been at least 20 outbreaks of blastomycosis in the United States since the mid-1950s. Wisconsin, Minnesota, and North Carolina have had multiple outbreaks. The majority of outbreaks have been in rural areas, but several have occurred in urban settings. Activities associated with outbreaks include construction (of homes, cabins, factories, and roads), excavation of dirt, participation in water sports (canoeing, tubing on a river, and fishing), and exposure to a community compost pile or to beaver dams. *Blastomyces* infection is typically acquired from disturbed soil, which liberates infectious particles that are then inhaled into the lungs.

An investigation of a blastomycosis outbreak in Marathon County, Wisconsin (2009–2010), found that 45% of patients were of Hmong ethnicity. A retrospective study from the Marshfield Clinic in Wisconsin (1999–2014) found that 14.4% of patients with blastomycosis were of Asian ethnicity—a figure higher than was anticipated given that <2.5% of the population within the catchment area is Asian, including a large Hmong population. These findings suggest that persons of Hmong ethnicity have an increased risk of acquiring blastomycosis. A combination of whole genome sequencing and immunologic analyses indicated that polymorphisms in the interleukin 6 (IL-6) gene in the Hmong population result in decreased IL-6 production, which in turn impairs development of IL-17-producing $CD4^+$ T lymphocytes. IL-17 is a critical cytokine for recruitment and activation of innate immune cells such as neutrophils and macrophages active against *Blastomyces*. Thus, alterations in IL-6 production may be responsible for the increased risk of blastomycosis in the Hmong population. Although data are limited, persons of Hmong ethnicity do not appear to be at increased risk for disseminated blastomycosis. Increased incidence rates of blastomycosis have also been reported in indigenous people of Canada and the United States. Compared with Caucasians, Asian and indigenous persons with blastomycosis tend to have fewer underlying medical conditions and to be younger.

PATHOGENESIS

A defining feature of the *Blastomyces* species complex is the ability to respond to shifts in temperature by switching between hyphal and yeast forms. In the soil, *Blastomyces* grows as mold cells with hyphae that produce conidia. Hyphal growth promotes environmental survival, genetic diversity through mating, and production of infectious conidia that facilitate transmission of *Blastomyces* from the environment to mammals, including humans. At 37°C (the core temperature of mammals), *Blastomyces* hyphae and conidia convert into pathogenic yeast that upregulate yeast phase–specific virulence factors and downregulate host immune defenses, thereby facilitating infection. Virulence traits that *Blastomyces* shares with *Histoplasma*, *Coccidioides*, *Sporothrix*, and *Paracoccidioides* are thermotolerance at 37°C, intracellular survival, and capacity to cause infection in persons with either

healthy or impaired immune defenses. Although *Emergomyces* and *Talaromyces marneffei* (formerly *Penicillium marneffei*) exhibit thermal dimorphism, growth as yeast at 37°C, and intracellular survival, these dimorphic fungi tend to cause infection primarily in immunocompromised persons.

The morphologic switch from hyphae to yeast at 37°C is driven chiefly by temperature and is coupled with the uptake of exogenous cysteine. Cysteine uptake is required to complete the transition to the yeast form because it helps restart mitochondrial respiration, which ceases during the morphologic switch. Over the past two decades, knowledge about the genetic mechanisms that promote the temperature-dependent transition between hyphae and yeast has substantially increased. The discovery of dimorphism-regulating kinase 1 (*DRK1*), which encodes a group III hybrid histidine kinase that is part of the high-osmolarity glycerol (HOG) signaling pathway, provided genetic proof that that the transition to yeast is essential for virulence of the thermally dimorphic fungi. Disruption of *DRK1* by gene deletion or RNA interference resulted in *Blastomyces* cells that grew as hyphae at 37°C instead of yeast. Although viable at 37°C, these cells had altered cell-wall composition, failed to upregulate the *Blastomyces* adhesin 1 (*BAD1*, formerly WI-1) virulence factor, and were avirulent in a mouse model of lethal pulmonary infection. Subsequent studies of *Histoplasma* and *Talaromyces* demonstrated that the function of *DRK1* is conserved with regard to thermal dimorphism and virulence.

The temperature-dependent transition in the other direction—from yeast to hyphae—is regulated in part by a GATA-transcription factor encoded by siderophore biosynthesis repressor in *Blastomyces* (*SREB*), which influences neutral lipid metabolism. In addition, sensing of chitin by *NGT1* and *NGT2 N*-acetylglucosamine transporters accelerates the conversion to hyphae following a drop in temperature from 37°C to 22°C. These two mechanisms are conserved in *Histoplasma capsulatum*.

As a primary fungal pathogen, *Blastomyces* is one of the few fungi that can infect immunocompetent persons. In its yeast form, *Blastomyces* evades and modulates immune defenses. Following disruption of soil, conidia that are aerosolized and inhaled into the lungs are phagocytosed by pulmonary macrophages, in which a subset of the conidia germinate as yeast and replicate during the early phases of infection. *Blastomyces* is also capable of replicating outside of macrophages. Upon conversion to the yeast phase, an essential virulence factor encoded by *BAD1* is upregulated. *BAD1* encodes a multifunctional 120-KDa cell-surface protein that facilitates yeast adherence to lung epithelial cells via interaction with heparin sulfate, attachment to host immune cells by binding to CR3 and CD14 complement receptors, and downregulation of tumor necrosis factor alpha (TNF-α) in macrophages and neutrophils. In addition, the BAD1 protein impairs activation of CD4+ T lymphocytes, thereby decreasing the production of IL-17 and interferon gamma (IFN-γ). In vivo transcriptional profiling of *B. dermatitidis* yeast during pulmonary infection demonstrated that *BAD1* is the most highly upregulated gene. Deletion of *BAD1* renders *B. dermatitidis* avirulent in a murine model of pulmonary infection. Thus, BAD-1 is essential for virulence in *B. dermatitidis* and likely in *B. gilchristii* as well. In contrast, *BAD1* is absent from the sequenced genomes of *B. helicus*, *B. parvus*, *B. silverae*, *B. percursus*, and *B. emzantsi*.

Additional factors that contribute to the virulence of *Blastomyces* yeast include relative resistance to oxidative stress, upregulation of catalase and superoxide dismutase during infection, active uptake of zinc by a *PRA1*-encoded zincophore and transmembrane transporter (*ZRT1*), and cleavage of granulocyte-macrophage colony-stimulating factor by dipeptidyl peptidase IVA, which blocks activation of innate immune cells (macrophages, neutrophils) and their recruitment to the lung.

APPROACH TO THE PATIENT

Blastomycosis

On the basis of outbreak investigations, it is estimated that 50% of persons exposed to *Blastomyces* develop symptomatic infection after a 3-week to 3-month incubation period. The relatively long incubation period means that patients can be diagnosed with blastomycosis throughout the year. Blastomycosis has been referred to as the "the great pretender" because it can mimic infectious and noninfectious diseases. Blastomycotic pneumonia clinically and radiographically resembles community-acquired bacterial pneumonia, viral pneumonia, tuberculosis, and lung cancer. Patients often receive two or three courses of antibiotics before pulmonary blastomycosis is diagnosed. Without fungal stain and culture, cutaneous lesions can mimic skin cancer, sarcoidosis, and pyoderma gangrenosum. Rarely, blastomycosis can mimic laryngeal cancer. The most important aspect of the approach to a patient with a compatible illness is the consideration of *Blastomyces* as an etiologic agent in the differential diagnosis. This awareness facilitates early diagnosis and treatment, enhancing the potential for improved clinical outcomes. Clinical clues to blastomycosis, especially in persons who reside in or visit endemic regions, include pneumonia that does not improve with antibiotic treatment, pneumonia with extrapulmonary manifestations (e.g., skin lesions, osteomyelitis, central nervous system [CNS] involvement), and skin ulcers that do not respond to standard therapy. Blastomycosis should also be considered in persons from (or visited) an endemic area who have unexplained respiratory failure or acute respiratory distress syndrome (ARDS). In addition, a detailed exposure history can elevate blastomycosis in the differential diagnosis; approximately 50–60% of patients will have environmental risk factors for blastomycosis. This history should also include inquiries about a pet or family member with blastomycosis; these factors have been reported in 7.7–10% and 4–9% of patients, respectively.

CLINICAL MANIFESTATIONS

Pulmonary Blastomycosis Pulmonary manifestations occur in 69–93% of patients with symptomatic blastomycosis and are the most common clinical feature of infection. Signs and symptoms can include fever, chills, productive or nonproductive cough, shortness of breath, hemoptysis, malaise, and decreased appetite. Pulmonary blastomycosis also can manifest as asymptomatic infection, a brief influenza-like illness, acute pneumonia, chronic pneumonia, or ARDS. Radiographic findings in the lungs include lobar consolidation, a mass lesion, interstitial infiltrates, nodule(s), a miliary pattern, cavitary disease, and diffuse involvement of multiple lobes. Hilar adenopathy, pleural effusion, and empyema are uncommon. No distinctive features differentiate blastomycosis from other pulmonary diseases. Diabetes, receipt of a solid organ transplant, immunosuppression, and multilobar pneumonia are risk factors for severe pulmonary blastomycosis. Approximately 4–15% of patients with pulmonary blastomycosis develop ARDS, which is characterized by a fulminant course and high mortality rates ranging from 40 to 89% in most studies. The mortality rate in ARDS is increased when the diagnosis is delayed.

Disseminated Blastomycosis Disseminated blastomycosis occurs in 15–48% of patients and has the potential to involve nearly any organ in the body. The most common site of dissemination is the skin, in which the infection can manifest as papules, ulcers, verrucous lesions, or abscesses. The second most common site is bone, with consequent osteomyelitis characterized by bone pain, soft tissue swelling, soft tissue abscess, and sinus tract formation. Typically, a single bone is involved; however, multifocal osteomyelitis can occur. The most common sites for osteomyelitis include the spine, long bones, and ribs. Dissemination to the CNS (e.g., manifesting as meningitis, an abscess, or a mass lesion), the larynx, or the genitourinary system (e.g., to the prostate or epididymis) occurs in fewer than 10%; the majority of the affected patients have concomitant involvement of other organs, such as the lung or the skin.

Factors that influence dissemination include the infecting *Blastomyces* species, the duration of pulmonary symptoms, and concomitant AIDS. Multiple studies from Wisconsin, a state in which *B. dermatitidis* and *B. gilchristii* are endemic, have demonstrated that *B. dermatitidis* is more likely to cause disseminated infection (31.4–47.8% of cases), whereas *B. gilchristii* tends to remain localized to the lung (90.7–92.2%). Surprisingly, immunosuppression has only a minimal

influence on dissemination, an observation suggesting that *Blastomyces* virulence factors have a greater impact than host immune defenses. The frequency of disseminated blastomycosis among solid organ transplant recipients, persons receiving cancer chemotherapy, and patients undergoing pharmacologic immunosuppression is similar to that among patients with intact immune systems. Although patients treated with TNF-α antagonists are considered at risk for blastomycosis, the clinical manifestations and frequency of disseminated disease are unknown in this group because of a paucity of published data. Persons with AIDS and $CD4^+$ T lymphocyte counts of <100/μL are an exception: they are at increased risk for CNS dissemination. Blastomycosis in pregnancy is uncommon, is typically diagnosed in the second or third trimester (91%), and most frequently manifests as pneumonia (74%) or disseminated infection (48%). Transmission to the neonate by either the transplacental route or aspiration of infected vaginal secretions is rare. Persons infected with *B. helicus* can have localized pulmonary infection or disseminated disease; they are typically immunosuppressed (e.g., as a result of solid organ transplantation, chemotherapy, HIV infection, or lupus) and have a high mortality rate (71.4% in seven patients). In contrast to *B. dermatitidis* and *B. gilchristii*, *B. helicus* commonly causes fungemia. Infections with *B. percursus* and *B. emzantsi* are often of long duration (persisting for 4 weeks to 5 years) and can involve the lungs or become disseminated (skin, bone, brain).

DIAGNOSIS

Timely diagnosis of blastomycosis requires a high degree of clinical suspicion because its clinical and radiographic presentations mimic more common etiologies, such as community-acquired pneumonia, malignancy, and tuberculosis. Laboratory findings such as leukocytosis, mild anemia, increased C-reactive protein level, and elevated erythrocyte sedimentation rate are nonspecific. Once suspected, the diagnosis of blastomycosis is straightforward and involves microscopic examination of stained specimens, fungal culture, and antigen testing. The poor sensitivity of complement fixation (9%) and immunodiffusion (28%) renders serologic testing diagnostically dispensable. However, a recently developed serologic test designed to detect antibodies to BAD1 has a sensitivity of 87% and a specificity of 94–99%.

A presumptive diagnosis of blastomycosis can be made by staining of clinical specimens and looking for broad-based budding yeast with a doubly refractile cell wall. Along with the broad-based budding pattern, yeast size (4–29 μm) allows *Blastomyces* to be distinguished from other fungi. An exception is *B. helicus*, which has the potential to be confused with *Histoplasma* because of its small-sized yeast. Respiratory tract specimens such as sputum, tracheal aspirate, and bronchoalveolar (BAL) fluid can be stained with calcofluor, 10% potassium hydroxide, or Papanicolaou stain. Purulent drainage can be stained in a similar manner. The sensitivity of staining of respiratory samples ranges from 50 to 90%. Tissue samples for histopathology should be stained with Gomori methenamine silver or periodic acid–Schiff stain and assessed for pyogranulomatous inflammation and broad-based budding yeast. Traditional stains, such as Gram's stain or hematoxylin and eosin, do not permit optimal visualization of *Blastomyces* yeast.

Growth of *Blastomyces* in cultures of respiratory tissue or body fluid samples provides a definitive diagnosis of blastomycosis but typically requires 5–28 days of incubation. Special media such as Sabouraud dextrose, potato dextrose, and brain–heart infusion are required because *Blastomyces* does not grow well on standard bacteriologic media. Most clinical microbiology laboratories incubate fungal cultures at 25–30°C, a temperature that results in hyphal growth of *Blastomyces*. Unfortunately, *Blastomyces* hyphae are not morphologically distinct enough to confirm diagnosis. Thus, fungal identification and diagnosis are commonly confirmed via chemiluminescent DNA probe or, less commonly, via conversion to yeast upon incubation at 37°C. Diagnosis can also be confirmed by polymerase chain reaction. Neither the chemiluminescent DNA probe nor morphologic analysis of yeast by light microscopy differentiates among the different species of *Blastomyces*. Moreover, some species, such as *B. emzantsi*, are difficult to convert to yeast at 37°C. The species of *Blastomyces* is not typically determined in clinical labs because DNA sequencing is required.

An antigen test that detects a conserved galactomannan component in the *Blastomyces* cell wall has supplanted serologic testing. This test can be performed on urine, blood, BAL fluid, and cerebrospinal fluid. The sensitivity of the antigen test is 85–93% for urine and 57–82% for serum. Infection burden appears to influence test sensitivity, with a lower burden of infection resulting in reduced sensitivity. The antigen test can detect *B. dermatitidis*, *B. gilchristii*, and *B. helicus*; however, its utility for detection of other *Blastomyces* species is unknown. Cross-reactions in the antigen test occur during infection with other dimorphic fungi, including *H. capsulatum* (96%), *Paracoccidioides* species (100%), and *T. marneffei* (70%). Among these, only *H. capsulatum* is found in the same endemic region as *Blastomyces*. Rare cross-reactions can occur with *Aspergillus* and *Cryptococcus* infections. Antigen levels in urine and blood decline with successful treatment, and their measurement can be used to monitor the response to antifungal therapy.

TREATMENT

Blastomycosis

Guidelines for the treatment of blastomycosis have been published by the Infectious Diseases Society of America (2008), the American Thoracic Society (2011), the American Society of Transplantation (2019), and European Confederation of Medical Mycology (2021). Although there are isolated reports of self-limited pulmonary blastomycosis, there are no criteria to determine which patients will experience a resolution of infection. Thus, treatment is recommended for all patients with blastomycosis in order to prevent progressive infection, respiratory failure, and disseminated disease. Antifungal selection is influenced by immune status, CNS involvement, pregnancy, medical comorbidities (e.g., congestive heart failure, prolonged QT interval), and drug–drug interactions. Antifungal drugs active against *Blastomyces* include amphotericin B (AmB) formulations and triazoles. The minimal amount of beta-(1,3)-glucan in the *Blastomyces* yeast cell wall renders echinocandins ineffective, and they should not be used to treat blastomycosis. Hematologic, hepatic, and renal function should be assessed prior to initiation of antifungal therapy, and possible drug–drug interactions should be evaluated. In addition, patients should be educated about proper administration of triazole antifungals. For example, itraconazole capsules require an acidic gastric environment for optimal absorption and should be taken with food and an acidic beverage to improve bioavailability; they cannot be used by persons taking antacids, H2 antagonists, or proton pump inhibitors. In contrast, itraconazole solution can be given to patients receiving gastric acid–lowering therapies and should be taken without food.

Treatment for blastomycosis is summarized in **Table 220-1**. For immunocompetent patients with pulmonary or disseminated blastomycosis of mild or moderate severity (e.g., treatable in the outpatient setting), itraconazole therapy for 6 months is recommended. For severe blastomycosis (e.g., that requiring hospitalization), induction therapy with lipid AmB for 7–14 days (or until clinical improvement), followed by itraconazole treatment for 6–12 months, is recommended. Although not well studied, combination antifungal therapy with lipid AmB and itraconazole (or another azole) can be considered for patients with severe pulmonary blastomycosis. In patients with ARDS, prednisone can be considered; however, the benefits of steroids are unclear. Osteomyelitis due to blastomycosis requires at least 12 months of antifungal therapy, and some patients may require surgical debridement. For blastomycosis involving the CNS, lipid AmB is administered for 4–6 weeks and is followed by treatment with voriconazole, itraconazole, or fluconazole for at least 12 months. Although fluconazole has excellent CNS penetration, its minimum inhibitory concentration (MIC) against *B. dermatitidis* and *B. gilchristii* is higher than that of either itraconazole or voriconazole. Emerging data suggest that isavuconazonium sulfate can be used for treatment of CNS blastomycosis.

Immunosuppressed patients should be treated with 7–14 days of lipid AmB followed by 12 months of itraconazole. For patients

TABLE 220-1 Treatment of Blastomycosis

PATIENT POPULATION	SEVERITY OF INFECTION	SITE OF INFECTION	THERAPY
Immunocompetent	Mild to moderate[a]	Lung	Itraconazole for 6–12 months[b]
		Disseminated	Itraconazole for 6–12 months[b] (≥12 months for osteomyelitis)
	Severe[c]	CNS	Lipid AmB (5 mg/kg daily[d,e] for 4–6 weeks) followed by voriconazole (200–400 mg bid), itraconazole[b] or fluconazole (800 mg daily) for at least 12 months of treatment
		Lung	Lipid AmB (3–5 mg/kg daily[e,f] for 7–14 days) followed by itraconazole[b] for 6–12 months
		Disseminated	Lipid AmB (3–5 mg/kg daily[e,f] for 7–14 days) followed by itraconazole[b] for 12 months of treatment (≥12 months for osteomyelitis)
Immunocompromised	Any severity	CNS	Lipid AmB (5 mg/kg daily[d,e] for 4–6 weeks) followed by voriconazole (200–400 mg bid), itraconazole[b] or fluconazole (800 mg daily) for at least 1 year of treatment[g]
		Lung or disseminated	Lipid AmB (3–5 mg/kg daily[e,f] for 7–14 days) followed by itraconazole[b] for 12 months[g]
Pregnant[h]	Any severity	Any site	Lipid AmB (3–5 mg/kg daily[e,f] for 6–8 weeks), with avoidance of azole antifungals

[a]Mild to moderate infections can typically be managed in the outpatient setting. [b]A loading dose of 200 mg PO tid for 3 days followed by 200 mg PO daily or bid, with dosing based on serum itraconazole levels. The goal for levels of total itraconazole (i.e., itraconazole plus hydroxyitraconazole) is 1–5 μg/mL. Liquid itraconazole has greater bioavailability than the capsule formulation. Liquid itraconazole and oral capsules are administered differently (see text for details). Serum itraconazole levels should be measured after steady state has been reached (2 weeks). Because of the drug's long half-life, blood for serum itraconazole determinations can be drawn regardless of the time of administration. In contrast, serum drug levels for voriconazole, posaconazole, and isavuconazole should be measured before a dose is administered when steady state has been reached (~1 week). [c]Severe blastomycosis requires hospitalization on a medical ward, an intermediate care unit, or an intensive care unit. [d]Lipid amphotericin B (AmB) is the preferred formulation because it has the best central nervous system (CNS) penetration among AmB formulations. For patients with CNS blastomycosis that results in neurologic dysfunction, surgical intervention should be considered. [e]For patients with CNS blastomycosis, severe pulmonary blastomycosis, or severe disseminated blastomycosis, combination therapy with lipid AmB plus a triazole antifungal can be considered; however, this combination has not been formally studied. For patients with acute respiratory distress syndrome, adjunctive steroid therapy with prednisone (40–60 mg daily for 1–2 weeks) can be considered; however, the benefit of steroid administration is not well defined. [f]If lipid AmB is not available, then AmB deoxycholate (0.7–1. 0 mg/kg daily) can be substituted; however, this formulation is associated with higher rates of nephrotoxicity and infusion reactions than lipid AmB. [g]Consider lifelong suppression with itraconazole (200 mg daily) if immunosuppression cannot be reversed. This decision should be made on a case-by-case basis; not all immunosuppressed patients require lifelong suppressive therapy. In addition, lifelong antifungal suppression can be considered in patients who experience relapse after appropriate therapy. [h]All women of childbearing age should undergo pregnancy testing before initiation of therapy.

requiring irreversible immunosuppression, indefinite suppressive azole therapy may be needed; however, in light of the heterogeneity of this patient population, a decision about suppressive therapy should be made on a case-by-case basis. The majority of solid organ transplant recipients do not require lifelong suppression because rates of relapse are low when treatment guidelines are followed.

For pregnant women, lipid AmB treatment for 6–8 weeks is recommended because, unlike the triazole antifungals, lipid AmB is not teratogenic. Fluconazole can cause craniofacial, skeletal, and cardiac defects in the developing fetus (Antley-Bixler-like syndrome); voriconazole and posaconazole also can result in skeletal abnormalities. Itraconazole increases the risk of spontaneous abortion. Before starting antifungal therapy, women of childbearing age with blastomycosis should have a pregnancy test.

Voriconazole, posaconazole, and isavuconazonium sulfate have potent activity against *B. dermatitidis* and *B. gilchristii* and can be considered as alternatives for persons who cannot tolerate itraconazole. These agents, along with itraconazole and AmB, also exhibit good activity against newly identified species of *Blastomyces*, such as *B. helicus*, *B. percursus*, and *B. emzantsi*. Fluconazole MICs against *B. percursus* and *B. emzantsi* are higher than those of other triazoles. Moreover, fluconazole appears to have poor activity against *B. helicus*, *B. parvus*, and *B. silverae*.

PROGNOSIS

Mortality rates for blastomycosis range from 5 to 13%; most deaths are associated with respiratory failure due to ARDS. Analysis of 11,776 hospital admissions for blastomycosis from 2010 through 2020 (HCUP data) demonstrated a 7.9% mortality rate, with increased mortality in patients who were older or who had underlying chronic obstructive pulmonary disease or concomitant malignancy (solid or hematologic). The vast majority of patients who recover from pulmonary blastomycosis do not experience long-term loss of pulmonary function. Cutaneous blastomycosis typically results in scarring.

PREVENTION

Prevention of blastomycosis is challenging because most infections are sporadic and unpredictably acquired from the environment. However, substantial progress has been made in understanding vaccine-mediated immunity conferred by a live, attenuated vaccine strain that is deficient in BAD1. When injected subcutaneously into mice, the *B. dermatitidis* BAD1-null vaccine strain induces sterilizing immunity by activating T_H17 lymphocytes to protect against lethal pulmonary challenge. Major antigenic components of the vaccine identified to date include calnexin and *Blastomyces* endoglucanase-2, which is conserved in other pathogenic fungi, including *Histoplasma capsulatum*, *Coccidioides* species, *Aspergillus* species, *Fonsecaea pedrosoi*, and *Pseudogymnoascus destructans*. Neither the BAD1-null attenuated vaccine nor recombinant antigen-based vaccines are commercially available.

221 Cryptococcosis

Arturo Casadevall, Shmuel Shoham

DEFINITION AND ETIOLOGY

Cryptococcus, a genus of yeast-like fungi, is the etiologic agent of cryptococcosis. In 2022, the World Health Organization (WHO) declared *Cryptococcus neoformans* as a critical priority pathogen. Until recently, cryptococcal strains were separated into two species. However, genome sequencing studies have now revealed tremendous diversity among isolates previously assigned to each species, leading to the proposal that each of the prior species classifications includes numerous new species. Hence, *C. neoformans* and *C. gattii* are now considered as

species complexes. However, for clinical purposes, these species complexes cause indistinguishable disease referred to as cryptococcosis. Consequently, this chapter will continue to use the nomenclature *C. neoformans* and *C. gattii* with the understanding that these terms refer to species complexes.

EPIDEMIOLOGY

Cryptococcosis was first described in the 1890s but remained rare until the mid-twentieth century, when advances in diagnosis and increases in the number of immunosuppressed individuals markedly raised its reported prevalence. Although serologic evidence of cryptococcal *infection* is common among immunocompetent individuals, cryptococcal *disease* (cryptococcosis) is rare in the absence of impaired immunity. Conditions associated with high risk for *C. neoformans* infection include hematologic malignancies, receipt of solid-organ transplants, advanced liver disease, diabetes mellitus, illnesses necessitating glucocorticoid therapy, and advanced HIV infection with CD4+ T lymphocyte counts of <200/μL. In contrast, *C. gattii*–related disease is not generally associated with specific immune deficits and often occurs in immunocompetent individuals but is associated with autoantibodies to granulocyte-macrophage colony-stimulating factor.

Cryptococcal infection is acquired from the environment. *C. neoformans* and *C. gattii* species complexes inhabit different ecologic niches. *C. neoformans* is frequently found in soils contaminated with avian excreta and can be recovered from shaded and humid soils contaminated with pigeon droppings. In contrast, *C. gattii* is not found in bird feces. Instead, it inhabits a variety of arboreal species, including eucalyptus trees. *C. neoformans* strains are found throughout the world; however, var. *grubii* (serotype A) strains are far more common than var. *neoformans* (serotype D) strains among both clinical and environmental isolates. *C. gattii* was thought to be largely limited to tropical regions until an outbreak of cryptococcosis caused by a new serotype B strain began in Vancouver in 1999. This outbreak has extended into the United States, and *C. gattii* infections are being encountered increasingly in several states in the Pacific Northwest.

The global burden of cryptococcosis was estimated in 2012 at ~1 million cases, with >600,000 deaths annually, although the prevalence of this disease has declined since then with the greater availability of antiretroviral therapy (ART) for HIV. Since the onset of the HIV pandemic in the early 1980s, the overwhelming majority of cryptococcosis cases have occurred in patients with AIDS **(Chap. 208)**. To comprehend the impact of HIV infection on the epidemiology of cryptococcosis, it is instructive to note that in the early 1990s there were >1000 cases of cryptococcal meningitis each year in New York City—a figure far exceeding that for all cases of bacterial meningitis. With the advent of effective ART, the incidence of AIDS-related cryptococcosis has been sharply reduced among treated individuals. Therefore, most cases of cryptococcosis now occur in resource-limited regions of the world. The disease remains distressingly common in regions where ART is not readily available (e.g., parts of Africa and Asia); in these regions, up to one-third of patients with AIDS have cryptococcosis. Among HIV-infected persons, those with a decreased percentage of memory B cells expressing IgM may be at greater risk for cryptococcosis. In wealthier countries, most cryptococcosis cases are in people without HIV.

PATHOGENESIS

Cryptococcal infection is almost always acquired by inhalation of aerosolized particles. The exact nature of the infectious particles is not known; the two leading candidate forms are small desiccated yeast cells and basidiospores. Occasionally, infection is acquired via direct inoculation of the skin. Little is known about the pathogenesis of initial infection. Serologic studies have shown that cryptococcal infection is acquired in childhood, but it is not known whether the initial infection is symptomatic. Given that cryptococcal infection is common while disease is rare, the consensus is that pulmonary defense mechanisms in immunologically intact individuals are highly effective at containing this fungus. It is not clear whether initial infection leads to a state of immunity or whether most individuals are subject throughout life to frequent and recurrent infections that resolve without clinical disease.

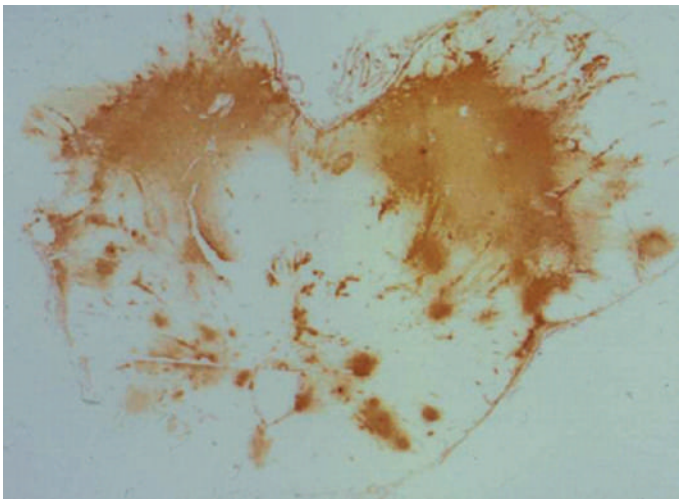

FIGURE 221-1 Cryptococcal antigen in human brain tissue, as revealed by immunohistochemical staining. Brown areas show polysaccharide deposits in the midbrain of a patient who died of cryptococcal meningitis. *(Reproduced with permission from SC Lee et al: Immunohistochemical localization of capsular polysaccharide antigen in the central nervous system cells in cryptococcal meningoencephalitis. Am J Pathol 148:1267, 1996.)*

However, some human cryptococcal infections lead to a state of latency in which viable organisms are harbored for prolonged periods, possibly in granulomas. Thus, the inhalation of cryptococcal cells and/or spores can be followed by either clearance or establishment of the latent state. The consequences of prolonged harboring of cryptococcal cells in the lung are not known, but evidence from animal studies indicates that the organisms' prolonged presence could alter the immunologic milieu in the lung and predispose to allergic airway disease.

Cryptococcosis usually presents clinically as pulmonary disease and/or chronic meningoencephalitis. The mechanisms by which the fungus undergoes extrapulmonary dissemination and enters the central nervous system (CNS) remain poorly understood. Current evidence suggests that both direct fungal-cell migration across the endothelium and fungal-cell carriage inside macrophages as "Trojan horse" invaders can occur. *Cryptococcus* species have well-defined virulence factors that include the expression of the polysaccharide capsule, the ability to make melanin, and the elaboration of enzymes (e.g., phospholipase and urease) that enhance the survival of fungal cells in tissue. Among these virulence factors, the capsule and melanin production have been most extensively studied. The cryptococcal capsule is antiphagocytic, and the capsular polysaccharide has been associated with numerous deleterious effects on host immune function. Cryptococcal infections can elicit little or no tissue inflammatory response. The immune dysfunction seen in cryptococcosis has been attributed to the release of copious amounts of capsular polysaccharide into tissues, where it probably interferes with local immune responses **(Fig. 221-1)**. In clinical practice, the capsular polysaccharide is the antigen that is measured as a diagnostic marker of cryptococcal infection.

APPROACH TO THE PATIENT

Cryptococcosis

Cryptococcosis should be included in the differential diagnosis when any patient presents with findings suggestive of chronic pulmonary or CNS infection. Concern about cryptococcosis is heightened by a history of headache and neurologic symptoms in a patient with an underlying immunosuppressive disorder such as advanced HIV infection, malignancy, immunosuppressive use, or solid-organ transplantation. Evaluation of cerebrospinal fluid (CSF) is critical for diagnosis of CNS disease and should include measurements of CSF pressure, protein, glucose, cell count, Gram stain, cultures, and a cryptococcal antigen assay.

CLINICAL MANIFESTATIONS

The clinical manifestations reflect the site of infection. The spectrum of disease consists predominantly of meningoencephalitis and pneumonia, but skin and soft tissue infections also occur and cryptococcosis can affect any tissue or organ. Symptoms may arise from fungal tissue invasion and from an overactive immune response. In CNS disease, symptoms may reflect elevated intracranial pressure (ICP). CNS involvement usually presents as signs and symptoms of chronic meningitis, such as headache, fever, lethargy, sensory deficits, memory deficits, cranial nerve paresis, vision deficits, and meningismus. Cryptococcal meningitis differs from bacterial meningitis in that many patients present with symptoms of several weeks in duration. In addition, classic characteristics of meningeal irritation, such as meningismus, may be absent. Indolent cases can present as subacute dementia or depression. Meningeal cryptococcosis can lead to sudden catastrophic vision loss.

Pulmonary cryptococcosis usually presents as cough, increased sputum production, and chest pain. Radiographic findings include nodules, infiltrates, and masses. *C. gattii* pneumonia can present with granulomatous masses known as *cryptococcomas*. Fever develops in a minority of cases. Pulmonary cryptococcosis can follow an indolent course, and many cases probably do not come to clinical attention. In fact, many cases are discovered incidentally during the workup of an abnormal chest radiograph obtained for other purposes. Pulmonary cryptococcosis can be associated with antecedent diseases such as malignancy, diabetes, and tuberculosis.

Skin lesions are common in patients with disseminated cryptococcosis and can be highly variable, including papules, plaques, purpura, vesicles, tumor-like lesions, and rashes. The spectrum of cryptococcosis in HIV-infected patients is so varied and has changed so much since the advent of ART that a distinction between HIV-related and HIV-unrelated cryptococcosis is no longer pertinent. In highly immunosuppressed patients, the lesions of cutaneous cryptococcosis often resemble those of molluscum contagiosum **(Fig. 221-2; Chap. 201)**.

DIAGNOSIS

A diagnosis of cryptococcosis requires the demonstration of cryptococcal cells or antigen in normally sterile tissues. Visualization of encapsulated fungal cells in CSF mixed with India ink remains a useful rapid diagnostic technique. Cryptococcal cells can also be visualized on Gram stain. However, these staining techniques may yield negative results in patients with a low fungal burden or be misread as positive by inexperienced operators. Cultures of CSF and blood that are positive for cryptococcal cells are diagnostic for cryptococcosis. CSF examination usually reveals evidence of chronic meningitis with mononuclear cell pleocytosis and increased protein levels. A particularly useful test is cryptococcal antigen (CRAg) detection in CSF and blood. The assay is based on serologic detection of cryptococcal polysaccharide and is both sensitive and specific. A major advance in recent years was the introduction of rapid point-of-care CRAgs that provide results in minutes. A positive CRAg test provides strong presumptive evidence for cryptococcosis; however, because the result is often negative in pulmonary cryptococcosis, the test is less useful for diagnosing pulmonary disease and is of only limited usefulness in monitoring the response to therapy. Polymerase chain reaction is available and effective for the diagnosis of cryptococcosis, but physicians should seek confirmation of positive or negative tests with independent methods such as CRAg and culture.

In areas of Africa where there is a high prevalence of HIV infection, routine screening of blood for CRAg in HIV-infected patients with low CD4+ T lymphocyte counts may identify individuals at high risk of cryptococcal disease who are candidates for antifungal therapy. CRAg screening has shown that a significant proportion of HIV-infected patients hospitalized with pneumonia in Thailand harbor cryptococcal infection. Inexpensive point-of-care CRAg tests in the form of lateral flow assays provide rapid and accurate information and are of great diagnostic benefit in resource-limited regions.

FIGURE 221-2 Disseminated fungal infection. A liver transplant recipient developed six cutaneous lesions similar to the one shown. Biopsy and serum antigen testing demonstrated *Cryptococcus*. Important features of the lesion include a benign-appearing fleshy papule with central umbilication resembling molluscum contagiosum. *(Photo courtesy of Dr. Lindsey Baden; with permission.)*

TREATMENT

Cryptococcosis

When the infection is nonsevere and limited to the lungs or other non-CNS sites, treatment is typically with fluconazole. While pulmonary cryptococcosis in an immunocompetent host sometimes resolves without therapy, given the propensity of *Cryptococcus* species to disseminate from the lung, the inability to gauge the host's immune status precisely, and the availability of low-toxicity therapy in the form of fluconazole, the current recommendation for nonsevere pulmonary cryptococcosis in an immunocompetent individual is fluconazole 400 mg daily for 6–12 months. Fluconazole can cause drug interactions, QT interval prolongation, and liver dysfunction (especially at higher doses), and the dose should be adjusted for renal function. In general, extrapulmonary cryptococcosis without CNS involvement requires less intensive therapy, with the caveat that morbidity and death are associated with meningeal involvement. Thus, the decision to categorize cryptococcosis as "extrapulmonary without CNS involvement" should be made only after evaluation of the CSF reveals no evidence of cryptococcal infection.

When cryptococcosis is severe or involves the CNS, treatment involves induction, consolidation, and maintenance phases. The induction phase ideally includes a combination of intravenous amphotericin B (AmB) and oral flucytosine (5-FC). If feasible, lipid formulations of AmB should be used because those have less toxicity than deoxycholate AmB. The recommended daily doses are liposomal AmB 3–5 mg/kg, AmB lipid complex 5 mg/kg, and deoxycholate AmB 0.7–1 mg/kg. The dose of 5-FC is 25 mg/kg four times daily. 5-FC can cause bone marrow suppression, and the dose should be adjusted for renal function. The duration of induction therapy is a minimum of 2 weeks but may require extension to 4–6 weeks when there is poor initial response to therapy, neurologic complications, or brain cryptococcomas and in people without HIV. Cryptococcal cells with negative cultures may be seen on CSF staining, and elevated cryptococcal antigen may be present in CSF and blood, long after clearance of cultures. These do not indicate treatment failure.

For people with HIV, WHO recommends several alternative approaches to induction. These include a single dose of liposomal AmB 10 mg/kg given along with 14 days of 5-FC at 25 mg/kg four times daily *and* fluconazole 1200 mg daily. If liposomal AmB is not available, a 7-day course of AmB deoxycholate 1 mg/kg per day can be used in its place. If AmB is not available, an all-oral 14-day induction regimen of fluconazole 1200 mg daily and 5-FC 25 mg/kg four times daily can be used. The consolidation phase is typically with fluconazole 400–800 mg daily for 8 weeks. This is followed by fluconazole maintenance at 200–400 mg daily for a year or longer.

The goal of maintenance is to prevent recurrent disease, and its duration depends on the immune status of the patient. Individuals who remain deeply immunocompromised, such as those with HIV whose CD4+ T lymphocyte counts remain <200/μL or have not attained control of HIV with ART may need to remain on fluconazole indefinitely. Newer triazoles like voriconazole, posaconazole, and isavuconazole are highly active against cryptococcal strains and appear to be clinically effective, but clinical experience with these agents is limited. An oral formulation (cochleated) of AmB is in development. The echinocandins are not effective against *Cryptococcus* species. Addition of a short course of interferon γ to antifungal therapy in patients with HIV infection increases clearance of cryptococci from the CSF. Antifungal drug resistance has not been a major problem with cryptococcal strains, but there are increasing reports of drug-resistant strains, including some emerging during the prolonged therapy needed for cryptococcosis. Hence, cryptococcosis that is refractory to antifungal therapy should prompt an investigation into the susceptibility of the clinical isolates in question.

Cryptococcal meningoencephalitis may be associated with increased ICP, which can damage the brain and cranial nerves. CSF pressure should be measured and increased ICP diligently managed in such patients. The mechanism leading to increased ICP is often excess CSF fluid. Neurologic symptoms, including headache, blurred vision, cranial nerve abnormalities, and altered mental status, are typical clues to increased ICP. Management requires reduction of pressure by repeated therapeutic lumbar punctures and the placement of shunts. Neither mannitol nor acetazolamide is effective. Glucocorticoids are not helpful unless the elevated ICP is from a brain lesion with associated mass effect and edema.

Several clinical syndromes in cryptococcosis are driven by an overactive immune response. In people with HIV disease who are treated with ART, an immune reconstitution inflammatory syndrome (IRIS) occurs when immunity rebounds in the setting of treated cryptococcosis (or an undiagnosed asymptomatic infection). Similar syndromes can occur in transplant recipients whose immunosuppressive regimens have been reduced to help control the infection and even in non-immunocompromised people with infection that had appeared to be resolving. The immune response triggers an inflammatory reaction that can be difficult to distinguish from a relapsing infection. Symptoms can include fevers, headache, lymphadenopathy, and pulmonary, CNS, and cutaneous manifestations. Administration of prophylactic dexamethasone in HIV-associated cryptococcosis is not recommended because it has been associated with reduced fungal clearance and increased mortality. The approach to patients that have already developed IRIS and the related immune-driven syndromes must attempt to balance resurgent immunity against immune-mediated damage. Management is individualized and can involve the use of glucocorticoids to reduce inflammation. Apart from the difficulties in distinguishing these inflammatory syndromes from cryptococcal relapse, their management is complex because the cause is often triggered by the desirable outcome of improving immunity, which is important in controlling cryptococcal infection and preventing relapses.

A major consideration for clinicians treating symptomatic AIDS-related cryptococcosis is when to begin ART, which can trigger rebounding immunity. Current recommendations are to start ART 4–6 weeks after initiating antifungal therapy. Screening with serum CRAg is recommended for asymptomatic people with HIV and CD4+ T lymphocyte counts of <100–200/μL. Positive tests should be followed up with careful evaluation for active disease including CSF analysis. For those with antigenemia but no evidence of active disease, a preemptive fluconazole regimen is recommended with 14 days of induction dosing at 800 mg daily and up to 1200 mg daily when fungal burden is high (e.g., CRAg titers exceed 1:80) followed by consolidation and maintenance dosing. Initiation of ART should start 2 weeks after initiation of antifungal therapy in such circumstances.

PROGNOSIS AND COMPLICATIONS

Even with antifungal therapy, cryptococcosis is associated with high rates of morbidity and death. For most patients with cryptococcosis, the most important prognostic factors are the extent and the duration of the underlying immunologic deficits that predisposed them to develop the disease. Cryptococcosis is often curable with antifungal therapy in individuals with no apparent immunologic dysfunction, but in patients with irreversible immunosuppression, the best that can be hoped for is that antifungal therapy will induce remission, which can then be maintained with lifelong suppressive therapy. Before the advent of ART, the median overall survival period for AIDS patients with cryptococcosis was <1 year. Cryptococcosis in patients with underlying neoplastic disease has a particularly poor prognosis. For CNS cryptococcosis, poor prognostic markers are a CSF assay positive for yeast cells on initial India ink examination (evidence of a heavy fungal burden), high CSF pressure, low CSF glucose levels, low CSF pleocytosis (<2/μL), recovery of yeast cells from extraneural sites, absence of antibody to capsular polysaccharide, a CSF or serum cryptococcal antigen level of ≥1:32, and concomitant glucocorticoid therapy or hematologic malignancy. A response to treatment does not guarantee cure since relapse of cryptococcosis is common even among patients with relatively intact immune systems and immune reconstitution syndromes can occur in patients who had been improving with antifungal therapy. Complications of CNS cryptococcosis include cranial nerve deficits, vision and hearing loss, and cognitive impairment.

PREVENTION

No vaccine is available for cryptococcosis. Primary prophylaxis with fluconazole 100–200 mg daily is an approach in high-risk HIV patients (e.g., CD4+ T lymphocyte count <100/μL) and can be used in places where cryptococcal antigen testing is not readily available. Since ART raises the CD4+ T lymphocyte count, it constitutes an immunologic form of prophylaxis.

222 Candidiasis

Michail S. Lionakis, Shakti Singh, Ashraf S. Ibrahim, John E. Edwards, Jr.

The genus *Candida* encompasses >150 species, only a few of which cause disease in humans. With rare exceptions (although the exceptions are increasing in number), the human pathogens are *C. albicans*, *C. guilliermondii* (recently revised to *Meyerozyma guilliermondii*), *C. krusei* (recently revised to *Pichia kudriavzevii*), *C. parapsilosis*,

C. tropicalis, *C. lusitaniae* (recently revised to *Clavispora lusitaniae*), *C. dubliniensis*, *C. glabrata* (recently revised to *Nakaseomyces glabratus*), and the emerging, multidrug-resistant *C. auris*, which has been responsible for several outbreaks in health care facilities in recent years. Ubiquitous in nature, they inhabit the gastrointestinal tract (including the mouth and oropharynx), the female genital tract, and the skin in the majority of healthy persons. Although cases of candidiasis have been described since antiquity in debilitated patients, the advent of *Candida* species as common human pathogens dates to the introduction of modern therapeutic approaches that suppress normal host defense mechanisms. Of those advances, the most important are the use of antibacterial agents that alter the normal human microbiota and allow nonbacterial species to become more prevalent in the commensal flora, the use of indwelling intravenous catheters, and the use of cytotoxic, immunosuppressive treatments for malignant and autoimmune disorders. With the introduction of antifungal agents, the causes of *Candida* infections shifted from an almost complete dominance of *C. albicans* to the common involvement of *C. glabrata* and the other species listed above. The non-*albicans* species now account for approximately half of all cases of candidemia and hematogenously disseminated candidiasis. Recognition of this change is clinically important since the various species differ in susceptibility and are increasingly resistant to the newer antifungal agents.

Candida is a small, thin-walled, ovoid yeast that measures 4–6 μm in diameter and reproduces by budding. Organisms of this genus occur in three forms in tissue: blastospores, pseudohyphae, and hyphae. *Candida* grows readily on simple media; lysis centrifugation enhances its recovery from blood. Species are identified by biochemical testing (currently with automated devices) or on special agar (e.g., CHROMagar).

EPIDEMIOLOGY

Candida are present in humans as commensals, in animals, in foods, and on inanimate objects. In developed countries, where contemporary medical therapeutics are commonly used, *Candida* species are now among the most common nosocomial pathogens. In the United States, these species are among the four most common pathogens isolated from the blood of hospitalized patients. In fact, in a recent point-prevalence study in the United States, *Candida* species were the most common organisms infecting the bloodstream of hospitalized patients. In regions where advanced medical care is not readily available, mucocutaneous *Candida* infections, such as thrush, are more common than deep-organ infections, which rarely occur. However, the incidence of deep-organ candidiasis has been increasing steadily as advances in health care—such as therapy with broad-spectrum antibiotics, more aggressive treatment of cancer, and the use of immunosuppression for sustaining organ transplants—have been implemented. In aggregate, the global incidence of infections due to *Candida* species has risen over the past few decades.

C. auris is an emerging species of *Candida* that has spread rapidly in recent years to >50 countries and is a major public health concern. It was designated an urgent threat in the 2019 Centers for Disease Control and Prevention (CDC) Antimicrobial Resistance Threat Report, and it was included within the critical priority group in the 2022 World Health Organization (WHO) fungal priority pathogens list. This concern stems from its occurrence in health care facilities, its ability to adhere to and persist long term on inanimate objects (in hospitals) and the human skin despite decolonization efforts, its association with substantial mortality, its propensity for misidentification as other *Candida* species, the incomplete understanding of its environmental reservoirs, and its multidrug resistance to the current antifungal therapeutic armamentarium, with some *C. auris* strains being resistant to all antifungal drug classes currently available for treatment. *C. auris* (*auris* meaning *ear* in Latin) was first identified in 2009 from the ear drainage of a patient with an ear infection in Japan. However, subsequent retrospective analysis of *Candida* strain collections identified the earliest known *C. auris* strain to date back to 1996 in South Korea. Notably, whole genome sequencing analysis of *C. auris* strains from South Asia, East Asia, South America, South Africa, and Iran found that although strains within each geographic region are closely related to each other, they are distinct compared to strains from other geographic regions. These findings indicate that *C. auris* emerged independently in multiple geographic locations around the same time; the epidemiologic reasons for this emergence remain poorly understood but may relate to the increasing use of antifungal drugs and climate change.

The presence of a central venous catheter and/or other invasive medical devices and recent residence in nursing homes are major risk factors for *C. auris* colonization and infection. Screening of selected patients who are in a hospital or nursing home where *C. auris* has been cultured and are at risk for dissemination from a colonization site may help in implementing effective infection control measures. Hand hygiene with an alcohol-based hand sanitizer is recommended when hands are not visibly soiled, in which case washing with soap and water is preferred. Identifying the source of contamination, if possible, and using an Environmental Protection Agency (EPA)-registered hospital-grade disinfectant effective against *Clostridioides difficile* spores are desirable. If a patient develops an invasive or bloodstream infection, it is recommended that the health care facility informs the CDC, or a similar agency in other countries, and adheres to recommendations for infection control, including isolation of patients (contact or enhanced barrier precautions), use of proper personal protective coverings, enforcement of hospital environment hygiene, and communicating with other health care facilities if the patient is being transferred.

PATHOGENESIS

In the most severe form of *Candida* infection, the organisms disseminate hematogenously and form microabscesses and small macroabscesses in major organs. Although the exact mechanism is not known, *Candida* probably enters the bloodstream from mucosal surfaces after growing to large numbers as a consequence of bacterial suppression by antibacterial drugs and breaches in the integrity of the mucosal barrier; alternatively, in some instances, the organism may enter the bloodstream from the skin via central venous catheters. A change from the blastospore stage to the pseudohyphal and hyphal stages is generally considered integral to *Candida*'s penetration into tissue. However, *C. glabrata* and *C. auris* can cause life-threatening infection, even though they do not transform into pseudohyphae or hyphae. Adherence to both epithelial and endothelial cells is thought to be the first step in invasion and infection; several adhesins have been identified as well as a mucosal toxin, candidalysin. Biofilm formation also is considered important in pathogenesis. Numerous reviews of cases of hematogenously disseminated candidiasis have identified the predisposing factors or conditions associated with disease **(Table 222-1)**.

Several genes that are involved in the pathogenesis of other *Candida* species—such as those responsible for biofilm formation, proteinases, lipases, phospholipases, hydrolases, adhesins, secreted aspartyl proteases, and transporters involved in azole resistance—are also present in *C. auris*. Unlike other *Candida* species, several *C. auris* strains exhibit aggregate-forming properties in vivo, which may enable immune evasion. In addition, *C. auris* shows a unique tolerance to high temperature and saline concentrations and can grow optimally at up to 42°C and in a 10% saline concentration, making it possible to exist and persist in harsh environments. Furthermore, *C. auris* has significant affinity for

TABLE 222-1 Well-Recognized Factors and Conditions Predisposing to Hematogenously Disseminated Candidiasis

Antibacterial agents	Abdominal and thoracic surgery
Indwelling intravenous catheters	Cytotoxic chemotherapy

Indwelling urinary catheters	Respirators
Parenteral glucocorticoids	Myeloperoxidase deficiency
Severe burns	Neutropenia
CARD9 deficiency (central nervous system)	Low birth weight (neonates)
	Diabetes

abiotic surfaces such as plastic materials and medical devices, as well as human skin and nasal and ear cavities, which may account for its persistent colonization capabilities. The *C. auris*–specific adhesin surface colonization factor 1 (SCF1) was recently identified as a key fungal factor governing biofilm formation, colonization of skin and medical devices, and virulence during invasive infection.

Innate immunity is the most important defense mechanism against hematogenously disseminated candidiasis, and the neutrophil is the most potent component of this defense. Macrophages also play an important host defense role. On the other hand, interleukin (IL) 17–producing innate and adaptive lymphoid cells contribute significantly to defense against mucocutaneous candidiasis as evidenced by several monogenic disorders of IL-17 receptor signaling that manifest with *chronic mucocutaneous candidiasis* (CMC) (see "Clinical Manifestations," below). Although many immunocompetent individuals have antibodies to *Candida*, the role of these antibodies in defense against the organism is not clear. Multiple genetic polymorphisms in host immune-related genes that predispose to both disseminated and focal candidiasis have been identified and may contribute to patient susceptibility.

CLINICAL MANIFESTATIONS

Mucocutaneous Candidiasis *Thrush* is characterized by white, adherent, painless, discrete or confluent patches in the mouth, on the tongue, or in the esophagus, occasionally with fissuring at the corners of the mouth. This form of disease caused by *Candida* can also occur at points of contact with dentures (called "denture sore mouth"). Organisms are identifiable in gram-stained scrapings from lesions. The occurrence of thrush in a young, otherwise healthy-appearing person should prompt an investigation for underlying HIV infection. More commonly, thrush is seen as a nonspecific manifestation of severe debilitating illness. Vulvovaginal candidiasis is accompanied by pruritus, pain, and vaginal discharge, which is usually thin but may contain whitish "curds" in severe cases. In contrast to oral thrush, HIV is not considered a major risk factor for vulvovaginal candidiasis. Instead, many women who receive antibiotics, particularly β-lactams, may develop vulvovaginal candidiasis. A subset of patients with recurrent vulvovaginitis may have a deficiency in the surface expression of Dectin-1, encoded by *CLEC7A*, a major recognition factor for β-glucan on the surface of *Candida* and/or in the downstream adaptor molecule CARD9, which ultimately increases the propensity for recurrent mucocutaneous (including vaginal) infections.

Other *Candida* skin infections include *paronychia*, a painful swelling at the nail–skin interface; *onychomycosis*, a fungal nail infection rarely caused by this genus; *intertrigo*, an erythematous irritation with redness and pustules in the skin folds; *balanitis*, an erythematous-pustular infection of the glans penis; *erosio interdigitalis blastomycetica*, an infection between the digits of the hands or toes; *folliculitis*, with pustules developing most frequently in the area of the beard; *perianal candidiasis*, a pruritic, erythematous, pustular infection surrounding the anus; *mastitis*; and *diaper rash*, a common erythematous, pustular perineal infection in infants. *Generalized disseminated cutaneous candidiasis*, another form of infection that occurs primarily in infants, is characterized by widespread eruptions over the trunk, thorax, and extremities. The diagnostic macronodular lesions of hematogenously disseminated candidiasis **(Fig. 222-1)** indicate a high probability of dissemination to multiple organs as well as the skin. While the lesions are seen predominantly in immunocompromised patients treated with cytotoxic drugs, they may also develop in patients without neutropenia.

CMC is a heterogeneous infection of the hair, nails, skin, and mucous membranes that persists despite intermittent antifungal therapy. The onset of disease usually comes in infancy or within the first two decades of life, but in rare cases, it occurs in later life. The condition may be mild and limited to a specific area of the skin or nails, or it may take a severely disfiguring form (*Candida* granuloma) characterized by exophytic outgrowths on the skin. CMC is usually associated with specific immunologic dysfunction; most frequently reported is a failure of lymphocytes to secrete or respond to type-17 cytokines following stimulation by *Candida* antigens in vitro. A subset of the affected patients has mutations in the IL-17 receptors IL-17RA or IL-17RC, its adaptor molecule ACT1 (TRAF3IP2), or, more often, in STAT1.

FIGURE 222-1 Macronodular skin lesions associated with hematogenously disseminated candidiasis. *Candida* organisms are usually but not always visible on histopathologic examination. The fungi grow when a portion of the biopsied specimen is cultured. Therefore, for optimal identification, both histopathology and culture should be performed. *(Image courtesy of Dr. Noah Craft and the Victor Newcomer collection at UCLA, archived by Logical Images, Inc.; with permission.)*

Approximately half of patients with CMC have associated endocrine abnormalities either in the setting of gain-of-function mutations in *STAT1* or in the context of *a*utoimmune *p*oly*e*ndocrinopathy–*c*andidiasis–*e*ctodermal *d*ystrophy (APECED) syndrome. This syndrome is due to mutations in the autoimmune regulator (*AIRE*) gene and is most prevalent among Finns, Iranian Jews, and Sardinians. Conditions that usually follow the onset of the disease include hypoparathyroidism, adrenal insufficiency, autoimmune thyroiditis, autoimmune hepatitis, autoimmune pneumonitis, alopecia, pernicious anemia, intestinal malabsorption, and primary hypogonadism. In addition, dental enamel dysplasia, vitiligo, nail dystrophy, asplenia, and calcification of the brain and tympanic membranes may occur. Patients with CMC rarely develop hematogenously disseminated candidiasis, reflecting their intact neutrophil function.

Deeply Invasive Candidiasis Deeply invasive *Candida* infections may or may not be due to hematogenous seeding. Deep esophageal infection may result from penetration by organisms from superficial esophageal erosions; joint or deep-wound infection from contiguous spread of organisms from the skin; kidney infection from catheter-initiated ascending spread of organisms through the urinary tract; infection of intraabdominal organs and the peritoneum from perforation of the gastrointestinal tract; and gallbladder infection from retrograde migration of organisms from the gastrointestinal tract into the biliary drainage system.

However, more commonly, deeply invasive candidiasis results from hematogenous seeding of various organs as a complication of candidemia. Once the organism gains access to the intravascular compartment (either from the gastrointestinal tract or, less often, from the skin through the site of an indwelling intravascular catheter), it may spread hematogenously to a variety of deep organs. The brain, chorioretina **(Fig. 222-2)**, heart, and kidneys are most commonly infected and the liver and spleen are less commonly affected in nonneutropenic hosts (but most often involved in neutropenic patients). In fact, nearly any organ can become involved, including the endocrine glands, pancreas, heart valves (native or prosthetic), skeletal muscle, joints (native or prosthetic), bones, and meninges. *Candida* organisms can also spread hematogenously to the skin and cause classic macronodular lesions (Fig. 222-1). Frequently, painful muscular involvement is evident beneath the area of affected skin. Chorioretinal involvement and skin involvement are highly significant since both findings are associated with a very high probability of abscess formation in multiple

FIGURE 222-2 Hematogenous *Candida* endophthalmitis. A classic off-white lesion projecting from the chorioretina into the vitreous causes the surrounding haze. The lesion is composed primarily of inflammatory cells rather than organisms. Lesions of this type may progress to cause extensive vitreal inflammation and eventual loss of the eye. Partial vitrectomy, combined with IV and possibly intravitreal antifungal therapy, may be helpful in controlling the lesions. *(Image courtesy of Dr. Gary Holland; with permission.)*

deep organs as a result of generalized hematogenous seeding. Ocular involvement (Fig. 222-2) may require specific treatment (e.g., partial vitrectomy or intraocular injection of antifungal agents) to prevent permanent blindness. An ocular examination is indicated for patients with candidemia, whether or not they have ocular manifestations. *C. auris* invasive infections are similar to those of other *Candida* species and are most frequently associated with recent surgical procedures, immunosuppression, invasive devices such as catheters or various support or drainage tubes, and extended hospital stays. In the majority of invasive infections, *C. auris* has been isolated from the blood, but invasion of the kidney or spleen, and its recovery from cerebrospinal, bile, peritoneal, and pleural fluids demonstrate its invasiveness and dissemination potential. *C. auris*–associated candidemia can be life-threatening, with a crude mortality rate of 30–60%.

DIAGNOSIS

The diagnosis of *Candida* infection is established by visualization of pseudohyphae or hyphae on wet mount (saline and 10% KOH), tissue Gram stain, periodic acid–Schiff stain, or methenamine silver stain in the presence of inflammation. Absence of organisms on hematoxylin-eosin staining does not reliably exclude *Candida* infection. The most challenging aspect of diagnosis is determining which patients with *Candida* isolates have hematogenously disseminated candidiasis. For instance, recovery of *Candida* from sputum, urine, or peritoneal catheters may indicate mere colonization rather than deep-seated infection, and *Candida* isolation from the blood of patients with indwelling intravascular catheters may reflect inconsequential seeding of the blood from or growth of the organisms on the catheter. Despite extensive research into both antigen and antibody detection systems, there is currently no widely available and validated diagnostic test to distinguish patients with inconsequential seeding of the blood from those whose positive blood cultures represent hematogenous dissemination to multiple organs. Many studies have examined the utility of the β-glucan test; at present, its greatest utility is its negative predictive value (~90%). Meanwhile, the presence of ocular or macronodular skin lesions is highly suggestive of widespread infection of multiple deep organs. Despite extensive diagnostic tests for hematogenous dissemination, such as polymerase chain reaction and T2 technology, no test is fully validated or widely available at present. Matrix-assisted laser desorption–ionization–time-of-flight mass spectrometry (MALDI-TOF MS) is now being used extensively for detection and speciation and is useful for the correct diagnosis of *C. auris*.

C. auris can be misdiagnosed in the microbiology laboratory, often leading to inappropriate treatment and delay in the implementation of appropriate infection control measures. Preliminary testing by culturing the fungus and examination of colony morphology may help in the initial identification, but this must be confirmed with more advanced diagnostic methods. For example, features such as budding yeast morphology, absence of hyphal growth or germ tubes, and growth at 40–42°C (unlike other *Candida* species) on CHROMagar that may appear white, pink, red, or purple should raise suspicion for *C. auris* **(Fig. 222-3)**.

Several advanced molecular techniques accurately identify *C. auris* strains and therefore are being used for the follow-up testing and confirmation of the specimens that failed to be identified by traditional methods. MALDI-TOF equipment with upgraded libraries, such as Bruker Biotyper MALDI-TOF (CA System library version claim 4 or research use only [RUO] libraries versions 2014 [5627] and more recent), and using the bioMérieux VITEK MALDI-TOF MS (IVD v3.2 or RUO libraries with Saramis Ver 4.14 database and Saccharomycetaceae update), are the most common methods of *C. auris* identification. Other supplemental MALDI-TOF databases, such as MicrobeNet, which include additional *C. auris* strains from the four phylogenetic clades (i.e., South Asian, East Asian, South American, and South African) also can be used for the identification of *C. auris* strains. Sequencing of the D1–D2 region of the 28s rDNA or the internal transcribed region (ITS) of rDNA can also correctly identify *C. auris*. Recently, an automated, qualitative nucleic acid multiplex in vitro diagnostic test by GenMark called ePlex Blood Culture Identification Fungal Pathogen (BCID-FP) Panel was approved by the U.S. Food and Drug Administration for *C. auris* testing. Also, several polymerase chain reaction–based detection methods have been reported to identify

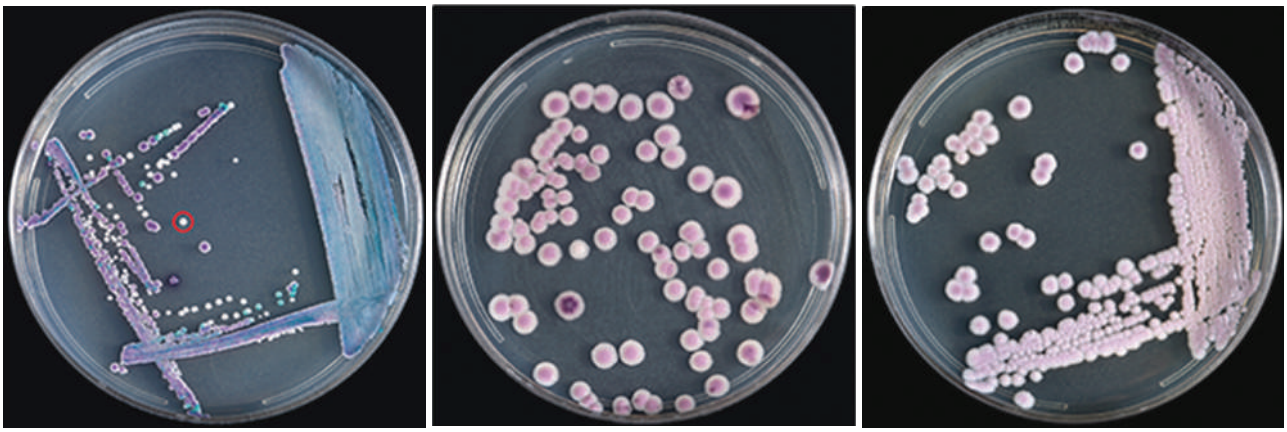

FIGURE 222-3 *C. auris* colony morphology and color on CHROMagar plates. *A.* *Candida* mixed culture: culture of *C. glabrata* (purple), *C. tropicalis* (navy blue), and *C. auris* (white, circled in red). ***B.*** *C. auris* showing multiple colony morphologies. ***C.*** *C. auris* after Salt SAB Dulcitol Broth enrichment. *(From CDC: Identification of Candida auris. C. auris in various specimens. Table 222-2 outlines the typical decision-making steps in the diagnosis of *C. auris* by using different methods. A suspicious *C. auris* specimen is usually sent to a regional reference laboratory for further testing and confirmation of *C. auris*.

TREATMENT

Candida Infections

MUCOCUTANEOUS *CANDIDA* INFECTION

The treatment of mucocutaneous candidiasis is summarized in Table 222-3.

CANDIDEMIA AND SUSPECTED HEMATOGENOUSLY DISSEMINATED CANDIDIASIS

All patients with candidemia are treated with a systemic antifungal agent. A certain percentage of patients, including many of those who have candidemia associated with an indwelling intravascular catheter, probably have "benign" candidemia rather than deep-organ seeding. However, because there is no reliable way to distinguish benign candidemia from deep-organ infection, and because antifungal drugs less toxic than amphotericin B are available, antifungal treatment for candidemia—with or without clinical evidence of deep-organ involvement—has become the standard of practice. In addition, if an indwelling intravascular catheter is

TABLE 222-3 Treatment of Mucocutaneous Candidal Infections

DISEASE	PREFERRED TREATMENT	ALTERNATIVES
Cutaneous	Topical azole	Topical nystatin
Vulvovaginal	Oral fluconazole (150 mg) or ibrexafungerp (300 mg twice daily for 1 day) or azole cream or suppository	Nystatin suppository
Oral (thrush)	Fluconazole tablets (100–200 mg/d)	Clotrimazole trashes, nystatin
Esophageal	Fluconazole tablets (100–200 mg/d) or itraconazole solution (200 mg/d)	Caspofungin, micafungin, or amphotericin B

TABLE 222-4 Agents for the Treatment of Disseminated Candidiasis

AGENT	ROUTE OF ADMINISTRATION	DOSE[a]	COMMENT
Amphotericin B deoxycholate	IV only	0.5–1.0 mg/kg daily	Mostly replaced by lipid formulations
Amphotericin B lipid formulations			Not approved as primary therapy by the U.S. Food and Drug Administration, but used commonly because they are less toxic than amphotericin B deoxycholate
Liposomal (AmBiSome, Abelcet)	IV only	3.0–5.0 mg/kg daily	
Lipid complex (ABLC)	IV only	3.0–5.0 mg/kg daily	
Colloidal dispersion (ABCD)	IV only	3.0–5.0 mg/kg daily	Associated with frequent infusion reactions
Azoles[b]			
Posaconazole	IV and oral	300 mg/d (IV) 200 mg tid (oral)	Approved for prophylaxis
Fluconazole	IV and oral	400 mg/d	Most commonly used
Voriconazole	IV and oral	400 mg/d	Multiple drug interactions, visual hallucinations, fluorosis, phototoxicity Approved for candidemia in nonneutropenic patients
Echinocandins			Broad spectrum against *Candida* species; approved for disseminated candidiasis; less toxic than amphotericin B formulations
Caspofungin	IV only	50 mg/d	
Anidulafungin	IV only	100 mg/d	
Micafungin	IV only	100 mg/d	
Rezafungin	IV only	400 mg loading dose, 200 mg once weekly thereafter	

[a]For loading doses and adjustments in renal failure, see Pappas PG et al: Clinical practice guidelines for the management of candidiasis: 2016 update by the Infectious Diseases Society of America. Clin Infect Dis 62:e1, 2016. The recommended duration of therapy is 2 weeks beyond the last positive blood culture and the resolution of signs and symptoms of infection. [b]Although ketoconazole is approved for the treatment of disseminated candidiasis, it has been replaced by the newer agents listed in this table. Posaconazole has been approved for prophylaxis in neutropenic patients and for oropharyngeal candidiasis.

present, it is best to remove or replace the device whenever feasible. Moreover, an infectious disease consultation is recommended as it has been associated with improved patient outcomes.

The drugs used for the treatment of candidemia and suspected disseminated candidiasis are listed in **Table 222-4**. Various lipid formulations of amphotericin B, four echinocandins, the azoles fluconazole and voriconazole, and in some instances, the newer triazole posaconazole are used; no agent within a given class has been clearly identified as superior to the others. Most institutions choose an agent from each class on the basis of their own specific microbial epidemiology, strategies to minimize toxicities, and cost considerations. An echinocandin is the first choice of treatment. The U.S. Food and Drug Administration (FDA) recently approved the new-generation echinocandin rezafungin for the treatment of candidemia and invasive candidiasis in adult patients; rezafungin has a prolonged half-life, which allows for once-weekly 200-mg dosing following a 400-mg front-loading dose. Echinocandin treatment continues until sensitivities or speciation is determined. In stable patients, many centers then switch to fluconazole if a sensitive strain is identified and there is no evidence of hematogenous dissemination. For hemodynamically unstable or neutropenic patients, initial treatment with echinocandins is warranted, and once the clinical response has been assessed and the pathogen specifically identified, the regimen can be altered according to the sensitivities. At present, the vast majority of *C. albicans* isolates are sensitive to fluconazole. Isolates of *C. glabrata* and *C. krusei* are less sensitive to fluconazole and more sensitive to polyenes and echinocandins. *C. parapsilosis* is less sensitive to echinocandins in vitro; however, this lesser sensitivity is considered clinically insignificant. Posaconazole has been approved for prophylaxis, including against *Candida*, in neutropenic patients. Itraconazole is rarely used for *Candida* nowadays, and isavuconazole is not recommended for this indication.

Antifungal drug resistance is one of the hallmarks of *C. auris* infections. Some *C. auris* strains have multidrug resistance with elevated minimal inhibitory concentrations (MICs) to all three major antifungal classes—azoles, echinocandins, and polyenes—resulting in limited treatment options. A CDC study reported antifungal resistance in *C. auris* strains obtained from 54 patients in India, Pakistan, South Africa, and Venezuela: 93% were resistant to fluconazole, 35% to amphotericin B, and 7% to echinocandins; 41% of the tested strains were resistant to two antifungal classes, and, alarmingly, 4% of the tested strains were resistant to all three classes of antifungal drugs. A 2023 CDC report indicated that rates of *C. auris* echinocandin resistance tripled in 2021 compared to the prior 2 years. Almost all *C. auris* strains that have been identified have elevated MICs for fluconazole with variable susceptibilities to other triazoles **(Table 222-5)**, associated with mutations in *ERG11*-encoded lanosterol demethylase and/or overexpression of drug transporters/efflux pumps.

Due to the high rates of azole resistance among *C. auris* strains, the use of echinocandins is recommended as first-line therapy for *C. auris* infection. By contrast, the CDC discourages the use of antifungal drugs for the treatment of colonization of *C. auris* in the absence of invasive or bloodstream infection. A history of patient travel or residence in a health care or nursing facility with a known

TABLE 222-5 Typical MICs of Available Antifungal Drugs for *C. auris*

DRUG	TENTATIVE RESISTANCE BREAKPOINTS[a]	MIC RANGE, μg/mL		
		MIC	MIC_{50}	MIC_{90}
Amphotericin B	≥2	0.06–8	0.5–1	2–4
Fluconazole	≥32	0.12–≥64	≥64	≥64
Itraconazole	N/A	0.032–2	0.06–0.5	0.25–1
Voriconazole	N/A	0.032–16	0.5–2	2–8

outbreak of *C. auris* infection, as well as drug susceptibility data of identified strains, act as a guide for the effective choice of treatment of invasive and bloodstream infections. *C. auris* is known to develop antibiotic resistance during treatment. Therefore, the emergence of antifungal resistance should be closely monitored with follow-up cultures and repeat susceptibility testing. Antibiotic stewardship should be implemented to ameliorate the risk of development of drug resistance. Patients may remain colonized with *C. auris* during or after the successful treatment of invasive *C. auris* infection. Therefore, infection control measures should be implemented throughout patient care. Table 222-6 outlines CDC-recommended echinocandin doses for the initial antifungal treatment for *C. auris* infections.

In cases of echinocandin resistance, liposomal amphotericin B (5 mg/kg per day) can be considered. For neonates and infants (<2 months old), amphotericin B deoxycholate (1 mg/kg per day) treatment can be initiated. If this fails, liposomal amphotericin B (5 mg/kg per day) can be given. In very severe cases, if all treatment options fail, echinocandins per CDC recommendations can be given (Table 222-6). Other considerations for *C. auris* infection management can be referenced from the 2016 Infectious Diseases Society of America (IDSA) Clinical Practice Guideline for the Management of Candidiasis.

Some generalizations exist regarding the management of specific *Candida* infections. Recovery of *Candida* from sputum is almost never indicative of underlying pulmonary candidiasis and does not by itself warrant antifungal treatment. Similarly, *Candida* in the urine of a patient with an indwelling bladder catheter may represent colonization only, rather than bladder or kidney infection. However, the threshold for systemic treatment is lower in general in severely ill patients in this category since it is impossible to distinguish colonization from lower or upper urinary tract infection. If the isolate is *C. albicans*, most clinicians use oral fluconazole rather than a bladder washout with amphotericin B, which was more commonly used in the past. Although echinocandins are poorly excreted into the urine, they may be an option, especially for non-*albicans* isolates. The doses and duration are the same as for disseminated candidiasis. The significance of the recovery of *Candida* from abdominal drains in postoperative patients is unclear, but again, the threshold for treatment is generally low because most of the affected patients have been subjected to risk factors predisposing them to disseminated candidiasis. In addition, there has been a considerable increase in the recognition and diagnosis of intraabdominal candidiasis.

Removal of the infected valve and long-term antifungal administration constitute appropriate treatment for *Candida* endocarditis. Although definitive studies are not available, patients usually are treated for weeks with a systemic antifungal agent (Table 222-4) and then given chronic suppressive therapy for months or years (sometimes indefinitely) with an oral azole (usually fluconazole at 400–800 mg/d).

Hematogenous *Candida* endophthalmitis is a special problem requiring ophthalmologic consultation. When lesions are expanding or are threatening the macula, an IV polyene combined with flucytosine (25 mg/kg four times daily) has been the regimen of choice, although comparative studies with other regimens have not yet been reported. As more data on the newer triazoles (e.g., voriconazole) and the echinocandins become available, new strategies involving these agents are developing, although it is important to note that echinocandins exhibit low penetration in ocular tissue. Of paramount importance is the decision to perform a partial vitrectomy. This procedure debulks the infection and can preserve sight, which may otherwise be lost due to vitreal scarring. All patients with candidemia should undergo ophthalmologic examination because of the relatively high frequency of this ocular complication (up to 15–20% in some case series). This examination can detect a developing eye lesion early in its course; in addition, identification of a lesion signifies a probability of ~90% of deep-organ abscesses and may prompt prolongation of therapy for candidemia beyond the recommended 2 weeks after the last positive blood culture. Although the basis for the consensus is a very small data set, the recommended treatment for *Candida* meningitis is a polyene (Table 222-4) plus flucytosine (25 mg/kg four times daily). Development of *Candida* meningoencephalitis in an otherwise immunocompetent individual should raise suspicion for deficiency in the C-type lectin receptor adaptor molecule CARD9 and should prompt genetic testing to rule out this monogenic disorder. Successful treatment of *Candida*-infected prosthetic material (e.g., an artificial joint) nearly always requires removal of the infected material followed by long-term administration of an antifungal agent selected on the basis of the isolate's sensitivity and the logistics of administration.

PROPHYLAXIS

The use of antifungal agents to prevent *Candida* infections has been controversial, but some general principles have emerged. Most centers administer prophylactic fluconazole (400 mg/d) to recipients of allogeneic hematopoietic stem cell transplantation. High-risk liver transplant recipients are also given fluconazole prophylaxis in most centers. The use of prophylaxis for neutropenic patients has varied considerably from center to center; many centers that elect to give prophylaxis to this population use either fluconazole (200–400 mg/d) or a lipid formulation of amphotericin B (AmBisome, 1–2 mg/d). Caspofungin (50 mg/d) also has been used. Posaconazole (200 mg three times daily) has been approved by the FDA for prophylaxis in neutropenic patients; it is gaining in popularity and may replace fluconazole in settings when mold activity is desired.

Prophylaxis is sometimes given to surgical patients at very high risk for candidiasis. The widespread use of prophylaxis for nearly all patients in general surgical or medical intensive care units is not—and should not be—a common practice for three reasons: (1) the incidence of disseminated candidiasis is relatively low, (2) the cost–benefit ratio is suboptimal, and (3) increased resistance with widespread prophylaxis is a valid concern.

Prophylaxis for oropharyngeal or esophageal candidiasis in HIV-infected patients is not recommended unless there are frequent recurrences.

223 Aspergillosis

David W. Denning

Aspergillosis is the collective term used to describe all disease entities caused by any one of ~50 pathogenic and allergenic species of *Aspergillus*. Only those species that grow at 37°C can cause invasive infection, although some species without this ability can cause allergic syndromes. Each common pathogenic species is actually a complex of many species (many of them cryptic) but is referred to as a single species here for simplicity. *A. fumigatus* is responsible for most cases of invasive aspergillosis, >95% of cases of chronic aspergillosis, and most allergic syndromes. *A. flavus* is more prevalent in some hospitals and causes a higher proportion of cases of sinus infections, cutaneous infections, and keratitis than *A. fumigatus*. *A. niger* can cause invasive infection but more commonly colonizes the respiratory tract and causes external otitis. *A. terreus* causes only invasive disease, usually with a poor prognosis. *A. nidulans* occasionally causes invasive infection, primarily in patients with chronic granulomatous disease (CGD).

EPIDEMIOLOGY AND ECOLOGY

Aspergillus has a worldwide distribution, most commonly growing in decomposing plant materials (i.e., compost) and in bedding. This hyaline (nonpigmented), septate, branching mold produces vast numbers of conidia (spores) on stalks above the surface of mycelial growth. *Aspergilli* are found in indoor and outdoor air, on surfaces, and in water from surface reservoirs. Daily exposures vary from a few to many millions of conidia; high numbers of conidia are encountered in hay barns and other very dusty environments. The required size of the infecting inoculum is uncertain; however, only intense exposures (e.g., during construction work, handling of moldy bark or hay, or composting) are demonstrated to cause disease—acute community-acquired pulmonary aspergillosis—in healthy immunocompetent individuals or exacerbations of COPD. Allergic syndromes are exacerbated by continuous antigenic exposure arising from sinus or airway colonization or from nail infection. High-efficiency particulate air (HEPA) filtration is often protective against infection; thus, HEPA filters should be installed and monitored for efficiency in operating rooms, burn units and in areas of the hospital that house high-risk patients.

The incubation period of invasive aspergillosis after exposure is highly variable, extending in documented cases from 2 to 90 days. Thus, community acquisition of an infecting strain frequently manifests as invasive infection during hospitalization, although nosocomial acquisition is also common. Outbreaks usually are directly related to a contaminated air source or construction in the hospital.

Global aspergillosis incidence and prevalence have been estimated (Table 223-1). The frequency of different manifestations of aspergillosis varies considerably with geographic location; most notably, chronic granulomatous sinusitis is rare outside the Middle East and India. Fungal (mycotic) keratitis is particularly common in Southeast Asia but occurs globally. Chronic pulmonary aspergillosis follows pulmonary tuberculosis in ~6–13% of treated cases and also mimics pulmonary tuberculosis as smear-negative or "clinically diagnosed" tuberculosis. *Aspergillus* onychomycosis, usually of the toenail, has been reported in as low as <1% and as high as 35% of cases of onychomycosis and is more common in diabetes.

RISK FACTORS AND PATHOGENESIS

The primary risk factors for invasive aspergillosis are profound neutropenia, glucocorticoid use, and underlying respiratory disease; risk increases with longer duration of these conditions. Higher doses of glucocorticoids increase the risk of both acquisition of invasive aspergillosis and death from the infection. Neutrophil and/or phagocyte dysfunction also is an important risk factor, as evidenced by aspergillosis in CGD, advanced HIV infection, and relapsed leukemia. Invasive aspergillosis is increasingly recognized (if actively sought) in medical intensive care units (2–5%), those with severe influenza (8–25%) and severe COVID-19 (~10%), and patients admitted to hospital with chronic obstructive pulmonary disease (COPD; 1.3–3.9%). Temporary abrogation of protective responses from glucocorticoid use or compensatory anti-inflammatory response syndrome is a significant risk factor. Many patients have some evidence of prior pulmonary disease—typically, a history of pneumonia or COPD. Many new immunomodulating agents, such as infliximab and ibrutinib, increase the risk of invasive aspergillosis, as does severe liver disease.

Patients with chronic pulmonary aspergillosis have a wide spectrum of underlying pulmonary disease, including current and prior tuberculosis, sarcoidosis, prior pneumothorax, or COPD. These patients are apparently immunocompetent, but natural killer and/or interleukin 12 or gamma interferon production defects are common. Their inflammatory immune (T_H1-like) response is suboptimal, and persistent inflammation is typical. Glucocorticoids accelerate disease progression.

Allergic bronchopulmonary aspergillosis (ABPA) usually complicates asthma and cystic fibrosis. Many genetic associations indicate a strong basis for the development of a T_H2-like and "allergic" response to *A. fumigatus*. Remarkably, high-dose glucocorticoid treatment for exacerbations of ABPA almost never leads to invasive aspergillosis. Fungal, and especially *Aspergillus*, sensitization is especially common in those with poorly controlled asthma. Environmental exposure and *Aspergillus* sensitization drive some COPD exacerbations. Most patients with *Aspergillus* bronchitis have bronchiectasis, with or without cystic fibrosis, including heterozygous *CFTR* mutations.

Different genetic traits are associated with invasive, chronic, and allergic aspergillosis; the majority of people probably are not at risk for aspergillosis. Multiple gene variants appear to be necessary for susceptibility to each form of aspergillosis.

TABLE 223-1 Disease Frequency and Diagnostic Sensitivity for Different Manifestations of Aspergillosis

PARAMETER	TYPE OF DISEASE

[a]Denning DW: Global incidence and mortality of severe fungal disease. Lancet Infect Dis 24:e428, 2024. [b]Allergic fungal disease can develop at any age, usually in adulthood; the annual frequency with which it occurs is not known. [c]Allergic bronchopulmonary aspergillosis and severe asthma with fungal sensitization. [d]Key for sensitivity: 1 check = limited (as the text indicates, 10–30% for culture); 2 checks = higher; 3 checks = >80%; and 4 checks = ~95%. [e]Multiple specimens, fungal media, and high-volume fungal culture increase sensitivity. [f]High cross-reactivity between *A. fumigatus* and other *Aspergillus* spp. [g]IgG is a useful assay in subacute invasive and nonneutropenic patients but may not be positive on initial testing.

Abbreviation: PCR, polymerase chain reaction.

CLINICAL FEATURES AND APPROACH TO THE PATIENT

(Table 223-2)

Invasive Pulmonary Aspergillosis Both the frequency of invasive disease and the pace of its progression increase with greater

TABLE 223-2 Major Manifestations of Aspergillosis

ORGAN	TYPE OF DISEASE			
	INVASIVE (ACUTE AND SUBACUTE)	CHRONIC	SAPROPHYTIC	ALLERGIC
Lung	Angioinvasive (in neutropenia), nonangioinvasive, granulomatous	Chronic cavitary, chronic fibrosing, bronchitis, *Aspergillus* nodule	Aspergilloma (single), airway colonization	Allergic bronchopulmonary, severe asthma with fungal sensitization, hypersensitivity pneumonitis
Sinus	Acute invasive	Chronic invasive, chronic granulomatous	Maxillary fungal ball	Allergic fungal sinusitis, eosinophilic fungal rhinosinusitis
Brain	Abscess, hemorrhagic infarction, meningitis	Granulomatous, meningitis	None	None
Skin	Acute disseminated, locally invasive (trauma, burns, IV access)	External otitis, onychomycosis	None	None
Heart	Endocarditis (native or prosthetic), pericarditis	None	None	None
Eye	Keratitis, endophthalmitis	None	None	None described

degrees of immunocompromise. Invasive aspergillosis is arbitrarily classified as acute and subacute, with courses of ≤1 month and 1–3 months, respectively. More than 80% of cases of invasive aspergillosis involve the lungs, and most are community acquired. The most common clinical features are no symptoms at all, fever, cough (sometimes productive), nondescript chest discomfort, trivial hemoptysis, and shortness of breath. Although the fever often responds to glucocorticoids, the disease progresses. In ventilated patients, screening for *Aspergillus* antigen on tracheobronchial lavage fluid is necessary for diagnosis as radiology is not distinctive. The keys to early diagnosis in at-risk patients are a high index of suspicion, screening for circulating antigen (in leukemia), and urgent computed tomography (CT) of the thorax. Invasive aspergillosis is one of the most common diagnostic errors revealed at autopsy.

Invasive Sinusitis The sinuses are involved in 5–10% of cases of invasive aspergillosis, especially affecting patients with leukemia and recipients of hematopoietic stem cell transplants. In addition to fever, the most common features are nasal or facial discomfort, blocked nose, and nasal discharge (sometimes bloody). Endoscopic examination of the nose reveals pale, dusky or necrotic-looking tissue in any location. CT or magnetic resonance imaging (MRI) of the sinuses is essential but does not distinguish invasive *Aspergillus* sinusitis from preexisting allergic or bacterial sinusitis early in the disease process.

Tracheobronchitis Occasionally, only the airways are infected by *Aspergillus*. The resulting manifestations seen on bronchoscopy range from acute or chronic bronchitis to ulcerative or pseudomembranous tracheobronchitis. These entities are particularly common among lung transplant recipients and patients on artificial ventilation. Obstruction with mucous plugs may occur and is called obstructing bronchial aspergillosis in immunocompromised patients and mucous impaction in other patients, such as those with ABPA.

Aspergillus Bronchitis Recurrent chest infections that only partially improve with antibiotic treatment and are associated with significant breathlessness or coughing up of thick sputum plugs are typical features of *Aspergillus* bronchitis. Patients are not significantly immunocompromised and usually have bronchiectasis or cystic fibrosis. Occasional patients present with respiratory failure because of airway obstruction with mucus. Concurrent bacterial bronchitis is common. The diagnosis rests on recurrent detection of *Aspergillus* in the airway by microscopy, culture, or polymerase chain reaction (PCR). *Aspergillus* IgG is usually detectable.

Disseminated Aspergillosis In the most severely immunocompromised patients, *Aspergillus* disseminates from the lungs to multiple organs—most often to the brain but also to the skin, thyroid, bone, kidney, liver, gastrointestinal tract, eye (endophthalmitis), and heart valve. Aside from cutaneous lesions, the most common features are gradual clinical deterioration over 1–3 days, with low-grade fever and features of mild sepsis, and nonspecific abnormalities in laboratory tests. In most cases, at least one localization becomes apparent before death. Blood cultures are almost always negative.

Cerebral Aspergillosis Hematogenous dissemination to the brain is a devastating complication of invasive aspergillosis. Single or multiple lesions may develop. In acute disease, hemorrhagic infarction is most typical, and cerebral abscess is common. Rarer manifestations include meningitis, mycotic aneurysm, and cerebral granuloma (mimicking a brain tumor). Local spread from cranial sinuses also occurs. Postoperative infection develops rarely and is exacerbated by glucocorticoids, which are often given after neurosurgery. The presentation can be either acute or subacute, with mood changes, focal signs, seizures, and decline in mental status. MRI is the most useful immediate investigation; unenhanced CT of the brain is usually nonspecific, and contrast is often contraindicated because of poor renal function. Cerebral aspergillosis is disproportionately common in those on ibrutinib.

Endocarditis Most cases of *Aspergillus* endocarditis are prosthetic-valve infections resulting from contamination during surgery. Native-valve disease is reported, especially as a feature of disseminated infection and in persons using illicit IV drugs. Culture-negative endocarditis with large vegetations is the most common presentation; embolectomy occasionally reveals the diagnosis.

Cutaneous Aspergillosis Dissemination of *Aspergillus* occasionally results in cutaneous features, usually an erythematous or purplish nontender area that progresses to a necrotic eschar. Direct invasion of the skin occurs in neutropenic patients at the site of IV catheter insertion and in burn patients. Surgical, burn, and trauma wounds may become infected with *Aspergillus* (especially *A. flavus*).

Chronic Pulmonary Aspergillosis The hallmark of chronic cavitary pulmonary aspergillosis **(Fig. 223-1)** is one or more pulmonary cavities expanding over a period of months or years in association with pulmonary symptoms and systemic manifestations such as fatigue and weight loss. Often mistaken initially for tuberculosis, >90% of chronic cavitary pulmonary aspergillosis cases occur in patients with prior pulmonary disease (e.g., current or past tuberculosis or nontuberculous mycobacterial infection, sarcoidosis, rheumatoid lung disease, pneumothorax, bullae) or lung surgery. The onset is insidious, and systemic features (weight loss, fatigue) may be more prominent than pulmonary symptoms. On CT scan, an irregular internal cavity surface and thickened cavity walls are typical and indicative of disease activity. Irregular material, fluid level, and a well-formed fungal ball are seen in some cavities. Multiple cavities are more common than a single cavity, and most cavities are in the upper lobes. Pleural thickening and pericavitary infiltrates are typical and most obvious if a positron emission tomography scan has been done as part of the workup. Chronic cavitary pulmonary aspergillosis is usually caused by *A. fumigatus*, but *A. niger* has been implicated, particularly in diabetic patients, as have other species. IgG antibodies to *Aspergillus* are detectable in ~90% of patients with chronic cavitary pulmonary aspergillosis. Some patients have concurrent infections with mycobacteria and/or other bacterial pathogens. The most significant complication is life-threatening hemoptysis, which may be the presenting manifestation. If untreated, chronic cavitary pulmonary aspergillosis typically

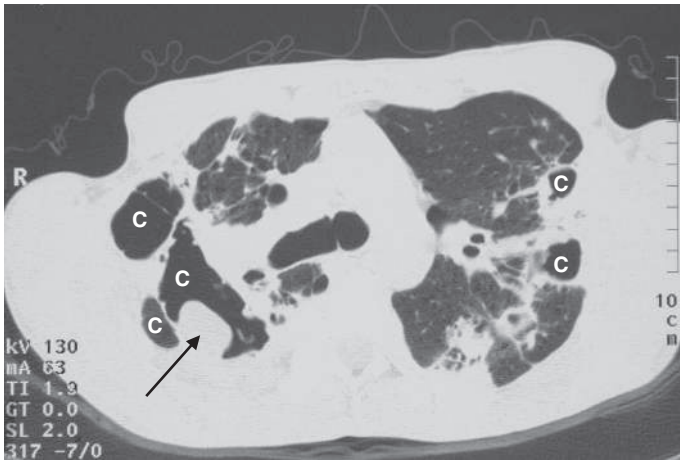

FIGURE 223-1 Computed tomography (CT) scan image of the chest in a patient with long-standing bilateral chronic cavitary pulmonary aspergillosis. This patient had a history of several bilateral pneumothoraces and had required bilateral pleurodesis in 1990. CT then demonstrated multiple bullae, and sputum cultures grew *A. fumigatus*. The patient had initially weakly and later strongly positive serum IgG *Aspergillus* antibody tests. This scan (2003) shows a mixture of thick- and thin-walled cavities in both lungs (each marked with *C*), with a probable fungal ball (*black arrow*) protruding into the large cavity on the patient's right side (*R*). There is also considerable pleural thickening bilaterally.

progresses (sometimes relatively rapidly) to unilateral or upper-lobe fibrosis. This end-stage entity is termed *chronic fibrosing pulmonary aspergillosis* (destroyed lung).

Aspergilloma Aspergilloma (fungal ball) is a late manifestation of chronic cavitary pulmonary aspergillosis, but some patients are asymptomatic. The inside of a pulmonary cavity allows fungal growth that peels off, forming the layers of the fungal ball. Signs and symptoms associated with single (simple) aspergillomas are minor, including cough (sometimes productive), hemoptysis, wheezing, and mild fatigue. More significant signs and symptoms are associated with chronic cavitary pulmonary aspergillosis and should be treated as such. About 10% of fungal balls resolve spontaneously (by being coughed up), but the cavity may still be infected and the patient symptomatic.

***Aspergillus* Nodule** A recently recognized form of chronic pulmonary aspergillosis is the *Aspergillus* nodule, which may resemble early lung carcinoma and may cavitate. Nodules may be single or multiple and 5–50 mm in diameter. Larger mass lesions are rarely seen. Nodules are usually avid on positron emission tomography. IgG antibodies to *Aspergillus* are detectable in ~65% of patients with an *Aspergillus* nodule.

Chronic *Aspergillus* Sinusitis Three entities are subsumed under this broad designation: fungal ball of the sinus, chronic invasive sinusitis, and chronic granulomatous sinusitis. Fungal ball of the sinus is limited to the maxillary sinus (except in rare cases involving the sphenoid sinus) in which the sinus cavity is filled with a fungal ball. Maxillary disease is associated with prior upper-jaw root canal work and chronic (bacterial) sinusitis. About 90% of CT scans show focal hyperattenuation related to concretions; on MRI scans, the T2-weighted signal is decreased, whereas it is increased in bacterial sinusitis. Removal of the fungal ball is curative. No tissue invasion is demonstrable histologically or radiologically.

In contrast, chronic invasive sinusitis is a slowly destructive process that most commonly affects the ethmoid and sphenoid sinuses. Patients are usually but not always immunocompromised to some degree (e.g., as a result of diabetes or HIV infection). Imaging of the cranial sinuses shows opacification of one or more sinuses, local bone destruction, and invasion of local structures. The differential diagnosis is wide, including other infections. Apart from a history of chronic nasal discharge and blockage, loss of the sense of smell, and persistent headache, the usual presenting features are related to local involvement of critical structures. The orbital apex syndrome (blindness and proptosis) is characteristic. Facial swelling, cavernous sinus thrombosis, carotid artery occlusion, and pituitary fossa and brain and skull-base invasion are complications.

Chronic granulomatous sinusitis due to *Aspergillus* is most commonly seen in the Middle East and India and is often caused by *A. flavus*. It typically presents late, with facial swelling and unilateral proptosis. The prominent granulomatous reaction histologically distinguishes this disease from chronic invasive sinusitis, in which tissue necrosis with a low-grade mixed-cell infiltrate is typical. IgG antibodies to *A. flavus* are usually detectable.

Allergic Bronchopulmonary Aspergillosis In almost all cases, ABPA represents a hypersensitivity reaction to *A. fumigatus*; other causes are other aspergilli and other fungi. ABPA occurs in ~2.5% of patients with asthma who are referred to secondary care, although it may be less common in the United States and more common in those from the Indian subcontinent. In cystic fibrosis, up to 15% of teenagers are affected. Episodes of bronchial obstruction with mucous plugs leading to coughing fits, "pneumonia," consolidation, and breathlessness are typical. Many patients report coughing up thick sputum casts, often brown in color. Eosinophilia commonly develops before systemic glucocorticoids are given. The cardinal diagnostic test is detection of *Aspergillus*-specific IgE (or a positive skin-prick test in response to *A. fumigatus* extract) together with an elevated serum level of total IgE (usually >1000 IU/mL). The presence of hyperattenuated mucus in airways is highly specific. Bronchiectasis is characteristic, and a few patients develop chronic cavitary pulmonary aspergillosis.

Severe Asthma with Fungal Sensitization (SAFS) Many adults with severe asthma do not fulfill the criteria for ABPA and yet are allergic to fungi. Although *A. fumigatus* is a common allergen, numerous other fungi (e.g., *Cladosporium* and *Alternaria* species) are implicated by skin-prick testing and/or specific IgE testing. Serum total IgE concentrations are <1000 IU/mL, and bronchial-wall thickening is common. ABPA and SAFS are collectively referred to as *fungal asthma*.

Allergic Fungal Rhinosinusitis Like the lungs, the sinuses manifest allergic responses to *Aspergillus* and other fungi. The affected patients present with chronic (i.e., perennial) sinusitis that is relatively unresponsive to antibiotics. Many of these patients have nasal polyps, and all have congested nasal mucosae and sinuses full of mucoid material. The histologic hallmarks of allergic fungal sinusitis are local eosinophilia and Charcot-Leyden crystals. Removal of abnormal mucus and polyps, with local and occasionally systemic administration of glucocorticoids, usually leads to resolution. Persistent or recurrent signs and symptoms may require more extensive surgery (ethmoidectomy) and sometimes oral antifungal therapy. Recurrence is common, often after another bacterial or viral infection.

Superficial Aspergillosis *Aspergillus* can cause keratitis, onychomycosis, and otitis externa. The first can be difficult to diagnose early enough to save the patient's sight. Natamycin (5%) eye drops are the optimal therapy for fungal keratitis, often with surgery. Otitis externa usually resolves with debridement and local application of antifungal agents.

DIAGNOSIS

Several techniques are required to establish the diagnosis of any form of aspergillosis with confidence (Table 223-1).

Acute Invasive Aspergillosis Patients with acute invasive aspergillosis have a relatively heavy load of fungus in the affected organ; thus, antigen detection, PCR, microscopy, culture, and/or histopathology usually confirm the diagnosis. However, the pace of progression leaves only a narrow window for making the diagnosis without losing the patient, and some invasive procedures are not possible because of coagulopathy, respiratory compromise, and other factors. Many cases of invasive aspergillosis are missed clinically and are diagnosed only at autopsy. Histologic examination of affected tissue reveals either infarction, with invasion of blood vessels by many fungal hyphae, or acute necrosis, with limited inflammation and fewer hyphae. *Aspergillus* hyphae are hyaline, narrow, and septate, with branching at 45° in infected tissue. Hyphae can be seen in cytology or microscopy

preparations, which therefore provide a rapid means of presumptive diagnosis.

One *Aspergillus* antigen test relies on detection of galactomannan release from *Aspergillus* organisms during growth, the other a novel protein antigen. Respiratory sample antigen detection is more sensitive than serum and is critical in the intensive care unit patient in whom radiology is nonspecific. Positive serum antigen results usually precede clinical or radiologic features by several days. The sensitivity of antigen detection is reduced by antifungal therapy.

A positive culture supports the diagnosis, given that multiple other (rarer) fungi can mimic *Aspergillus* species histologically, but only 10–30% of patients with invasive aspergillosis have a positive culture. Bacterial agar is less sensitive than fungal media for culture; thus, if physicians do not request fungal culture, the diagnosis may be missed. High-volume fungal cultures enhance yield. A positive culture may represent noninvasive forms of aspergillosis or airway colonization. Both antigen detection and real-time PCR are faster and much more sensitive than culture of respiratory samples and blood.

Definitive confirmation of a diagnosis of invasive aspergillosis requires (1) a positive culture of a sample taken directly from an ordinarily sterile site (e.g., a brain abscess) or (2) positive results of both histologic testing and culture (or molecular confirmation of *Aspergillus* spp.) of a sample taken from an affected organ (e.g., sinuses or skin). Most diagnoses of invasive aspergillosis are inferred from fewer data, including the presence of the *halo sign* on a thoracic CT scan—a localized ground-glass appearance representing hemorrhagic infarction surrounds a nodule or consolidation. Halo signs are present for ~7 days early in the course of infection in neutropenic patients and are a good prognostic feature, reflecting an early diagnosis. Nodules with halo signs are a feature of COVID-19 itself; invasive aspergillosis diagnosis requires supportive evidence. Other characteristic radiologic features of invasive pulmonary aspergillosis include nodules and pleural-based infarction or cavitation, but nonspecific consolidation is common **(Fig. 223-2)**.

Chronic Aspergillosis For chronic aspergillosis, *Aspergillus* antibody testing combined with characteristic imaging is sufficient for the diagnosis. Biopsy of *Aspergillus* nodules reveals hyphae surrounded by cells of chronic inflammation and sometimes granulomas. Antibody titers fall slowly with successful therapy. Cultures are infrequently positive but are important in checking for azole resistance. PCR of sputum is often strongly positive. Some patients with chronic pulmonary aspergillosis often have elevated titers of total and *Aspergillus*-specific IgE.

ABPA, SAFS, and Allergic *Aspergillus* Sinusitis ABPA and SAFS are diagnosed serologically with elevated specific and total serum IgE levels or with skin-prick tests. Allergic *Aspergillus* sinusitis is usually diagnosed histologically, accompanied by *Aspergillus* IgE antibody.

A

B

FIGURE 223-2 Markedly different appearances of invasive aspergillosis on computed tomography scan of the thorax. *A.* Patient with myelodysplasia and moderate neutropenia showing small right-sided nodules with minimal surrounding ground glass and a separate area of ground glass only on the left laterally. ***B.*** Patient with multiple myeloma undergoing intensive chemotherapy with corticosteroids showing bilateral areas of consolidation and some nonspecific atelectasis with probable ground glass surrounding the right-sided lesion. The anterior component of the left-sided lesion is demarcated by the fissure.

TREATMENT

Aspergillosis

Antifungal drugs active against *Aspergillus* include voriconazole, itraconazole, posaconazole, isavuconazole, caspofungin, micafungin, and amphotericin B (AmB). Possible interactions with other drugs must be considered before azoles are prescribed. In addition, plasma itraconazole and voriconazole concentrations vary substantially from one patient to another, and many authorities recommend monitoring levels to ensure that drug concentrations are adequate but not excessive. Initial IV administration is preferred for acute invasive aspergillosis and oral administration for all other diseases that require antifungal therapy. Current recommendations are shown in **Table 223-3**.

Voriconazole, isavuconazole, and posaconazole are the preferred agents for invasive aspergillosis; caspofungin, micafungin, and lipid-associated AmB are second-line agents. AmB is not active against *A. terreus* or *A. nidulans*; multi-azole resistance in *A. fumigatus* is present in 3–20% of isolates but is increasing, especially in Southeast Asia; and *A. niger* is resistant to isavuconazole. An infectious disease consultation is advised for patients with invasive disease, given the complexity of management. Immune reconstitution can complicate recovery. The duration of therapy for invasive aspergillosis varies from ~3 months to several years, depending on the patient's immune status and response to therapy. Relapse occurs if the response is suboptimal and immune reconstitution is not complete.

Voriconazole is currently the preferred oral agent for chronic aspergillosis with itraconazole or posaconazole as substitutes when failure, emergence of resistance, or adverse events occur. Because chronic cavitary pulmonary aspergillosis responds slowly, therapy for at least 12 months is necessary, and disease control may require years of treatment, whereas the duration of treatment for other forms of chronic and allergic aspergillosis requires case-by-case evaluation. Glucocorticoids should be avoided in chronic cavitary pulmonary aspergillosis unless covered by adequate antifungal therapy; mortality is increased by 240% with corticosteroids. Acute exacerbations of ABPA respond well to voriconazole, itraconazole, or a short course of glucocorticoids—long-term azole therapy usually helps minimize corticosteroid exposure and maintain remission. Antifungal response in *Aspergillus* bronchitis is gratifying, but relapse after 4 months of therapy is common.

Resistance in *A. fumigatus* to one or more azoles, although uncommon, is increasingly found globally. Resistance may be derived from azole fungicide use for crops. Resistance arising from multiple mechanisms may develop during long-term treatment, and a positive culture during antifungal therapy is an indication for susceptibility testing.

Surgical treatment is important in several forms of aspergillosis, including fungal ball of the sinus and single aspergillomas, in which

TABLE 223-3 Treatment of Aspergillosis[a]

INDICATION	PRIMARY TREATMENT	PRECAUTIONS	SECONDARY TREATMENT	COMMENTS
Invasive disease[b]	Voriconazole, isavuconazole, posaconazole	Drug interactions (especially with voriconazole)[c]	AmB, caspofungin, micafungin	As primary therapy, azoles have a 20% higher response rate than AmB. Therapeutic drug monitoring is recommended for voriconazole and isavuconazole in ICU patients.
Prophylaxis	Posaconazole tablet, itraconazole solution SUBA-itraconazole	Vincristine, cyclophosphamide interaction	Micafungin, aerosolized AmB	Some centers monitor plasma levels of itraconazole and posaconazole.
Single aspergilloma	Surgical resection	Multicavity disease: poor outcome of surgery, medical therapy preferable	Itraconazole, voriconazole, intracavity AmB	Single large cavities with an aspergilloma are best resected. Relapse reduced by pre- and perioperative antifungal therapy.
Chronic pulmonary disease[b]	Voriconazole, itraconazole	Poor absorption of itraconazole capsules with proton pump inhibitors or H_2 blockers	Posaconazole, IV AmB, IV micafungin	Resistance may emerge during treatment, especially if plasma drug levels are low. Therapeutic azole drug monitoring recommended.
ABPA/SAFS ("fungal asthma")	Itraconazole	Some glucocorticoid interactions, including with inhaled formulations	Voriconazole, posaconazole, inhaled AmB	Long-term therapy is helpful in most cases. No evidence indicates whether therapy modifies progression to bronchiectasis/fibrosis.

[a]For information on duration of therapy and drug resistance in certain *Aspergillus* species, see text. [b]An infectious disease consultation is appropriate for these patients. [c]Online drug-interaction resource: *www.aspergillus.org.uk/content/antifungal-drug-interactions*.

Note: After loading doses, the oral dose is usually 200 mg bid for voriconazole and itraconazole, 65 mg bid for SUBA-itraconazole, 300 mg qd for posaconazole tablets, and 200 mg qd for isavuconazole. The IV dose of voriconazole for adults is 6 mg/kg twice at 12-h intervals (loading doses) followed by 4 mg/kg q12h; a larger dose is required for children and teenagers; a lower dose may be safer for persons >70 years of age. Plasma monitoring is helpful in optimizing the dosage. The IV dose of isavuconazole is 200 mg tid for 2 days (loading dose) followed by 200 mg qd. Caspofungin is given as a single loading dose of 70 mg and then at 50 mg/d; some authorities use 70 mg/d for patients weighing >80 kg, and lower doses are required with hepatic dysfunction. Micafungin is given as 50 mg/d for prophylaxis and as at least 150 mg/d for treatment; this drug has not yet been approved by the U.S. Food and Drug Administration (FDA) for this indication. AmB deoxycholate is given at a daily dose of 1 mg/kg if tolerated. Several strategies are available for minimizing renal dysfunction. Lipid-associated AmB is given at 3 mg/kg (AmBisome) or 5 mg/kg (Abelcet). Different regimens are available for aerosolized AmB, but none is FDA approved. Other considerations that may alter dose selection or route include age; concomitant medications; renal, hepatic, or intestinal dysfunction; and drug tolerability.

Abbreviations: ABPA, allergic bronchopulmonary aspergillosis; AmB, amphotericin B; SAFS, severe asthma with fungal sensitization ICU, intensive care unit.

surgery is curative; invasive aspergillosis involving bone, heart valve, sinuses, and proximal areas of the lung (to avoid catastrophic hemoptysis); brain abscess; keratitis; and endophthalmitis. In allergic fungal sinusitis, removal of abnormal mucus and polyps, with local and occasionally systemic glucocorticoid treatment, usually leads to resolution. Persistent or recurrent signs and symptoms may require more extensive surgery (ethmoidectomy) and possibly antifungal therapy. Surgery is problematic in chronic cavitary pulmonary aspergillosis, often resulting in serious complications. Bronchial artery embolization is preferred for problematic hemoptysis.

PROPHYLAXIS

In situations in which moderate or high risk is predicted (e.g., after induction therapy for acute myeloid leukemia), the need for antifungal prophylaxis for superficial and systemic candidiasis and for invasive aspergillosis is generally accepted. Fluconazole is commonly used in these situations but has no activity against *Aspergillus* species. Itraconazole solution or super bioavailability (SUBA)-itraconazole capsules provide enough bioavailability for modest efficacy, the latter with fewer adverse events. Posaconazole tablets are more effective in reducing infection rates and the need for empirical antifungal therapy. Some data support the use of IV micafungin in those with azole contraindications. No prophylactic regimen is completely successful.

OUTCOME

Invasive aspergillosis is curable if immune reconstitution occurs, whereas allergic and chronic forms are not. The mortality rate for invasive aspergillosis is 30–70% if the infection is treated but is 100% if the diagnosis is missed. Cerebral aspergillosis, *Aspergillus* endocarditis, and bilateral extensive invasive pulmonary aspergillosis have very poor outcomes, as does invasive infection in persons with late-stage AIDS, relapsed uncontrolled leukemia or liver failure.

For those with chronic cavitary pulmonary aspergillosis, ~70% deteriorate clinically without antifngal therapy. The mortality rate for chronic cavitary pulmonary aspergillosis is 15–20% in the first year, ~40% over 5 years, and 50–60% over 10 years if the patient is actively treated with antifungal agents. Antifungal therapy fails in ~30% of recipients and still more often if azole resistance is present.

Both ABPA and SAFS patients respond to glucocorticoids and antifungal therapy; ~60% respond to itraconazole and ~80% to voriconazole and posaconazole (if tolerated). Inhaled amB is effective in and tolerated by ~15% of patients. Long-term antifungal therapy often allows oral glucocorticoids to be stopped and inhaled glucocorticoid dose. Relapse after discontinuation is common.

224 Mucormycosis

Brad Spellberg, Ashraf S. Ibrahim

Mucormycosis represents a group of life-threatening infections caused by fungi of the order Mucorales of the subphylum Mucoromycotina. Mucormycosis is highly invasive and relentlessly progressive, resulting in higher rates of morbidity and mortality than many other infections. The mortality rates from mucormycosis have declined in recent years as a result of early initiation of more effective antifungal therapies. However, mortality remains high overall, often driven by progression of the underlying predisposing condition.

TABLE 224-1 Taxonomy of Fungi Causing Mucormycosis (Subphylum Mucoromycotina, Order Mucorales)

FAMILY	GENUS (SPECIES LISTED FOR SOME)
Mucoraceae	*Rhizopus oryzae* *Rhizopus delemar* *Rhizopus microsporus* *Rhizomucor* *Mucor* *Actinomucor*
Lichtheimiaceae	*Lichtheimia* (formerly *Mycocladus*, formerly *Absidia*)
Cunninghamellaceae	*Cunninghamella*
Thamnidiaceae	*Cokeromyces*
Mortierellaceae	*Mortierella*
Saksenaceae	*Saksenaea* *Apophysomyces*
Syncephalastraceae	*Syncephalastrum*

ETIOLOGY

The fungal order Mucorales consists of seven families that are known to cause mucormycosis **(Table 224-1)**. *Rhizopus oryzae* and *R. delemar* (both in the family Mucoraceae) are by far the most common causes of mucormycosis in the Western Hemisphere. Less frequently isolated species of the Mucoraceae that cause a similar spectrum of infections include *R. microsporus*, *Rhizomucor pusillus, Lichtheimia corymbifera* (formerly *Absidia corymbifera*), *Apophysomyces elegans*, and *Mucor* species. Increasing numbers of cases of mucormycosis due to infection by mold in the family Cunninghamellaceae have also been reported, particularly in highly immunocompromised patients. Other Mucorales can be the major cause of disease in certain geographic areas (e.g., *A. elegans* in India and *M. irregularis* in China), or in outbreaks following natural disasters (e.g., *A. trapeziformis* outbreak following Joplin tornado). Only rare case reports have demonstrated the ability of fungi in the remaining families of the Mucorales to cause mucormycosis.

PATHOGENESIS

The Mucorales are ubiquitous environmental fungi to which humans are constantly exposed. These fungi cause infection primarily in patients with uncontrolled diabetes, defects in phagocytic function (e.g., neutropenia or exposure to high doses of corticosteroids), and/or elevated levels of free iron, which supports fungal growth in serum and tissues. In the past, iron-overloaded patients with end-stage renal failure who were treated with deferoxamine had a high risk of developing rapidly fatal disseminated mucormycosis; deferoxamine is an iron chelator for the human host, but it serves as a fungal xenosiderophore, directly delivering iron to the Mucorales. Furthermore, patients with diabetic ketoacidosis (DKA) are at high risk of developing rhinocerebral mucormycosis. The acidosis causes dissociation of iron from sequestering proteins, resulting in enhanced fungal survival and virulence. The ketoacid β-hydroxybutyrate also increases expression of host and fungal receptors that result in fungal adherence and penetration into tissues.

Nevertheless, the majority of diabetic patients who present with mucormycosis are not acidotic, and, even absent acidosis, hyperglycemia directly contributes to the risk of mucormycosis by at least four likely mechanisms: (1) hyperglycation of iron-sequestering proteins, disrupting normal iron sequestration; (2) upregulation of a mammalian cell receptor (GRP78) that binds to Mucorales, enabling tissue penetration (due to both a direct effect of hyperglycemia and increasing levels of free iron); (3) induction of poorly characterized defects in phagocytic function; and (4) enhanced expression of CotH, a Mucorales-specific protein that mediates host cell invasion by binding to GRP78 (due to hyperglycemia and the resulting free iron).

EPIDEMIOLOGY

Mucormycosis typically occurs in patients with diabetes mellitus, solid-organ or hematopoietic stem cell transplantation (HSCT), prolonged neutropenia or corticosteroid use, or malignancy. During the pandemic, mucormycosis occurred commonly as a co-infection in patients with COVID-19 severe enough to warrant hospitalization. Such infections were heavily described in low- and middle-income countries (LMICs) and in India in particular. However, the incidence of mucormycosis was higher in India than most other countries even before the pandemic. Hence, it is unclear if the virus itself somehow predisposed to fungal superinfection or if the routine use of high-dose corticosteroid therapy for COVID-19, possibly combined with high rates of diabetes mellitus in affected populations, was the primary driver of such infections.

As mentioned, the majority of diabetic patients are not acidotic on presentation with mucormycosis. Furthermore, patients often have no previously recognized history of diabetes mellitus when they present with mucormycosis. In these instances, presentation with mucormycosis may result in the first clinical recognition of hyperglycemia, which often has been unmasked by recent glucocorticoid use. Thus, a high index of suspicion of mucormycosis must be maintained, even in the absence of a known history of diabetes, if hyperglycemia is present and patients present with sinusitis, particularly with possible orbital extension.

In patients undergoing HSCT, mucormycosis develops at least as commonly during nonneutropenic as during neutropenic periods, probably because of glucocorticoid treatment of graft-versus-host disease. Mucormycosis can occur as isolated cutaneous or subcutaneous infection in immunologically normal individuals after traumatic implantation of soil or vegetation (e.g., due to natural disasters, motor vehicle accidents, or severe injuries in war zones) or in nosocomial settings via direct access through intravenous catheters, subcutaneous injections, or maceration of the skin by a moist dressing.

Patients receiving antifungal prophylaxis with either itraconazole or voriconazole may be at increased risk of mucormycosis. These patients typically present with disseminated mucormycosis, the most lethal form of disease. Breakthrough mucormycosis also has been described in patients receiving posaconazole, isavuconazole, or echinocandin prophylaxis.

CLINICAL MANIFESTATIONS

Mucormycosis presentations are often as one of five well-defined clinical syndromes: rhino-orbital-cerebral, pulmonary, cutaneous, gastrointestinal, and disseminated disease. However, infection of any body site can occur. Patients with specific defects in host defense tend to develop specific syndromes. For example, patients with diabetes mellitus and/or DKA typically develop the rhino-orbital-cerebral form and much more rarely develop pulmonary or disseminated disease. In contrast, pulmonary mucormycosis occurs most commonly in leukemic patients who are receiving chemotherapy and in patients undergoing HSCT.

Rhino-Orbital-Cerebral Disease Rhino-orbital-cerebral mucormycosis continues to be the most common form of the disease worldwide. Most cases occur in patients with diabetes, although such cases are also described in the transplantation setting, often along with glucocorticoid-induced diabetes mellitus. The initial symptoms of rhino-orbital-cerebral mucormycosis are nonspecific and include eye or facial pain and facial numbness followed by the onset of conjunctival suffusion and swelling, and blurry vision. In contrast to the acute, bright red, periocular skin manifestations typical of acute bacterial orbital cellulitis, periorbital skin in patients with rhino-orbital-cerebral mucormycosis may take on a more dusky, subacute appearance. Fever may be absent in up to half of cases. White blood cell counts are typically elevated as long as the patient has functioning bone marrow. If untreated, infection usually spreads from the ethmoid sinus to the orbit, resulting in compromise of extraocular muscle function and proptosis, typically with chemosis. From the orbit, the fungus can spread contiguously or hematogenously to the frontal lobe of the brain and/or via venous drainage to the cavernous sinus. Onset of signs and symptoms in the contralateral eye, with resulting bilateral proptosis, chemosis, vision loss, and ophthalmoplegia, is ominous, suggesting the development of cavernous sinus thrombosis.

Upon visual inspection, infected tissue often has a normal appearance during the earliest stages of fungal spread, which can make diagnosis difficult; blind biopsies of normal-appearing sinus tissue are warranted when suspicion for mucormycosis is high. Tissue then progresses through an erythematous phase, with or without edema, before the onset of a violaceous appearance and finally the development of a black necrotic eschar. Infection can sometimes extend from the sinuses into the mouth and produce painful necrotic ulcerations of the hard palate, but this is a late finding that suggests extensive, well-established infection.

One common misperception about mucormycosis is that it is always rapidly progressive. In fact, the rate of progression is extremely variable and is possibly dependent on the immune status of the patient, the infectious inoculum, and the causative Mucorales species, some of which are more virulent and/or have faster growth rates than others. Patients may go from initial symptoms to death in days; alternatively, it can take months or even a year or more for lethal progression to occur.

Pulmonary Disease Pulmonary mucormycosis is the second most common manifestation. Symptoms include dyspnea, cough, and chest pain; fever is often but not invariably present. Angioinvasion results in necrosis, cavitation, and/or hemoptysis. Lobar consolidation, isolated masses, nodular disease, cavities, or wedge-shaped infarcts may be seen on chest radiography. Chest computed tomography (CT) is the best method for determining the extent of pulmonary mucormycosis and may demonstrate evidence of infection before it is seen on chest x-ray. In the setting of cancer, where mucormycosis may be difficult to differentiate from aspergillosis, the presence of ≥10 pulmonary nodules, pleural effusion, or concomitant sinusitis make mucormycosis more likely. It is important to distinguish mucormycosis from aspergillosis because treatments for these infections may differ. Indeed, voriconazole—the first-line treatment for aspergillosis—exacerbates mucormycosis in mouse and fly models of infection. Isavuconazole was noninferior to voriconazole for the treatment of aspergillosis in a randomized controlled trial and also has activity against Mucorales. Hence if there is doubt about whether infection is caused by a septated mold (e.g., *Aspergillus*) or a Mucorales, inclusion of isavuconazole in a treatment regimen is a reasonable consideration. Consideration must also be given to the possibility of dual infection with both a septated mold and Mucorales; dual infection is not infrequently encountered in highly compromised patients.

Cutaneous Disease Cutaneous mucormycosis may result from external implantation of the fungus or from hematogenous dissemination. External implantation–related infection has been described in the setting of soil exposure from trauma (e.g., in a motor vehicle accident, a natural disaster, or combat-related injuries), penetrating injury with plant material (e.g., a thorn), injections of medications (e.g., insulin), catheter insertion, contamination of surgical dressings, and use of tape to secure endotracheal tubes. Cutaneous disease can be highly invasive, penetrating into muscle, fascia, and even bone. Necrotizing fasciitis caused by mucormycosis carries a mortality rate approaching 80%. Necrotic cutaneous lesions in the setting of hematogenous dissemination also are associated with an extremely high mortality rate. However, with prompt, aggressive surgical debridement, isolated, nonnecrotizing cutaneous mucormycosis has a favorable prognosis and a low mortality rate.

Gastrointestinal Disease In the past, gastrointestinal mucormycosis occurred primarily in premature neonates in association with disseminated disease and necrotizing enterocolitis. However, there has been a marked increase in case reports describing adults with neutropenia, glucocorticoid use, or other immunocompromising conditions. In addition, gastrointestinal disease has been reported as a nosocomial process following administration of medications mixed with contaminated wooden applicator sticks. Nonspecific abdominal pain and distention associated with nausea and vomiting are the most common symptoms. Gastrointestinal bleeding is common, and fungating masses may be seen in the stomach at endoscopy. The disease may progress to visceral perforation, with extremely high mortality rates.

Disseminated and Miscellaneous Forms of Disease Hematogenously disseminated mucormycosis may originate from any primary site of infection. The most common site of dissemination is the brain, but metastatic lesions may also be found in any other organ. Mortality rates for widely disseminated mucormycosis exceed 90%; however, these high rates are likely to be due in part to the underlying predisposing condition leading to the infection and the inability to surgically remove the infected foci.

Mucormycosis may affect any body site, including bones, mediastinum, trachea, kidneys, peritoneum (in association with dialysis), scalp (causing a kerion), and even isolated infection of teeth.

DIAGNOSIS

A high index of suspicion is required for diagnosis of mucormycosis. Unfortunately, autopsy series have shown that up to half of cases are diagnosed only postmortem. Because the Mucorales are environmental isolates, definitive diagnosis requires a positive culture from a sterile site (e.g., a needle aspirate, a tissue biopsy specimen, or pleural fluid) or histopathologic evidence of invasive mucormycosis. A probable diagnosis of mucormycosis can be established by culture from a nonsterile site (e.g., sputum or bronchoalveolar lavage) or the detection of Mucorales on the surface of histopathology samples (without visualization of evidence of invasion) when a patient has appropriate risk factors as well as clinical and radiographic evidence of disease. In such cases, given the urgency of administering therapy early, the patient should be treated while confirmation of the diagnosis is awaited.

Biopsy with histopathologic examination remains the most sensitive and specific modality for definitive diagnosis **(Fig. 224-1)**. Biopsy reveals characteristic wide (≥6- to 30-μm), thick-walled, ribbon-like, aseptate hyphal elements that branch at right angles. Other fungi, including *Aspergillus, Fusarium*, and *Scedosporium* species, have septa, are thinner, and branch at acute angles. However, artificial septa may result from folding of tissue during processing (which may also alter the appearance of the angle of branching), which can make Mucorales appear to have septa. Thus, the width and the ribbon-like form of the fungus are likely the most reliable features distinguishing mucormycosis from other pathogenic molds. The Mucorales are visualized most effectively with periodic acid–Schiff or hematoxylin and eosin; in contrast to many other fungi, methenamine silver may not result in optimal staining. While histopathology can identify the Mucorales, species can be identified only by culture. Several studies showed that polymerase chain reaction (PCR) of Mucorales-specific targets is useful in diagnosing mucormycosis. However, the U.S. Food and Drug Administration (FDA) has not approved any of these PCR-based assays for this purpose.

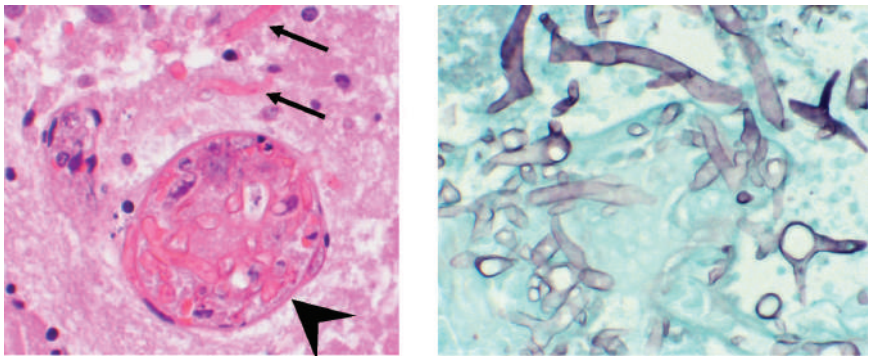

FIGURE 224-1 Histopathology sections of *Rhizopus delemar* in infected brain. *A.* Broad, ribbon-like, nonseptate hyphae in the parenchyma (*arrows*) and a thrombosed blood vessel with extensive intravascular hyphae (*arrowhead*) (hematoxylin and eosin). ***B.*** Extensive, broad, ribbon-like hyphae invading the parenchyma (Gomori methenamine silver).

Unfortunately, cultures are positive in fewer than half of cases of mucormycosis. Nevertheless, the Mucorales are not fastidious organisms and tend to grow quickly (i.e., within 48–96 h) on culture media. The likely explanation for the low sensitivity of culture is that the Mucorales form long filamentous structures that are killed by tissue homogenization—the standard method for preparing tissue cultures in the clinical microbiology laboratory. Therefore, the laboratory should be advised when a diagnosis of mucormycosis is suspected, and the tissue should be cut into sections and placed in the center of culture dishes rather than homogenized. Because there is also substantial variability among isolates in optimal growth temperature, growth at both room temperature and 37°C is advisable.

Imaging techniques often yield subtle findings that underestimate the extent of disease. For example, the most common finding on CT or magnetic resonance imaging (MRI) of the head or sinuses of a patient with rhino-orbital mucormycosis is sinusitis that is indistinguishable from bacterial sinusitis. While sinusitis is almost always seen on CT scans in patients with the rhino-orbital-cerebral disease, erosion through the sinus bones and into the orbit is rarely seen on CT even when it is clinically present. MRI is more sensitive (~80%) for detecting orbital and central nervous system (CNS) disease than is CT. High-risk patients should always undergo endoscopy and/or surgical exploration, with biopsy of the areas of suspected infection. If mucormycosis is suspected, initial empirical therapy with a polyene antifungal agent should be initiated while the diagnosis is being confirmed.

DIFFERENTIAL DIAGNOSIS

Other mold infections, including aspergillosis, scedosporiosis, fusariosis, and infections caused by the dematiaceous fungi (brown-pigmented soil organisms), can cause clinical syndromes identical to mucormycosis. Histopathologic examination usually allows distinction of the Mucorales from these other organisms, and a positive culture permits definitive species identification. As stated above, it is important to distinguish the Mucorales from these other fungi, as the preferred antifungal treatments differ (i.e., polyenes for the Mucorales vs expanded-spectrum triazoles for most septate molds). The entomophthoromycoses caused by *Basidiobolus* and *Conidiobolus* also can cause identical clinical syndromes. These fungi cannot be readily distinguished from the Mucorales by histopathology but can be reliably distinguished by culture. Fortunately, entomophthoromycoses are uncommon in developed countries and can be treated with polyenes; it is not urgent to distinguish them from mucormycosis.

In a patient with sinusitis and proptosis, orbital cellulitis and cavernous sinus thrombosis caused by bacterial pathogens (most commonly *Staphylococcus aureus*, but also streptococcal and gram-negative species) must be excluded. *Klebsiella rhinoscleromatis* is a rare cause of an indolent facial rhinoscleroma syndrome that may appear similar to mucormycosis. Finally, the Tolosa-Hunt syndrome is characterized by painful ophthalmoplegia, ptosis, headache, and cavernous sinus inflammation; biopsies and clinical follow-up may be needed to distinguish the Tolosa-Hunt syndrome from mucormycosis; there is a lack of progression of the former entity.

TREATMENT

Mucormycosis

GENERAL PRINCIPLES

Optimizing the chances for successful treatment of mucormycosis requires four steps: (1) early initiation of therapy; (2) surgical debridement, when possible; (3) rapid reversal of underlying predisposing risk factors, if possible; and (4) proceeding to treat underlying malignancy, if present, without waiting to complete antifungal therapy first.

Early initiation of antifungal therapy requires maintaining a high index of suspicion for at-risk patients. Multiple studies have found that earlier initiation of polyene-based therapy improves survival of patients with mucormycosis. Because the disease can present subtly at first and because confirmation of the diagnosis can take days, therapy often must be started empirically before the diagnosis is established. When there is a reasonable suspicion of mucormycosis, clinicians should not hesitate to initiate therapy with a lipid polyene as soon as possible, since the toxicity of lipid polyenes (unlike that of amphotericin B [AmB] deoxycholate) is rarely substantial after one or two doses.

Blood vessel thrombosis and resulting tissue necrosis during mucormycosis can result in poor penetration of antifungal agents to the site of infection. Therefore, debridement of all necrotic tissues can help eradicate the disease. Surgery has been found (by logistic regression and in multiple case series) to be an independent variable for favorable outcome in patients with mucormycosis. However, these data are confounded by the fact that sicker patients are often unable to tolerate surgical procedures. Thus, a moderated approach in which tissue is debrided when and to the extent it is safe to do so is advisable. Limited data from a retrospective study support the use of intraoperative frozen sections to delineate the margins of infected tissues, with sparing of tissues lacking evidence of infection.

Rapidly reversing hyperglycemia, acidosis, or iron overload, and lowering corticosteroid doses are important to achieving cure. Indeed, a recent study confirmed that resolution of acidosis in mice with DKA via the administration of sodium bicarbonate (used in the mice in lieu of insulin) improved survival. Administration of glucocorticoids predisposes animals to death from mucormycosis in experimental models. Similarly, iron administration to patients with active mucormycosis should be avoided, as iron exacerbates infection in experimental models. Blood transfusion typically results in some liberation of free iron due to hemolysis, so a conservative approach to red blood cell transfusions is advisable.

One of the most common errors made in management of mucormycosis is the belief that mucormycosis must be eradicated before an underlying malignancy can be treated. This belief can result in halting or delaying treatment for the underlying disease (e.g., chemotherapy or transplantation) until the mucormycosis is cured. Three fallacies belie this concern. First, mucormycosis will not be definitively eradicated until near-normal immunity is restored; the antifungals provide a holding action and are unlikely to be curative until the underlying disease is treated. Second, modern antifungals can halt progression of mucormycosis temporarily, enabling aggressive chemotherapy or transplantation to be administered to cure the underlying disease. Finally, the primary driver of death in such patients is typically progression of the underlying disease due to failure to treat it appropriately.

Initially, some consideration can be given to moderating the level of aggressiveness of the chemotherapy and resulting duration and depth of neutropenia. The aggressiveness of immune suppression and antifungal therapy can then be adjusted during the course of treatment in response to changes in clinical status. Nevertheless, chemotherapy should be given sufficiently aggressively to attempt cure of the underlying disease. These patients are extremely complex, and multidisciplinary, team-based care is advisable.

ANTIFUNGAL THERAPY

Primary therapy for mucormycosis should be based on a polyene antifungal agent **(Table 224-2)**, except perhaps in mild localized infection (e.g., isolated suprafascial cutaneous infection) that has been mostly excised surgically in an immunocompetent patient. Lipid formulations of AmB are significantly less nephrotoxic than AmB deoxycholate, can be administered at higher doses, and are probably more effective for this purpose. Liposomal amphotericin B (LAmB) may be preferred to amphotericin B lipid complex (ABLC) for management of brain infection based on retrospective survival data and superior brain penetration; there is no clear efficacy advantage of either agent for infections outside the brain, although LAmB may be less nephrotoxic than ABLC (but is also considerably more expensive in many settings).

Starting dosages of 1 mg/kg per day for AmB deoxycholate and 5 mg/kg per day for LAmB and ABLC are commonly given to adults

TABLE 224-2 Antifungal Options for the Treatment of Mucormycosis[a]

DRUG	RECOMMENDED DOSAGE	ADVANTAGES AND SUPPORTING STUDIES	DISADVANTAGES
First-Line Antifungal Therapy			
AmB deoxycholate	1.0–1.5 mg/kg once per day	• >5 decades of clinical experience • Inexpensive • FDA approved for treatment of mucormycosis	• Highly toxic • Poor CNS penetration
LAmB	5–10 mg/kg once per day	• Less nephrotoxic than AmB deoxycholate • Better CNS penetration than AmB deoxycholate or ABLC • Better outcomes than with AmB deoxycholate in murine models and a retrospective clinical review	• Expensive
ABLC	5 mg/kg once per day	• Less nephrotoxic than AmB deoxycholate • Murine and retrospective clinical data suggest benefit of combination therapy with echinocandins	• Expensive • Possibly less efficacious than LAmB for CNS infection
Second-Line/Salvage Option			
Isavuconazole	200 mg of isavuconazole (372 mg of isavuconazonium sulfate), load q8h × 6 followed by once-daily dosing	• Efficacy similar to that of LAmB in mouse models • FDA approved for treatment of mucormycosis • May be a rational empirical option when septate mold vs mucormycosis is not yet established	• Much less clinical experience • Clinical study supporting approval was small and historically controlled
Posaconazole	200 mg four times per day	• In vitro activity against the Mucorales, with lower MICs than isavuconazole • Retrospective data for salvage therapy in mucormycosis	• Substantially lower blood levels than isavuconazole • No data on initial therapy for mucormycosis, and no evidence for posaconazole in combination with other therapy • Experience limited, potential use for salvage therapy
Combination Therapy[b]			
Echinocandin plus lipid polyene	Standard echinocandin doses	• Favorable toxicity profile • Synergistic in murine disseminated mucormycosis • Retrospective clinical data suggest superior outcomes for rhino-orbital-cerebral mucormycosis.	• Limited clinical data on combination therapy
Lipid polyene plus azole (posaconazole or isavuconazole)	Standard doses	• Favorable toxicity profile	• Limited efficacy data, with no available evidence of superiority vs monotherapy
Triple therapy (lipid polyene plus echinocandin plus azole)	Standard doses	• Maximal aggressiveness	• Limited efficacy data, with no available evidence for superiority vs monotherapy or dual therapy

[a]Primary therapy should generally include a polyene. Non-polyene-based regimens may be appropriate for patients who refuse polyene therapy or for relatively immunocompetent patients with mild disease (e.g., isolated suprafascial cutaneous infection) that can be surgically eradicated. [b]Prospective randomized trials are necessary to confirm the suggested benefit (from animal and small retrospective human studies) of combination therapy for mucormycosis. Dose escalation of any echinocandin is not recommended because of a paradoxical loss of benefit of combination therapy at echinocandin doses of ≥3 mg/kg per day.

Abbreviations: ABLC, AmB lipid complex; AmB, amphotericin B; CNS, central nervous system; FDA, U.S. Food and Drug Administration; LAmB, liposomal AmB; MIC, minimal inhibitory concentration.

and children to treat mucormycosis. Dose escalation of LAmB to 7.5 or 10 mg/kg per day for CNS mucormycosis may be considered in light of the limited penetration of polyenes into the brain. A recent observational study failed to find superior outcomes of LAmB dosed at 10 mg/kg per day. However, very few patients with brain involvement were included, and the analysis was not stratified by site of infection. Therefore, 10 mg/kg per day may be reasonable to consider for treating aggressive brain infection but is unlikely of benefit, and will increase toxicity, for other patients. Because of autoinduction of metabolism, which results in paradoxically lower drug levels, there is no advantage to escalating the LAmB dose above 10 mg/kg per day, and doses of 5 mg/kg per day are probably adequate for nonbrain infections. ABLC dose escalation above 5 mg/kg per day is not advisable given the lack of relevant data and the drug's potential toxicity.

In multiple studies, various combinations of lipid polyenes (both ABLC and LAmB) plus echinocandins (e.g., caspofungin, micafungin, and anidulafungin) improved survival rates among mice with disseminated mucormycosis (including CNS disease). Furthermore, combination lipid polyene–echinocandin therapy was associated with significantly better outcomes than polyene monotherapy in a retrospective clinical study involving patients with rhino-orbital-cerebral mucormycosis (including CNS disease). The effect of echinocandins appears to be to downmodulate the virulence of the fungus and reduce tissue necrosis and destruction from fungal invasion. On the basis of such data, some experts prefer combination lipid polyene–echinocandin therapy as a first-line option. However, at least one retrospective study did not find an advantage of any combination regimens (including polyene-azole, polyene-echinocandin, or others) in patients who primarily had malignancy as the underlying disease. Ultimately, definitive randomized controlled trials are needed to establish whether the combination is superior in efficacy to monotherapy for mucormycosis. When used, echinocandins should be administered at standard, FDA-approved doses, since dose escalation has resulted in paradoxical loss of efficacy in preclinical models.

In contrast to deferoxamine, the iron chelator deferasirox is fungicidal against clinical isolates of the Mucorales. In mice with DKA and disseminated mucormycosis, combination deferasirox–LAmB therapy resulted in synergistic improvement of survival rates and reduced the fungal burden in the brain. Unfortunately, a small, randomized, double-blind, phase 2 safety clinical trial of adjunctive

therapy with deferasirox (plus LAmB) documented excess mortality among patients treated with deferasirox. Of note, the study population included primarily patients with active malignancy, and few patients in the study had diabetes mellitus as their only risk factor. Deferasirox is therefore contraindicated as therapy in patients with active malignancy, but its role in patients who have diabetes mellitus without malignancy (the setting in which its preclinical efficacy was optimal) remains uncertain.

Posaconazole and isavuconazole are the only FDA-approved azoles with reliable in vitro activity against the Mucorales. However, there are limited data regarding the efficacy of posaconazole monotherapy for mucormycosis, and in contrast to polyene-echinocandin therapy, no data support the use of combination posaconazole-polyene regimens. Although the minimal inhibitory concentrations (MICs) of isavuconazole against the Mucorales are four- to eightfold higher than those of posaconazole, blood levels may be higher with standard isavuconazole dosing than with posaconazole. Isavuconazole is FDA-approved for the treatment of mucormycosis based on a small, historically controlled study. Given this limited dataset, many experts continue to think that lipid polyenes are first-line options and that isavuconazole, like posaconazole, is best reserved for oral transitional therapy in patients whose condition has substantially improved on polyene-based therapy, or for salvage therapy in patients who are intolerant of polyene-based regimens or whose infection is refractory to these regimens.

No studies in mice or humans have ever shown benefit of adding posaconazole to another antifungal agent for combination therapy of mucormycosis. In contrast, in mice, a combination of isavuconazole plus polyene regimens did prolong survival time and lowered tissue fungal burden compared to monotherapy. However, this combination has not been studied compared to monotherapy in people. Some experts use triple therapy with a polyene, echinocandin, and either posaconazole or isavuconazole for patients who have extensive disease or whose disease has progressed on prior therapy. Empirical, dual lipid polyene–azole therapy is a rational choice in a patient with likely invasive mold infections when septate molds and mucormycosis are both in the differential diagnosis and the etiologic agent has not yet been confirmed. Alternatively, initial therapy with isavuconazole monotherapy may be reasonable for a brief period of time in a stable patient if mucormycosis is felt to be possible but less likely than a septated mold infection.

The roles of recombinant cytokines and neutrophil transfusions in the primary treatment of mucormycosis are not clear, although it is intuitive that earlier recovery of neutrophil counts should improve survival rates. Limited data from uncontrolled case series have described the use of hyperbaric oxygen in centers with the appropriate technical expertise and facilities; its efficacy remains undefined. As mentioned previously, one study in mice with DKA found that administration of sodium bicarbonate improved survival from mucormycosis; however, because insulin was not administered to the mice, it is unclear whether the therapeutic effect is clinically relevant.

In general, antifungal therapy for mucormycosis should be continued until resolution of clinical signs and symptoms of infection and resolution of underlying immunosuppression. However, after a week or two of daily therapy in a patient who is clinically improving, it is reasonable to consider switching to thrice-weekly lipid polyene doses—with ultimate weaning down to twice-weekly doses—for maintenance therapy. For patients with mucormycosis who are receiving immunosuppressive medications, secondary antifungal prophylaxis is typically continued for as long as the immunosuppressive regimen is administered. Transitioning to azoles for chronic suppression is a reasonable alternative to continuing polyene therapy in this setting, with re-initiation of polyenes during periods of deep neutropenia.

One common source of error in the long-term management of mucormycosis is follow-up radiology. Analysis of data from the DEFEAT Mucor study indicated that early radiographic progression (within the first 2 weeks) did not predict long-term mortality. Changing the therapeutic plan based on early radiographic changes can result in therapeutic errors. For example, it is common for CNS Mucorales to cavitate in the brain parenchyma over time. This does not necessarily reflect therapeutic failure, but rather may reflect increased immune reactivity to the fungus, particularly in patients recovering from neutropenia or with removal of immune suppression. Thus, it may not be advisable to obtain serial radiographic studies in the short-term, and if such studies are obtained, caution should be used in reacting to their results. Greater emphasis should be placed on clinical response, particularly within the first 2–4 weeks after initiation of therapy.

PROGNOSIS

Over the past two decades, the prognosis of mucormycosis has substantially improved with aggressive antifungal therapy. Even CNS infection is often successfully treated. As mentioned, the key driver of outcome may be control of the patient's predisposing condition.

225 Superficial Fungal Infections

Joseph Pechacek, Carol A. Kauffman, Michail S. Lionakis

Fungal infections of the skin and skin structures are caused by molds and yeasts that do not invade deeper tissues but rather cause disease merely by inhabiting the superficial layers of skin, hair follicles, and nails. These agents cause the most common human fungal infections but only rarely cause serious infections.

MALASSEZIA INFECTIONS

Etiologic Agents, Epidemiology, and Pathogenesis *Malassezia* species, primarily *M. furfur* and *M. pachydermatis*, are lipophilic yeasts that generally cause only minor skin infections but, on occasion, can cause invasive infection. *Malassezia* species are part of the indigenous human microbiota found in the stratum corneum of the back, chest, scalp, and face—areas rich in sebaceous glands. The organisms do not invade below the stratum corneum and generally elicit little inflammation. Cutaneous interleukin (IL)-17 signaling controls *Malassezia* species in the skin, but excessive, *Malassezia*-induced IL-17 responses have been associated with exacerbating atopic inflammation.

Clinical Manifestations *Malassezia* species cause tinea versicolor (also called *pityriasis versicolor*), folliculitis, and seborrheic dermatitis. Tinea versicolor presents as flat round scaly patches of hypo- or hyperpigmented skin on the neck, chest, or upper arms. The lesions are usually asymptomatic but can be pruritic. They can be mistaken

for vitiligo, but the latter is not scaly. Folliculitis occurs on the back and chest and mimics bacterial folliculitis. Seborrheic dermatitis manifests as erythematous pruritic scaly lesions in the eyebrows, moustache, nasolabial folds, and scalp (dandruff). Seborrheic dermatitis can be severe in patients with AIDS. Fungemia and disseminated infection occur rarely with *Malassezia* species, and they almost always occur in premature neonates receiving parenteral lipid nutrition preparations.

Diagnosis *Malassezia* infections are diagnosed clinically in most cases. If scrapings are collected on a microscope slide on which a drop of potassium hydroxide has been placed, a mixture of budding, bottle-shaped yeasts and short septate hyphae is seen. To culture *Malassezia* from patients with suspected disseminated infection, sterile olive oil must be added to the medium.

Treatment and Prognosis Topical creams and lotions, including selenium sulfide shampoo, ketoconazole shampoo or cream, and terbinafine cream, are effective in treating *Malassezia* infections and are usually given for 2 weeks. Mild topical steroid creams are sometimes used to treat seborrheic dermatitis. For extensive disease, oral itraconazole or fluconazole (200 mg/day) can be used for 5–7 days. The rare cases of fungemia caused by *Malassezia* species are treated with amphotericin B (AmB) or an azole, such as voriconazole, prompt removal of central catheters, and discontinuation of parenteral lipid infusions. *Malassezia* skin infections are benign and self-limited, although recurrences are common. The outcome of systemic infection depends on the host's underlying conditions, but most infected neonates do well.

MUCOCUTANEOUS *CANDIDA* INFECTIONS

Candidiasis is discussed in **Chap. 222**, and this section briefly describes mucocutaneous manifestations of candidiasis.

Etiologic Agents, Epidemiology, and Pathogenesis The most common species responsible for mucocutaneous candidiasis—e.g., oral thrush, esophageal candidiasis, vulvovaginal candidiasis (VVC)—is *Candida albicans*. *Candida* species are commensal organisms residing primarily in the oral mucosa, gastrointestinal tract, and genitourinary tract with the skin being colonized in certain settings, such as after antibiotic use in the intensive care unit or by certain species such as *C. parapsilosis* or *C. auris*. *C. auris* is an emerging multidrug-resistant species with a propensity for long-term colonization of the human skin, health care environments, and medical devices and for causing nosocomial outbreaks. *C. auris* grows avidly in human sweat and colonizes deep skin layers including hair follicles. IL-17–producing lymphoid cells at mucocutaneous barrier sites such as T_H17 cells, γδ T cells, and innate lymphoid cells mediate control against *Candida*. Risk factors for oral thrush include inherited and pharmacologic defects of IL-17 signaling, AIDS, and conditions with excessive mucosal interferon γ responses such as autoimmune polyendocrine syndrome type 1. Antibiotic use, diabetes, and pregnancy are major risk factors for VVC. Skin candidiasis is uncommon and most often seen in inborn errors of immunity that cause chronic mucocutaneous candidiasis, primarily *STAT1* gain-of-function.

Diagnosis Diagnosis of oral thrush is generally clinical with white mucosal plaques that are removed with gentle scraping. Culture reveals the responsible *Candida* species. Biopsy of affected tissue may be needed to differentiate thrush from mimics such as leukoplakia. Biopsy of affected oral or esophageal tissue shows yeasts, pseudohyphae, and hyphae invading into the epithelium; observing only yeast forms superficial to epithelial tissue usually represents solely colonization. VVC is diagnosed with culture and microscopy of vaginal secretions collected via swabs. Skin and nail candidiasis is diagnosed by skin biopsy or nail clippings with culture and microscopy.

Treatment and Prognosis Mild oral thrush may be treated with topical agents such as nystatin suspension or clotrimazole troches, but moderate and severe disease or esophageal involvement should be treated with systemic, primarily azole therapy. VVC may be treated with topical or oral azoles. Newer options for VVC include the triterpenoid antifungal ibrexafungerp, which inhibits β-glucan, and oteseconazole, a long-acting tetrazole that cannot be used in patients of reproductive potential owing to potential fetal ocular toxicity.

DERMATOPHYTE INFECTIONS

Etiologic Agents, Epidemiology, and Pathogenesis The molds that cause skin infections in humans include the genera *Trichophyton*, *Microsporum*, and *Epidermophyton*. These organisms, which are not components of the normal skin microbiota, can live within the keratinized structures of the skin—hence the term *dermatophytes*. Dermatophytes occur worldwide, and infections with these organisms are extremely common with an estimated ~1 billion people affected globally. Some organisms cause disease only in humans and can be transmitted by person-to-person contact and by fomites, such as hairbrushes or wet floors, that have been contaminated by infected individuals. Several species cause infections in cats and dogs and can readily be transmitted from these animals to humans, and others are spread from contact with soil. The characteristic ring shape of cutaneous lesions is the result of the organisms' outward growth in a centrifugal pattern in the stratum corneum. Fungal nail invasion usually occurs through the lateral or superficial nail plates and then spreads throughout the nail; when hair shafts are invaded, the organisms can be found either within the shaft or surrounding it. Symptoms are caused by the inflammatory reaction elicited by fungal antigens and not by tissue invasion. Dermatophyte infections are restricted by IL-17 responses and occur more often in males; progesterone can inhibit dermatophyte growth.

Clinical Manifestations Dermatophyte infection of the skin is often called *ringworm*. This term is confusing because worms are not involved. *Tinea*, the Latin word for *worm*, describes the serpentine nature of the skin lesions. Tinea is a less confusing term and can be used with the name of the body part affected—e.g., tinea capitis (head), tinea pedis (feet), tinea corporis (body), tinea cruris (crotch), and tinea unguium (nails, more often termed *onychomycosis*).

Tinea capitis occurs most commonly in 3- to 7-year-old children. Children with tinea capitis usually present with well-demarcated scaly patches in which hair shafts are broken off right above the skin; alopecia can result. Tinea corporis manifests as well-demarcated, annular, pruritic, scaly lesions that undergo central clearing. Usually, one or several small lesions are present; however, in some patients, tinea corporis can involve much of the trunk. The rash should be differentiated from contact dermatitis, eczema, and psoriasis. Tinea cruris is seen almost exclusively in men. The perineal rash is erythematous and pustular, has a discrete scaly border, is without satellite lesions, and is usually pruritic. The rash must be differentiated from intertriginous candidiasis, erythrasma, and psoriasis.

Tinea pedis also is also more common among men. It usually starts in the web spaces of the toes; peeling, maceration, and pruritus are followed by development of a scaly pruritic rash along the lateral and plantar surfaces of the feet. Hyperkeratosis of the soles of the feet often ensues. Tinea pedis has been implicated in lower-extremity cellulitis, as streptococci and staphylococci can gain entrance to the tissues through fissures between the toes. Onychomycosis affects toenails more often than fingernails and is most common among persons who have tinea pedis. The nail becomes thickened and discolored and may crumble; onycholysis almost always occurs. Onychomycosis is more common in older adults and in persons with vascular disease, diabetes mellitus, and nail trauma. Fungal infection must be differentiated from psoriasis, which can mimic onychomycosis but usually has associated skin lesions.

Diagnosis Many dermatophyte infections are diagnosed by their clinical appearance. If the diagnosis is in doubt, scrapings should be taken from the edge of a lesion with a scalpel blade, transferred to a slide to which a drop of potassium hydroxide is added, and examined under a microscope for the presence of hyphae. Cultures are indicated if an outbreak is suspected or the patient does not respond to therapy.

Treatment and Prognosis Dermatophyte infections usually respond to topical therapy with azoles or terbinafine. Lotions or sprays

TABLE 225-1 Suggested Oral Treatment for Extensive Tinea Infections and Onychomycosis

ANTIFUNGAL AGENT	SUGGESTED DOSAGE	COMMENTS
Extensive Tinea Infection		
Terbinafine	250 mg/day for 1–2 weeks	Adverse reactions minimal with short treatment period
Itraconazole[a]	200 mg/day for 1–2 weeks	Adverse reactions minimal with short treatment period except for drug interactions
Onychomycosis		
Terbinafine	250 mg/day for 3 months	Slightly superior to itraconazole; monitor for hepatotoxicity
Itraconazole[a]	200 mg/day for 3 months *or* 200 twice daily for 1 week each month for 3 months	Drug interactions frequent; monitor for hepatotoxicity; rarely causes hypokalemia, hypertension, edema; use with caution in patients with congestive heart failure Other triazoles such as posaconazole may be considered as alternative therapy

[a]Itraconazole capsules require food and gastric acid for absorption, whereas itraconazole solution is taken on an empty stomach. The newer SUBA-itraconazole formulation exhibits improved oral bioavailability and reduced interpatient variability.

FIGURE 225-1 Several nodular lesions in a lymphangitic spread pattern that developed on the patient's arm after traumatic inoculation. Cultures from the biopsied lesion (*circle*) yielded growth of *Sporothrix schenckii*.

are easier than creams to apply to large or hairy areas. Particularly for tinea cruris, the affected area should be kept as dry as possible. When patients have extensive skin lesions, oral itraconazole or terbinafine can hasten resolution (Table 225-1). Terbinafine interacts with fewer drugs than itraconazole and is generally the first-line systemic agent.

Onychomycosis generally does not respond to topical therapy, although efinaconazole topical solution applied to the affected nail for as long as a year has been beneficial in several trials. Itraconazole and terbinafine both accumulate in the nail plate and can treat onychomycosis (Table 225-1). The major decision to be made regarding therapy is whether the extent of nail involvement justifies the use of systemic antifungal agents that may have adverse effects, may interact with other drugs, and are costly. Relapses of tinea cruris and tinea pedis are common and should be treated as early as possible with topical creams to avoid development of more extensive disease. Relapses of onychomycosis follow treatment in 25–30% of cases.

SPOROTRICHOSIS

Etiologic Agent, Epidemiology, and Pathogenesis *Sporothrix schenckii* complex comprises six closely related organisms; *S. schenckii* and *S. brasiliensis* are the species that cause most human infections. *S. globosa* has grown in importance in Asia. *Sporothrix* species are relatively intolerant to heat and are found worldwide in sphagnum moss, decaying vegetation, and soil. Sporotrichosis most commonly affects persons who participate in outdoor activities such as landscaping, gardening, and tree farming. Infected animals—such as dogs, armadillos, and most commonly cats—can transmit *S. schenckii* to humans. A large ongoing outbreak of sporotrichosis in Brazil caused by *S. brasiliensis* has been traced to cats, which are highly susceptible to this infection. Sporotrichosis is primarily a localized infection of skin and subcutaneous tissues that follows traumatic conidial inoculation. Osteoarticular sporotrichosis is uncommon, occurring most often in middle-aged men who abuse alcohol, and pulmonary sporotrichosis occurs almost exclusively in persons with chronic obstructive pulmonary disease following fungal inhalation. Dissemination occurs almost entirely in markedly immunocompromised patients, especially those with AIDS.

Clinical Manifestations and Differential Diagnosis Days or weeks after inoculation, a papule develops at the site and then usually ulcerates but is not very painful. Similar lesions develop sequentially along the lymphatic channels proximal to the original lesion (Fig. 225-1). Some patients develop a fixed cutaneous lesion that can be verrucous or ulcerative and that remains localized without lymphatic extension. The differential diagnosis of lymphocutaneous sporotrichosis includes nocardiosis (especially by *Nocardia brasiliensis*), tularemia, nontuberculous mycobacterial infection (especially by *Mycobacterium marinum*), and leishmaniasis. Osteoarticular sporotrichosis is usually monoarticular and can present as chronic synovitis or septic arthritis. Pulmonary sporotrichosis presents with cavitary or occasionally multifocal noncavitary pneumonia and must be differentiated from tuberculosis and other fungal pneumonias. Numerous ulcerated skin lesions, with or without spread to visceral organs (including the central nervous system [CNS]), are characteristic of disseminated sporotrichosis.

Diagnosis *S. schenckii* usually grows readily as a mold on Sabouraud's agar when material from a cutaneous lesion biopsy is incubated at room temperature. Histopathologic examination of biopsy material shows a mixed granulomatous and pyogenic reaction, and tiny oval or cigar-shaped yeasts sometimes can be seen with special stains.

Treatment and Prognosis Guidelines for the management of the various forms of sporotrichosis have been published by the Infectious Diseases Society of America (Table 225-2). Itraconazole is the drug of choice for cutaneous and lymphocutaneous sporotrichosis. Fluconazole is less effective, voriconazole is ineffective, and posaconazole has been used successfully in a small number of patients. Saturated solution of potassium iodide (SSKI) continues to be used for lymphocutaneous infection because of its low cost; however, SSKI is poorly

TABLE 225-2 Suggested Treatment for Sporotrichosis

DISEASE	FIRST-LINE THERAPY	ALTERNATIVES/COMMENTS
Cutaneous, lymphocutaneous	Itraconazole, 200 mg/day until 2–4 weeks after lesions resolve	SSKI, increasing doses[a] Terbinafine, 500 mg twice daily
Pulmonary, osteoarticular	Itraconazole, 200 mg twice daily for 12 months	Lipid AmB[b] for severe pulmonary disease until stable; then itraconazole
Disseminated, central nervous system	Lipid AmB[b] for 4–6 weeks	Itraconazole, 200 mg twice daily after AmB for 12 months Patients with AIDS: itraconazole maintenance, 200 mg/day until CD4+ T cell count is >200/μL for ≥12 months

[a]The starting dosage is 5–10 drops three times daily in water or juice. The dosage is increased weekly by 10 drops per dose, as tolerated, up to 40–50 drops three times daily. [b]The dose of lipid AmB is 3–5 mg/kg daily; the higher dose should be used when the central nervous system is involved.

Abbreviations: AmB, amphotericin B; SSKI, saturated solution of potassium iodide.

tolerated because of adverse reactions, including metallic taste, salivary gland swelling, rash, and fever. High-dose terbinafine may be effective for lymphocutaneous infection. Treatment for lymphocutaneous sporotrichosis is continued for 2–4 weeks after all lesions have resolved, usually for a total of 3–6 months. The success rate for treatment of lymphocutaneous sporotrichosis is 90–100%.

Pulmonary and osteoarticular forms of sporotrichosis are treated with itraconazole for at least 1 year. Severe pulmonary infection and disseminated sporotrichosis, including that involving the CNS, should be treated initially with amphotericin B (AmB), with a switch to itraconazole after improvement has been noted. Lifelong suppressive therapy with itraconazole is often required for patients with AIDS. These forms of sporotrichosis respond poorly to antifungal therapy.

EUMYCETOMA AND CHROMOBLASTOMYCOSIS

Etiologic Agents, Epidemiology, and Pathogenesis Dematiaceous or brown-black fungi, the common soil organisms that cause phaeohyphomycoses, contain melanin, which causes the hyphae and conidia to be darkly pigmented. The term *phaeohyphomycosis* is used to describe any infection with a pigmented mold. This definition encompasses two cutaneous syndromes discussed herein—eumycetoma and chromoblastomycosis—and all other types of invasive infections caused by these organisms, which are discussed in **Chap. 226**. It is important to note that eumycetomas can be caused by hyaline molds and by brown-black molds and that only ~50% of all mycetomas are due to fungi. Actinomycetes cause the remainder **(Chap. 180)**.

The most common cause of eumycetoma is *Madurella* species. *Fonsecaea*, *Phialophora*, and *Cladophialophora* species are responsible for most cases of chromoblastomycosis and exhibit a pathogenic muriform phase. These infections are most often seen in resource-limited rural settings and affect mostly adult men. Inoculation is via minor, often unnoticed, trauma with soil or plant material contamination. Although exposure to these pathogens is common, the development of clinical disease is infrequent. Eumycetoma is found predominantly in tropical and subtropical areas with most cases reported from Sudan, Mexico, and India. Neutrophils mediate early inflammation around the hyphae-containing grains, and macrophages form granulomas at the site of infection.

Chromoblastomycosis is also prevalent in tropical and subtropical regions, with most cases reported from Latin America, Madagascar, and China. A broader geographic distribution is seen with certain species such as *Cladophialophora carrionii*, which thrives in semiarid climates and is a chief cause of chromoblastomycosis in Australia. Following traumatic inoculation, transformation of the fungus into thick-walled, multiseptated, muriform cells ensues. These cells can evade phagocytosis, resulting in chronic disease development.

Clinical Manifestations and Differential Diagnosis Eumycetoma—commonly called Madura foot—is a chronic cutaneous and subcutaneous infection that usually occurs on the lower extremities and manifests with swelling, sinus tract development, and appearance of grains that are actually fungal colonies discharged from the sinus tract. As the infection progresses, adjacent fascia and bony structures may become involved. The disease is indolent and disfiguring, progressing slowly over years. Complications include fractures of infected bone and bacterial superinfection.

Chromoblastomycosis is an indolent subcutaneous infection characterized by nodular, verrucous, or plaque-like painless lesions that occur predominantly on the lower extremities and grow slowly over months to years. There is hardly ever extension to adjacent structures, as is seen with eumycetoma. Long-term consequences include bacterial superinfection, chronic lymphedema, and (rarely) the development of squamous cell carcinoma.

Diagnosis A tentative clinical diagnosis of mycetoma can be made when a patient presents with a lesion characterized by swelling, sinus tracts, and grains. Histopathologic examination and culture are necessary to confirm that the etiologic agent is a mold and not an actinomycete. In chromoblastomycosis, the diagnosis rests on the histologic demonstration of muriform cells or "sclerotic bodies" in tissues; culture establishes the causative pigmented mold. In culture-negative cases, PCR-based detection of the 28S ribosomal subunit or the rRNA internal transcribed spacer (ITS) may assist with identification.

Treatment and Prognosis Treatment of eumycetoma and chromoblastomycosis involves both surgical excision of lesions and antifungal therapy. Surgical removal of lesions is most effective if performed before extensive spread has occurred and is strongly recommended as a mainstay of treatment for both syndromes. In chromoblastomycosis, cryosurgery, heat therapy, and laser therapy have been used with variable success. Optimal antifungal therapy may vary depending on the causative fungal agent. Eumycetoma has been treated with itraconazole, voriconazole, posaconazole, and less commonly terbinafine with variable success rates. Long-term antifungal therapy is required, and cost or tolerability of these agents may limit their use. Itraconazole, terbinafine, and flucytosine have been used to treat chromoblastomycosis, again with variable success and with cost or tolerability limiting long-term treatment. Muriform cells may respond to antifungal therapy differently from hyphal forms, so caution is needed in interpreting in vitro susceptibility results. Species identification may be useful in determining optimal therapy, as different dematiaceous molds can differ in their susceptibilities to azoles, AmB, and flucytosine.

226 Uncommon Disseminated Fungal Infections

Joseph Pechacek, Carol A. Kauffman, Michail S. Lionakis

ENDEMIC MYCOSES (DIMORPHIC FUNGI)

Dimorphic fungi—so named for their ability to convert between mold and yeast forms (or spherules or adiaspores in the case of *Coccidioides* and *Emmonsia crescens*, respectively) in a temperature-dependent manner—are found in discrete environmental niches as molds that produce conidia, which are the infectious form. In infected tissues and at temperatures of >35°C, they are found in the yeast form. The most common invasive endemic mycoses in the United States—histoplasmosis, coccidioidomycosis, and blastomycosis—are discussed in **Chaps. 218–220**, respectively, and sporotrichosis is discussed in **Chap. 225**.

PARACOCCIDIOIDOMYCOSIS

Etiologic Agent, Epidemiology, and Pathogenesis The species constituting the *Paracoccidioides brasiliensis* complex and the less frequently reported *Paracoccidioides lutzii* are thermally dimorphic fungi found in humid areas of Central and South America. The highest incidence of *Paracoccidioides* infections is seen in Brazil, Colombia, Venezuela, and Ecuador although infections have been identified as far north as Mexico. Most cases are found in an ecological niche

characterized by high rainfall and humidity and the presence of tropical or subtropical forests. A striking male-to-female ratio ranges from 14:1 to as high as 70:1 in various reports; this observation is largely accounted for by chronic disease, as the acute form of the infection lacks this stark male predominance. Most patients are middle-aged or elderly men from rural areas. Paracoccidioidomycosis develops after the inhalation of aerosolized conidia encountered in the environment into the lungs. In this early stage, neutrophils and macrophages play an important role in controlling the infection and preventing dissemination. Granulomas may be found in the lung and at sites of extrapulmonary dissemination in infected patients. Disease rarely develops at the time of the initial infection but appears years later, presumably after reactivation of a latent infection. Inborn errors of immunity affecting the interleukin (IL)-12/interferon (IFN)-γ signaling axis predispose to severe, disseminated paracoccidioidomycosis.

Clinical Manifestations The majority of patients exposed to *Paracoccidioides* develop asymptomatic pulmonary disease, which is contained and does not become clinically apparent. When clinical disease develops, two major syndromes are associated with paracoccidioidomycosis: the acute or juvenile form and the chronic or adult form. The acute form is uncommon, develops typically in persons <30 years old, and manifests primarily as disseminated infection of the reticuloendothelial system. The interval from initial fungal exposure to developing the acute form of paracoccidioidomycosis varies from as early as 45 days to as late as several months. Immunocompromised individuals also can develop this type of rapidly progressive disease. Peripheral eosinophilia is often seen in this form of the disease. The chronic form of paracoccidioidomycosis accounts for ~90% of cases and predominantly affects older men. The primary manifestations are progressive pulmonary disease, primarily in the lower lobes, with fibrosis and ulcerative and nodular mucocutaneous lesions that occur primarily in mucous membranes of the upper respiratory tract and that must be differentiated from leishmaniasis **(Chap. 233)** and squamous cell carcinoma **(Chap. 82)**. Metastatic foci of paracoccidioidomycosis may also occur via hematogenous or lymphatic spread, most often involving the central nervous system (CNS), skin, or adrenal glands, which can lead to the development of adrenal insufficiency.

Diagnosis The diagnosis is established by growth of the mold form of *Paracoccidioides* in culture at room temperature. A presumptive diagnosis can be made by detection of the distinctive thick-walled yeast in tissue biopsy specimens, which appears as a central yeast with multiple daughter cells attached circumferentially via narrow-necked buds and is classically described as a mariner's wheel. Serologic testing also can aid in diagnosis, although it should be noted that certain available tests may not detect *P. lutzii*.

Treatment and Prognosis Itraconazole is the treatment of choice for paracoccidioidomycosis **(Table 226-1)** owing to its longer-standing experience in this disease, although voriconazole and posaconazole also are active in vitro and have been effective in small patient cohorts. Sulfonamides have been used for years and are the least costly agents; however, the response is slower and the relapse rate higher. Seriously ill patients, such as those with respiratory failure, should be initially treated with amphotericin B (AmB) with subsequent azole therapy following clinical improvement. Patients with paracoccidioidomycosis have an excellent response to therapy, regardless of the causative species, but pulmonary fibrosis can be progressive in those with chronic disease.

TABLE 226-1 Suggested Treatment for Uncommon Disseminated Fungal Infections

DISEASE	FIRST-LINE THERAPY	ALTERNATIVES/COMMENTS
Paracoccidioidomycosis		
Chronic (adult form)	Itraconazole[a], 100–200 mg/day for 6–12 months	Voriconazole[a], 200 mg twice daily for 6–12 months Posaconazole[a], 300 mg/day for 6–12 months TMP-SMX, 160/800 mg twice daily for 12–36 months
Acute (juvenile form)	Lipid AmB[b] until improvement	Itraconazole[a], 200 mg twice daily after AmB for 12 months Voriconazole or posaconazole at doses noted above may be used
Talaromycosis		
Mild or moderate	Itraconazole[a], 200 mg twice daily for 12 weeks	Voriconazole[a], 200 mg twice daily Posaconazole[a] 300 mg/day
Severe	Lipid AmB[b] until improvement	Itraconazole[a], 200 mg twice daily after AmB for 12 weeks Voriconazole or posaconazole may be considered as an alternative
Maintenance therapy (AIDS)	Itraconazole, 200 mg/day until CD4+ T cell count is >100/μL for ≥6 months	
Emergomycosis (Emmonsiosis)		
Mild or moderate	Itraconazole[a] 200 mg twice daily for 12 weeks	Voriconazole[a], 200 mg twice daily Posaconazole[a] 300 mg/day
Severe	Lipid AmB[b] until improvement	Itraconazole[a], 200 mg twice daily after AmB for 12 weeks Voriconazole or posaconazole may be considered as an alternative
Phaeohyphomycosis	Voriconazole[a], 200 mg twice daily Itraconazole[a], 200 mg twice daily Posaconazole[a], 300 mg/day	Lipid AmB may be effective against some mold species
Fusariosis	Voriconazole[a], 200–300 mg twice daily Lipid AmB, 5 mg/kg/day Posaconazole[a], 300 mg/day	Lipid AmB plus voriconazole or posaconazole is used by some physicians for initial therapy. Investigational olorofim or fosmanogepix may be considered if available.
Scedosporiosis and lomentosporiosis	Voriconazole[a], 200–300 mg twice daily Posaconazole[a], 300 mg/day	Not susceptible to AmB. *Lomentospora prolificans* is resistant to almost all commercially available antifungal drugs. Investigational olorofim or fosmanogepix may be considered if available.
Trichosporonosis	Voriconazole[a], 200–300 mg twice daily	Posaconazole[a], 300 mg/day

[a]Dosing should be adjusted for appropriate drug trough levels. [b]The dose of lipid AmB is 3–5 mg/kg daily; the higher dose should be used when the central nervous system is involved.

Abbreviations: AmB, amphotericin B; TMP-SMX, trimethoprim-sulfamethoxazole.

TALAROMYCOSIS

Etiologic Agent, Epidemiology, and Pathogenesis *Talaromyces marneffei* (formerly *Penicillium marneffei*) is a thermally dimorphic fungus that is endemic in the soil in certain areas of Vietnam, Thailand, and other southeastern Asian countries. The epidemiology of talaromycosis (formerly *penicilliosis*) is linked to bamboo rats that are infected with the fungus but rarely manifest disease. The disease occurs most often among persons living in rural areas in which the rats are found, but there is no evidence for transmission of the infection directly from rats to humans. Accidental laboratory inoculation has also been reported. Infection is rare in immunocompetent hosts, and most cases are reported in persons who have advanced AIDS. Other immune deficiencies associated with a higher risk of developing talaromycosis include corticosteroid use, solid organ transplantation, idiopathic CD4 lymphocytopenia, inborn errors of immunity affecting the IL-12/IFN-γ signaling axis, and neutralizing autoantibodies against IFN-γ. Infection is presumed to result from the inhalation of conidia from the environment though a definitive environmental reservoir that has yet to be identified. The organism converts to the yeast phase in the lungs and then spreads hematogenously throughout the reticuloendothelial system. IFN-γ–primed monocytes/macrophages and neutrophils both play a role in control of *Talaromyces* via fungal phagocytosis and killing.

Clinical Manifestations The clinical manifestations of talaromycosis mimic those of disseminated histoplasmosis and include fever, fatigue, weight loss, dyspnea, lymphadenopathy, hepatosplenomegaly, and mucocutaneous lesions, which appear as papules that often umbilicate and resemble molluscum contagiosum (Chap. 201). Patients with mild talaromycosis may present with isolated skin lesions.

Diagnosis Talaromycosis is diagnosed by culture of *T. marneffei* from blood or from biopsy samples of skin, bone marrow, or lymph node. The organism usually grows within 1 week as a mold producing a distinctive red pigment that diffuses into the agar. Histopathologic examination of tissues, blood smears, or material from skin lesions shows oval or elliptical yeast-like organisms that reproduce via bipolar fission (i.e., appearing as two elliptical yeasts separated by a central septation) and can quickly establish a presumptive diagnosis. Intramacrophage yeast-like organisms can also be seen on tissue or lymph node sections or bone marrow aspirates. *T. marneffei*–specific antigen and polymerase chain reaction (PCR)-based assays are under investigation.

Treatment and Prognosis Disseminated talaromycosis is usually fatal if not treated. With treatment, the mortality rate is ~10%. For mild or moderate infection, itraconazole is the drug of choice. Voriconazole also can be used, and posaconazole has good in vitro activity and has been successfully used in few case reports. Severe infection should be treated with AmB until clinical improvement occurs; then therapy can be changed to an effective triazole (Table 226-1). For patients with AIDS, suppressive therapy with itraconazole is recommended until the CD4+ T cell count has been >100 cells/μL for at least 6 months. Primary prophylaxis may be considered in certain patients with AIDS in endemic areas who are unable to receive effective antiretroviral therapy.

EMERGOMYCOSIS (DISSEMINATED EMMONSIOSIS)

Etiologic Agents, Epidemiology, and Pathogenesis As the name implies, *Emergomyces* (several members of which are formerly of the genus *Emmonsia*) is a genus of emerging thermally dimorphic fungi consisting of seven species, six of which have been shown to cause human disease. Among them, *E. pasteurianus* is the most geographically widespread species, and *E. africanus* has been the most studied given its relatively high incidence of infection in South Africa. Infection by *Emergomyces* species have now been reported in Europe, Asia (primarily in China and India), Africa (Uganda and South Africa), and North America (United States and Canada). Although *Emergomyces* has yet to be cultured from the environment and no animal reservoir has been identified thus far, infection is thought to begin, as with other dimorphic fungi, through inhalation of conidia released by the mold form of the pathogen in the environment. The organism then undergoes temperature-dependent transformation into the invasive yeast form within the lungs and disseminates hematogenously to cause systemic disease in immunocompromised patients. Clinically apparent disease appears largely restricted to patients with impaired cellular immunity, including those with AIDS, hematologic malignancy, or solid organ transplantation, and recipients of immunosuppressive therapy such as corticosteroids.

Clinical Manifestations Pulmonary disease can manifest with parenchymal lesions and/or endobronchial lesions. Although isolated lung involvement has been described, the vast majority of patients with pulmonary disease have concomitant cutaneous involvement, which most frequently manifests with disseminated ulcers, papules, or nodules. Dissemination to the liver, bone marrow, and lymph nodes may also occur, whereas dissemination to the CNS is rare.

Diagnosis Diagnosis is made by culturing *Emergomyces* species from blood or tissue or by showing tissue invasion upon histologic examination. *Emergomyces* may grow from aerobic blood culture bottles within 7 days; the use of fungal isolator culture bottles may improve sensitivity. The yeast form appears on histopathology as intracellular and extracellular round or ovoid yeasts with narrow-based budding that may be misidentified as *Histoplasma capsulatum*; therefore, definitive identification is made on mold phase in culture. It is worth noting that the commercially available *Histoplasma* antigen test has a high degree of cross-reactivity with *Emergomyces* species.

Treatment and Prognosis Given the lack of clinical trials to guide optimal treatment of emergomycosis, treatment recommendations are currently based on expert opinion and largely mirror treatment recommendations for disseminated histoplasmosis. Immunosuppressed patients with emergomycosis should initiate treatment with AmB until clinical improvement occurs followed by therapy with a mold-active azole. Itraconazole is the azole most often used, although in vitro susceptibility testing results of voriconazole and posaconazole have been favorable. In case reports, itraconazole monotherapy has been used successfully for mild disease. Prolonged secondary prophylaxis may be considered in patients without a reversible cause of immunodeficiency.

ADIASPIROMYCOSIS

Adiaspiromycosis is a rare infection caused predominantly by the mold *Emmonsia crescens*, which is found in soil. Occupational dust exposure is a major risk factor. Human infections have been broadly reported including from the Americas, Europe, and Asia. The lungs are by far the most frequently affected organ, although cases of ocular and appendiceal disease have been described. The disease is defined by the presence of adiaspores in affected tissue, which results in a marked inflammatory response. After exposure to conidia via inhalation, ingestion, or mucosal contact with dust, the host mounts an immune response leading to the development of noncaseating granulomas. Once within host tissue and driven by thermal pressure, the conidia enlarge to thick-walled adiaspores measuring up to 500 μm in diameter that are incapable of budding or replication. Clinical sequelae, including respiratory failure, are caused by the host's granulomatous inflammatory response in infected tissue. As *E. crescens* has not been cultured from human tissue with adiaspiromycosis, diagnosis depends upon histopathologic identification of adiaspores with surrounding granulomas, often with the assistance of molecular methods. The disease is often self-limiting. However, in severe disease, corticosteroids, with or without antifungal therapy, have been used successfully in several reports.

MOLD INFECTIONS

Molds produce conidia or spores, which cause infection via inhalation or traumatic skin inoculation. In infected tissues, filamentous structures termed *hyphae* form. The most common invasive mold infections—aspergillosis and mucormycosis—are discussed

in Chaps. 223 and 224, respectively. Dematiaceous or brown-black molds cause phaeohyphomycoses that can be either localized or disseminated infections, the latter mostly in immunocompromised patients. Three genera of hyaline (nonpigmented) molds, *Fusarium*, *Scedosporium*, and *Lomentospora*, have become prominent pathogens among immunocompromised patients. Infections with these fungi mimic aspergillosis in their clinical manifestations and their histopathologic appearance in tissues.

PHAEOHYPHOMYCOSES

Dematiaceous or brown-black fungi cause phaeohyphomycoses. The term *phaeohyphomycosis* is used to describe any infection with a melanin-producing fungus with filamentous growth. Melanin is a virulence factor for all pigmented molds. Most dematiaceous fungi cause localized subcutaneous infections after direct inoculation. Disseminated infections and serious focal visceral infections can occur in immunocompetent individuals but are much more often seen in immunocompromised patients. Two specific cutaneous phaeohyphomycoses—eumycetoma and chromoblastomycosis—are discussed in Chap. 225.

Etiologic Agents, Epidemiology, and Pathogenesis A large number of genera and species of pigmented molds can cause human infection. Most are found in the soil or on plants, and some cause economically important plant diseases. *Alternaria*, *Exophiala*, *Curvularia*, *Cladophialophora*, *Bipolaris*, and *Wangiella* species are among the more common pigmented molds reported to cause human infection. Infections with dematiaceous molds are acquired by traumatic inoculation into the eye or through the skin, by inhalation, or by injection of contaminated medication. In 2012, *Exserohilum* species caused a large outbreak in the United States of severe—and in some patients fatal—infections of the CNS following the injection of methylprednisolone contaminated with this fungus. Subcutaneous infections follow traumatic inoculation and are frequently caused by *Curvularia*, *Exophiala*, and *Phialophora*, among other genera. Several organisms, specifically *Cladophialophora bantiana* and *Rhinocladiella mackenziei*, are neurotropic and likely to cause CNS infection. When a patient is immunocompromised or when a pigmented mold is injected directly into a deep structure, these organisms become opportunistic pathogens, invading blood vessels and mimicking better-known opportunistic infections, such as aspergillosis.

Disseminated phaeohyphomycosis may occur in patients with solid organ or hematopoietic stem cell transplantation or after corticosteroid use. It has also been described in patients with autosomal recessive deficiency in CARD9, an intracellular adaptor protein that relays fungus-sensing signals from multiple cell-surface C-type lectin receptors (CLRs). A recent report indicated that ~70% of putatively immunocompetent patients who developed disseminated and brain phaeohyphomycosis carried deleterious variants in *CLEC7A*, the gene that encodes for the CARD9-coupled CLR Dectin-1, which recognizes fungal cell wall β-glucan. Dectin-1 and CARD9 protect against this infection by mediating the production of proinflammatory cytokines in response to fungal infection, promoting macrophage fungal killing.

Clinical Manifestations Dematiaceous molds are the most common cause of allergic fungal sinusitis and a less common cause of invasive fungal sinusitis. Keratitis occurs with traumatic corneal inoculation. Even in many immunocompromised patients, inoculation through the skin generally produces only localized nodular lesions at the entry site. Other immunocompromised patients develop pneumonia, brain abscess, or disseminated infection. Patients with brain abscess often have no other signs of dissemination at the time of diagnosis and typically present with an indolent course. Certain species, such as *Cladophialophora bantiana*, exhibit a propensity for intraventricular spread within the CNS. In the *Exserohilum* outbreak mentioned above, epidural injections of fungus-contaminated glucocorticoids led to meningitis, basilar stroke, epidural abscess and phlegmon, vertebral osteomyelitis, and arachnoiditis.

Diagnosis The specific diagnosis of infection with a pigmented mold is established by growth of the organism in culture. Histologically, observation of melanized hyphal forms appearing golden-brown on biopsy specimens stained with hematoxylin and eosin supports the diagnosis of phaeohyphomycosis. Specialized melanin stains, such as the Fontana-Masson stain, highlight melanized fungal structures in infected tissues and provide important diagnostic support (Fig. 226-1). PCR assays are increasingly used in the diagnosis of infection due to dematiaceous molds but are available only through fungal reference laboratories.

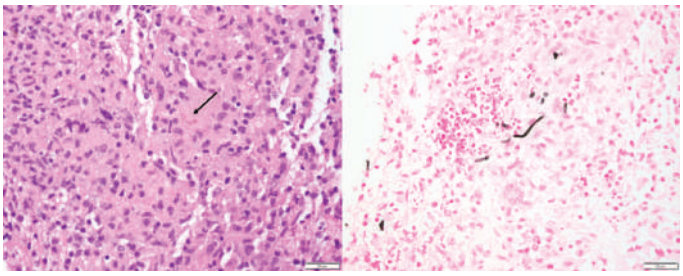

FIGURE 226-1 Histologic stains revealing pigmented mold from brain biopsy of a man with multifocal brain lesions. Cultures grew *Cladophialophora bantiana*. Images show tissue stained with hematoxylin and eosin (*left panel*) showing golden-brown pigmented hyphae (*arrow*) within multinucleated giant cells and associated neutrophilic infiltrate and Fontana-Masson stain (*right panel*) highlighting the melanin found in the cell wall of this organism. Scale bars, 20 μm. *(Images taken by Dr. Stefania Pittaluga, NCI.)*

Treatment and Prognosis Surgical debridement is vital for the treatment of phaeohyphomycosis in addition to antifungal treatment, which may need to be prolonged, especially in patients with CNS involvement. The choice of antifungal agent to treat disseminated and focal visceral infections with brown-black molds is based on the location and extent of the infection, in vitro test results, and clinical experience with the specific infecting organism. AmB is not effective against many of these organisms but has been used successfully against some species (Table 226-1). Itraconazole, voriconazole, or posaconazole can be used in the treatment of localized infections. Voriconazole has been the preferred azole when infections involve the CNS because it reaches adequate concentrations at that anatomic site; recent reports support posaconazole as an alternative azole. For certain pigmented molds, such as *C. bantiana*, flucytosine may have a role in addition to AmB or an azole. Disseminated and focal visceral infections, especially those involving the CNS, are associated with high mortality rates.

FUSARIOSIS

Etiologic Agent, Epidemiology, and Pathogenesis *Fusarium* species, which are found worldwide in soil and on plants, have emerged as major opportunistic pathogens in markedly immunocompromised patients. Strains of the *F. solani* complex are most commonly responsible for human infections, followed by *F. oxysporum*, *F. proliferatum*, and other species. *Fusarium* are molds with distinctive banana-shaped macroconidia. While *Fusarium* keratitis and onychomycosis can occur in immunocompetent patients, disseminated disease develops in immunodeficient patients. An outbreak of severe *Fusarium* keratitis among soft contact lens wearers was traced back to a particular brand of contact lens solution and individual contact lens cases that had been contaminated with this mold. In 2022 and 2023, two separate outbreaks of *F. solani* meningitis were reported in previously healthy young women who had received epidural anesthesia for plastic surgery procedures at two private clinics in Mexico. The case-fatality rate was ~50%.

Disseminated infection is reported most often in patients who have a hematologic malignancy, are neutropenic, have received hematopoietic stem cell or solid organ transplantation or corticosteroids, or have severe burn wounds. Neutrophils are the most critical cells for protection against fusariosis; hence the correlation with profound and prolonged neutropenia and susceptibility to disseminated infection. Neutrophil-derived reactive oxygen species are partly responsible for effective host defense against *Fusarium*. Patients with chronic granulomatous disease (CGD), who carry deleterious mutations in the NADPH oxidase complex that impair the phagocyte oxidative burst,

are at risk for fusariosis, albeit with far lower frequency compared with aspergillosis. Several studies have shown that the prognosis of fusariosis in neutropenic patients is significantly improved in those who recovered their neutrophil counts relative to those who remained persistently neutropenic.

Exposure to *Fusarium* can be through inhalation of conidia or direct inoculation via trauma, but disseminated disease can also occur secondary to pre-existing local disease, such as sinusitis or onychomycosis. For example, the presence of *Fusarium* onychomycosis preceding allogeneic hematopoietic stem cell transplantation has been associated with a higher risk of developing disseminated fusariosis post-transplantation.

Clinical Manifestations In immunocompetent persons, *Fusarium* species cause localized infections of various organs. These organisms are a common cause of fungal keratitis, which can extend into the anterior chamber of the eye, cause loss of vision, and require corneal transplantation. Onychomycosis due to *Fusarium* species, while a potential source of discomfort in immunocompetent patients, is a source of subsequent hematogenous dissemination and should be aggressively sought and treated in neutropenic patients. In profoundly immunocompromised patients, fusariosis is angioinvasive, and clinical manifestations mimic those of aspergillosis. Pulmonary infection is characterized by multiple nodular lesions that are best identified on CT scan. Fusariosis typically presents with persistent fever in neutropenic patients despite the administration of broad-spectrum antibiotics. Disseminated fusariosis differs from disseminated aspergillosis in that skin lesions are extremely common with fusariosis and may develop shortly after or even concurrently with the development of fever; the lesions are nodular or necrotic, are usually painful, and may appear over time in different locations **(Fig. 226-2)**.

Diagnosis The diagnostic approach usually includes both documentation of the growth of *Fusarium* species from involved tissue and demonstration of invasion by histopathologic techniques that show acute angle septate hyphae in tissues. The organism is difficult to differentiate from *Aspergillus* species in tissues; therefore, identification with culture is imperative. An extremely helpful diagnostic clue is growth in blood cultures, which are positive in as many as 50% of patients with disseminated fusariosis. A positive blood culture may lead to rapid identification; subsequent rapid growth on agar reveals the characteristic banana-shaped macroconidia of *Fusarium*. Further identification of the species and antimicrobial susceptibility testing, generally in a reference laboratory, may aid in choosing the most appropriate therapy.

Treatment and Prognosis *Fusarium* species are resistant to many antifungal agents. A lipid formulation of AmB, voriconazole, or posaconazole is recommended. Many physicians use both a lipid formulation of AmB and either voriconazole or posaconazole because susceptibility information is not standardized and is not always predictive of clinical response, bearing in mind that the prognosis is largely dictated by the degree of immune restoration. *F. solani* complex is frequently resistant to all azoles, while other species may have lower minimum inhibitory concentrations (MICs) to voriconazole and posaconazole. AmB is the most active antifungal drug against *Fusarium*; however, the MICs are relatively high for these organisms compared with other molds (Table 226-1). Mortality rates for disseminated fusariosis can be as high as 85%, with survival dependent on reversal of neutropenia. With the improved antifungal therapy now available, mortality rates have fallen to ~50%. However, if neutropenia persists, the mortality rate approaches 100%.

Two newer investigational antifungal agents show promise for the treatment of fusariosis. Fosmanogepix, which inhibits fungal Gwt1 and glycosylphosphatidylinositol–mannoprotein synthesis and anchoring, exhibits in vitro activity against *F. solani*, including against strains that are resistant to all available antifungals; it has been reported to successfully treat a few patients with meningeal and disseminated fusariosis. Olorofim, which inhibits fungal dihydroorotate dehydrogenase and pyrimidine synthesis, has shown favorable, but strain-specific, activity against *F. solani* complex in vitro.

FIGURE 226-2 Painful necrotic foot lesion that developed over a week in a woman with acute leukemia who had been neutropenic for 2 months. *Fusarium* species grew from a punch biopsy. *(Courtesy of Dr. Nessrine Ktaich.)*

SCEDOSPORIOSIS AND LOMENTOSPORIOSIS

Etiologic Agent, Epidemiology, and Pathogenesis *Scedosporium apiospermum* complex, which is composed of several related species, is reported more often as a cause of human infection than *Lomentospora prolificans*, formerly *Scedosporium prolificans*, but both are major emerging opportunistic pathogens in immunocompromised hosts and can cause pneumonia, disseminated infection, and brain abscess. Organisms of the *S. apiospermum* complex are found worldwide in temperate climates in tidal flats, swamps, ponds, manure, and soil. *L. prolificans* is also found in soil but is more geographically restricted with a greater representation of reported infections from Australia and Spain. Infection occurs predominantly through inhalation of conidia, but direct traumatic inoculation through the skin or the eye can also occur. *S. apiospermum* infections of the lungs and CNS have been described in putatively immunocompetent patients following near-drowning accidents, likely owing to the associated heavy burden of fungal exposure from contaminated water.

Clinical Manifestations Among immunocompetent persons, *Scedosporium* and *Lomentospora* species are a prominent cause of eumycetoma **(Chap. 225)**. Keratitis resulting from accidental corneal inoculation is a sight-threatening infection. Traumatic inoculation during accidents may also lead to deep-seated infections, such as osteoarticular infections including septic arthritis, in immunocompetent patients. In patients who have hematologic malignancies, especially those with acute leukemia and prolonged neutropenia, recipients of solid organ or hematopoietic stem cell transplants, CGD patients, and patients receiving corticosteroids, these organisms are angioinvasive and can cause pneumonia and extrapulmonary dissemination, with a propensity for CNS spread. Pulmonary infection mimics that of aspergillosis both clinically and in appearance on CT scan: nodules, cavities, and lobar infiltrates are common radiographic findings. Contiguous spread from the lung to adjacent anatomic sites, such as the vertebrae, has rarely been described. Disseminated infection often involves the heart, brain, and many other organs. Skin lesions are not as common or as painful as those in patients with fusariosis.

Diagnosis Diagnosis depends on the growth of *Scedosporium* or *Lomentospora* species from infected tissue and the histologic demonstration of acute-angle septate hyphae invading tissues. Culture evidence is essential because these molds are difficult to morphologically differentiate from *Aspergillus* in tissues. Demonstration of tissue invasion is essential because these ubiquitous environmental molds can be mere contaminants or colonizers in the respiratory tract, especially in persons with bronchiectasis. As with *Fusarium*, *L. prolificans* can grow in blood cultures, but *S. apiospermum* usually does not.

Treatment and Prognosis *Scedosporium* and *Lomentospora* species are intrinsically resistant to AmB, echinocandins, and some azoles. Voriconazole has been the agent of choice for *S. apiospermum*, and posaconazole has been increasingly used for this infection (Table 226-1). *L. prolificans* is resistant in vitro to almost every commercially available antifungal agent; the addition of agents such as terbinafine to a voriconazole regimen has been attempted because in vitro data suggest possible synergy between these two agents against some strains of *L. prolificans*. Mortality rates for invasive *S. apiospermum* infection are ~50%, but those for invasive *L. prolificans* infection remain as high as 85–100%. The novel antifungal agents fosmanogepix and olorofim have shown in vitro activity against both *S. apiospermum* and *L. prolificans* and have demonstrated efficacy in preclinical mouse models of these infections. Ongoing clinical trials for these agents will help determine their clinical efficacy in infected patients.

YEAST INFECTIONS

In addition to the far more common human pathogenic yeasts *Candida* and *Cryptococcus*, which are discussed in **Chaps. 221** and **222** the yeast-like fungus *Trichosporon* has emerged as a significant opportunistic pathogen among immunocompromised patients.

TRICHOSPORONOSIS

Etiologic Agent, Epidemiology, and Pathogenesis The genus *Trichosporon* encompasses many species, some of which cause localized infection of hair and nails; white piedra is a superficial infection of the hair and scalp caused by *T. ovoides* that is characterized by the appearance of white nodules along the hair shaft. The most common species responsible for invasive infection is *Trichosporon asahii,* although other species also can cause disseminated disease. *Trichosporon* species grow as yeast-like colonies in vitro; in vivo, however, hyphae, pseudohyphae, and arthroconidia can be seen in addition to yeast forms. These yeasts are commonly found in soil, sewage, and water and in rare instances can colonize the human skin and the gastrointestinal and respiratory tracts. Most infections follow inhalation or entry via central venous catheters. The presence of foreign material is a risk factor for trichosporonosis, as both catheter-associated infections and prosthetic cardiac valve infections have been described. Systemic infection occurs almost exclusively in immunocompromised hosts, especially those who have hematologic malignancies, are neutropenic, have received a solid organ or hematopoietic stem cell transplantation, or are receiving corticosteroids. Severe neutropenia is a major risk factor for disseminated disease. Myeloid phagocytes and their oxidative burst are critical for protection against *Trichosporon*, as illustrated by the development of invasive trichosporonosis in patients with CARD9 deficiency or CGD.

Clinical Manifestations Disseminated trichosporonosis resembles invasive candidiasis, and fungemia is often the initial manifestation of infection typically presenting with fever. Pneumonia, skin lesions, and sepsis are common, although many patients can present without clinically apparent lung infection. The skin lesions in disseminated disease begin as papules or nodules surrounded by erythema and progress to central necrosis. Renal involvement is common in disseminated disease and may cause funguria and hematuria. A rare chronic form of infection mimics hepatosplenic candidiasis, now known as chronic disseminated candidiasis.

Diagnosis The diagnosis of systemic *Trichosporon* infection is established by growth of the organism from infected tissues or from blood. Histopathologic examination of a skin lesion showing a mixture of yeast forms, arthroconidia, pseudohyphae, and hyphae can lead to an early presumptive diagnosis of trichosporonosis. The presence of arthroconidia in particular can help differentiate trichosporonosis from candidemia. The serum cryptococcal antigen latex agglutination test may be positive in patients with disseminated trichosporonosis because *T. asahii* and *Cryptococcus neoformans* share polysaccharide antigens.

Treatment and Prognosis Rates of response to AmB have been disappointing, and many *Trichosporon* isolates are resistant to AmB in vitro. Voriconazole has been the antifungal agent of choice (Table 226-1). The mortality rates for disseminated *Trichosporon* infection have been as high as 70% but are decreasing with the use of voriconazole; however, neutrophil recovery is vital in overcoming this infection, and mortality rates with persistent neutropenia remain very high despite antifungal therapy.

227 *Pneumocystis* Infections

Alison Morris, Henry Masur

DEFINITION AND DESCRIPTION

Pneumocystis is an opportunistic pathogen that is an important cause of pneumonia in immunocompromised hosts, particularly those with HIV infection **(Chap. 208)**, organ transplants, or hematologic malignancies and those receiving high-dose glucocorticoids or certain immunosuppressive monoclonal antibodies. *Pneumocystis* was discovered in rodents in 1909 and was initially believed to be a protozoan. Because *Pneumocystis* cannot be cultured, understanding its biology has been limited, but molecular techniques have demonstrated that the organism is actually a fungus. Formerly known as *Pneumocystis carinii*, the species specific to humans has been renamed *Pneumocystis jirovecii*; the species that is specific to rats is *Pneumocystis carinii*; there are multiple variants of *Pneumocystis* that are specific to other animals.

EPIDEMIOLOGY

Pneumocystis jirovecii pneumonia (PCP) came to medical attention in the early 1950s when pathologists in Czechoslovakia recognized *Pneumocystis* in the alveolar exudates of infants involved in nursery outbreaks of interstitial pneumonia, outbreaks that had been described in Europe since the 1920s. Among adults, PCP was rarely recognized until the populations of immunosuppressed adults increased due to the development of immunosuppressive therapies for solid-organ transplantation, bone marrow transplantation, cancer, and autoimmune disorders, and until the development of better pulmonary diagnostic techniques such as bronchoscopy. In 1981, PCP was first reported in men who had sex with men and in intravenous (IV) drug users who had no obvious cause of immunosuppression. These cases were subsequently recognized as the first cases of what came to be known as the acquired immunodeficiency syndrome (AIDS) **(Chap. 208)**.

The incidence of PCP increased dramatically as the AIDS epidemic grew: without PCP chemoprophylaxis or antiretroviral therapy (ART), 80–90% of patients with HIV/AIDS in North America and Western Europe ultimately developed one or more episodes of PCP. While its incidence declined with the introduction of anti-*Pneumocystis*

prophylaxis and durably effective ART, PCP has continued to be an important cause of AIDS-associated morbidity in the United States and Western Europe, particularly in individuals who do not know they are infected with HIV until they are profoundly immunosuppressed and in people living with HIV (PLWH) with CD4+ T lymphocyte counts of <200/μL who are not receiving ART or PCP prophylaxis.

PCP also develops in HIV-uninfected patients who are immunocompromised secondary to congenital immunodeficiencies, hematologic or malignant neoplasms, stem cell or solid-organ transplantation, and treatment with immunosuppressive medications. The incidence of PCP depends on the degree and duration of immunosuppression. PCP is increasingly reported among individuals receiving tumor necrosis factor α inhibitors and certain (but not all) immunosuppressive monoclonal antibodies for autoimmune, rheumatologic, or neoplastic diseases. In many health care systems, PCP occurs more often due to non-HIV-related immunosuppression than due to HIV infection.

While clinical disease due to *Pneumocystis* in immunocompetent hosts has not been clearly documented, studies have shown that *Pneumocystis* organisms can cause subclinical infection among children and adults who are not immunocompromised and can be associated with pulmonary pathology. The relevance of these organisms to acute or chronic clinical syndromes, such as chronic obstructive pulmonary disease (COPD), in immunocompetent patients is being investigated.

In some developing countries, the incidence of PCP among PLWH has been reported to be lower than that in more industrialized countries. This lower incidence may be due to competing mortality from infectious diseases such as tuberculosis and bacterial pneumonia, which typically occur before patients become immunosuppressed enough to develop PCP. Geographic variations in *Pneumocystis* exposure and underdiagnosis attributable to lack of diagnostic resources also may explain the apparent lower frequency of PCP in some countries.

PATHOGENESIS AND PATHOLOGY

Life Cycle and Transmission The life cycle of *Pneumocystis* likely involves both sexual and asexual reproduction. The organism exists as a trophic form, a cyst, and a precyst. Studies in rodents show that immunocompetent animals can serve as reservoirs for respiratory transmission of *P. carinii* (the infecting species in rats) to immunocompetent and immunosuppressed rats. Human *Pneumocystis* is thought to be transmitted by a respiratory route as well. *P. jirovecii*, like all pneumocystis species, is host-specific. Thus, humans are not infected, for example, by *P. carinii* (rodents) or *P. oryctolagi* (rabbits), but are only infected by *P. jirovecii,* which is from other humans.

Serologic and molecular studies have demonstrated that most humans are exposed to *P. jirovecii* and infected early in life. It was historically thought that *Pneumocystis* pneumonia usually developed from reactivation of latent infection. However, molecular evidence makes it clear that children and adults can develop PCP from primary infection or reinfection. The source of infection is thought to be either healthy or immunosuppressed individuals who themselves experienced recent infection or reinfection, or immunosuppressed persons with clinical PCP. Nosocomial outbreaks among immunosuppressed persons occur in inpatient and outpatient settings. The utility of droplet or airborne isolation for preventing transmission from patients with PCP to other immunosuppressed individuals has been debated; no clear evidence exists, although it seems prudent to isolate patients with active PCP from other immunosuppressed patients using at least droplet precautions.

Role of Immunity Defects in cellular and/or humoral immunity predispose to development of PCP. Such defects may be congenital, or they may be acquired as a result of HIV infection or treatment with certain immunosuppressive drugs such as glucocorticoids, fludarabine, temozolomide, temsirolimus, rituximab, or alemtuzumab. CD4+ T cells are critical in host defense against *Pneumocystis*. Among PLWH, the incidence of PCP is inversely related to the CD4+ T-cell count: at least 80% of cases occur at counts of <200/μL, and most cases actually develop at counts of <100/μL. HIV viral load is another factor that predisposes patients to PCP. Clinicians must recognize that PCP can occur at CD4+ T-cell counts >200/μL in persons with HIV infection, but such occurrences are uncommon, especially with CD4+ T-cell counts substantially higher than 200/μL.

CD4+ T-cell counts are less useful in predicting the risk of PCP in patients who are immunosuppressed for reasons other than HIV infection. In these populations, a CD4+ T-cell count <200/μL is a sensitive indicator of susceptibility to PCP. However, a CD4+ T-cell count >200/μL in many populations does not imply protection.

Lung Pathology *Pneumocystis* has a unique tropism for the lung. Organisms are presumably inhaled into the alveolar space after being exhaled by another human. Clinically apparent pneumonia occurs only if an individual is immunocompromised. *Pneumocystis* proliferates in the lung, provoking a mononuclear cell response. The alveoli become filled with proteinaceous material, and alveolar damage results in increased alveolar-capillary injury and surfactant abnormalities. Stained lung sections typically show foamy, vacuolated alveolar exudates composed largely of viable and nonviable organisms **(Fig. 227-1*A*)**. Interstitial edema and fibrosis may develop, and organisms can be seen in the alveolar space with silver or other stains. The organisms can also be seen when tissue is subjected to colorimetric or immunofluorescent staining **(Fig. 227-1*B*–*D*)**.

CLINICAL FEATURES

Clinical Presentation PCP presents as acute or subacute pneumonia that may initially be characterized by a vague sense of dyspnea alone, but that subsequently manifests as fever and nonproductive cough with progressive shortness of breath. Patients may ultimately progress to respiratory failure and death. Extrapulmonary manifestations of PCP are rare, but can include involvement of almost any organ, most notably the lymph nodes, spleen, and liver.

Physical Examination, Oxygen Saturation, and Imaging The physical examination findings in PCP are nonspecific. Patients have decreased oxygen saturation—at rest or with exertion—that, without treatment, progresses to severe hypoxemia. Patients may initially have a normal chest examination and no adventitious sounds, but later develop diffuse rales and signs of consolidation.

Laboratory Findings The results of routine laboratory tests are nonspecific in PCP. Serum levels of lactate dehydrogenase (LDH) are often elevated as a result of pulmonary damage; however, a normal LDH level does not rule out PCP, nor is an elevated LDH value specific for PCP. The peripheral white blood cell count may be elevated in relation to the patient's baseline values, but the increase is usually modest and the baseline may have been below usual normal limits due to HIV infection. Hepatic and renal function are typically normal.

Radiographic Findings Although the initial chest radiograph may be normal when patients have mild symptoms, the classic radiographic appearance of symptomatic PCP consists of diffuse bilateral interstitial infiltrates that are perihilar and symmetric **(Fig. 227-2*A*)**—another finding that is not specific for PCP. The interstitial infiltrates can progress to alveolar filling **(Fig. 227-2*B*)**. High-resolution chest computed tomography (CT) shows diffuse ground-glass opacities in virtually all patients with PCP, often before a routine chest radiograph becomes abnormal **(Fig. 227-2*C*)**. A normal chest CT essentially rules out the diagnosis of PCP. Pneumatoceles and pneumothoraces are characteristic chest radiographic findings, especially in patients with HIV infection **(Fig. 227-2*D*)**. A wide variety of atypical radiographic findings have been described, including asymmetric patterns, upper-lobe infiltrates, mediastinal adenopathy, nodules, cavities, and effusions.

DIAGNOSIS

The optimal sample for a specific microbiologic diagnostic examination depends on how ill the patient is and what resources are available. Before the 1990s, diagnoses of PCP were usually established by open lung biopsy; later, transbronchial lung biopsy was employed. Hematoxylin and eosin (H and E) staining of pulmonary tissue

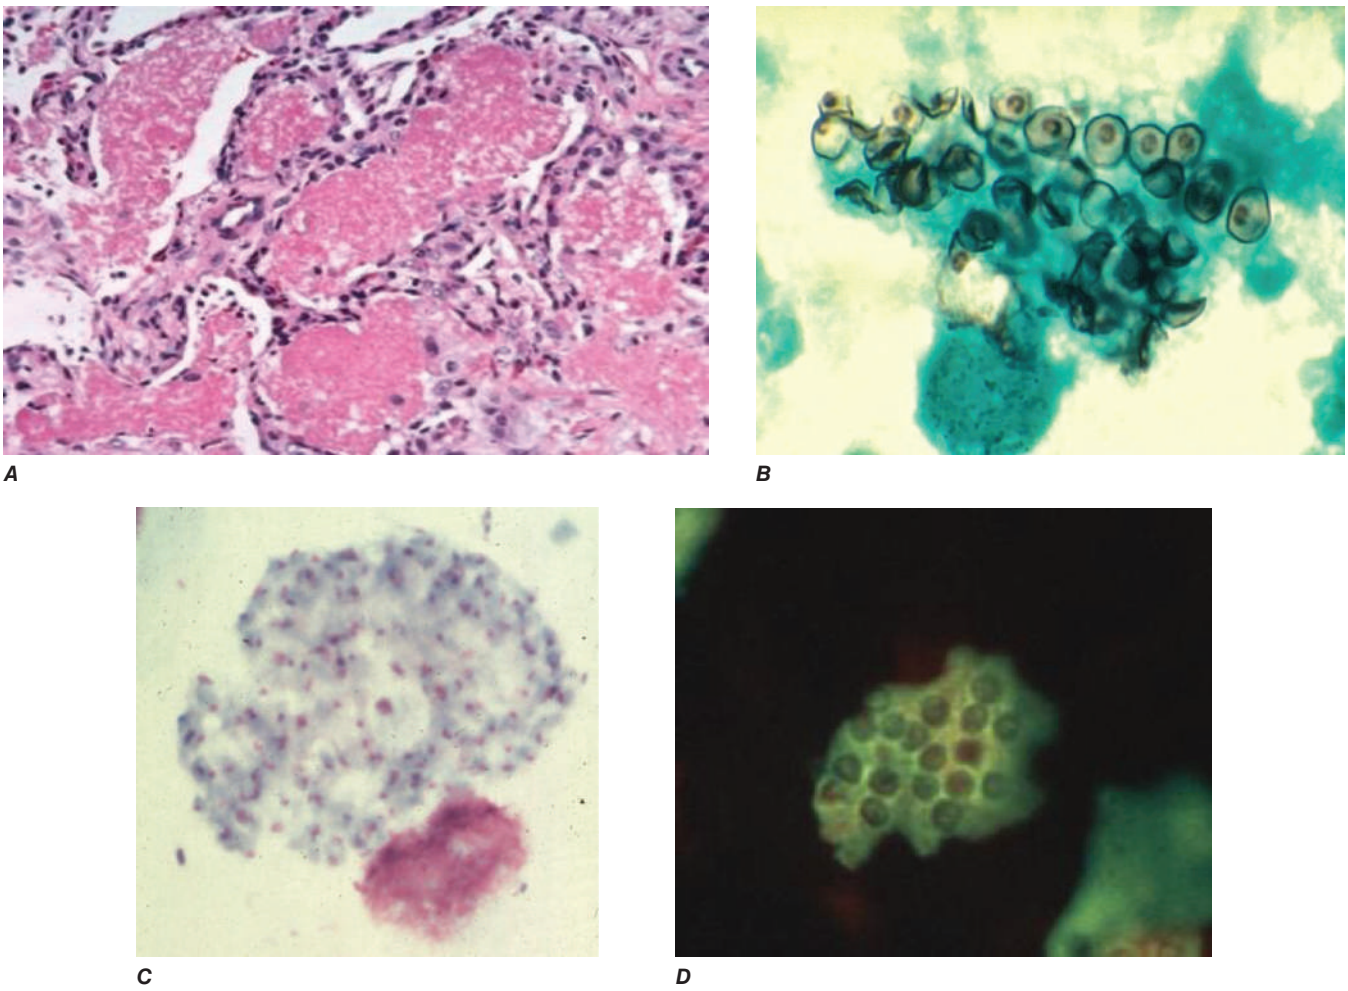

FIGURE 227-1 Direct microscopy of *Pneumocystis* pneumonia. ***A.*** Transbronchial lung biopsy stained with hematoxylin and eosin shows eosinophilic alveolar filling. ***B.*** Methenamine silver–stained bronchoalveolar lavage (BAL) fluid. ***C.*** Giemsa-stained BAL fluid. ***D.*** Immunofluorescent stain of BAL fluid.

demonstrates a foamy alveolar filling and a mononuclear interstitial infiltrate (Fig. 227-1*A*). This appearance is pathognomonic for PCP even though the organisms cannot be specifically identified with this H and E stain. Since human pneumocystis has never been successfully cultured, the diagnosis is typically established in lung tissue or pulmonary secretions by staining of the cyst and or trophozoite—e.g., with methenamine silver (Fig. 227-1*B*), toluidine blue O, or Giemsa (Fig. 227-1*C*)—or by staining with a specific immunofluorescent antibody (Fig. 227-1*D*).

Since the 1990s, bronchoalveolar lavage (BAL) has become the most common method for obtaining a sample of respiratory secretions in which to detect *Pneumocystis* organisms. The demonstration of organisms in BAL fluid is almost 100% sensitive and specific for PCP. The organisms are identified in pulmonary secretions with the specific stains indicated above for lung biopsy. While expectorated sputum or throat swabs have very low sensitivity, an induced sputum sample obtained and interpreted by an experienced provider can be highly sensitive and specific; however, the sensitivity is dependent on both the characteristics of the patient, the quality of the sputum sample, and the experience of the center conducting the test and is widely variable (55–90%).

Many laboratories offer polymerase chain reaction (PCR) testing of respiratory specimens for *Pneumocystis* in preference to direct microscopy of stained respiratory secretions. However, PCR tests are so sensitive that it is difficult to distinguish patients with colonization (i.e., those whose acute lung disease is due to some other process but who have low levels of *Pneumocystis* DNA in their lungs) from those with acute pneumonia due to *Pneumocystis*. The PCR cycle number is probably helpful, i.e., the lower the cycle number, the more DNA was detected. However, PCR tests for PCP are not standardized and specimen collection can vary considerably resulting in variable quality of the specimens assessed. Therefore, there is no specific PCR threshold that can be deemed to be especially convincing. Such PCR tests on appropriate samples may be more useful for ruling out a diagnosis of PCP if they are negative than for definitively attributing the disease to *Pneumocystis* if they are positive.

There has been considerable interest in serologic tests, such as assays for (1→3)-β-D-glucan, a component of the fungal cell wall. Serum (1→3)-β-D-glucan levels are frequently elevated in patients with PCP. However, serum or BAL (1→3)-β-D-glucan levels are not perfectly sensitive or highly specific for PCP. There are increasing numbers of studies of serum PCR tests for *Pneumocystis*, but such serum tests are not yet useful for establishing the presence or absence of PCP.

COURSE AND PROGNOSIS

Untreated, PCP is invariably fatal. Patients with HIV infection often have an indolent course that may present early as mild exercise intolerance or chest tightness without fever or cough and a normal or nearly normal posterior–anterior chest radiograph. However, this process progresses over days, weeks, or even a few months to fever, cough, diffuse alveolar infiltrates, and profound hypoxemia. Some patients with HIV infection and most patients with other types of immunosuppression have more acute disease that progresses over a few days to respiratory failure. Rare patients also develop distributive shock due to PCP. A few unusual patients present with extrapulmonary manifestations in the skin or soft tissue, retina, brain, liver, kidney, or spleen. Extrapulmonary disease is nonspecific in presentation and can be diagnosed only by histology. When there is extrapulmonary clinical disease in a

patient with PCP, the priority is to determine what other concurrent infectious or neoplastic process might be present, given the rarity of extrapulmonary pneumocystosis.

Factors that influence mortality risk of PCP include the patient's age and degree of immunosuppression as well as the presence of preexisting lung disease, the need for mechanical ventilation, and the development of a pneumothorax. With advances in supportive critical care, the prognosis for patients with PCP who require intubation and respiratory support has improved and now depends to a large extent on comorbidities and the prognosis of the underlying disease. Some patients do not respond to therapy for 4–8 days, and thus supportive care for a minimum of 10 days is a reasonable consideration if such support is compatible with the patient's wishes and the prognosis of comorbidities. In fact, if patients of any level of severity are treated with specific therapy but without corticosteroids, they often deteriorate during the first few days, presumably due to enhanced inflammation induced by dying organisms. Patients whose condition continues to deteriorate after 3 or 4 days or have not improved after 7–10 days should be reevaluated to determine whether other infectious processes are present (either having been missed on initial evaluation or having developed during treatment), whether initial anti-*Pneumocystis* treatment has failed, or whether noninfectious processes (e.g., congestive heart failure, pulmonary emboli, pulmonary hypertension, drug toxicity, or a neoplastic process) are causing pulmonary dysfunction.

TREATMENT

P. jirovecii Pneumonia

The treatment of choice for PCP is trimethoprim-sulfamethoxazole (TMP-SMX), given either IV or PO for 14 days to non-HIV-infected patients with mild disease and for 21 days to all other patients (Table 227-1). TMP-SMX, which interferes with the organism's folate metabolism, is at least as effective as alternative agents and is better tolerated. TMP-SMX can cause leukopenia, hepatitis, rash, fever, elevation of potassium and creatinine, and anaphylactic and anaphylactoid reactions. Patients with HIV infection have an unusually high incidence of hypersensitivity to TMP-SMX. Monitoring of serum drug levels is useful if renal function or toxicities are issues in order to enhance the likelihood that therapy will be effective and toxicity will be avoided. Maintenance of a 2-h post-dose serum sulfamethoxazole level of 100–150 μg/mL has been associated with a successful outcome. Resistance to TMP-SMX cannot be measured by organism growth inhibition in the laboratory because human *Pneumocystis* cannot be successfully cultured. However, mutations in the target gene for sulfamethoxazole that confer in vitro sulfa resistance when found in other organisms have been recognized in *Pneumocystis*. The clinical relevance of these mutations for the response to therapy is uncertain. Sulfadiazine plus pyrimethamine, an oral regimen more often used for treatment of toxoplasmosis, also is highly effective.

TABLE 227-1 Treatment of *Pneumocystis* Pneumonia[a]

DRUG(S)	DOSE, ROUTE	ADVERSE EFFECTS
First-Choice Agent		
TMP-SMX	TMP (5 mg/kg) plus SMX (25 mg/kg) q6–8h PO or IV (i.e., 2 double-strength tablets tid or qid)	Fever, rash, cytopenias, hepatitis, hyperkalemia
Alternative Agents		
Atovaquone	750 mg bid PO	Rash, fever, hepatitis
Clindamycin ***plus*** Primaquine	300–450 mg q6h PO or 600 mg q6–8h IV 15–30 mg qd PO	Hemolysis (G6PD deficiency), methemoglobinemia, neutropenia, rash
Pentamidine	3–4 mg/kg qd IV	Hypotension, azotemia, cardiac arrhythmias (torsades des pointes), pancreatitis, dysglycemias, hypocalcemia, neutropenia, hepatitis
Adjunctive Agent		
Prednisone or methylprednisolone	40 mg bid × 5 d, 40 mg qd × 5 d, 20 mg qd × 11 d; PO or IV	Peptic ulcer disease, hyperglycemia, mood alteration, hypertension

[a]Treatment can be administered for 14 days to non-HIV-infected patients with mild disease and for 21 days to all other patients.

Abbreviations: G6PD, glucose-6-phosphate dehydrogenase; TMP-SMX, trimethoprim-sulfamethoxazole.

Either intravenous pentamidine or the combination of clindamycin plus primaquine is are options for patients who cannot tolerate TMP-SMX and for patients in whom treatment with TMP-SMX appears to be failing. Pentamidine must be administered IV over at least 60 min to avoid potentially lethal hypotension. Adverse effects can be severe and irreversible and include renal dysfunction, dysglycemia (life-threatening hypoglycemia that can occur days or weeks after initial infusion and be followed by hyperglycemia), neutropenia, and torsades de pointes. Clindamycin plus primaquine is effective, but primaquine can be given only by the oral route—a disadvantage for patients who cannot ingest or absorb oral drugs and primaquine can cause hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency and can cause methemoglobinemia. Oral atovaquone is also a reasonable option for patients with mild disease who have no impediments to absorbing an oral drug that requires a high-fat meal for optimal absorption. There is some evidence for activity of echinocandins against the cyst form (but not the trophozoite form) of *Pneumocystis*, but the role for echinocandins as part of combination therapy is currently uncertain, and these drugs should never be used as single drug therapy for PCP.

A major advance in therapy for PCP was the recognition that glucocorticoids could improve survival rates among PLWH with moderate to severe disease (initial room air Po_2 <70 mmHg or alveolar–arterial oxygen gradient ≥35 mmHg). Glucocorticoids appear to reduce the pulmonary inflammation that occurs after specific therapy is started and organisms begin to die, eliciting inflammation. Therapy with glucocorticoids should be the standard of care for patients with HIV infection and moderate to severe PCP. Therapy with glucocorticosteroids is also probably effective for patients with other immunodeficiencies who have moderate to severe PCP. This treatment should be started for moderate or severe disease when therapy for PCP is initiated, even if the diagnosis is suspected but has not yet been confirmed. If PLWH or HIV-uninfected patients are receiving high-dose glucocorticoids when they develop PCP, there are theoretical advantages to decreasing the steroid dose to improve immune function, but there is no convincing evidence on which to base any specific strategy.

No definitive trials have identified the best therapeutic algorithm for patients in whom TMP-SMX treatment for PCP is failing. If no other treatable infectious or noninfectious processes are detected and pulmonary dysfunction appears to be due to PCP alone, many authorities would switch from TMP-SMX to either IV pentamidine or IV clindamycin plus oral primaquine. Clindamycin-primaquine is certainly less toxic than IV pentamidine. Some authorities would add the second drug or drug combination to TMP-SMX rather than switching regimens. If patients are not already receiving them, glucocorticoids should be added to the regimen; the dosage and regimen are usually chosen empirically and depend on what glucocorticoid regimen (if any) the patient was receiving when PCP therapy was begun.

For PLWH who present with PCP before the initiation of ART, ART should be started within the first 2 weeks of therapy for PCP in most situations. Immune reconstitution inflammatory syndrome (IRIS) can occur, and the decision to initiate ART thus requires considerable clinical judgement that factors in the severity of pneumonia, the response of PCP to therapy, and concurrent medical conditions.

PREVENTION

The most effective method for preventing PCP is to eliminate the cause of immunosuppression by withdrawing immunosuppressive therapy or treating the underlying cause (e.g., HIV infection). Patients who are susceptible to PCP benefit from chemoprophylaxis during the period of susceptibility. For patients with HIV infection, CD4+ T-cell counts are a reliable marker of susceptibility, and counts <200/μL are an indication to start or continue prophylaxis **(Table 227-2)**.

For patients who are immunosuppressed as a result of factors other than HIV infection, CD4+ T-cell counts <200/μL are a plausible but not absolute marker of susceptibility. However, counts >200/μL are not a reliable marker of protection from PCP. For these patients who are immunosuppressed due to causes other than HIV infection, the period of susceptibility is usually estimated on the basis of experience with the underlying disease and the specific immunosuppressive regimen. Cessation of prophylaxis has been associated with clusters of cases in certain patient populations, such as solid-organ transplant recipients, where the period of susceptibility is not well-defined. Patients receiving a prolonged course of high-dose glucocorticoids

TABLE 227-2 Prophylaxis of *Pneumocystis* Pneumonia

DRUG(S)	DOSE, ROUTE	COMMENTS
First-Choice Agent		
TMP-SMX	1 tablet (double- or single-strength) qd PO	Incidence of hypersensitivity is high. Rechallenge for non-life-threatening hypersensitivity; consider dose-escalation protocol.
Alternative Agents		
Dapsone	50 mg bid or 100 mg qd PO	Hemolysis is associated with G6PD deficiency.
Dapsone ***plus*** Pyrimethamine ***plus*** Leucovorin	50 mg qd PO 50 mg weekly PO 25 mg weekly PO	Leucovorin ameliorates cytopenias due to pyrimethamine.
Dapsone ***plus*** Pyrimethamine ***plus*** Leucovorin	200 mg weekly PO 75 mg weekly PO 25 mg weekly PO	Leucovorin ameliorates cytopenias due to pyrimethamine.
Pentamidine	300 mg monthly via Respirgard II nebulizer	Aerosol may cause bronchospasm. Pentamidine is probably less effective than TMP-SMX or dapsone regimens.
Atovaquone	1500 mg qd PO	Requires fatty meal for optimal absorption.

Abbreviations: G6PD, glucose-6-phosphate dehydrogenase; TMP-SMX, trimethoprim-sulfamethoxazole.

appear to be particularly susceptible to PCP. The glucocorticoid exposure threshold that warrants chemoprophylaxis is ill-defined, but such preventive therapy should be strongly considered for any patient who is receiving more than the equivalent of 20 mg of prednisone daily for 30 days or who is receiving glucocorticoids in conjunction with other immunosuppressive agents. Clinical experience also suggests that chemoprophylaxis is useful for patients receiving certain immunosuppressive agents (e.g., tumor necrosis factor inhibitors, antithymocyte globulin, rituximab, and alemtuzumab). The duration of such chemoprophylaxis is empirically estimated based on prior clinical experience and immunologic factors that would plausibly relate to immunity, such as CD4+ T-cell counts, recognizing that such estimates are not precise.

TMP-SMX is the most effective prophylactic drug; few patients experience a PCP breakthrough when they are reliably taking a recommended TMP-SMX chemoprophylactic regimen. Several TMP-SMX regimens have been used successfully. Regimens of one single-strength or double-strength tablet daily are the regimens with which there is the most experience, but one double-strength tablet two or three times weekly also has been recommended for various PLWH and non-HIV-infected populations of patients.

For patients who cannot tolerate TMP-SMX (usually because of hypersensitivity or bone marrow suppression), alternative drugs include daily dapsone, weekly dapsone-pyrimethamine, atovaquone, and monthly aerosol pentamidine. Patients who develop hypersensitivity to TMP-SMX can sometimes tolerate the drug if a gradual dose-escalation protocol is used. Atovaquone is effective and well tolerated; however, this drug is available only as an oral preparation, and gastrointestinal absorption is unpredictable in patients with abnormal gastrointestinal motility or function. Aerosolized pentamidine is effective, but it is not as effective as TMP-SMX and may not provide protection in areas of the lung that are not well-ventilated. Dapsone cross-reacts with sulfonamides in a substantial fraction of patients and is rarely useful in patients with a history of life-threatening reactions to TMP-SMX.

Section 17 Protozoal and Helminthic Infections: General Considerations

228 Introduction to Parasitic Infections

Sharon L. Reed, Charles E. Davis

The word *parasite* comes originally from the Greek *parasitos* (*para*, alongside of; and *sitos*, food), meaning someone who eats at another's table or lives at another's expense. Although the same is true of many bacteria and viruses, the designation *parasite* is reserved, by convention, for helminths and protozoa. These organisms are larger and more complex than bacteria, with a eukaryotic cell structure similar to that of human host cells. Historically, this similarity has made it difficult to find effective antiparasitic agents that do not cause unacceptable toxicity to human cells. Fortunately, intensive research and modern techniques have now provided suitable agents for safe and effective treatment of most parasitic infections. **See Chap. S12 for details on diagnostic procedures and Chap. 229 for details on treatment.**

Internal parasites of human beings are divided into two types: helminths (worms) and protozoa. *Helminths* are multicellular organisms that can often be seen with the naked eye **(Chap. 237)**. There are two phyla: Platyhelminthes (flat worms) and Nemathelminthes (roundworms). Both phyla include some genera that mature in the gastrointestinal tract and others that migrate through the tissue after ingestion or skin penetration. **Tables S12-1 and S12-2** present the helminthic genera, their definitive and intermediate hosts, their geographic distributions, and the parasitic stages in the human body.

The key to understanding which helminths use humans as definitive hosts is to remember that helminth ova develop into larvae, and larval stages develop into adults. Humans serve as the definitive host when they ingest helminth larvae, which develop into adults in the intestine and usually cause mild disease, often without any symptoms. (The exception is ingestion of the late-stage larvae of the somatic or tissue flukes, as shown in **Table S12-1**.) In contrast, if humans ingest helminth ova and serve as the intermediate host, the ova develop into larvae, which penetrate the intestine, migrate through the tissue, and invade organs where they mature into adults. Intermediate hosts with parasitic invasion of organs may experience severe disease.

Protozoa are microscopic single-celled organisms. Among the many differences between helminths and protozoans, the most important is the ability of protozoa (like bacteria) to multiply within the human body and cause overwhelming infections. A major mechanism promoting unrestrained growth is evasion of the host immune response either by antigenic variation (*Trypanosoma brucei*) or by survival inside host cells (e.g., *Plasmodium*, *Babesia*, *Cryptosporidium*, *Leishmania*, and *Toxoplasma*). In contrast, almost all helminths require stages in other hosts to complete their life cycles and multiply. As a result, except for *Strongyloides* and *Capillaria*, which can complete their life cycle in humans, increases in the burden of infection with helminths require repeated exogenous reinfections. Thus, permanent residents of endemic countries, who are exposed repeatedly, may have heavy severe infections, while most travelers with one or two exposures are unlikely to experience the full spectrum of chronic helminthic infections.

In contrast to helminthic infections, naïve patients with their first protozoal infection usually are the most severely affected because partial immunity often limits the number of parasites during recurrent infections. Protozoan replication to large numbers in the host also promotes the development of drug-resistant forms, especially in malaria **(Chap. 229)**. Because protozoa belong to many different phyla, it is easier to understand the pathogenesis and management of protozoal infections when they are classified by the site of infection (intestinal protozoans, free-living amebae, and blood and tissue protozoans)

(Table S12-3). Immunocompromised hosts are at risk of disseminated infection with several protozoa, including *Leishmania*, *Toxoplasma*, *Cryptosporidium*, *and Trypanosoma cruzi*, which are AIDS-defining illnesses. Among the helminths, *Strongyloides* can disseminate in immunocompromised individuals.

HELMINTHIC INFECTIONS

The Platyhelminthes (flatworms) are categorized as tapeworms (cestodes) and flukes (trematodes). Tapeworms are composed of a head or scolex bearing the holdfast organs and segments, which become gravid as they mature. Some tapeworms can reach lengths of many yards; the longest tapeworms develop in the intestine, where they rarely cause serious disease. In contrast, flukes are small leaf-shaped organisms whose size is not a measure of disease severity.

FLATWORMS

Cestodes Tapeworms cause either intestinal or somatic infection, depending on the species. *Intestinal* infections occur when the human host ingests larvae in the tissue of the intermediate host, whereas *somatic* infections occur when humans accidentally ingest ova excreted from the wild or domesticated definitive animal host.

INTESTINAL TAPEWORMS As shown in Table S12-1, humans acquire most intestinal tapeworms by eating the insufficiently cooked flesh of the intermediate host. Thus, *Taenia saginata* is commonly called the beef tapeworm, *Taenia solium* the pork tapeworm, and *Diphyllobothrium latum* the fish tapeworm. *Hymenolepis nana* is capable of completing its life cycle in the human intestine and is acquired by ingestion of infected grain beetles or of ova from infected humans or mice. None of these parasites causes significant damage, and infection is usually asymptomatic. There are two occasional exceptions. When people ingest *T. solium* ova from their own intestine or from another infected individual, it can cause somatic infection. *D. latum* avidly absorbs vitamin B_{12} in the intestine and can cause pernicious anemia in 1–2% of infected Scandinavians with a genetic predisposition.

SOMATIC TAPEWORMS There are three major causes of somatic tapeworm infections. Two species of *Echinococcus* cause echinococcosis. *E. granulosus* is acquired by accidental ingestion of ova from dogs infected when fed the infected tissues of sheep or other animals by sheepherders or hunters. *E. multilocularis* is transmitted primarily in sub-Arctic areas when humans ingest ova from foxes, dogs, or cats that have been infected through consumption of the tissues of infected rodents. Both species cause hydatid cysts when the eggs hatch into larvae, penetrate the intestine, and migrate into the liver or lung. Ingested *T. solium* ova cause somatic disease (cysticercosis) when the larvae penetrate the intestine, migrate into tissue, and form cysts (*cysterci*), usually in the muscles or central nervous system (CNS).

Trematodes Flukes also cause both intestinal and somatic infections (Chap. 241 and Table S12-1). Most fluke infections are localized to Asia, Africa, Southeast Asia, or the Pacific islands. Infection with intestinal flukes is usually asymptomatic, although heavy infections sometimes cause abdominal discomfort and mucous diarrhea. Liver flukes and lung flukes cause somatic infections when humans ingest a larval form from an intermediate host. Adults develop in the intestine, migrate into adjacent tissues, and cause disease. The major liver flukes (*Clonorchis sinensis*, *Opisthorchis* spp., and *Fasciola hepatica*) are causes of recurrent bacterial cholangitis (due to obstruction) or portal hypertension and cirrhosis. Only *F. hepatica* can be acquired worldwide; it is especially common in sheep-raising areas, where the animals ingest water plants (e.g., watercress). The lung flukes (*Paragonimus* spp.) occur globally except in Europe; most lesions occur as pulmonary cysts, although occasional lesions develop in the CNS or the abdominal cavity.

The blood flukes cause schistosomiasis, one of the most common and serious parasitic infections (Chap. 241 and Table S12-1). The major species are *Schistosoma mansoni*, S. *haematobium*, and *S. japonicum*. All are transmitted to humans when free-swimming larvae exit an infected snail in freshwater and penetrate the skin. Swimmer's itch sometimes follows skin penetration but is usually of short duration. The larvae then wander in the skin until they find a blood vessel and migrate to the target organ. *S. mansoni* and *S. japonicum* migrate to the mesentery vessels and eventually make their way to the liver, while *S. haematobium* targets the veins around the ureter and bladder. Extensive egg deposition by *S. mansoni* and *S. japonicum* and the immune reactions to the ova cause granuloma formation and, with many repeated exposures, portal vein obstruction and cirrhosis. The same process in the ureters and bladders during infection with *S. haematobium* eventually interferes with urine flow and leads to repeated urinary tract infections and kidney damage.

ROUNDWORMS

Nematodes Roundworms are nonsegmented bisexual organisms. The species that infect humans include intestinal and tissue groups. Humans may also acquire certain nonhuman mammalian roundworms that either can be limited to the skin or can migrate to tissues and cause serious disease (the larva migrans syndromes).

INTESTINAL ROUNDWORMS The major intestinal roundworms are *Ascaris lumbricoides*, *Necator americanus* (New World hookworms), *Ancylostoma duodenale* (Old World hookworms), *Trichuris trichiura* (whipworms), *Enterobius vermicularis* (pinworms), and *Strongyloides stercoralis*. Taken together, infections caused by intestinal roundworms are the most common infections in the world. *Ascaris*, hookworms, and *Trichuris* infect about 900 million individuals, and at least 100–370 million have strongyloidiasis. These infections are most common in resource-poor developing countries, especially where people defecate outside and/or human feces is used as fertilizer ("night soil"). Infection is transmitted either by ingestion of ova (*A. lumbricoides*, *T. trichiura*, and *E. vermicularis*) or by active penetration of the skin by larvae (hookworms and *S. stercoralis*) (Table S12-2).

Intestinal roundworms cause serious health problems in residents of endemic regions with poor sanitation, but travelers are at low risk of developing significant disease from most of these parasites. Intestinal blockage and malnutrition from heavy *Ascaris* infections and anemia from heavy hookworm infections are now restricted to areas of heavy endemicity. Except in the case of *Strongyloides* and *Capillaria*, which can reproduce in the body, multiple exposures over time are necessary for the development of severe disease. S*trongyloides* infection persists over decades and can disseminate when the immune system is compromised. Although *Capillaria* remains localized to the intestine, infections can become so heavy that protein-losing enteropathy and malnutrition cause serious disease.

The life cycles of *Ascaris* and the hookworms involve migration through the heart and lungs before development into adults in the intestine. In particular, *Ascaris* occasionally causes eosinophilic pneumonia (Loeffler's syndrome) during heavy infections. Pinworms are the most common causes of intestinal roundworm infection persisting in the United States and other developed countries. The anal and perineal itching caused by pinworm migration out of the anus and subsequent egg deposition is well known to families throughout the world.

TISSUE ROUNDWORMS The major diseases caused by tissue roundworms are filariasis, angiostrongyliasis, gnathostomiasis, and trichinellosis. By far, the most important globally is filariasis; the thread-like filarial worms infect an estimated 80 million individuals in tropical and subtropical areas of the world. Four filarial species cause three distinct diseases: lymphatic filariasis (*Wuchereria bancrofti* and *Brugia malayi*), river blindness (*Onchocercus volvulus*), and loiasis (*Loa loa*, the African eye worm). Humans, the major reservoir, acquire these infections from bites of infected arthropods (Table S12-2). The larvae develop into adults, which remain static in tissue: the lymphatics for lymphatic filariasis and subcutaneous tissue for *O. volvulus* and *L. loa*. After adults mate, next-stage larvae are produced, and their migration causes additional damage.

Repeated bouts of migrating larvae and blocking of the lymphatics by adults are necessary to establish the syndrome of lymphatic filariasis; thus, it is unusual for the short-term traveler (<3 months' residence in an endemic region) to develop significant disease. In river blindness, the larvae produced by adult *O. volvulus* migrate through the skin and

eye, causing skin damage and eventual blindness. Loiasis is a milder disease restricted to central and western Africa. Although both the adults and the larvae of *L. loa* migrate through the skin and eye, many infected individuals are asymptomatic, and the infection is often diagnosed only when an adult worm migrates across the subconjunctival tissue and is visible to the patient and the physician. Red lumps in the skin from heavy cutaneous migration are called *Calabar swellings*.

The other four major roundworm tissue infections are acquired by ingestion of larvae in undercooked food. The sources for trichinellosis are swine and other large mammals; for gnathostomiasis, freshwater fish and chicken; for ancylostomiasis, snails, fish, prawns, and crabs; and for Guinea worm, infected water fleas. Guinea worm infection (dracunculiasis, caused by *Dracunculus medinensis*) has been almost eradicated. *Trichinella spiralis* larvae penetrate the intestine and migrate widely, with a preference for skeletal tissue; the release of eosinophils and IgE causes muscle soreness and may cause palpebral swelling and other manifestations of generalized allergic reactions. *Angiostrongylus cantonensis* is the most common parasitic cause of eosinophilic meningitis. Ingested larvae penetrate the intestine and migrate to the brain and meninges, where they quickly die and attract massive numbers of eosinophils. Although complications can occur, most individuals recover spontaneously. *Gnathostoma spinigerum* larvae also penetrate the intestine and migrate, showing a preference for the skin, eyes, and meninges. Mechanical damage from the migration and inflammation produced by the resultant immune reaction can cause boil-like lesions on the skin, painful eye damage, and eosinophilic meningitis. Although eosinophilic meningitis caused by *G. spinigerum* is less common than that caused by *A. cantonensis*, it is often more severe and can result in paralysis or brain hemorrhage.

PROTOZOAL INFECTIONS

INTESTINAL PROTOZOA

Entamoeba histolytica is the one intestinal protozoan that causes invasive disease. This disease consists of dysentery or bloody diarrhea that must be differentiated from that due to bacteria such as *Salmonella*, *Campylobacter*, and *Shigella*. Although amebiasis usually has a slower onset with lower fever than these bacterial infections, *E. histolytica* can disseminate from the bloodstream to cause distant abscesses, particularly of the liver. The diagnosis cannot be made by identification of the characteristic cyst or trophozoites **(Chap. 230)**, as they are identical to those of the noninvasive *E. dispar*, which is more common globally.

Cryptosporidium and *Giardia* are the most common water-borne protozoal infections. *Cryptosporidium* can cause major outbreaks because it is highly infectious and resistant to high levels of chlorine **(Chap. 236)**. Without immune reconstitution, immunosuppressed patients, particularly those with AIDS, can develop severe, even fatal watery diarrhea. Infections caused by the remaining intestinal protozoans—*Giardia*, *Isospora*, *Cyclospora*, and microsporidia **(Chap. 236)**—have a much more indolent course, with intermittent diarrhea. Microsporidia, unique intracellular protozoa that form infectious spores, may cause limited gastrointestinal infection in immunocompetent hosts, but patients with AIDS can develop chronic diarrhea and wasting or disseminated infection to the biliary or respiratory tract.

FREE-LIVING AMOEBAS

The free-living amoebas *Acanthamoeba* and *Naegleria* are found worldwide in freshwater and brackish water **(Chap. 230 and Table S12-3)**. Organisms of these two genera cause very different syndromes. In immunocompromised individuals, *Acanthamoeba* may cause invasive infection, with brain masses and skin lesions. However, all humans are susceptible to *Acanthamoeba* keratitis after trauma to the eye and exposure to contaminated water. In contrast, naeglerial meningitis, acquired in warm lakes or hot springs, causes sudden pyogenic and usually fatal meningitis. *Balamuthia*, reported only from the Americas, causes indolent meningoencephalitis, with both cerebrospinal fluid pleocytosis and a space-occupying lesion, in immunocompetent patients. Despite the availability of miltefosine, which is active in vitro against *Naegleria*, infection of the CNS is almost universally fatal.

BLOOD AND TISSUE PROTOZOANS

Plasmodium* and *Babesia Malaria, caused by six species of *Plasmodium*, carries higher mortality rates than any other parasitic infection **(Chap. 231)**. All species are transmitted in tropical and subtropical areas by female *Anopheles* mosquitoes. *Plasmodium falciparum* is most common in sub-Saharan Africa, where it causes more than 80% of malaria infections and 90% of malarial deaths. Infection with *P. falciparum* may be particularly severe because the organism can invade any erythrocyte, reaches very high parasite loads, damages organs by adhering to vascular epithelium, and is the most likely *Plasmodium* species to be resistant to antimalarial drugs. *Plasmodium vivax*, the dominant cause of malaria outside sub-Saharan Africa, reaches lower levels of parasitemia and exhibits less drug resistance because it invades only reticulocytes with Duffy antigen. Many Africans, especially in the western part of the continent, lack the Duffy blood group; consequently, *Plasmodium ovale*, another cause of milder malaria, can compete successfully with *P. vivax*. Both *P. vivax* and *P. ovale* produce persistent liver forms, which must be treated with primaquine **(Chap. 229)**. Because malaria can cause a variety of symptoms ranging from acute fever to coma, this diagnosis must be considered in any traveler or immigrant from a malarial area. Recently, locally acquired *P. vivax* malaria has been detected in Florida and Texas and *P. falciparum* in Maryland; thus, malaria should be included in the differential diagnoses of unexplained fever even in patients who have never left the United States. *Babesia* also infects erythrocytes and may cause a nonspecific febrile illness or, in asplenic patients, severe infection. This parasite is carried by ixodid ticks and is geographically limited to the northeastern and midwestern United States, with only sporadic cases in Europe and other temperate areas.

Trypanosomes The three species of trypanosomes all have flagellated bloodstream forms, but they cause very different diseases. *T. cruzi*, the cause of Chagas disease, is transmitted in South and Central America in the feces of blood-sucking reduviid bugs **(Chap. 234)**. After initial parasitemia, patients are often asymptomatic for years while the parasite multiplies intracellularly in muscle and ganglion cells. Although only a minority of patients go on to develop organ damage (megaesophagus and cardiomyopathy), all infected patients can spread the disease through transfusions, mother-to-child transmission, and organ transplants.

African trypanosomiasis is limited to sub-Saharan Africa, where it is transmitted by the bite of a tsetse fly. A history of a tsetse bite and the presence of a painful chancre are strong diagnostic clues **(Chap. 234)**. Although the parasites causing this disease in western Africa (*Trypanosoma brucei gambiense*) and eastern Africa (*T. brucei rhodesiense*) look identical, they are genetically and clinically distinct. *T. b. gambiense* causes low-level parasitemia with cyclical fevers over months or years before CNS invasion, whereas *T. b. rhodesiense* causes high-level parasitemia, invades the CNS early on, and can lead to death within weeks of onset.

Leishmania Leishmaniasis is caused by more than 20 species of obligate intracellular protozoa transmitted by sandflies, which are present in almost 100 countries in tropical and temperate zones **(Chap. 233)**. A wide spectrum of clinical symptoms result, ranging from self-healing, painless skin ulcers to mucocutaneous disease with destruction of the nose and palate to disseminated visceral leishmaniasis with hepatic and splenic involvement. The resulting disease depends on the infecting strain and the host immune response. Visceral leishmaniasis can present as an acute febrile illness, with the later development of hepatosplenomegaly, and is an AIDS-defining illness in HIV-infected patients. More than 90% of cases of visceral leishmaniasis occur in India, Bangladesh, Ethiopia, Sudan, and Brazil.

Toxoplasma *Toxoplasma gondii* is an obligate intracellular parasite that is found worldwide. Infection follows ingestion of oocysts in food or water contaminated by cat feces, ingestion of tissue cysts in undercooked meat, or transplacental transmission. After gastrointestinal invasion, tachyzoites can invade any nucleated cell and cause lifelong infection in most patients **(Chap. 235)**. Clinical manifestations depend

on the host's age and immune status at the time of infection. Congenital toxoplasmosis results from primary maternal infection; outcomes are most severe early in pregnancy and include visual, hearing, and cognitive impairments. Babies infected later in pregnancy may appear normal but can develop chorioretinitis decades later. Primary infection in immunocompetent hosts may be asymptomatic, may present as an infectious mononucleosis–like syndrome, or may manifest as chorioretinitis during outbreaks. During immunosuppression by AIDS or organ transplantation, reactivation of latent cerebral infection can be fatal unless diagnosed and treated early.

APPROACH TO THE PATIENT

Parasitic Infection

A thorough history and physical examination are the keys to diagnosis of any disease and particularly of parasitic infections. Because many of the more serious parasitic infections are uncommon in the United States, a travel history, particularly to developing nations, is a critical component. The longer the stay in an area endemic for significant parasitic infections, the greater the risk, even for healthy travelers. In addition, other factors increase the chance of acquiring these infections. Notably, immunocompromise greatly increases the likelihood of developing some of the more serious parasitic infections. Even healthy travelers with adventure itineraries, extensive travel to rural areas, or involvement in war zones or refugee camps are at increased risk. Immigrants from developing countries may seek care for symptoms or signs associated with parasitic infections.

Information on the patient's immunization history and adherence to appropriate malarial chemoprophylaxis is critical. The recent approval of the first parasitic vaccines against *P. falciparum* is very exciting, but it will be targeted initially only for children in high prevalence areas. Typhoid fever is much less likely to be the cause of prolonged fever in an immunized individual. Similarly, hepatitis A or B is unlikely to be the cause of jaundice and fever in fully immunized patients. In this era of increasing drug resistance, even adherence to appropriate malarial chemoprophylaxis does not guarantee that fever is not malarial. Nevertheless, most travelers who acquire malaria have taken inadequate or no prophylaxis. Although these considerations do not prove that the symptoms are caused by parasites, they narrow the differential diagnosis.

There are many other important aspects of the history, including when symptoms began. Was the individual still in the endemic area at the time, or did the symptoms commence after return to the United States? If they started during travel, was any treatment received? Malaria must be the first consideration in a febrile patient returning from an endemic area. If the patient was well upon return from travel, the timing of symptom onset is a critical point. For example, if the chief manifestation is fever that began >10–14 days after departure from the endemic region, many tropical diseases can be ruled out, including dengue fever, chikungunya fever, and Zika virus infection. On the other hand, fever beginning several months or later after return makes malaria a likely diagnosis. Travelers' diarrhea, the most common complaint of travelers, is usually caused by bacteria or viruses and resolves in a short time with or without treatment. Travelers' diarrhea that persists for weeks is much more likely to be parasitic in origin.

Most patients who consult physicians after international travel either have troublesome symptoms or have been referred for symptoms or signs whose source was unclear to a referring caregiver. After a careful travel history including the individual's symptoms and the exact geographic zones visited, a thorough physical examination must be conducted. The symptoms, signs, and physical findings should help to establish possible diagnoses. **Table 228-1** breaks down the symptoms of major parasitic infections by organ system and geographic distribution, with comments on clinical and epidemiologic associations.

TABLE 228-1 Parasitic Infections, by Organ System and Signs/Symptoms[a]

ORGAN SYSTEM, MAJOR SIGN(S)/SYMPTOM(S)	PARASITE(S)	GEOGRAPHIC DISTRIBUTION	COMMENTS
Skin			
Serpentine rash	Hookworm	Worldwide	Can cause anemia in heavy infections
	Strongyloides	Moist tropics and subtropics	Disseminated infection in immunocompromise
	Toxocara (animal roundworm)	Tropical and temperate zones	Cutaneous or visceral larva migrans
Itchy skin rash	*Onchocerca*	Mexico, Central/South America, Africa	Larvae detectable in skin snips and nodules
Painless ulcers	*Leishmania*	Tropics and subtropics	Amastigotes detectable in biopsies; may cause destructive mucocutaneous infection; AIDS-defining infection
Skin nodules	*Onchocerca*	Mexico, South America, Africa	Large nodules of adult worms
	Loa loa (African eye worm)	Western and central Africa	Migratory nodules
	Gnathostoma	Southeast Asia and China	Migratory nodules with eosinophilia
Painful nodules, especially involving feet	*Dracunculus* (Guinea worm)	Africa	Nearly eradicated
Central Nervous System			
Somnolence, seizures, coma	*Plasmodium falciparum*	Subtropics and tropics	Cerebral malaria, especially in children
	Trypanosoma brucei rhodesiense	Sub-Saharan eastern Africa	Painful chancre from tsetse fly bite; death in weeks to months
Space-occupying lesions, seizures	*Acanthamoeba*	Worldwide	Immunocompromised individuals
	Balamuthia	Americas	Indolent meningoencephalitis with brain mass
	Toxoplasma	Worldwide	Reactivation disease in immunocompromise; ring-enhancing lesions; AIDS-defining infection
	Taenia solium	Mexico, Central/South America, Africa	Cysticercosis; variable sized or calcified larval cysts on CT
	Schistosoma japonicum	Far East	Aberrant eggs can form brain or spinal cord masses.
	Schistosoma mansoni	Africa, Central/South America	Aberrant eggs can form brain or spinal cord masses.

(*Continued*)

TABLE 228-1 Parasitic Infections, by Organ System and Signs/Symptoms[a] (Continued)

ORGAN SYSTEM, MAJOR SIGN(S)/SYMPTOM(S)	PARASITE(S)	GEOGRAPHIC DISTRIBUTION	COMMENTS
Pyogenic meningitis	*Naegleria*	Worldwide	Motile trophozoites in fresh cerebrospinal fluid; pyogenic; rapid death
Eosinophilic meningitis	*Angiostrongylus* (rat lung worm)	Southeast Asia, Pacific, Caribbean	Most common cause globally of eosinophilic meningitis; spontaneous resolution
	Gnathostoma	Southeast Asia and China	Migratory nodules
Eyes			
Painful corneal ulcers	*Acanthamoeba*	Worldwide	Freshwater and brackish water; corneal trauma; long-wear contact lenses
Corneal opacification	*Onchocerca*	Mexico, Central/South America, Africa	Immune response to microfilaria in cornea
Congenital or adult visual loss	*Toxoplasma*	Worldwide	Primary infection in pregnancy and normal hosts; reactivation infection in immunocompromised
Retinal mass	*Toxocara*	Worldwide	Ocular larva migrans
Visible roundworm in eye	*Onchocerca*	Mexico, Central/South America, Africa	Worms may cross eye during migration.
	L. loa	Western and central Africa	Worms may cross eye during migration.
Pain, possible vision loss	*Gnathostoma*	Southeast Asia and China	Migratory skin nodules, eosinophilia
Lungs			
Pulmonary nodule/abscess	*Paragonimus*	Far East, Africa, Americas	Ectopic migration to abdomen or central nervous system
Cough, transient infiltrates, eosinophilia	Migrating helminths	Worldwide	Loeffler's syndrome from migrating *Ascaris*, hookworm, *Strongyloides*
Heart			
Pulmonary edema	*P. falciparum* (complication)	Tropics and subtropics	End-organ damage from severe malaria
Cardiomegaly, arrhythmias	*Trypanosoma cruzi*	Mexico, Central/South America	Late amastigote infection of myocardium; AIDS-defining infection
Gastrointestinal Tract			
Hepatosplenomegaly	Malaria (multiple episodes)	Tropics and subtropics	Splenomegaly with anemia and recurrent fever are hallmarks of malaria.
	S. mansoni	Africa, Central/South America	Portal obstruction with cirrhosis and late varices
	Leishmania donovani complex	Tropics and subtropics	Visceral leishmaniasis; AIDS-defining infection
Hepatomegaly	*Entamoeba histolytica*	Tropics	Acute with fever, right-upper-quadrant pain; or chronic with enlarged liver; hypoechoic abscess(es) on ultrasound or CT
	Echinococcus	Sheep-raising areas	Characteristic cysts of liver > lung
	Fasciola	Sheep-raising areas	Eosinophilia
Cholangitis	*Clonorchis*	China, Southeast Asia	Recurrent cholangitis and late cholangiocarcinoma
	Microsporidia	Worldwide	AIDS
	Cryptosporidium	Worldwide	AIDS-defining infection
Bloody diarrhea	*E. histolytica*	Tropics	Less fever than in diarrhea of bacterial etiology
	S. mansoni	Africa, Central/South America	Only in heavy, acute infection with fever and eosinophilia
	S. japonicum	Far East	Only in heavy, acute infection
Watery diarrhea	*Cryptosporidium*	Worldwide	Severe in immunocompromised patients
	Giardia	Worldwide	Foul-smelling stool with steatorrhea
	Isospora belli	Worldwide	Fever, abdominal pain, chronic diarrhea
	Microsporidia	Worldwide	Chronic diarrhea with AIDS
	Capillaria	Southeast Asia, Egypt	Malabsorption, wasting
Passage of large roundworm (>6 cm)	*Ascaris*	Worldwide	Patients may confuse the roundworm with an earthworm.
Small roundworms visible around anus	Pinworm	Worldwide	Anal itching; eggs rarely detected by ova and parasite (O&P) exam
	Trichuris	Worldwide	Rectal prolapse with heavy infection in children
Passage of tapeworm segments	*T. solium* or *Taenia saginata*	Worldwide	Usual reason for seeking medical care
	Diphyllobothrium latum	Worldwide	Pernicious anemia in genetically predisposed Scandinavians
Genitourinary System			
Itchy discharge	*Trichomonas vaginalis*	Worldwide	Common sexually transmitted disease of both sexes
Hematuria	*Schistosoma haematobium*	Africa	Hematuria with negative cultures, urinary tract infections, and late bladder cancer

(*Continued*)

TABLE 228-1 Parasitic Infections, by Organ System and Signs/Symptoms[a] (Continued)

ORGAN SYSTEM, MAJOR SIGN(S)/SYMPTOM(S)	PARASITE(S)	GEOGRAPHIC DISTRIBUTION	COMMENTS
Muscular System			
Myalgias, myositis	*Trichinella*	Worldwide	Palpebral swelling; high-level eosinophilia
Bloodstream			
Fever without localizing symptoms	*Plasmodium*	Tropics and subtropics	Consider in any patient from a malarious area.
	Babesia	New England, United States	Geographically limited; worse with splenectomy
	T. brucei rhodesiense, T. brucei gambiense	Sub-Saharan Africa	Limited to tsetse fly range; painful chancre; adenopathy and cyclical fevers; early (*rhodesiense*) or late (*gambiense*) central nervous system involvement
	Filariae	Asia, India	Periodic fever with eosinophilia, adenolymphangitis, chronic lymphangitis
	L. donovani complex	Tropics and subtropics	Hepatosplenomegaly, fever, wasting; AIDS-defining infection

229 Agents Used to Treat Parasitic Infections

Thomas A. Moore

Parasitic infections continue to afflict more than half of the world's population and impose a substantial health burden, particularly in underdeveloped nations, where they are most prevalent. The reach of some parasitic diseases, including malaria, has expanded over the past few decades due to factors such as deforestation, population shifts, global warming, and other climatic events. Although there have been significant advances in vaccine development and vector control, chemotherapy remains the single most effective means of controlling parasitic infections. Efforts to combat the spread of some diseases are hindered by the development and spread of drug resistance, the limited introduction of new antiparasitic agents, the proliferation of counterfeit medications, profiteering, and, most recently, the widespread and unsupported use of antiparasitic agents to treat COVID-19, all of which have dramatically increased the cost of these once-affordable agents. However, there are good reasons to be optimistic. Ambitious global initiatives aimed at controlling or eliminating threats such as AIDS, tuberculosis, and malaria continue to demonstrate success. The ongoing efforts of multinational partnerships to address the substantial burden imposed by neglected tropical diseases have generated new effective antiparasitic agents. In addition, agents approved for other uses are being re-evaluated for antiparasitic efficacy, and some have been subsequently repurposed.

This chapter deals exclusively with the agents used to treat infections due to parasites. Specific treatment recommendations for the parasitic diseases of humans are listed in subsequent chapters. Many of the agents discussed herein are approved by the U.S. Food and Drug Administration (FDA) but are considered investigational for the treatment of certain infections. Drugs marked in the text with an asterisk (*) are available through the Centers for Disease Control and Prevention (CDC) Drug Service (telephone: 404-639-3670; email: drugservice@cdc.gov). Drugs marked with a dagger (†) are available only through their manufacturers; contact information for these manufacturers may be available from the CDC.

Table 229-1 presents a brief overview of each agent (including some drugs that are covered in other chapters), along with major toxicities, spectrum of activity, and safety for use during pregnancy and lactation.

Albendazole Like all benzimidazoles, albendazole acts by selectively binding to free β-tubulin in nematodes, inhibiting the polymerization of tubulin and the microtubule-dependent uptake of glucose. Irreversible damage occurs in gastrointestinal (GI) cells of the nematodes, resulting in starvation, death, and expulsion by the host. This fundamental disruption of cellular metabolism offers treatment for a wide range of parasitic diseases.

Albendazole is poorly absorbed from the GI tract, a feature that is advantageous for the treatment of intestinal helminths but not for that of tissue helminth infections (e.g., hydatid disease and neurocysticercosis), which requires a sufficient amount of active drug to reach the site of infection. Administration with a high-fat meal (~40 g) increases the drug's absorption by up to fivefold. The metabolite albendazole sulfoxide is responsible for the drug's therapeutic effect outside the gut lumen. Albendazole sulfoxide crosses the blood-brain barrier, reaching a level significantly higher than that achieved in plasma. The high concentrations of albendazole sulfoxide attained in cerebrospinal fluid (CSF) may explain the efficacy of albendazole in the treatment of neurocysticercosis.

Albendazole is extensively metabolized in the liver, but there are few data regarding the drug's use in patients with hepatic disease. Single-dose albendazole therapy in humans is largely without side effects (overall frequency, ≤1%). More prolonged courses (e.g., as administered for cystic and alveolar echinococcal disease) have been associated with liver function abnormalities and bone marrow toxicity. Thus, when prolonged use is anticipated, the drug should be administered in treatment cycles of 28 days interrupted by 14-day intervals off therapy. Prolonged therapy with full-dose albendazole (800 mg/d) should be approached cautiously in patients also receiving drugs with known effects on the cytochrome P450 system.

Amodiaquine Amodiaquine has been widely used in the treatment of malaria for >60 years. Like chloroquine (the other major 4-aminoquinoline), amodiaquine is now of limited use because of the spread of resistance. Amodiaquine interferes with hemozoin formation through complexation with heme. It is rapidly absorbed and acts as a prodrug after oral administration; the principal plasma metabolite, monodesethylamodiaquine, is the predominant antimalarial agent. Amodiaquine

TABLE 229-1 Overview of Agents Used for the Treatment of Parasitic Infections

DRUGS BY CLASS	PARASITIC INFECTION(S)	ADVERSE EFFECTS	MAJOR DRUG–DRUG INTERACTIONS	PREGNANCY CLASS[a]	BREAST MILK
4-Aminoquinolines					
Amodiaquine	Malaria[b]	Agranulocytosis, hepatotoxicity	No information	Not assigned	Yes[c]
Chloroquine	Malaria[b]	*Occasional:* pruritus, nausea, vomiting, headache, hair depigmentation, exfoliative dermatitis, reversible corneal opacity *Rare:* irreversible retinal injury, nail discoloration, blood dyscrasias	Antacids and kaolin: reduced absorption of chloroquine Ampicillin: bioavailability reduced by chloroquine Cimetidine: increased serum levels of chloroquine Cyclosporine: serum levels increased by chloroquine	Not assigned[d]	Yes[c]
Piperaquine	Malaria[b]	*Occasional:* GI disturbances	None reported	Not assigned	Yes
8-Aminoquinolines					
Primaquine	Malaria[b]	*Frequent:* hemolysis in patients with G6PD deficiency *Occasional:* methemoglobinemia, GI disturbances *Rare:* CNS symptoms	Quinacrine: potentiated toxicity of primaquine	Contraindicated	Yes
Tafenoquine	Malaria[b]	*Frequent:* hemolysis in patients with G6PD deficiency, mild GI upset *Occasional:* methemoglobinemia, headache	No information	Not assigned	Yes
Aminoalcohols					
Halofantrine	Malaria[b]	*Frequent:* abdominal pain, diarrhea *Occasional:* ECG disturbances (dose-related prolongation of QTc and PR interval), nausea, pruritus; contraindicated in persons who have cardiac disease or who have taken mefloquine in the preceding 3 weeks	Concomitant use of agents that prolong QTc interval contraindicated	C	No information
Lumefantrine	Malaria[b]	*Occasional:* nausea, vomiting, diarrhea, abdominal pain, anorexia, headache, dizziness	Plasma levels increased by darunavir and nevirapine, decreased by etravirine	Not assigned	No information
Aminoglycosides					
Paromomycin	Amebiasis,[b] infection with *Dientamoeba fragilis*, giardiasis, cryptosporidiosis, leishmaniasis	*Frequent:* GI disturbances (oral dosing only) *Occasional:* nephrotoxicity, ototoxicity, vestibular toxicity (parenteral dosing only)	No major interactions	Oral: B Parenteral: not assigned[d]	No information
Amphotericin B Amphotericin B deoxycholate Amphotec (InterMune) Amphotericin B lipid complex, ABLC (Abelcet) Amphotericin B, liposomal (AmBisome)	Leishmaniasis,[e] amebic meningoencephalitis	*Frequent:* fever, chills, hypokalemia, hypomagnesemia, nephrotoxicity *Occasional:* vomiting, dyspnea, hypotension	Antineoplastic agents: renal toxicity, bronchospasm, hypotension Glucocorticoids, ACTH, digitalis: hypokalemia Zidovudine: increased myelo- and nephrotoxicity	B	No information
Antimonials Meglumine antimoniate[h]	Leishmaniasis	*Frequent:* arthralgias/myalgias, pancreatitis, ECG changes (QT prolongation, T-wave flattening or inversion)	Antiarrhythmics and tricyclic antidepressants: increased risk of cardiotoxicity	Not assigned	No information
Artemisinin and derivatives	Malaria[g]	*Occasional:* neurotoxicity (ataxia, convulsions), nausea, vomiting, anorexia, contact dermatitis			
Arteether			No information	Not assigned	Yes[c]
Artemether			Artemether levels decreased by darunavir, etravirine, and nevirapine	C	Yes[c]
Artesunate[h]			Mefloquine: levels decreased and clearance accelerated by artesunate	C	Yes[c]
Dihydroartemisinin			Mefloquine: increased absorption	Not assigned	Yes[c]

(*Continued*)

TABLE 229-1 Overview of Agents Used for the Treatment of Parasitic Infections (Continued)

DRUGS BY CLASS	PARASITIC INFECTION(S)	ADVERSE EFFECTS	MAJOR DRUG–DRUG INTERACTIONS	PREGNANCY CLASS[a]	BREAST MILK
Atovaquone	Malaria,[b] babesiosis	*Frequent:* nausea, vomiting *Occasional:* abdominal pain, headache	Plasma levels decreased by rifampin, tetracycline, atazanavir, efavirenz, lopinavir/ritonavir; bioavailability decreased by metoclopramide	C	No information
Azoles Fluconazole Itraconazole Ketoconazole	Leishmaniasis	*Serious:* hepatotoxicity *Rare:* exfoliative skin disorders, anaphylaxis	Warfarin, oral hypoglycemics, phenytoin, cyclosporine, theophylline, digoxin, dofetilide, quinidine, carbamazepine, rifabutin, busulfan, docetaxel, vinca alkaloids, pimozide, alprazolam, diazepam, midazolam, triazolam, verapamil, atorvastatin, cerivastatin, lovastatin, simvastatin, tacrolimus, sirolimus, indinavir, ritonavir, saquinavir, alfentanil, buspirone, methylprednisolone, trimetrexate: plasma levels increased by azoles Carbamazepine, phenobarbital, phenytoin, isoniazid, rifabutin, rifampin, antacids, H_2-receptor antagonists, proton pump inhibitors, nevirapine: decreased plasma levels of azoles Clarithromycin, erythromycin, indinavir, ritonavir: increased plasma levels of azoles	C	Yes
Benzimidazoles					
Albendazole	Ascariasis, capillariasis, clonorchiasis, cutaneous larva migrans, cysticercosis,[b] echinococcosis,[b] enterobiasis, eosinophilic enterocolitis, gnathostomiasis, hookworm, lymphatic filariasis, microsporidiosis, strongyloidiasis, trichinellosis, trichostrongyliasis, trichuriasis, visceral larva migrans	*Occasional:* nausea, vomiting, abdominal pain, headache, reversible alopecia, elevated aminotransferases *Rare:* leukopenia, rash	Dexamethasone, praziquantel: plasma level of albendazole sulfoxide increased by ~50%	C	Yes[c]
Mebendazole	Ascariasis,[b] capillariasis, eosinophilic enterocolitis, enterobiasis,[b] hookworm,[b] trichinellosis, trichostrongyliasis, trichuriasis,[b] visceral larva migrans	*Occasional:* diarrhea, abdominal pain, elevated aminotransferases *Rare:* agranulocytosis, thrombocytopenia, alopecia	Cimetidine: inhibited mebendazole metabolism	C	No information
Thiabendazole	Strongyloidiasis,[b] cutaneous larva migrans,[b] visceral larva migrans[b]	*Frequent:* anorexia, nausea, vomiting, diarrhea, headache, dizziness, asparagus-like urine odor *Occasional:* drowsiness, giddiness, crystalluria, elevated aminotransferases, psychosis *Rare:* hepatitis, seizures, angioneurotic edema, Stevens-Johnson syndrome, tinnitus	Theophylline: serum levels increased by thiabendazole	C	No information
Triclabendazole	Fascioliasis, paragonimiasis	*Occasional:* abdominal cramps, diarrhea, biliary colic, transient headache	No information	Not assigned	Yes
Benznidazole	Chagas disease	*Frequent:* rash, pruritus, nausea, leukopenia, paresthesias	No major interactions	Not assigned	No information
Clindamycin	Babesiosis, malaria, toxoplasmosis	*Occasional:* pseudomembranous colitis, abdominal pain, diarrhea, nausea/vomiting *Rare:* pruritus, skin rashes	No major interactions	B	Yes[c]
Diloxanide furoate	Amebiasis	*Frequent:* flatulence *Occasional:* nausea, vomiting, diarrhea *Rare:* pruritus	None reported	Contraindicated	No information

(*Continued*)

TABLE 229-1 Overview of Agents Used for the Treatment of Parasitic Infections (Continued)

DRUGS BY CLASS	PARASITIC INFECTION(S)	ADVERSE EFFECTS	MAJOR DRUG–DRUG INTERACTIONS	PREGNANCY CLASS[a]	BREAST MILK
Eflornithine[f] (difluoromethylornithine, DFMO)	Trypanosomiasis	*Frequent:* pancytopenia *Occasional:* diarrhea, seizures *Rare:* transient hearing loss	No major interactions	Contraindicated	No information
Emetine and dehydroemetine	Amebiasis, fascioliasis	*Severe:* cardiotoxicity *Frequent:* pain at injection site *Occasional:* dizziness, headache, GI symptoms	None reported	X	No information
Folate antagonists					
Dihydrofolate reductase inhibitors					
Pyrimethamine	Malaria,[b] isosporiasis, toxoplasmosis[b]	*Occasional:* folate deficiency *Rare:* rash, seizures, severe skin reactions (toxic epidermal necrolysis, erythema multiforme, Stevens-Johnson syndrome)	Sulfonamides, proguanil, zidovudine: increased risk of bone marrow suppression when used concomitantly	C	Yes
Proguanil and chlorproguanil	Malaria	*Occasional:* urticaria *Rare:* hematuria, GI disturbances	Atazanavir, efavirenz, lopinavir/ritonavir: plasma levels of proguanil decreased	C	Yes
Trimethoprim	Cyclosporiasis, isosporiasis	Hyperkalemia, GI upset, mild stomatitis	Methotrexate: reduced clearance Warfarin: effect prolonged Phenytoin: hepatic metabolism increased	C	Yes
Dihydropteroate synthetase inhibitors: sulfonamides Sulfadiazine Sulfamethoxazole Sulfadoxine	Malaria,[b] toxoplasmosis[b]	*Frequent:* GI disturbances, allergic skin reactions, crystalluria *Rare:* severe skin reactions (toxic epidermal necrolysis, erythema multiforme, Stevens-Johnson syndrome), agranulocytosis, aplastic anemia, hypersensitivity of the respiratory tract, hepatitis, interstitial nephritis, hypoglycemia, aseptic meningitis	Thiazide diuretics: increased risk of thrombocytopenia in elderly patients Warfarin: effect prolonged by sulfonamides Methotrexate: levels increased by sulfonamides Phenytoin: metabolism impaired by sulfonamides Sulfonylureas: effect prolonged by sulfonamides	B	Yes
Dihydropteroate synthetase inhibitors: sulfones					
Dapsone	Leishmaniasis, malaria, toxoplasmosis	*Frequent:* rash, anorexia *Occasional:* hemolysis, methemoglobinemia, neuropathy, allergic dermatitis, anorexia, nausea, vomiting, tachycardia, headache, insomnia, psychosis, hepatitis *Rare:* agranulocytosis	Rifampin: lowered plasma levels of dapsone	C	Yes
Fumagillin	Microsporidiosis	*Rare:* neutropenia, thrombocytopenia	None reported	No information	No information
Furazolidone	Giardiasis	*Frequent:* nausea/vomiting, brown urine *Occasional:* rectal itching, headache *Rare:* hemolytic anemia, disulfiram-like reactions, MAO inhibitor interactions	Risk of hypertensive crisis when administered for >5 days with MAO inhibitors	C	No information
Iodoquinol	Amebiasis,[b] balantidiasis, *D. fragilis* infection	*Occasional:* headache, rash, pruritus, thyrotoxicosis, nausea, vomiting, abdominal pain, diarrhea *Rare:* optic neuritis, peripheral neuropathy, seizures, encephalopathy	No major interactions	C	No information
Lactones					
Ivermectin	Ascariasis, cutaneous larva migrans, gnathostomiasis, loiasis, lymphatic filariasis, onchocerciasis,[b] scabies, strongyloidiasis,[b] trichuriasis	*Occasional:* fever, pruritus, headache, myalgias *Rare:* hypotension	No major interactions	C	Yes[c]
Moxidectin	Onchocerciasis	*Occasional:* fever, pruritus, headache, myalgias *Rare:* orthostatic hypotension, elevated transaminases	No major interactions	C	Yes[c]

TABLE 229-1 Overview of Agents Used for the Treatment of Parasitic Infections (Continued)

DRUGS BY CLASS	PARASITIC INFECTION(S)	ADVERSE EFFECTS	MAJOR DRUG–DRUG INTERACTIONS	PREGNANCY CLASS[a]	BREAST MILK
Macrolides					
Azithromycin	Babesiosis	*Occasional:* nausea, vomiting, diarrhea, abdominal pain *Rare:* angioedema, cholestatic jaundice	Cyclosporine and digoxin: levels increased by azithromycin Nelfinavir: increased levels of azithromycin	B	Yes
Spiramycin[h]	Toxoplasmosis	*Occasional:* GI disturbances, transient skin eruptions *Rare:* thrombocytopenia, QT prolongation in an infant, cholestatic hepatitis	No major interactions	Not assigned[d]	Yes[c]
Mefloquine	Malaria[b]	*Frequent:* lightheadedness, nausea, headache *Occasional:* confusion; nightmares; insomnia; visual disturbance; transient and clinically silent ECG abnormalities, including sinus bradycardia, sinus arrhythmia, first-degree AV block, prolongation of QTc interval, and abnormal T waves *Rare:* psychosis, convulsions, hypotension	Administration of halofantrine <3 weeks after mefloquine use may produce fatal QTc prolongation. Mefloquine may lower plasma levels of anticonvulsants. Levels are decreased and clearance is accelerated by artesunate. Mefloquine decreases plasma levels of ritonavir and possibly other protease inhibitors.	C	Yes
Melarsoprol[f]	Trypanosomiasis	*Frequent:* myocardial injury, encephalopathy, peripheral neuropathy, hypertension *Occasional:* G6PD-induced hemolysis, erythema nodosum leprosum *Rare:* hypotension	No major interactions	Not assigned	No information
Metrifonate	Schistosomiasis	*Frequent:* abdominal pain, nausea, vomiting, diarrhea, headache, vertigo, bronchospasm *Rare:* cholinergic symptoms	No major interactions	B	No
Miltefosine	Leishmaniasis,[b] primary amebic meningoencephalitis	*Frequent:* mild and transient (1–2 days) GI disturbances within first 2 weeks of therapy (resolve after treatment completion); motion sickness *Occasional:* reversible elevations of creatinine and aminotransferases	No major interactions	Not assigned	No information
Niclosamide	Intestinal cestode infections[b]	*Occasional:* nausea, vomiting, dizziness, pruritus	No major interactions	B	No information
Nifurtimox	Chagas disease	*Frequent:* nausea, vomiting, abdominal pain, insomnia, paresthesias, weakness, tremors *Rare:* seizures (all reversible and dose-related)	No major interactions	Not assigned	No information
Nitazoxanide	Cryptosporidiosis,[b] giardiasis[b]	*Occasional:* abdominal pain, diarrhea *Rare:* vomiting, headache	Increases plasma levels of highly protein-bound drugs (e.g., phenytoin, warfarin)	B	No information
Nitroimidazoles					
Metronidazole	Amebiasis,[b] balantidiasis, dracunculiasis, giardiasis [b], trichomoniasis,[b] *D. fragilis* infection	*Frequent:* nausea, headache, anorexia, metallic aftertaste *Occasional:* vomiting, insomnia, vertigo, paresthesias, disulfiram-like effects *Rare:* seizures, peripheral neuropathy	Warfarin: effect enhanced by metronidazole Disulfiram: psychotic reaction Phenobarbital, phenytoin: accelerate elimination of metronidazole Lithium: serum levels elevated by metronidazole Cimetidine: prolonged half-life of metronidazole Oral solutions of antiretrovirals containing alcohol: disulfiram effect due to alcohol	B	Yes
Tinidazole	Amebiasis,[b] giardiasis, trichomoniasis	*Occasional:* nausea, vomiting, metallic taste	*See* metronidazole	C	Yes

TABLE 229-1 Overview of Agents Used for the Treatment of Parasitic Infections (Continued)

DRUGS BY CLASS	PARASITIC INFECTION(S)	ADVERSE EFFECTS	MAJOR DRUG–DRUG INTERACTIONS	PREGNANCY CLASS[a]	BREAST MILK
Oxamniquine	Schistosomiasis	*Occasional:* dizziness, drowsiness, headache, orange urine, elevated aminotransferases *Rare:* seizures	No major interactions	C	No information
Pentamidine isethionate	Leishmaniasis, trypanosomiasis	*Frequent:* hypotension, hypoglycemia, pancreatitis, sterile abscesses at IM injection sites, GI disturbances, reversible renal failure *Occasional:* hepatotoxicity, cardiotoxicity, delirium *Rare:* anaphylaxis	No major interactions	C	No information
Piperazine and derivatives					
Piperazine	Ascariasis, enterobiasis	*Occasional:* nausea, vomiting, diarrhea, abdominal pain, headache *Rare:* neurotoxicity, seizures	None reported	C	No information
Diethylcarbamazine[f]	Lymphatic filariasis, loiasis, tropical pulmonary eosinophilia	*Frequent:* dose-related nausea, vomiting *Rare:* fever, chills, arthralgias, headache	None reported	Not assigned[d]	No information
Praziquantel	Clonorchiasis,[b] cysticercosis, diphyllobothriasis, hymenolepiasis, taeniasis, opisthorchiasis, intestinal trematodes, paragonimiasis, schistosomiasis[b]	*Frequent:* abdominal pain, diarrhea, dizziness, headache, malaise *Occasional:* fever, nausea *Rare:* pruritus, singultus	No major interactions	B	Yes
Pyrantel pamoate	Ascariasis, eosinophilic enterocolitis, enterobiasis,[b] hookworm, trichostrongyliasis	*Occasional:* GI disturbances, headache, dizziness, elevated aminotransferases	No major interactions	C	No information
Pyronaridine	Malaria	*Occasional:* headache, nausea	None reported to date	B	Yes
Quinacrine[h]	Giardiasis[b]	*Frequent:* headache, nausea, vomiting, bitter taste *Occasional:* yellow-orange discoloration of skin, sclerae, urine; begins after 1 week of treatment and lasts up to 4 months after drug discontinuation *Rare:* psychosis, exfoliative dermatitis, retinopathy, G6PD-induced hemolysis, exacerbation of psoriasis, disulfiram-like effects	Primaquine: toxicity potentiated by quinacrine	C	No information
Quinine and quinidine	Malaria, babesiosis	*Frequent:* cinchonism (tinnitus, high-tone deafness, headache, dysphoria, nausea, vomiting, abdominal pain, visual disturbances, postural hypotension), hyperinsulinemia resulting in life-threatening hypoglycemia *Occasional:* deafness, hemolytic anemia, arrhythmias, hypotension due to rapid IV infusion	Carbonic anhydrase inhibitors, thiazide diuretics: reduced renal elimination of quinidine Amiodarone, cimetidine: increased quinidine levels Nifedipine: decreased quinidine levels; quinidine slows metabolism of nifedipine Phenobarbital, phenytoin, rifampin: accelerated hepatic elimination of quinidine Verapamil: reduced hepatic clearance of quinidine Diltiazem: decreased clearance of quinidine	X	Yes[c]
Quinolones					
Ciprofloxacin	Cyclosporiasis, isosporiasis	*Occasional:* nausea, diarrhea, vomiting, abdominal pain/discomfort, headache, restlessness, rash *Rare:* myalgias/arthralgias, tendon rupture, CNS symptoms (nervousness, agitation, insomnia, anxiety, nightmares, or paranoia); convulsions	Probenecid: increased serum levels of ciprofloxacin Theophylline, warfarin: serum levels increased by ciprofloxacin	C	Yes

(*Continued*)

TABLE 229-1 Overview of Agents Used for the Treatment of Parasitic Infections (Continued)

DRUGS BY CLASS	PARASITIC INFECTION(S)	ADVERSE EFFECTS	MAJOR DRUG–DRUG INTERACTIONS	PREGNANCY CLASS[a]	BREAST MILK
Suramin[f]	Trypanosomiasis	*Frequent:* immediate: fever, urticaria, nausea, vomiting, hypotension; delayed (up to 24 h): exfoliative dermatitis, stomatitis, paresthesias, photophobia, renal dysfunction *Occasional:* nephrotoxicity, adrenal toxicity, optic atrophy, anaphylaxis	No major interactions	Not assigned	No information
Tetracyclines	Balantidiasis, *D. fragilis* infection, malaria; lymphatic filariasis (doxycycline)	*Frequent:* GI disturbances *Occasional:* photosensitivity dermatitis *Rare:* exfoliative dermatitis, esophagitis, hepatotoxicity	Warfarin: effect prolonged by tetracyclines	D	Yes

[a]Based on U.S. Food and Drug Administration (FDA) pregnancy categories of A–D, X. [b]Approved by the FDA for this indication. [c]Not believed to be harmful. [d]Use in pregnancy is recommended by international organizations outside the United States. [e]Only AmBisome has been approved by the FDA for this indication. [f]Available through the CDC. [g]Only artemether (in combination with lumefantrine) and artesunate have been approved by the FDA for this indication. [h]Available through the manufacturer.

Abbreviations: ACTH, adrenocorticotropic hormone; AV, atrioventricular; CNS, central nervous system; ECG, electrocardiogram; G6PD, glucose 6-phosphate dehydrogenase; GI, gastrointestinal; MAO, monoamine oxidase.

and its metabolites are all excreted in urine, but there are no recommendations concerning dosage adjustment in patients with impaired renal function. Agranulocytosis and hepatotoxicity can develop with repeated use; therefore, this drug should not be used for prophylaxis. Indeed, because of its adverse effects and widespread resistance, amodiaquine is no longer in use in Europe or the United States, and it was dropped from malaria control programs as a single agent by the WHO in 1990; however, it remains effective in some areas when combined with other antimalarial drugs (e.g., artesunate, sulfadoxine-pyrimethamine).

Amphotericin B See Table 229-1 and Chap. 217.

Antimonials† Despite associated adverse reactions and the need for prolonged parenteral treatment, the pentavalent antimonial compounds (designated Sb^v) have remained the first-line therapy for all forms of leishmaniasis throughout the world, primarily because they are affordable and effective and have survived the test of time. Pentavalent antimonials are active only after bioreduction to the trivalent Sb(III) form, which inhibits trypanothione reductase, a critical enzyme involved in the oxidative stress management of *Leishmania* species. The fact that *Leishmania* species use trypanothione rather than glutathione (which is used by mammalian cells) may explain the parasite-specific activity of antimonials. The drugs are taken up by the reticuloendothelial system, and their activity against *Leishmania* species may be enhanced by this localization.

Resistance is a major problem in some areas. Although low-level unresponsiveness to Sb^v was identified in India in the 1970s, incremental increases in both the recommended daily dosage (to 20 mg/kg) and the duration of treatment (to 28 days) satisfactorily compensated for the growing resistance until around 1990. Since then, the capacity of Sb^v to induce long-term cure in patients with kala-azar who live in eastern India has steadily eroded. Co-infection with HIV impairs the treatment response.

Pentavalent antimonials are available in aqueous solution and are administered parenterally. Antimony appears to have two elimination phases. When the drug is administered IV, the mean half-life of the first phase is <2 h; the mean half-life of the terminal elimination phase is nearly 36 h. This slower phase may be due to conversion of pentavalent antimony to a trivalent form that is the likely cause of the side effects often seen with prolonged therapy.

In 2020, the global manufacturer of sodium stibogluconate notified the CDC that the product would be discontinued due to the inability to source the necessary raw materials. As a result, CDC ended its distribution program following expiration of the last lot in use. However, meglumine antimoniate is available from the manufacturer through the FDA (301-796-1400).

Artemisinin Derivatives* Artesunate, artemether, artemotil, and the parent compound artemisinin are sesquiterpene lactones derived from the wormwood plant *Artemisia annua*. These agents are at least 10-fold more potent in vivo than other antimalarial drugs and presently show no cross-resistance with known antimalarial drugs; thus, they have become first-line agents for the treatment of severe falciparum malaria. The artemisinin compounds are rapidly effective against the asexual blood forms of *Plasmodium* species but are not active against intrahepatic forms. With the exception of artesunate, artemisinin and its derivatives are highly lipid soluble and readily cross both host and parasite cell membranes. One factor that explains the drugs' highly selective toxicity against malaria is that parasitized erythrocytes concentrate artemisinin and its derivatives to concentrations 100-fold higher than those in uninfected erythrocytes. The antimalarial effect of these agents results primarily from the active metabolite dihydroartemisinin; in the presence of heme or molecular iron, the endoperoxide moiety of dihydroartemisinin decomposes, generating free radicals and other metabolites that damage parasite proteins. The compounds are available for oral, rectal, IV, or IM administration, depending on the derivative. Following FDA approval in May 2020, artesunate became commercially available in the United States.

Artemisinin and its derivatives are cleared rapidly from the circulation. Their short half-lives limit their value for prophylaxis and monotherapy. Side effects appear to be minor, although sinus bradycardia and transient first-degree heart block have been reported. Although seen in animal models, embryotoxicity and neurotoxicity have not been identified in humans despite active investigation. These agents should be used only in combination with another, longer-acting agent (e.g., artesunate-mefloquine, dihydroartemisinin-piperaquine). A combined formulation of artemether and lumefantrine is widely available for the treatment of acute uncomplicated falciparum malaria acquired in areas where *Plasmodium falciparum* is resistant to chloroquine and antifolates.

Atovaquone Atovaquone is a hydroxynaphthoquinone that exerts broad-spectrum antiprotozoal activity via selective inhibition of parasite mitochondrial electron transport. This agent exhibits potent activity against toxoplasmosis and babesiosis when used with pyrimethamine and azithromycin, respectively. Atovaquone possesses a novel mode of action against *Plasmodium* species, inhibiting the electron transport system at the level of the cytochrome bc1 complex. The drug is active against both the erythrocytic and the exoerythrocytic stages of *Plasmodium* species; however, because it does not eradicate hypnozoites from the liver, patients with *P. vivax* or *P. ovale* infections must be given radical prophylaxis.

Malarone is a fixed-dose combination of atovaquone and proguanil used for malaria prophylaxis as well as for the treatment of acute, uncomplicated *P. falciparum* malaria. Malarone has been shown to be effective in regions with multidrug-resistant *P. falciparum*. Resistance to atovaquone develops rapidly via mutations in the parasite's mitochondrial cytochrome b complex. However, the mutations result in sterility of female parasites; thus, atovaquone-resistant parasites cannot

be transmitted to another person. This situation may explain why clinical resistance has yet to be reported.

The bioavailability of atovaquone varies considerably. Absorption after a single oral dose is slow, increases two- to threefold with a fatty meal, and is dose-limited above 750 mg. The elimination half-life is increased in patients with moderate hepatic impairment. Because of the potential for drug accumulation, the use of atovaquone is generally contraindicated in persons with a creatinine clearance rate <30 mL/min. No dosage adjustments are needed in patients with mild to moderate renal impairment.

Azithromycin See Table 229-1 and Chap. 149.

Azoles See Table 229-1 and Chap. 217.

Benznidazole Introduced in 1971, this oral nitroimidazole derivative is used to treat Chagas disease, with cure rates of 80–90% recorded in acute infections. Benznidazole is believed to exert its trypanocidal effects by generating oxygen radicals to which the parasites are more sensitive than mammalian cells because of a relative deficiency in antioxidant enzymes. Benznidazole also appears to alter the balance between pro- and anti-inflammatory mediators by downregulating the synthesis of nitrite, interleukin (IL) 6, and IL-10 in macrophages. Benznidazole is highly lipophilic and readily absorbed. The drug is extensively metabolized; only 5% of the dose is excreted unchanged in the urine. Benznidazole is well tolerated; adverse effects are rare and usually manifest as GI upset or pruritic rash. Following FDA approval in 2018, this drug is now commercially available in the United States.

Chloroquine This 4-aminoquinoline has marked, rapid schizonticidal and gametocidal activity against blood forms of *P. ovale* and *P. malariae* and against susceptible strains of *P. vivax* and *P. falciparum*. It is not active against intrahepatic forms (*P. vivax* and *P. ovale*). Parasitized erythrocytes accumulate chloroquine in significantly greater concentrations than do normal erythrocytes. Chloroquine, a weak base, concentrates in the food vacuoles of intraerythrocytic parasites because of a relative pH gradient between the extracellular space and the acidic food vacuole. Once it enters the acidic food vacuole, chloroquine is rapidly converted to a membrane-impermeable protonated form and is trapped. Continued accumulation of chloroquine in the parasite's acidic food vacuoles results in drug levels that are 600-fold higher at this site than in plasma. The high accumulation of chloroquine results in an increase in pH within the food vacuole to a level above that required for the acid proteases' optimal activity, inhibiting parasite heme polymerase; as a result, the parasite is effectively killed with its own metabolic waste. Compared with susceptible strains, chloroquine-resistant plasmodia transport chloroquine out of intraparasitic compartments more rapidly and maintain lower chloroquine concentrations in their acid vesicles. Hydroxychloroquine, a congener of chloroquine, is equivalent to chloroquine in its antimalarial efficacy but is preferred to chloroquine for the treatment of autoimmune disorders because it produces less ocular toxicity when used in high doses.

Chloroquine is well absorbed. However, because it exhibits extensive tissue binding, a loading dose is required to yield effective plasma concentrations. A therapeutic drug level in plasma is reached 2–3 h after oral administration (the preferred route). Chloroquine can be administered IV, but excessively rapid parenteral administration can result in seizures and death from cardiovascular collapse. The mean half-life of chloroquine is 4 days, but the rate of excretion decreases as plasma levels decline, making once-weekly administration possible for prophylaxis in areas with sensitive strains. About one-half of the parent drug is excreted in urine, but the dose should not be reduced for persons with acute malaria and renal insufficiency.

Ciprofloxacin See Table 229-1 and Chap. 149.

Clindamycin See Table 229-1 and Chap. 149.

Dapsone See Table 229-1 and Chap. 188.

Dehydroemetine Emetine is an alkaloid derived from ipecac; dehydroemetine is synthetically derived from emetine and is considered less toxic. Both agents are active against *Entamoeba histolytica* and appear to work by blocking peptide elongation and thus inhibiting protein synthesis. Emetine is rapidly absorbed after parenteral administration, rapidly distributed throughout the body, and slowly excreted in the urine in unchanged form. Both agents are contraindicated in patients with renal disease.

Diethylcarbamazine* A derivative of the antihelminthic agent piperazine with a long history of successful use, diethylcarbamazine (DEC) remains the treatment of choice for lymphatic filariasis and loiasis and has also been used for visceral larva migrans. Although piperazine itself has no antifilarial activity, the piperazine ring of DEC is essential for the drug's activity. DEC's mechanism of action remains to be fully defined. Proposed mechanisms include immobilization due to inhibition of parasite cholinergic muscle receptors, disruption of microtubule formation, and alteration of helminthic surface membranes resulting in enhanced killing by the host's immune system. DEC enhances adherence properties of eosinophils. The development of resistance under drug pressure (i.e., a progressive decrease in efficacy when the drug is used widely in human populations) has not been observed, although DEC has variable effects when administered to persons with filariasis. Monthly administration provides effective prophylaxis against both bancroftian filariasis and loiasis.

DEC is well absorbed after oral administration, with peak plasma concentrations reached within 1–2 h. No parenteral form is available. The drug is eliminated largely by renal excretion, with <5% found in feces. If more than one dose is to be administered to an individual with renal dysfunction, the dose should be reduced commensurate with the reduction in creatinine clearance rate. Alkalinization of the urine prevents renal excretion and increases the half-life of DEC. Use in patients with onchocerciasis can precipitate a Mazzotti reaction, with pruritus, fever, and arthralgias. Like other piperazines, DEC is active against *Ascaris* species. Patients co-infected with this nematode may expel live worms after treatment.

Diloxanide Furoate Diloxanide furoate, a substituted acetanilide, is a luminally active agent used to eradicate the cysts of *E. histolytica*. After ingestion, diloxanide furoate is hydrolyzed by enzymes in the lumen or mucosa of the intestine, releasing furoic acid and the ester diloxanide; the latter acts directly as an amebicide.

Diloxanide furoate is given alone to asymptomatic cyst passers. For patients with active amebic infections, diloxanide is generally administered in combination with a 5-nitroimidazole such as metronidazole or tinidazole. Diloxanide furoate is rapidly absorbed after oral administration. When coadministered with a 5-nitroimidazole, diloxanide levels peak within 1 h and disappear within 6 h. About 90% of an oral dose is excreted in the urine within 48 h, chiefly as the glucuronide metabolite. Diloxanide furoate is contraindicated in pregnant and breast-feeding women and in children <2 years of age.

Eflornithine* Eflornithine (difluoromethylornithine, or DFMO) is a fluorinated analogue of the amino acid ornithine. Although originally designed as an antineoplastic agent, eflornithine has proven effective against some trypanosomatids.

Eflornithine has specific activity against all stages of infection with *Trypanosoma brucei gambiense*; however, it is inactive against *T. b. rhodesiense*. The drug acts as an irreversible suicide inhibitor of ornithine decarboxylase, the first enzyme in the biosynthesis of the polyamines putrescine and spermidine. Polyamines are essential for the synthesis of trypanothione, an enzyme required for the maintenance of intracellular thiols in the correct redox state and for the removal of reactive oxygen metabolites. However, polyamines are also essential for cell division in eukaryotes, and ornithine decarboxylase is similar in trypanosomes and mammals. The selective antiparasitic activity of eflornithine is partly explained by the structure of the trypanosomal enzyme, which lacks a 36-amino-acid C-terminal sequence found on mammalian ornithine decarboxylase. This difference results in a lower turnover of ornithine decarboxylase and a more rapid decrease of polyamines in trypanosomes than in the mammalian host. The diminished effectiveness of eflornithine against *T. b. rhodesiense* appears to be due

to the parasite's ability to replace the inhibited enzyme more rapidly than *T. b. gambiense*.

Eflornithine is less toxic but more costly than conventional therapy. It can be administered IV or PO. The dose should be reduced in renal failure. Eflornithine readily crosses the blood-brain barrier; CSF levels are highest in persons with the most severe central nervous system (CNS) involvement.

Flubendazole This agent, a methylcarbamate benzimidazole, is highly active against a broad spectrum of gut nematodes and filaria. Its antihelminthic effect is similar to other benzimidazoles; however, it is also an effective inducer of reactive oxygen species and disrupts glucose transport and metabolism. It has limited solubility in water, so bioavailability is very low, but absorption increases if taken after meals, and is further enhanced when reconstituted as a cyclodextrin-based formulation. It is approved for human use in Europe but not in the Unites States.

Fosmidomycin Originally developed in the 1970s as an antibiotic, this *Streptomyces*-derived agent is an aminopropylphosphonic acid that exhibits antimalarial activity through inhibition of 1-deoxy-D-xylulose 5-phosphate reductoisomerase, an essential enzyme on the non-mevalonate pathway of isoprenoid biosynthesis, a pathway that is common in most eukaryotes but absent in humans. For >15 years, fosmidomycin has been evaluated alone and in combination with other antimalarials, and it has demonstrated both safety and efficacy. However, the drug is highly charged—resulting in a short plasma half-life (3.5 h)—causing high rates of recrudescent malaria, particularly in children. It is not currently available, but clinical studies are ongoing.

Fumagillin† Originally discovered as an antiangiogenic compound derived from the fungus *Aspergillus fumigatus*, fumagillin is a water-insoluble antibiotic that is active against microsporidia and is used topically to treat ocular infections due to *Encephalitozoon* species. When given systemically, fumagillin was effective but caused thrombocytopenia in all recipients in the second week of treatment; this side effect was readily reversed when administration of the drug was stopped. Fumagillin acts by binding to methionine aminopeptidase 2, thus inhibiting microsporidial replication by irreversibly blocking the active site.

Furazolidone This nitrofuran derivative is an effective alternative agent for the treatment of giardiasis and also exhibits activity against *Isospora belli*. Because it is the only agent active against *Giardia* that is available in liquid form, it is most often used to treat young children. Furazolidone undergoes reductive activation in *Giardia lamblia* trophozoites—an event that, unlike the reductive activation of metronidazole, involves an NADH oxidase. The killing effect correlates with the toxicity of reduced products, which damage important cellular components, including DNA. Although furazolidone had been thought to be largely unabsorbed when administered orally, the occurrence of systemic adverse reactions indicates that this is not the case. More than 65% of the drug dose can be recovered from the urine as colored metabolites. Omeprazole reduces the oral bioavailability of furazolidone.

Furazolidone is a monoamine oxidase (MAO) inhibitor; thus, caution should be used in its concomitant administration with other drugs (especially indirectly acting sympathomimetic amines) and in the consumption of food and drink containing tyramine during treatment. However, hypertensive crises have not been reported in patients receiving furazolidone, and it has been suggested that—because furazolidone inhibits MAOs gradually over several days—the risks are small if treatment is limited to a 5-day course. Because hemolytic anemia can occur in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency and glutathione instability, furazolidone treatment is contraindicated in mothers who are breast-feeding and in neonates.

Halofantrine This 9-phenanthrenemethanol is one of three classes of arylaminoalcohols first identified as potential antimalarial agents by the World War II Malaria Chemotherapy Program. Its activity is believed to be similar to that of chloroquine, although it is an oral alternative for the treatment of malaria due to chloroquine-resistant *P. falciparum*.

Halofantrine is thought to share one or more mechanisms with the 4-aminoquinolines, forming a complex with ferriprotoporphyrin IX and interfering with the degradation of hemoglobin. It has been shown to bind to plasmepsin, a hemoglobin-degrading enzyme unique to plasmodia.

Halofantrine exhibits erratic bioavailability, but its absorption is significantly enhanced when it is taken with a fatty meal. The elimination half-life of halofantrine is 1–2 days; it is excreted mainly in feces. Halofantrine is metabolized into *N*-debutyl-halofantrine by the cytochrome P450 enzyme CYP3A4. Grapefruit juice should be avoided during treatment because it increases both halofantrine's bioavailability and halofantrine-induced QT interval prolongation by inhibiting CYP3A4 at the enterocyte level. Halofantrine should not be given simultaneously with or <3 weeks after mefloquine because of the potential occurrence of a fatal prolongation of the QTc interval on electrocardiography.

Iodoquinol Iodoquinol (diiodohydroxyquin), a hydroxyquinoline, is an effective luminal agent for the treatment of amebiasis, balantidiasis, and infection with *Dientamoeba fragilis*. Its mechanism of action is unknown. It is poorly absorbed. Because the drug contains 64% organically bound iodine, it should be used with caution in patients with thyroid disease. Iodine dermatitis occurs occasionally during iodoquinol treatment. Protein-bound serum iodine levels may be increased during treatment and can interfere with certain tests of thyroid function. These effects may persist for as long as 6 months after discontinuation of therapy. Iodoquinol is contraindicated in patients with liver disease. Most serious are the reactions related to prolonged high-dose therapy (optic neuritis, peripheral neuropathy), which should not occur if the recommended dosage regimens are followed.

Ivermectin Ivermectin (22,23-dihydroavermectin) is a derivative of the macrocyclic lactone avermectin produced by the soil-dwelling actinomycete *Streptomyces avermitilis*. Ivermectin is active at low doses against a wide range of helminths and ectoparasites. It is the drug of choice for the treatment of onchocerciasis, strongyloidiasis, cutaneous larva migrans, and scabies. Ivermectin is highly active against microfilariae of the lymphatic filariases but has no macrofilaricidal activity. When ivermectin is used in combination with other agents such as DEC or albendazole for treatment of lymphatic filariasis, synergistic activity is seen. Although active against the intestinal helminths *Ascaris lumbricoides* and *Enterobius vermicularis*, ivermectin is only variably effective in trichuriasis and is ineffective against hookworms. Widespread use of ivermectin for treatment of intestinal nematode infections in sheep and goats has led to the emergence of drug resistance in veterinary practice; this development may portend problems in human medical use.

Data suggest that ivermectin acts by opening the neuromuscular membrane-associated, glutamate-dependent chloride channels. The influx of chloride ions results in hyperpolarization and muscle paralysis—particularly of the nematode pharynx, with consequent blockage of the oral ingestion of nutrients. As these chloride channels are present only in invertebrates, paralysis is seen only in the parasite.

Ivermectin is available for administration to humans only as an oral formulation. The drug is highly protein bound; it is almost completely excreted in feces. Both food and beer increase the bioavailability of ivermectin significantly. Ivermectin is distributed widely throughout the body; animal studies indicate that it accumulates at the highest concentration in adipose tissue and liver, with little accumulation in the brain. Few data exist to guide therapy in hosts with conditions that may influence drug pharmacokinetics.

Ivermectin is generally administered as a single dose of 150–200 μg/kg. In the absence of parasitic infection, the adverse effects of ivermectin in therapeutic doses are minimal. Adverse effects in patients with filarial infections include fever, myalgia, malaise, lightheadedness, and (occasionally) postural hypotension. The severity of such side effects is related to the intensity of parasite infection, with more symptoms in individuals with a heavy parasite burden. In onchocerciasis, skin edema, pruritus, and mild eye irritation may also occur. The adverse effects are generally self-limiting and only occasionally require

symptom-based treatment with antipyretics or antihistamines. More severe complications of ivermectin therapy for onchocerciasis include encephalopathy in patients heavily infected with *Loa loa*.

Lumefantrine Lumefantrine (benflumetol), a fluorene arylaminoalcohol derivative synthesized in the 1970s by the Chinese Academy of Military Medical Sciences (Beijing), has marked blood schizonticidal activity against a wide range of plasmodia. This agent conforms structurally and in mode of action to other arylaminoalcohols (quinine, mefloquine, and halofantrine). Lumefantrine exerts its antimalarial effect as a consequence of its interaction with heme, a degradation product of hemoglobin metabolism. Although its antimalarial activity is slower than that of the artemisinin-based drugs, the recrudescence rate with the recommended lumefantrine regimen is lower. The pharmacokinetic properties of lumefantrine are reminiscent of those of halofantrine, with variable oral bioavailability, considerable augmentation of oral bioavailability by concomitant fat intake, and a terminal elimination half-life of ~4–5 days in patients with malaria.

Artemether and lumefantrine have synergistic activity, and the combined formulation of artemether and lumefantrine is effective for the treatment of falciparum malaria in areas where *P. falciparum* is resistant to chloroquine and antifolates.

Mebendazole This benzimidazole is a broad-spectrum antiparasitic agent widely used to treat intestinal helminthiases. Its mechanism of action is similar to that of albendazole; however, it is a more potent inhibitor of parasite malic dehydrogenase and exhibits a more specific and selective effect against intestinal nematodes than the other benzimidazoles.

Mebendazole is available only in oral form but is poorly absorbed from the GI tract; only 5–10% of a standard dose is measurable in plasma. The proportion absorbed from the GI tract is extensively metabolized in the liver. Metabolites appear in the urine and bile; impaired liver or biliary function results in higher plasma mebendazole levels in treated patients. No dose reduction is warranted in patients with renal function impairment. Because mebendazole is poorly absorbed, its incidence of side effects is low. Transient abdominal pain and diarrhea sometimes occur, usually in persons with massive parasite burdens.

Mefloquine Mefloquine is used for prophylaxis of chloroquine-resistant malaria; high doses can be used for treatment. Despite the development of drug-resistant strains of *P. falciparum* in parts of Africa and Southeast Asia, mefloquine remains an effective drug throughout most of the world. Cross-resistance of mefloquine with halofantrine and with quinine has been documented in limited areas. Like quinine and chloroquine, this quinoline is active only against the asexual erythrocytic stages of malarial parasites. Unlike quinine, however, mefloquine has a relatively poor affinity for DNA and, as a result, does not inhibit the synthesis of parasitic nucleic acids and proteins. Although both mefloquine and chloroquine inhibit hemozoin formation and heme degradation, mefloquine differs in that it forms a complex with heme that may be toxic to the parasite.

Mefloquine HCl is poorly water soluble and intensely irritating when given parenterally; thus, it is available only in tablet form. Its absorption is adversely affected by vomiting and diarrhea but is significantly enhanced when the drug is administered with or after food. About 98% of the drug binds to protein. Mefloquine is excreted mainly in the bile and feces; therefore, no dose adjustment is needed in persons with renal insufficiency. The drug and its main metabolite are not appreciably removed by hemodialysis. No dosage adjustments are indicated for the achievement of plasma concentrations in dialysis patients. Pharmacokinetic differences have been detected among various ethnic populations; however, these distinctions are of minor importance compared with host immune status and parasite susceptibility. In patients with impaired liver function, the elimination of mefloquine may be prolonged, leading to higher plasma levels.

Mefloquine should be used with caution by individuals participating in activities requiring alertness and fine-motor coordination because dizziness, vertigo, or tinnitus can develop and persist. If the drug is to be administered for a prolonged period, periodic evaluations are recommended, including liver function tests and ophthalmic examinations. Sleep abnormalities (insomnia, abnormal dreams) have occasionally been reported. Psychosis and seizures occur rarely; mefloquine should not be prescribed to patients with neuropsychiatric conditions. The development of acute anxiety, depression, restlessness, or confusion may be considered prodromal to a more serious event, and the drug should be discontinued.

Concomitant use of quinine, quinidine, or drugs producing β-adrenergic blockade may cause significant electrocardiographic abnormalities or cardiac arrest. Halofantrine must not be given simultaneously with or <3 weeks after mefloquine because a potentially fatal prolongation of the QTc interval on electrocardiography may occur. No data exist on mefloquine use after halofantrine use. Administration of mefloquine with quinine or chloroquine may increase the risk of convulsions. Mefloquine may lower plasma levels of anticonvulsants. Caution should be exercised with concomitant antiretroviral therapy, because mefloquine has been shown to exert variable effects on ritonavir pharmacokinetics that are not explained by hepatic CYP3A4 activity or ritonavir protein binding. Vaccinations with attenuated live bacteria should be completed at least 3 days before the first dose of mefloquine.

Women of childbearing age who are traveling to areas where malaria is endemic should be warned against becoming pregnant and encouraged to practice contraception during malaria prophylaxis with mefloquine and for up to 3 months thereafter. However, in the case of unplanned pregnancy, use of mefloquine is not considered an indication for pregnancy termination. Analysis of prospectively monitored cases demonstrates a prevalence of birth defects and fetal loss comparable to background rates.

Melarsoprol* Melarsoprol has been used since 1949 for the treatment of human African trypanosomiasis. This trivalent arsenical compound is indicated for the treatment of African trypanosomiasis with neurologic involvement and for the treatment of early disease that is resistant to suramin or pentamidine. Melarsoprol, like other drugs containing heavy metals, interacts with thiol groups of several different proteins; however, its antiparasitic effects appear to be more specific. Trypanothione reductase is a key enzyme involved in the oxidative stress management of both *Trypanosoma* and *Leishmania* species, helping to maintain an intracellular reducing environment by reduction of disulfide trypanothione to its dithiol derivative dihydrotrypanothione. Melarsoprol sequesters dihydrotrypanothione, depriving the parasite of its main sulfhydryl antioxidant, and inhibits trypanothione reductase, depriving the parasite of the essential enzyme system that is responsible for keeping trypanothione reduced. These effects are synergistic. The selectivity of arsenical action against trypanosomes is due at least in part to the greater melarsoprol affinity of reduced trypanothione than of other monothiols (e.g., cysteine) on which the mammalian host depends for maintenance of high thiol levels. Melarsoprol enters the parasite via an adenosine transporter; drug-resistant strains lack this transport system.

Melarsoprol is always administered IV. A small but therapeutically significant amount of the drug enters the CSF. The compound is excreted rapidly, with ~80% of the arsenic found in feces.

Melarsoprol is highly toxic. The most serious adverse reaction is reactive encephalopathy, which affects 6% of treated individuals and usually develops within 4 days of the start of therapy, with an average case–fatality rate of 50%. Glucocorticoids are administered with melarsoprol to prevent this development. Because melarsoprol is intensely irritating, care must be taken to avoid infiltration of the drug.

Metrifonate Metrifonate has selective activity against *Schistosoma haematobium*. This organophosphorous compound is a prodrug that is converted nonenzymatically to dichlorvos (2,2-dichlorovinyl dimethylphosphate, DDVP), a highly active chemical that irreversibly inhibits the acetylcholinesterase enzyme. Schistosomal cholinesterase is more susceptible to dichlorvos than is the corresponding human enzyme. The exact mechanism of action of metrifonate is uncertain, but the drug is believed to inhibit tegumental acetylcholine receptors that mediate glucose transport.

Metrifonate is administered in a series of three doses at 2-week intervals. After a single oral dose, metrifonate produces a 95% decrease in plasma cholinesterase activity within 6 h, with a fairly rapid return to normal. However, 2.5 months are required for erythrocyte cholinesterase levels to return to normal. Treated persons should not be exposed to neuromuscular blocking agents or organophosphate insecticides for at least 48 h after treatment.

Metronidazole and Other Nitroimidazoles See Table 229-1 and Chap. 149.

Miltefosine In the early 1990s, miltefosine (hexadecylphosphocholine), originally developed as an antineoplastic agent, was discovered to have significant antiproliferative activity against *Leishmania* species, *T. cruzi*, and *T. brucei* parasites in vitro and in experimental animal models. Miltefosine is the first oral drug that has proved to be highly effective and comparable to amphotericin B against visceral leishmaniasis in India, where antimonial-resistant cases are prevalent. Miltefosine is also effective in previously untreated visceral infections. Cure rates in cutaneous leishmaniasis are comparable to those obtained with antimony. Miltefosine is also effective against the free-living ameba *Naegleria fowleri*.

The activity of miltefosine is attributed to interaction with cell signal transduction pathways and inhibition of phospholipid and sterol biosynthesis. Resistance to miltefosine has not been observed clinically. The drug is readily absorbed from the GI tract, is widely distributed, and accumulates in several tissues. The efficacy of a 28-day treatment course in Indian visceral leishmaniasis is equivalent to that of amphotericin B therapy; however, it appears that a shortened course of 21 days may be equally efficacious.

General recommendations for the use of miltefosine are limited by the exclusion of specific groups from the published clinical trials: persons <12 or >65 years of age, persons with the most advanced disease, breast-feeding women, HIV-infected patients, and individuals with significant renal or hepatic insufficiency.

Moxidectin Like ivermectin, moxidectin is a macrocyclic lactone that is an effective antihelminthic. In 2018, the FDA approved its use for the treatment of onchocerciasis. The primary mode of action of moxidectin is believed to be like that of ivermectin; however, there are likely different binding sites, as suggested by the identification of ivermectin-resistant helminths that are susceptible to moxidectin. The drug is well tolerated, with most adverse effects attributed to death of microfilariae. Some adverse effects occurred more commonly compared with ivermectin, including orthostatic hypotension (5 vs 2%) and elevated transaminases (1 vs 0.6%). In clinical trials, no clinically significant differences in the pharmacokinetics were observed with age, gender, weight, or renal impairment. The effect of hepatic dysfunction is unknown.

Niclosamide† Niclosamide is active against a wide variety of adult tapeworms but not against tissue cestodes. The drug uncouples oxidative phosphorylation in parasite mitochondria, thereby blocking the uptake of glucose by the intestinal tapeworm and resulting in the parasite's death. Niclosamide rapidly causes spastic paralysis of intestinal cestodes in vitro. Its use is limited by its side effects, the necessarily long duration of therapy, the recommended use of purgatives, and—most important—limited availability (i.e., on a named-patient basis from the manufacturer).

Niclosamide is poorly absorbed. Tablets are given on an empty stomach in the morning after a liquid meal the night before, and this dose is followed by another 1 h later. For treatment of hymenolepiasis, the drug is administered for 7 days. A second course is often prescribed. The scolex and proximal segments of the tapeworms are killed on contact with niclosamide and may be digested in the gut. However, disintegration of the adult tapeworm results in the release of viable ova, which theoretically can result in autoinfection. Although fears of the development of cysticercosis in patients with *Taenia solium* infections have proved unfounded, it is still recommended that a brisk purgative be given 2 h after the first dose.

Nifurtimox This nitrofuran compound is an inexpensive and effective oral agent for the treatment of acute Chagas disease. Trypanosomes lack catalase and have very low levels of peroxidase; as a result, they are very vulnerable to by-products of oxygen reduction. When nifurtimox is reduced in the trypanosome, a nitro anion radical is formed and undergoes autooxidation, resulting in the generation of the superoxide anion O_2^-, hydrogen peroxide (H_2O_2), hydroperoxyl radical (HO_2), and other highly reactive and cytotoxic molecules. Despite the abundance of catalases, peroxidases, and superoxide dismutases that neutralize these destructive radicals in mammalian cells, nifurtimox has a poor therapeutic index. Prolonged use is required, but the course may have to be interrupted because of drug toxicity, which develops in 40–70% of recipients. Nifurtimox is well absorbed and undergoes rapid and extensive biotransformation; <0.5% of the original drug is excreted in urine. In 2020, the FDA approved this agent for the treatment of Chagas disease in children; it is now commercially available.

Nitazoxanide Nitazoxanide is a 5-nitrothiazole compound used for the treatment of cryptosporidiosis and giardiasis; it is active against other intestinal protozoa as well. The drug is approved for use in children 1–11 years of age.

The antiprotozoal activity of nitazoxanide is believed to be due to interference with the pyruvate-ferredoxin oxidoreductase (PFOR) enzyme–dependent electron transfer reaction that is essential to anaerobic energy metabolism. Studies have shown that the PFOR enzyme from *G. lamblia* directly reduces nitazoxanide by transfer of electrons in the absence of ferredoxin. The DNA-derived PFOR protein sequence of *Cryptosporidium parvum* appears to be similar to that of *G. lamblia*. Interference with the PFOR enzyme–dependent electron transfer reaction may not be the only pathway by which nitazoxanide exerts antiprotozoal activity.

After oral administration, nitazoxanide is rapidly hydrolyzed to an active metabolite, tizoxanide (desacetyl-nitazoxanide). Tizoxanide then undergoes conjugation, primarily by glucuronidation. It is recommended that nitazoxanide be taken with food; however, no studies have been conducted to determine whether the pharmacokinetics of tizoxanide and tizoxanide glucuronide differ in fasted versus fed subjects. Tizoxanide is excreted in urine, bile, and feces, and tizoxanide glucuronide is excreted in urine and bile. The pharmacokinetics of nitazoxanide in patients with impaired hepatic and/or renal function have not been studied. Tizoxanide is highly bound to plasma protein (>99.9%). Therefore, caution should be used when administering this agent concurrently with other highly plasma protein–bound drugs that have narrow therapeutic indices, as competition for binding sites may occur.

Oxamniquine This tetrahydroquinoline derivative is an effective alternative agent for the treatment of *S. mansoni*, although susceptibility to this drug exhibits regional variation. Oxamniquine exhibits anticholinergic properties, but its primary mode of action seems to rely on ATP-dependent enzymatic drug activation generating an intermediate that alkylates essential macromolecules, including DNA. In treated adult schistosomes, oxamniquine produces marked tegumental alterations like those seen with praziquantel but that develop less rapidly, becoming evident 4–8 days after treatment.

Oxamniquine is administered orally as a single dose and is well absorbed. Food retards absorption and reduces bioavailability. About 70% of an administered dose is excreted in urine as a mixture of pharmacologically inactive metabolites. Patients should be warned that their urine might have an intense orange-red color. Side effects are uncommon and usually mild, although hallucinations and seizures have been reported.

Paromomycin (Aminosidine) First isolated in 1956, this aminoglycoside is an effective oral agent for the treatment of infections due to intestinal protozoa. Parenteral paromomycin appears to be effective against visceral leishmaniasis in India.

Paromomycin inhibits protozoan protein synthesis by binding to the 30S ribosomal RNA in the aminoacyl-tRNA site, causing misreading

of mRNA codons. Paromomycin is less active against *G. lamblia* than standard agents; however, like other aminoglycosides, paromomycin is poorly absorbed from the intestinal lumen, and the high levels of drug in the gut compensate for this relatively weak activity. If absorbed or administered systemically, paromomycin can cause ototoxicity and nephrotoxicity. However, systemic absorption is very limited, and toxicity should not be a concern in persons with normal kidneys. Topical formulations are not generally available.

Pentamidine Isethionate This diamidine is an effective alternative agent for some forms of leishmaniasis and trypanosomiasis. It is available for parenteral and aerosolized administration. Although its mechanism of action remains undefined, it is known to exert a wide range of effects, including interaction with trypanosomal kinetoplast DNA; interference with polyamine synthesis by a decrease in the activity of ornithine decarboxylase; and inhibition of RNA polymerase, topoisomerase, ribosomal function, and the synthesis of nucleic acids and proteins.

Pentamidine isethionate is well absorbed, highly tissue bound, and excreted slowly over several weeks, with an elimination half-life of 12 days. No steady-state plasma concentration is attained in persons given daily injections; the result is extensive accumulation of pentamidine in tissues, primarily the liver, kidney, adrenal gland, and spleen. Pentamidine does not penetrate well into the CNS. Pulmonary concentrations of pentamidine are increased when the drug is delivered in aerosolized form, but not when it is delivered systemically.

Rapid (<1-h) infusion of intravenous pentamidine often results in hypotension. Because electrolyte disturbances and mild to moderate nephrotoxicity occur commonly, pentamidine should be used with caution with other nephrotoxic agents. Pancreatitis and QT prolongation may also occur; cumulative damage to pancreatic islet cells may result in drug-induced diabetes mellitus. Similarly, hypoglycemia can develop, although much less commonly when pentamidine is given by the inhaled route.

Piperaquine This bisquinoline was synthesized in the 1960s and used widely for malaria control in China until resistance emerged. The development of artemisinin-based combination therapy led to its evaluation as a partner drug, and it is now combined with dihydroartemisinin. Piperaquine is highly lipophilic and has a prolonged half-life (~20 days), thus providing a period of posttreatment prophylaxis. The drug's mechanisms of action and resistance have not been well studied but are presumed to be similar to the other 4-aminoquinolines.

Piperazine The antihelminthic activity of piperazine is confined to ascariasis and enterobiasis. Piperazine acts as an agonist at extrasynaptic γ-aminobutyric acid (GABA) receptors, causing an influx of chloride ions in the nematode somatic musculature. Although the initial result is hyperpolarization of the muscle fibers, the ultimate effect is flaccid paralysis, leading to the expulsion of live worms. Patients should be warned, as this occurrence can be unsettling.

Praziquantel This heterocyclic pyrazinoisoquinoline derivative is highly active against a broad spectrum of trematodes and cestodes. It is the mainstay of treatment for schistosomiasis and is a critical part of community-based control programs.

All of the effects of praziquantel can be attributed either directly or indirectly to an alteration of intracellular calcium concentrations. Although the exact mechanism of action remains unclear, the major mechanism is disruption of the parasite tegument, causing tetanic contractures with loss of adherence to host tissues and, ultimately, disintegration or expulsion. Praziquantel induces changes in the antigenicity of the parasite by causing the exposure of concealed antigens. Praziquantel also produces alterations in schistosomal glucose metabolism, including decreases in glucose uptake, lactate release, glycogen content, and ATP levels.

Praziquantel exerts its parasitic effects directly and does not need to be metabolized to be effective. It is well absorbed but undergoes extensive first-pass hepatic clearance. Levels of the drug are increased when it is taken with food, particularly carbohydrates, or with cimetidine. Serum levels are reduced by glucocorticoids, chloroquine, carbamazepine, and phenytoin. Praziquantel is completely metabolized in humans, with 80% of the dose recovered as metabolites in urine within 4 days. It is not known to what extent praziquantel crosses the placenta, but retrospective studies suggest that it is safe in pregnancy.

Patients with schistosomiasis who have heavy parasite burdens may develop abdominal discomfort, nausea, headache, dizziness, and drowsiness. Symptoms begin 30 min after ingestion, may require spasmolytics for relief, and usually disappear spontaneously after a few hours.

Primaquine Phosphate Primaquine, an 8-aminoquinoline, has a broad spectrum of activity against all stages of plasmodial development in humans but has been used most effectively for eradication of the hepatic stage of these parasites. Primaquine must be metabolized by the host to be effective. It is, in fact, rapidly metabolized; only a small fraction of the dose of the parent drug is excreted unchanged. Although the parasiticidal activity of the three oxidative metabolites remains unclear, they are believed to affect both pyrimidine synthesis and the mitochondrial electron transport chain. The metabolites appear to have significantly less antimalarial activity than primaquine; however, their hemolytic activity is greater than that of the parent drug.

Primaquine causes marked hypotension after parenteral administration and therefore is given only by the oral route. It is rapidly and almost completely absorbed from the GI tract. Patients should be tested for G6PD deficiency before they receive primaquine. The drug may induce the oxidation of hemoglobin into methemoglobin, regardless of the G6PD status of the patient. Primaquine is otherwise well tolerated.

Proguanil (Chloroguanide) Proguanil inhibits plasmodial dihydrofolate reductase and is used with atovaquone for oral treatment of uncomplicated malaria or with chloroquine for malaria prophylaxis in parts of Africa without widespread chloroquine-resistant *P. falciparum*.

Proguanil exerts its effect primarily by means of the metabolite cycloguanil, whose inhibition of dihydrofolate reductase in the parasite disrupts deoxythymidylate synthesis, thus interfering with a key pathway involved in the biosynthesis of pyrimidines required for nucleic acid replication. There are no clinical data indicating that folate supplementation diminishes drug efficacy; women of childbearing age for whom atovaquone/proguanil is prescribed should continue taking folate supplements to prevent neural tube birth defects.

Proguanil is extensively absorbed regardless of food intake. The drug is 75% protein bound. The main routes of elimination are hepatic biotransformation and renal excretion; 40–60% of the proguanil dose is excreted by the kidneys. Drug levels are increased and elimination is impaired in patients with hepatic insufficiency.

Pyrantel Pamoate Pyrantel is a tetrahydropyrimidine formulated as pamoate. This safe, well-tolerated, inexpensive drug is used to treat a variety of intestinal nematode infections but is ineffective in trichuriasis. Pyrantel pamoate is usually effective in a single dose. Its target is the nicotinic acetylcholine receptor on the surface of nematode somatic muscle. Pyrantel depolarizes the neuromuscular junction of the nematode, resulting in its irreversible paralysis and allowing the natural expulsion of the worm.

Pyrantel pamoate is poorly absorbed from the intestine; >85% of the dose is passed unaltered in feces. The absorbed portion is metabolized and excreted in urine. Piperazine is antagonistic to pyrantel pamoate and should not be used concomitantly.

Pyrantel pamoate has minimal toxicity at the oral doses used to treat intestinal helminthic infection. It is not recommended for pregnant women or for children <12 months old.

Pyrimethamine When combined with short-acting sulfonamides, this diaminopyrimidine is effective in malaria, toxoplasmosis, and isosporiasis. Unlike mammalian cells, the parasites that cause these infections cannot use preformed pyrimidines obtained through salvage pathways but rather rely completely on de novo pyrimidine synthesis, for which folate derivatives are essential cofactors. The efficacy of pyrimethamine is increasingly limited by the

development of resistant strains of *P. falciparum* and *P. vivax*. Single amino acid substitutions to parasite dihydrofolate reductase confer resistance to pyrimethamine by decreasing the enzyme's binding affinity for the drug.

Pyrimethamine is well absorbed; the drug is 87% bound to human plasma proteins. In healthy volunteers, drug concentrations remain at therapeutic levels for up to 2 weeks; drug levels are lower in patients with malaria.

At the usual dosage, pyrimethamine alone causes little toxicity except for occasional skin rashes and, more rarely, blood dyscrasias. Bone marrow suppression sometimes occurs at the higher doses used for toxoplasmosis; at these doses, the drug should be administered with folinic acid.

Pyronaridine This potent antimalarial is a benzonaphthyridine derivative first synthesized by Chinese researchers in 1970. Like chloroquine, pyronaridine targets hematin formation, inhibiting the production of β-hematin by forming complexes with it, with consequent enhancement of hematin-induced hemolysis. However, this drug is more potent than chloroquine: for complete lysis, pyronaridine is required at only 1/100th of the concentration needed with chloroquine. It also inhibits glutathione-dependent heme degradation. Despite its similar mode of action, pyronaridine remains effective against chloroquine-resistant strains. When combined with artesunate, it is effective for the treatment of acute, uncomplicated infection caused by *P. falciparum* or *P. vivax* in areas of low transmission with evidence of artemisinin resistance.

Pyronaridine is readily absorbed, widely distributed throughout the body, metabolized by the liver, and excreted in urine and stool. Its use is contraindicated in patients with severe liver or kidney impairment. Pyronaridine inhibits both CYP2D6 and P-glycoprotein in vitro, and these effects may have clinical relevance for patients taking medications for cardiac disease (e.g., metoprolol and digoxin).

Quinacrine† Despite being one of the first antimalarials, the antiprotozoal mechanism of quinacrine has not been fully elucidated. It is generally considered to intercalate into DNA and thereby inhibit replication and transcription. The drug also inhibits adenosine uptake, ATP incorporation into RNA, and NADH oxidase—the same enzyme that activates furazolidone. The differing relative quinacrine uptake rate between human cells and *G. lamblia* may explain the selective toxicity of the drug. Resistance correlates with decreased drug uptake.

Quinacrine is rapidly absorbed from the intestinal tract and is widely distributed in body tissues. Alcohol is best avoided because of a disulfiram-like effect. Although its production was discontinued in 1992, quinacrine can be obtained commercially from compounding pharmacies.

Quinine and Quinidine When combined with another agent, the cinchona alkaloid quinine is effective for the oral treatment of both uncomplicated, chloroquine-resistant malaria and babesiosis. Quinine acts rapidly against the asexual blood stages of all forms of the human malaria parasites. For severe malaria, only quinidine (the dextroisomer of quinine) is available in the United States. Quinine concentrates in the acidic food vacuoles of *Plasmodium* species. The drug inhibits the nonenzymatic polymerization of the highly reactive, toxic heme molecule into the nontoxic polymer pigment hemozoin.

Quinine is readily absorbed when given orally. In patients with malaria, the elimination half-life of quinine increases according to the severity of the infection. However, toxicity is avoided by an increase in the concentration of plasma glycoproteins. The cinchona alkaloids are extensively metabolized, particularly by CYP3A4; only 20% of the dose is excreted unchanged in urine. The drug's metabolites are also excreted in urine and may be responsible for toxicity in patients with renal failure. Renal excretion of quinine is decreased when cimetidine is taken and increased when the urine is acidic. The drug readily crosses the placenta.

Quinidine is both more potent as an antimalarial and more toxic than quinine. Its use requires cardiac monitoring. Dose reduction is necessary in persons with severe renal impairment.

Spiramycin† This macrolide is used to treat acute toxoplasmosis in pregnancy and congenital toxoplasmosis. While the mechanism of action is similar to that of other macrolides, the efficacy of spiramycin in toxoplasmosis appears to stem from its rapid and extensive intracellular penetration, which results in macrophage drug concentrations 10–20 times greater than serum concentrations.

Spiramycin is rapidly and widely distributed throughout the body and reaches concentrations in the placenta up to five times those in serum. This agent is excreted mainly in bile. Indeed, in humans, the urinary excretion of active compounds represents only 20% of the administered dose.

Serious reactions to spiramycin are rare. Of the available macrolides, spiramycin appears to have the lowest risk of drug interactions. Complications of treatment are rare but, in neonates, can include life-threatening ventricular arrhythmias that disappear with drug discontinuation.

Spiramycin is not formally approved for use in the United States, but it is accessible through a compassionate use program for toxoplasmosis in pregnancy through the FDA (301-796-1400).

Sulfonamides See Table 229-1 and Chap. 149.

Suramin* This derivative of urea is the drug of choice for the early stage of African trypanosomiasis. The drug is polyanionic and acts by forming stable complexes with proteins, thus inhibiting multiple enzymes essential to parasite energy metabolism. Suramin appears to inhibit all trypanosome glycolytic enzymes more effectively than it inhibits the corresponding host enzymes.

Suramin is parenterally administered. It binds to plasma proteins and persists at low levels for several weeks after infusion. Its metabolism is negligible. This drug does not penetrate the CNS.

Tafenoquine Tafenoquine is an 8-aminoquinoline with causal prophylactic activity. Its prolonged half-life (2–3 weeks) allows longer dosing intervals when the drug is used for prophylaxis. Tafenoquine has been well tolerated in clinical trials. When tafenoquine is taken with food, its absorption is increased by 50% and the most commonly reported adverse event—mild GI upset—is diminished. Like primaquine, tafenoquine is a potent oxidizing agent, causing hemolysis in patients with G6PD deficiency as well as methemoglobinemia. It has been commercially available since FDA approval in 2018.

Tetracyclines See Table 229-1 and Chap. 149.

Thiabendazole Discovered in 1961, thiabendazole remains one of the most potent of the numerous benzimidazole derivatives. However, its use has declined significantly because of a higher frequency of adverse effects than is seen with other, equally effective agents.

Thiabendazole is active against most intestinal nematodes that infect humans. Although the exact mechanism of its antihelminthic activity has not been fully elucidated, it is likely to be similar to that of other benzimidazole drugs: namely, inhibition of polymerization of parasite β-tubulin. The drug also inhibits the helminth-specific enzyme fumarate reductase. In animals, thiabendazole has anti-inflammatory, antipyretic, and analgesic effects, which may explain its usefulness in dracunculiasis and trichinellosis. Thiabendazole also suppresses egg and/or larval production by some nematodes and may inhibit the subsequent development of eggs or larvae passed in feces. Despite the emergence and global spread of thiabendazole-resistant trichostrongyliasis among sheep, there have been no reports of drug resistance in humans.

Thiabendazole is available in tablet form and as an oral suspension. The drug is rapidly absorbed from the GI tract but can also be absorbed through the skin. Thiabendazole should be taken after meals. This agent is extensively metabolized in the liver before ultimately being excreted; most of the dose is excreted within the first 24 h. The usual dose of thiabendazole is determined by the patient's weight, but some treatment regimens are parasite specific. No adjustments are recommended in patients with renal or hepatic failure; only cautious use is advised.

Coadministration of thiabendazole to patients taking theophylline can result in an increase in theophylline levels by >50%. Therefore,

serum levels of theophylline should be monitored closely in this situation.

Tinidazole This nitroimidazole is effective for the treatment of amebiasis, giardiasis, and trichomoniasis. Like metronidazole, tinidazole must undergo reductive activation by the parasite's metabolic system before it can act on protozoal targets. Tinidazole inhibits the synthesis of new DNA in the parasite and causes degradation of existing DNA. The reduced free-radical derivatives alkylate DNA, with consequent cytotoxic damage to the parasite. This damage appears to be produced by short-lived reduction intermediates, resulting in helix destabilization and strain breakage of DNA. The mechanism of action and side effects of tinidazole are similar to those of metronidazole, but adverse events appear to be less frequent and severe with tinidazole. In addition, the significantly longer half-life of tinidazole (>12 h) offers potential cure with a single dose.

Tribendimidine Tribendimidine, a diamidine derivative of aminophenylamidine amidantel, is a cholinergic agonist that is selective for the nicotinic acetylcholine receptors of nematode muscle. This novel agent has a broad spectrum of activity against a wide variety of helminths and is highly effective against food-borne trematodes, with a similar cure rate to praziquantel. Clinical trials have demonstrated efficacy of a single dose alone or in combination with other helminthics against soil-transmitted helminth infections. The drug is an L-type nicotinic acetylcholine receptor agonist and exhibits the same method of action as levamisole and pyrantel; therefore, it may not be effective in regions where resistance to these agents is widespread. It is not available in the United States.

Triclabendazole In contrast to other benzimidazoles, the antihelminthic activity of triclabendazole is highly specific for *Fasciola* and *Paragonimus* species, with little activity against nematodes, cestodes, and other trematodes. Triclabendazole is effective against all stages of *Fasciola* species. The active sulfoxide metabolite of triclabendazole binds to fluke tubulin by assuming a unique nonplanar configuration and disrupts microtubule-based processes. Resistance to triclabendazole in veterinary use has been reported in Australia and Europe; however, no resistance has been documented in humans.

Triclabendazole is rapidly absorbed after oral ingestion; administration with food enhances its absorption and shortens the elimination half-life of the active metabolite. Both the sulfoxide and the sulfone metabolites are highly protein bound (>99%). Treatment with triclabendazole is typically given in one or two doses. No clinical data are available regarding dose adjustment in renal or hepatic insufficiency; however, given the short course of therapy and extensive hepatic metabolism of triclabendazole, dose adjustment is unlikely to be necessary. No information exists on drug interactions.

Trimethoprim-Sulfamethoxazole See Table 229-1 and Chap. 149.

230 Amebiasis and Infection with Free-Living Amebae

Rosa M. Andrade, Sharon L. Reed

AMEBIASIS

DEFINITION

Amebiasis is an infection caused by *Entamoeba histolytica*, an intestinal protozoan. Its spectrum of clinical syndromes ranges from asymptomatic colonization (90% of cases) to invasive amebiasis, which accounts for 10% of affected individuals. Invasive amebiasis frequently presents as intestinal colitis (dysentery or diarrhea) or as extraintestinal amebiasis, in which abscesses of the liver are more commonly found than involvement of the lungs or brain.

LIFE CYCLE AND TRANSMISSION

E. histolytica is acquired by ingestion of viable cysts from fecally contaminated water, food, or hands **(Fig. 230-1)**. Food-borne exposure is the most prevalent form of transmission. It occurs when food handlers are shedding cysts or food is being grown with feces-contaminated soil, fertilizer, or water. Less common means of transmission include oral and anal sexual practices and, in rare instances, direct rectal inoculation through colonic irrigation devices. Motile trophozoites are released from cysts in the small intestine and, in most patients, remain as harmless commensals in the large bowel. After encystation, infectious cysts are shed in the stool and can survive for several weeks in a moist environment. In some patients, the trophozoites invade either the bowel mucosa, causing symptomatic colitis, or the bloodstream, causing distant abscesses of the liver, lungs, or brain. The trophozoites may not encyst in patients with active dysentery, and motile hematophagous trophozoites are frequently present in fresh stools. Trophozoites are rapidly killed by exposure to air or stomach acid and therefore cannot transmit infection.

EPIDEMIOLOGY

E. histolytica infection typically affects underdeveloped tropical regions with poor sanitation systems and hygiene, occurring often in children <5 years of age. This infection is widespread in the Indian subcontinent and Africa, parts of East Asia (Thailand), and Central and South America (Mexico and Colombia). According to the Global Burden of Disease 2016 study, amebiasis accounts for 26,748 all-age deaths, including 4567 children <5 years old.

In contrast, returning travelers, recent immigrants, men who have sex with men (MSM), military personnel, and inmates of institutions are the main groups at risk for amebiasis in developed countries. The GeoSentinel Surveillance Network, which encompasses information from tropical medicine clinics on six continents, showed that, among long-term travelers (trip duration, >6 months), diarrhea due to *E. histolytica* was among the most common diagnoses. In countries like Japan and Spain, amebiasis is emerging as a sexually transmitted disease, first reported in HIV-positive MSM. However, in Japan, *E. histolytica* infections, symptomatic or asymptomatic, seem to be steadily spreading among non-HIV men and women.

Worldwide, *E. histolytica* is the second most common cause of death related to parasitic infection (after malaria). Invasive colitis and liver abscesses are tenfold more common among men than among women; this difference has been attributed to a disparity in complement-mediated killing and effects of testosterone on the secretion of interferon γ. The wide spectrum of clinical disease caused by *Entamoeba* is due in part to the differences between the two major infecting species,

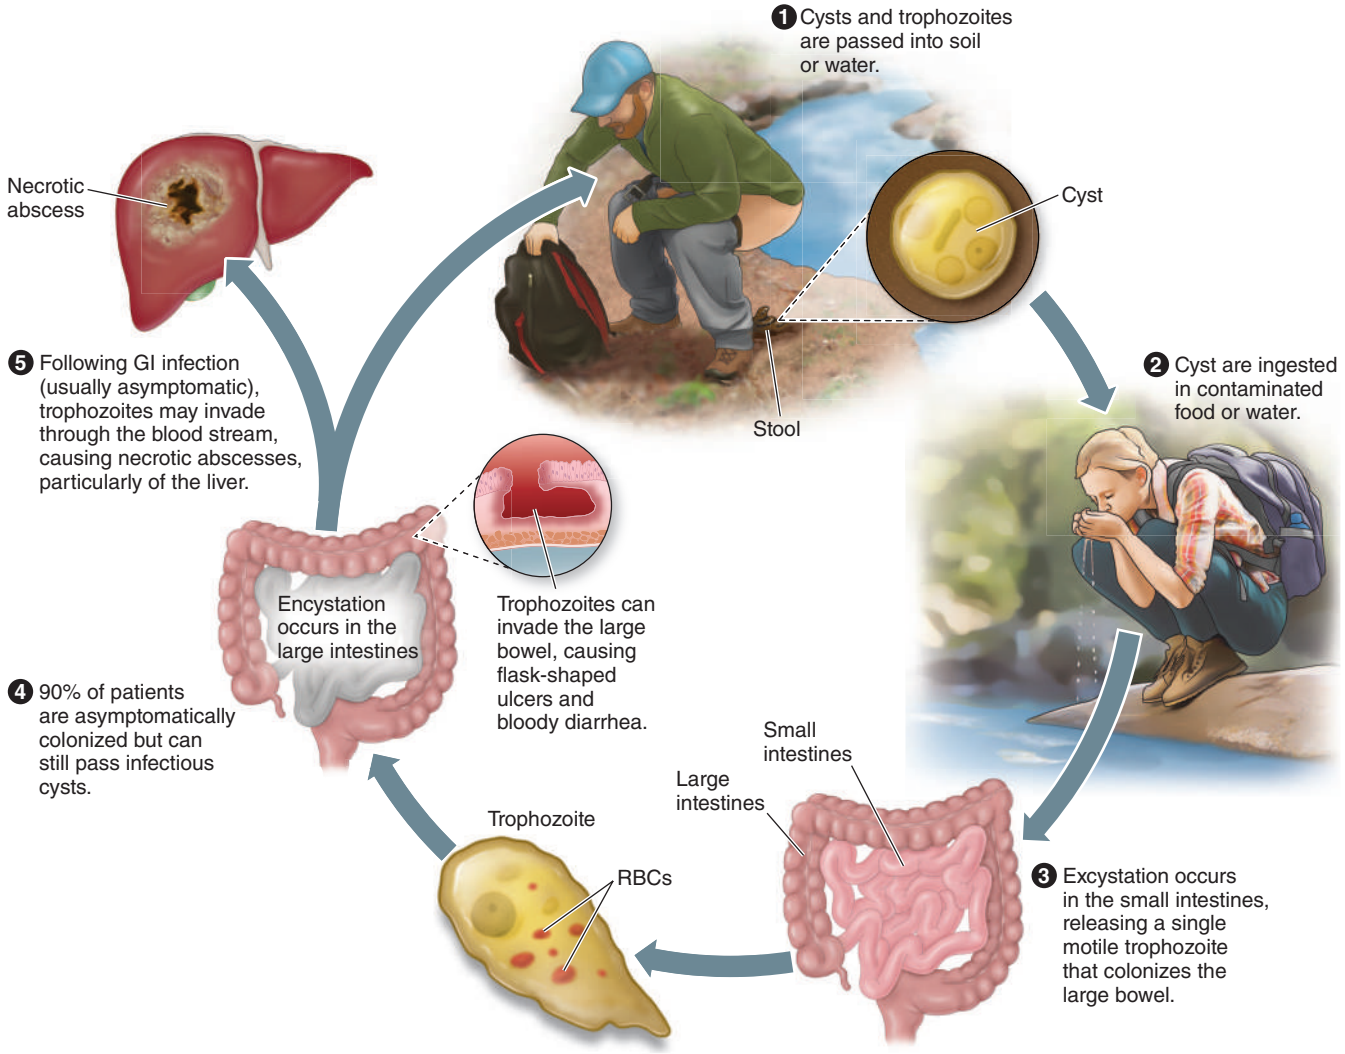

FIGURE 230-1 Life cycle of *Entamoeba histolytica*. GI, gastrointestinal; RBCs, red blood cells.

E. histolytica and *E. dispar*. *E. histolytica* has unique surface antigens, is genetically distinct, and possesses virulence properties that distinguish it from the morphologically identical *E. dispar*.

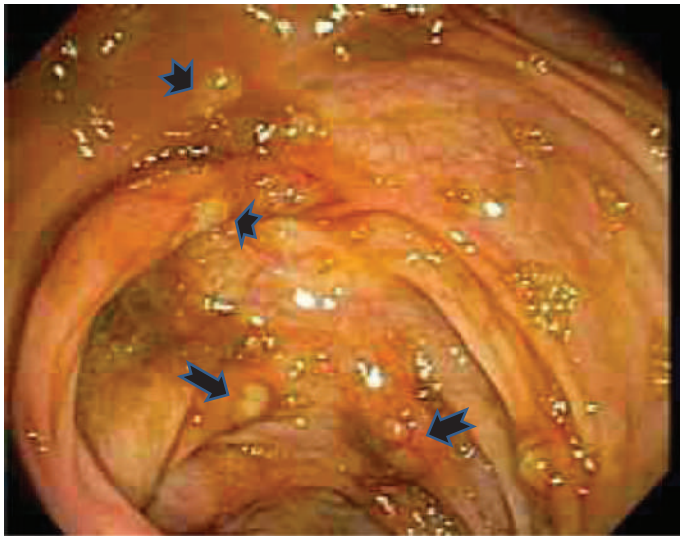
Most asymptomatic carriers, including MSM and patients with AIDS, harbor *E. dispar* and have self-limited infections. In this respect, *E. dispar* is dissimilar to other enteric pathogens such as *Cryptosporidium* and *Cystoisospora belli*, which can cause self-limited illnesses in immunocompetent hosts but devastating diarrhea in patients with AIDS. These observations indicate that *E. dispar* is incapable of causing invasive disease. Through genomic sequencing, new species of *Entamoeba* have been identified: *E. moshkovskii* and *E. bangladeshi*. These new species are microscopically indistinguishable from *E. histolytica*. Although *E. moshkovskii* causes diarrhea, weight loss, and colitis in mice, a prospective evaluation of children from the Mirpur community of Dhaka, Bangladesh, found that most children who had diarrheal diseases associated with *E. moshkovskii* were simultaneously infected with at least one other enteric pathogen. *E. bangladeshi nov.* sp., *Bangladesh* was first reported in 2012 in this Bangladeshi community; however, it has been isolated in South African subjects of all ages in recent years. Additional clinical and epidemiologic studies are needed to discern the true role of *E. bangladeshi* in the human host.

PATHOGENESIS AND PATHOLOGY

Both trophozoites and cysts are found in the intestinal lumen, but only trophozoites of *E. histolytica* invade tissue. The trophozoite is 20–60 μm in diameter and contains vacuoles and a nucleus with a characteristic central nucleolus. Trophozoites attach to colonic mucus and epithelial cells by Gal/GalNAc adherence lectin and release glycosidases and proteases that cause degradation of mucus polymers. Extracellular cysteine proteinases degrade collagen, elastin, IgA, IgG, and the anaphylatoxins C3a and C5a. After disruption of the mucous layer, trophozoites damage the mucosa by contact-dependent and contact-independent cytotoxicity. The contact-dependent cytotoxicity is attributable to induction of apoptotic cell death; trogocytosis-mediated cell death (ingestion of fragments of living cells); and lysis of inflammatory cells (neutrophils, monocytes, and lymphocytes), colonic cells, and hepatic cells through release of phospholipase A and pore-forming peptides. Contact-independent cytotoxicity follows production of inflammatory mediators, such as prostaglandin E2, by trophozoites, ultimately leading to increased ion permeability of intercellular tight junctions.

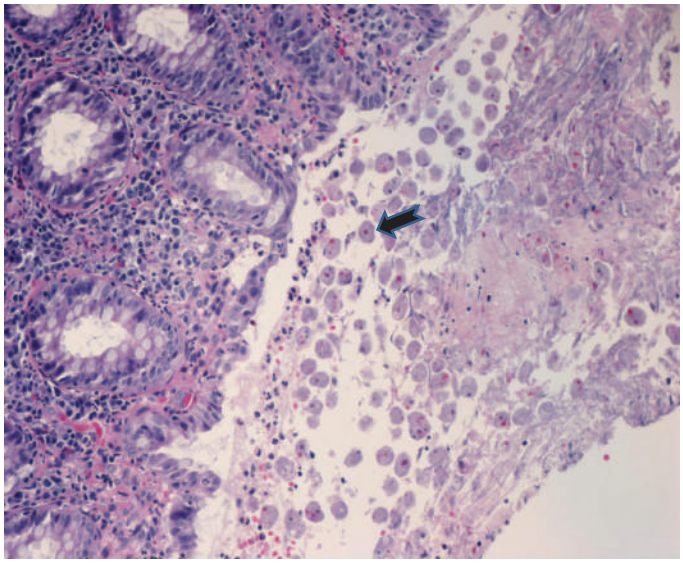
E. histolytica trophozoites are constantly exposed to reactive oxygen and nitrogen species arising from their own metabolism and from the host during tissue invasion. The ability to resist reactive oxygen species or reactive nitrogen species such as nitric oxide or *S*-nitrosothiols (e.g., *S*-nitrosoglutathione [GSNO] and *S*-nitrosocysteine [CySNO]) is also a virulence factor. Since *E. histolytica* lacks glutathione and glutathione reductase, it relies on its thioredoxin–thioredoxin reductase system to prevent, regulate, and repair the damage caused by oxidative stress. This antioxidant system is versatile: it has the ability to reduce reactive nitrogen species and use an alternative electron donor, such as nicotinamide adenine dinucleotide. In addition, trophozoites preincubated with *E. coli* 055 are more resistant to hydrogen peroxide–mediated killing by using bacterially produced malate dehydrogenase and oxaloacetate for protection from oxidative stress. Metronidazole, the current standard of therapy for amebiasis, seems to exert its antiparasitic effect through inhibition of this antioxidant system.

Phagocytosis is a virulence factor that leads to a defective proliferation of *E. histolytica* if inhibited. Trophozoites use membrane-associated carbohydrate-binding proteins to phagocytose intestinal bacteria, especially gram-negative Enterobacteriaceae, for their nutrients. Interactions with commensal bacteria, such as *Escherichia coli*, can attenuate the virulence of *E. histolytica* by decreasing the expression of Gal/GalNAc lectin. In contrast, ingestion of enteropathogenic bacteria, such as enteropathogenic *E. coli* and *Shigella dysenteriae*, increases expression of the Gal/GalNAc lectin and enhances *E. histolytica* cysteine protease activity.



The interactions between *E. histolytica* and the gut microbiome can determine the severity of disease. During the first 2 years of life, the gut immune system and the microbiome mature rapidly. In one study, ~80% of children from the Bangladeshi community of Dhaka were found to be infected with *E. histolytica* by 2 years of age. Fecal anti–Gal/GalNAc lectin IgA was associated with protection from reinfection, while a high parasite burden in the first year of life was associated with the expansion of *Prevotella copri* in their gut microbiome and presence of diarrhea. In adults, the diversity of the gut microbiome can determine the pathogenesis of disease. As shown in a Japanese cohort through next-generation sequencing analysis, the gut microbiome in asymptomatic *E. histolytica* carriers was more homogeneous, with high abundance of *Ruminococcaceae*, *Coriobacteriaceae*, and *Clostridiaceae*, while these bacteria were absent or in low abundance in patients with invasive disease (symptomatic). These observations suggest the protective role of these bacteria.

Antimicrobial peptides, such as cathelicidins, are an important component of innate immunity and are induced by *E. histolytica* upon intestinal invasion in a mouse model. In this model, cecal cathelicidin-related antimicrobial peptide mRNA increased by >4-fold at 3 days and >100-fold at 7 days. However, *E. histolytica* remained resistant to cathelicidin-mediated killing, probably because the antimicrobial peptide was digested by amebic cysteine proteinases. Other in vitro studies have shown that α- and β-defensins may damage *E. histolytica* membrane integrity.



IgA plays a critical role in acquired immunity to *E. histolytica*. A study in Bangladeshi schoolchildren revealed that an intestinal IgA response to Gal/GalNAc reduced the risk of new *E. histolytica* infection by 64%. Serum IgG antibody is not protective; titers correlate with the duration of illness rather than with the severity of disease. Indeed, Bangladeshi children with a serum IgG response were more likely than those without such a response to develop new *E. histolytica* infection. In infants from this same Bangladeshi community, passive immunity conferred by maternal parasite-specific IgA via breastfeeding resulted in a 39% reduced risk of infection and a 64% reduced risk of diarrheal disease from *E. histolytica* during the first year of life. However, this protection appeared to be species-specific, with little or no protection conferred from infections with other species such as *E. dispar* or *E. bangladeshi*.

This Bangladeshi cohort has furthered our understanding of the genetic susceptibility factors associated with *E. histolytica* disease. Heterozygosity of the major histocompatibility complex (MHC) class II allele DQB1*0601 was found to protect against amebic intestinal disease, which supports the role of antigen processing and CD4+ T cells in resistance to amebiasis. Adipocyte leptin receptors (LEPRs) are expressed on intestinal epithelial cells, prevent apoptosis, promote tissue repair, and may decrease neutrophil infiltration. In this cohort, a single amino acid substitution (Q223R) in LEPRs nearly quadrupled the risk for amebic intestinal disease in children and increased the risk for amebic liver abscesses in adults. Similarly, variations in the locus of cAMP-responsive element modulator/cullin 2 (CREM/CUL2) may increase the risk for diarrhea in children who acquired *E. histolytica* within their first year of life. Interestingly, both genetic variations, Q223R and CREM, are overrepresented in this geographical region.

The earliest intestinal lesions are microulcerations of the mucosa of the cecum, sigmoid colon, or rectum that release erythrocytes, inflammatory cells, and epithelial cells. A colonoscopy reveals small ulcers with heaped-up margins and normal intervening mucosa **(Fig. 230-2*A*)**. Submucosal extension of ulcerations under viable-appearing surface mucosa causes the classic "flask-shaped" ulcer containing trophozoites at the margins of dead and viable tissues. Although neutrophilic infiltrates may accompany early lesions in animals, human intestinal infection is marked by a paucity of inflammatory cells, probably in part because of the killing of neutrophils by trophozoites **(Fig. 230-2*B*)**. Treated ulcers characteristically heal with little or no scarring. Occasionally, however, full-thickness necrosis and perforation occur.

Rarely, intestinal infection results in the formation of a mass lesion, or *ameboma*, in the bowel lumen. The overlying mucosa is usually thin and ulcerated, while other layers of the wall are thickened, edematous, and hemorrhagic; this condition results in exuberant formation of granulation tissue with little fibrous-tissue response.

Amebic liver abscesses are age- and gender-dependent. Men 30–60 years of age are most commonly infected at a rate 10–12 times higher than women in the same age group. Studies in animal models have demonstrated that testosterone may increase susceptibility to amebic liver abscess by modulating the secretion of interferon γ by natural killer T cells, which are activated through *E. histolytica* lipopeptidophosphoglycan present on the surface of ameba trophozoites. Liver

abscesses are always preceded by intestinal colonization, which may be asymptomatic. Blood vessels may be compromised early by wall lysis and thrombus formation. Trophozoites invade veins to reach the liver through the portal venous system. *E. histolytica* is resistant to complement-mediated lysis—a property critical to survival in the bloodstream. Inoculation of amebae into the portal system of hamsters results in an acute cellular infiltrate consisting predominantly of neutrophils. Later, the neutrophils are lysed by contact with amebae, and the release of neutrophil toxins may contribute to necrosis of hepatocytes. The liver parenchyma is replaced by necrotic material that is surrounded by a thin rim of congested liver tissue. Although the necrotic contents of a liver abscess are classically described as "anchovy paste," the fluid is variable in color; it is composed of bacteriologically sterile granular debris with few or no cells. Amebae, if seen, tend to be found near the capsule of the abscess.

CLINICAL SYNDROMES

Intestinal Amebiasis The most common type of amebic infection is asymptomatic cyst passage (90% of patients). Even in highly endemic areas, most patients harbor *E. dispar*.

Symptomatic amebic colitis develops 2–6 weeks after the ingestion of infectious cysts. A gradual onset of lower abdominal pain and mild diarrhea is followed by malaise, weight loss, and diffuse lower abdominal or back pain. Cecal involvement may mimic acute appendicitis. Patients with full-blown dysentery may pass 10–12 stools per day. The stools contain little fecal material and consist mainly of blood and mucus. In contrast to those with bacterial diarrhea, fewer than 40% of patients with amebic dysentery are febrile. Virtually all patients have heme-positive stools.

More fulminant intestinal infection, with severe abdominal pain, high fever, and profuse diarrhea, is rare and occurs predominantly in children. Patients may develop toxic megacolon, in which there is severe bowel dilation with intramural air. Patients receiving glucocorticoids are at risk for severe amebiasis. The association between severe amebiasis complications and glucocorticoid therapy emphasizes the importance of excluding amebiasis when inflammatory bowel disease is suspected. An occasional patient presents with only an asymptomatic or tender abdominal mass caused by an ameboma, which is easily confused with cancer on barium studies. A positive serologic test or biopsy can prevent unnecessary surgery in this setting.

Environmental enteropathy ("impoverished gut"; blunted small-intestinal villi with lamina propria inflammation) is observed in tropical developing areas with endemic enteric infections, such as amebiasis. It is associated with functional gastrointestinal impairment causing malnutrition and stunted growth in children within the first 2 years of life. Bangladeshi children with symptomatic *E. histolytica* infections were 2.9 times more likely to be malnourished and 4.7 times more likely to be short for their age than were children without symptomatic infections. These factors affect their cognitive development and may be linked to loss of productivity in adulthood.

Amebic Liver Abscess Extraintestinal infection by *E. histolytica* most often involves the liver. Of travelers who develop an amebic liver abscess after leaving an endemic area, 95% do so within 5 months. Young patients with an amebic liver abscess are more likely than older patients to present in the acute phase with prominent symptoms of <10 days' duration. Most patients are febrile and have right-upper-quadrant pain, which may be dull or pleuritic in nature and may radiate to the shoulder. Point tenderness over the liver and right-sided pleural effusion are common. Jaundice is rare. Although the initial site of infection is the colon, fewer than one-third of patients with an amebic abscess have active diarrhea. Older patients from endemic areas are more likely to have a subacute course lasting 6 months, with weight loss and hepatomegaly. About one-third of patients with chronic presentations are febrile. Thus, the clinical diagnosis of an amebic liver abscess may be difficult to establish because the symptoms and signs are often nonspecific. Since 10–15% of patients present only with fever, amebic liver abscess must be considered in the differential diagnosis of fever of unknown origin **(Chap. 22)**.

Complications of Amebic Liver Abscess Pleuropulmonary involvement, which is reported in 20–30% of patients, is the most frequent complication of amebic liver abscess. Manifestations include sterile effusions, contiguous spread from the liver, and rupture into the pleural space. Sterile effusions and contiguous spread usually resolve with medical therapy, but frank rupture into the pleural space requires drainage. A hepatobronchial fistula may cause cough productive of large amounts of necrotic material that may contain amebae. This dramatic complication carries a good prognosis. Abscesses that rupture into the peritoneum may present as an indolent leak or an acute abdomen and require both percutaneous catheter drainage and medical therapy. Rupture into the pericardium, usually from abscesses of the left lobe of the liver, carries the gravest prognosis; it can occur during medical therapy and requires surgical drainage.

Involvement of Other Extraintestinal Sites The genitourinary tract may become involved by direct extension of amebiasis from the colon or by hematogenous spread of the infection. Painful genital ulcers, characterized by a punched-out appearance and profuse discharge, may develop secondary to extension from either the intestine or the liver. Both of these conditions respond well to medical therapy. Cerebral involvement has been reported in fewer than 0.1% of patients in large clinical series. Symptoms and prognosis depend on the size and location of the lesion.

DIAGNOSTIC TESTS

Laboratory Diagnosis Stool examinations, serologic tests, and noninvasive imaging of the liver remain the most important procedures in the diagnosis of amebiasis in most parts of the world. Fecal findings suggestive of amebic colitis include a positive test for heme, a paucity of neutrophils, and amebic cysts or trophozoites. The definitive diagnosis of amebic colitis is made by the demonstration of hematophagous trophozoites of *E. histolytica*. Because trophozoites are killed rapidly by water, drying, or barium, it is important to examine at least three fresh stool specimens. Examination of a combination of wet mounts, iodine-stained concentrates, and trichrome-stained preparations of fresh stool and concentrates for cysts or trophozoites confirms the diagnosis in 75–95% of cases. Cultures of amebae are more sensitive but are not routinely available. If stool examinations are negative, sigmoidoscopy with biopsy of the edge of ulcers may increase the yield, but this procedure is dangerous during fulminant colitis because of the risk of perforation. Trophozoites in a biopsy specimen from a colonic mass confirm the diagnosis of ameboma, but trophozoites are rare in liver aspirates because they are found in the abscess capsule and not in the readily aspirated necrotic center. Accurate diagnosis requires experience, since the trophozoites may be confused with neutrophils and the cysts must be differentiated morphologically from those of *Entamoeba hartmanni*, *Entamoeba coli*, and *Endolimax nana*, which do not cause clinical disease and do not warrant therapy. Unfortunately, the cysts of *E. histolytica* cannot be distinguished microscopically from those of *E. dispar*, *E. moshkovskii*, or *E. bangladeshi*. Therefore, the microscopic diagnosis of *E. histolytica* can be made only by the detection of *Entamoeba* trophozoites that have ingested erythrocytes.

Serology is an important addition to the methods used for parasitologic diagnosis of invasive amebiasis. Enzyme-linked immunosorbent assays are positive in >90% of cases with colitis, ameboma, or liver abscess. Positive results in conjunction with the appropriate clinical syndrome suggest active disease because serologic findings usually revert to negative within 6–12 months. Even in highly endemic areas such as South Africa, fewer than 10% of asymptomatic individuals have a positive amebic serology. The interpretation of the indirect hemagglutination test is difficult because titers may remain positive for as long as 10 years.

Early in infection, up to 10% of patients with acute amebic liver abscess may have negative serologic findings, which usually become positive within a week. In contrast to carriers of *E. dispar*, most asymptomatic carriers of *E. histolytica* develop antibodies. Thus, serologic tests are helpful in assessing the risk of invasive amebiasis in asymptomatic, cyst-passing individuals in nonendemic areas. Serologic tests

should also be performed in patients with ulcerative colitis before the institution of glucocorticoid therapy to prevent the development of severe colitis or toxic megacolon owing to unsuspected amebiasis.

More sensitive, specific, and rapid tests in stool are now in use in most developed countries. Enzyme immunoassays using monoclonal antibodies for the Gal/GalNAc lectin allow specific detection of *E. histolytica* in 96-well plates or a single cassette for rapid detection. Sensitivity is 87% and specificity >90% in stool and can also be used in liver abscess aspirates. The number of commercially available PCR tests has significantly expanded. Most are multiplex for GI protozoa alone or include major bacterial and viral pathogens, as well. The sensitivity and specificity approaches 100%, and results can be available in as little as an hour. Their cost precludes use in most developing countries.

Other amplification tests such as a loop-mediated isothermal amplification (LAMP) assay may be a potential alternative for direct detection of *E. histolytica* DNA in pus samples from amebic liver abscesses. LAMP is a relatively simple, rapid, and low-cost method of DNA amplification that could be a better alternative for diagnosis in developing countries.

Routine hematology and chemistry tests usually are not very helpful in the diagnosis of invasive amebiasis. About three-fourths of patients with an amebic liver abscess have leukocytosis (>10,000 cells/μL); this condition is particularly likely if symptoms are acute or complications have developed. Invasive amebiasis does not elicit eosinophilia. Anemia, if present, is usually multifactorial. Even with large liver abscesses, liver enzyme levels are normal or minimally elevated. The alkaline phosphatase level is most often elevated and may remain so for months. Aminotransferase elevations suggest acute disease or a complication.

Radiographic Studies Radiographic barium studies are potentially dangerous in acute amebic colitis. Amebomas are usually identified first by a barium enema, but biopsy is necessary for differentiation from carcinoma.

Radiographic techniques such as ultrasonography, CT, and MRI are all useful for detection of the round or oval hypoechoic cyst. More than 80% of patients who have had symptoms for >10 days have a single abscess of the right lobe of the liver **(Fig. 230-3)**. Approximately 50% of patients who have had symptoms for <10 days have multiple abscesses. Findings associated with complications include large abscesses (>10 cm) in the superior part of the right lobe, which may rupture into the pleural space; multiple lesions, which must be differentiated from pyogenic abscesses; and lesions of the left lobe, which may rupture into the pericardium. Because abscesses resolve slowly and may increase in size despite a clinical response to therapy, frequent follow-up ultrasonography may prove confusing. Complete resolution of a liver abscess within 6 months can be anticipated in two-thirds of patients, but 10% may have persistent abnormalities for a year.

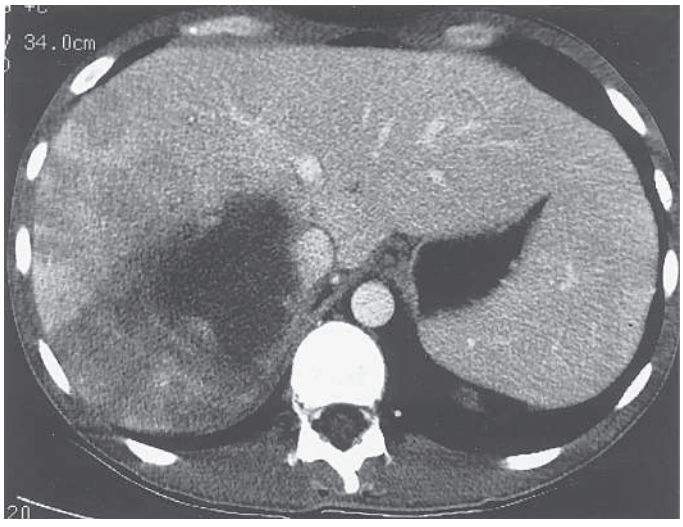

FIGURE 230-3 Abdominal CT scan of a large amebic abscess of the right lobe of the liver. *(Courtesy of the Department of Radiology, UCSD Medical Center, San Diego; with permission.)*

Differential Diagnosis The differential diagnosis of intestinal amebiasis includes bacterial diarrheas **(Chap. 138)** caused by *Campylobacter* **(Chap. 169)**; enteroinvasive *Escherichia coli* **(Chap. 166)**; and species of *Shigella* **(Chap. 172)**, *Salmonella* **(Chap. 171)**, and *Vibrio* **(Chap. 173)**. Because the typical patient with amebic colitis has less prominent fever than in these other conditions as well as heme-positive stools with few neutrophils, correct diagnosis requires bacterial cultures, microscopic examination of stools, amebic serologic testing, and stool specific antigens or PCR. As has been mentioned, amebiasis must be ruled out in any patient thought to have inflammatory bowel disease.

Because of the variety of presenting signs and symptoms, amebic liver abscess can easily be confused with pulmonary or gallbladder disease or with any febrile illness with few localizing signs, such as malaria **(Chap. 231)** or typhoid fever **(Chap. 171)**. The diagnosis should be considered in members of high-risk groups who have recently traveled outside the United States **(Chap. 130)** and in inmates of institutions. Once radiographic studies have identified an abscess in the liver, the most important differential diagnosis is between amebic and pyogenic abscess. Patients with pyogenic abscess typically are older and have a history of underlying bowel disease or recent surgery. Amebic serology is helpful, but aspiration of the abscess, with Gram's staining and culture of the material, may be required for differentiation of the two diseases.

TREATMENT

Amebiasis

INTESTINAL DISEASE **(TABLE 230-1)**

The drugs used to treat amebiasis can be classified according to their primary site of action. Luminal amebicides are poorly absorbed and reach high concentrations in the bowel, but their activity is limited to cysts and trophozoites close to the mucosa. Only two luminal drugs are available in the United States: iodoquinol and paromomycin. Indications for the use of luminal agents include eradication of cysts in patients with colitis or a liver abscess and treatment of asymptomatic carriers. The majority of asymptomatic individuals who pass cysts are colonized with *E. dispar*, which does not warrant specific therapy. However, it is prudent to treat asymptomatic individuals who pass cysts unless *E. dispar* colonization can be definitively demonstrated by specific antigen-detection tests.

Tissue amebicides reach high concentrations in the blood and tissue after oral or parenteral administration. The development of nitroimidazole compounds, especially metronidazole, was a major advance in the treatment of invasive amebiasis. Patients with amebic colitis should be treated with IV or oral metronidazole. Side effects include nausea, vomiting, abdominal discomfort, and a disulfiram-like reaction. Another, longer-acting imidazole compound, tinidazole, is likewise effective and is available in the United States. All patients should also receive a full course of therapy with

TABLE 230-1 Drug Therapy for Amebiasis

INDICATION	THERAPY
Asymptomatic carriage	Luminal agent: iodoquinol (650-mg tablets), 650 mg tid for 20 days; *or* paromomycin (250-mg tablets), 500 mg tid for 10 days
Acute colitis	Metronidazole (250- or 500-mg tablets), 750 mg PO or IV tid for 5–10 days; *or* tinidazole, 2 g/d PO for 3 days ***plus*** Luminal agent as above
Amebic liver abscess	Metronidazole, 750 mg PO or IV for 5–10 days; *or* tinidazole, 2 g PO once; *or* ornidazole,[a] 2 g PO once ***plus*** Luminal agent as above

[a]Not available in the United States.

a luminal agent, since metronidazole does not eradicate cysts. Resistance to metronidazole has been selected in the laboratory but has not been found in clinical isolates. Relapses are not uncommon and probably represent reinfection or failure to eradicate amebae from the bowel because of an inadequate dosage or duration of therapy.

AMEBIC LIVER ABSCESS

Metronidazole is the drug of choice for amebic liver abscess. Longer-acting nitroimidazoles (tinidazole and ornidazole) have been effective as single-dose therapy in developing countries. With early diagnosis and therapy, mortality rates from uncomplicated amebic liver abscess are <1%. There is no evidence that combined therapy with two drugs is more effective than the single-drug regimen. Studies of South Africans with liver abscesses demonstrated that 72% of patients without intestinal symptoms had bowel infection with *E. histolytica*; thus, all treatment regimens should include a luminal agent to eradicate cysts and prevent further transmission. Amebic liver abscess recurs rarely.

More than 90% of patients respond dramatically to metronidazole therapy with decreases in both pain and fever within 72 h. Indications for aspiration of liver abscesses are (1) the need to rule out a pyogenic abscess, particularly in patients with multiple lesions; (2) the lack of a clinical response in 3–5 days; (3) the threat of imminent rupture; and (4) the need to prevent rupture of left-lobe abscesses into the pericardium. There is no evidence that aspiration, even of large abscesses (up to 10 cm), accelerates healing. Percutaneous drainage may be successful even if the liver abscess has already ruptured. Surgery should be reserved for instances of bowel perforation and rupture into the pericardium.

PREVENTION

Amebic infection is spread by ingestion of food or water contaminated with cysts. Since an asymptomatic carrier may excrete up to 15 million cysts per day, prevention of infection requires adequate sanitation and eradication of cyst carriage. In high-risk areas, infection can be minimized by the avoidance of unpeeled fruits and vegetables and the use of bottled water. Because cysts are resistant to readily attainable levels of chlorine, disinfection by iodination (tetraglycine hydroperiodide) is recommended. There is no effective prophylaxis.

INFECTION WITH FREE-LIVING AMEBAE

EPIDEMIOLOGY

There are multiple genera of free-living amebae, but the major human pathogens are *Acanthamoeba*, *Naegleria*, and *Balamuthia*. All of these parasites can cause serious central nervous system (CNS) infections, which are almost always fatal. *Acanthamoeba* and *Naegleria* are distributed throughout the world and have been isolated from a wide variety of fresh and brackish water, including water from taps, lakes, hot springs, swimming pools, heating and air-conditioning units, and hospital water networks, and even from the nasal passages of healthy children. Encystation may protect these protozoa from desiccation and food deprivation. The persistence of *Legionella pneumophila* in water supplies is attributable in part to chronic infection of free-living amebae, particularly *Acanthamoeba*. In vitro studies have suggested that several pathogens that can resist phagosome-mediated killing may be able to survive within water systems in free-living amebae. These pathogens include *Pseudomonas aeruginosa*, nontuberculous *Mycobacteria* (both slow-growing species—e.g., those in the *Mycobacterium avium* complex, *M. kansasii*, and *M. gordonae*—and rapid-growing species—e.g., *M. chelonae and M. abscessus*), and viruses such as adenoviruses and echoviruses.

In contrast, the environmental niche of free-living amebae of the genus *Balamuthia* appears to be soil. A soil sample from a flowerpot was linked to a fatal infection in a child. Cases have been reported from all continents except Africa, but the majority of cases are from warm, dry areas of the southwestern United States and Latin America.

With better recognition of these pathogens, additional risk factors have been identified. Since 2010, five cases of *Naegleria fowleri* infection have been reported in northern U.S. states and have been associated with exposure to piped water, which represents a new ecologic niche. Since 2009, three clusters of *Balamuthia mandrillaris* infections have been associated with organ transplantation. *Acanthamoeba* species have caused large outbreaks of microbial keratitis associated with contact lens wear.

NAEGLERIA INFECTIONS

Primary amebic meningoencephalitis (PAM) is a fulminant CNS infection caused by the free-living ameba *Naegleria fowleri*, which thrives in warm freshwater of lakes and rivers. In the United States, 157 cases of PAM were reported from 1962 through 2022 for a total of 381 cases worldwide. Historically in southern states and more frequently during the summer, the number of infections reported annually has remained stable (0–8). However, cases in northern states have been on the rise. In 2010, a PAM case was reported for the first time from Minnesota; this case was followed by additional cases from Minnesota, Indiana, and Kansas in 2011 and 2012. With climate change, other areas may be at risk because of higher temperatures. It commonly affects healthy, male individuals (75%) with a median age of 14 years (range, 1 month–85 years). Most patients (91%) were exposed to recreational freshwater from lakes, reservoirs, rivers, streams, or ditches. The remaining cases were due to tap-water exposure through nasal irrigation with a neti pot, playing on a backyard waterslide, and swimming in a poorly maintained pool.

Despite evidence of extra-CNS dissemination of *N. fowleri* in PAM patients post-mortem, transplantation of their solid organs have not been associated with PAM in transplant recipients.

The risk of PAM in transplant recipients needs to be carefully considered in individual cases.

PAM occurs after *N. fowleri* trophozoites enter the CNS through the olfactory neuroepithelium following inhalation of water or dust contaminated with trophozoites or cysts. Trophozoites then migrate to the brain, avoiding the protective blood-brain barrier and invoking a neutrophilic response. After an incubation period of 2–15 days, severe headache, high fever, nausea, vomiting, and meningismus develop. Photophobia and palsies of the third, fourth, and sixth cranial nerves are common. Rapid progression to seizures and coma may follow. The prognosis is uniformly poor: most patients die within a week.

The diagnosis of *Naegleria* infection should be considered in any patient who has purulent meningitis without evidence of bacteria on Gram's staining, antigen detection assay, and culture. Other laboratory findings resemble those for fulminant bacterial meningitis, with elevated intracranial pressure, high white blood cell counts (up to 20,000/μL), and elevated protein concentrations and low glucose levels in cerebrospinal fluid (CSF). Diagnosis depends on the detection of motile trophozoites in wet mounts of fresh spinal fluid. Antibodies to *Naegleria* species have been detected in healthy adults; thus, serologic testing is not useful in the diagnosis of acute infection. Diagnostic PCR and histochemical staining of biopsies are available through the CDC.

A number of antimicrobial agents have in vitro activity against *N. fowleri*, but the prognosis remains poor. The few survivors have been treated with different combinations of amphotericin B, fluconazole, azithromycin, rifampin, and dexamethasone. The new antiparasitic agent miltefosine—an alkylphosphocholine compound used to treat breast cancer and visceral leishmaniasis—is active in vitro against *Naegleria*, *Acanthamoeba*, and *Balamuthia* and is now commercially available (*impavido.com*). All seven survivors among reported worldwide cases (381) included miltefosine as well as the five drugs above. Early diagnosis, prompt combination therapy including miltefosine, and aggressive management of neurologic complications, including therapeutic hypothermia, are important factors in better outcomes. A clinician whose patient may have PAM should contact the CDC Emergency Operations Center at (770) 488-7100 for assistance in diagnosis by PCR and treatment recommendations (which should include miltefosine).

ACANTHAMOEBA INFECTIONS

Granulomatous Amebic Encephalitis Infection with at least eight different *Acanthamoeba* species follows a more indolent course

than *Naegleria* infection and typically occurs in chronically ill or debilitated patients. Risk factors include lymphoproliferative disorders, chemotherapy, glucocorticoid therapy, lupus erythematosus, post-transplant, and AIDS. Infection usually reaches the CNS hematogenously from a primary focus in the sinuses, skin, or lungs. In the CNS, the onset is insidious, and the syndrome often mimics a space-occupying lesion. Altered mental status, headache, and stiff neck may be accompanied by focal findings such as cranial nerve palsies, ataxia, and hemiparesis. Cutaneous ulcers or hard nodules containing amebae are frequently detected in AIDS patients with disseminated *Acanthamoeba* infection.

Examination of the CSF for trophozoites may be diagnostically helpful, but lumbar puncture may be contraindicated because of increased intracerebral pressure. CT frequently reveals cortical and subcortical lesions of decreased density consistent with embolic infarcts. In other patients, multiple enhancing lesions with edema may mimic the CT appearance of toxoplasmosis **(Chap. 235)**. Demonstration of the trophozoites and cysts of *Acanthamoeba* on wet mounts or in biopsy specimens establishes the diagnosis. Culture on nonnutrient agar plates seeded with *Escherichia coli* also may be helpful. A real-time PCR assay to detect *Acanthamoeba*, *Naegleria*, and *Balamuthia* as well as a fluorescein-labeled antiserum for the detection of protozoa in biopsy specimens are available from the CDC. Granulomatous amebic encephalitis in patients with AIDS or transplant recipients may have an accelerated course (with survival for only 3–40 days) because of the difficulty these individuals have in forming granulomas. Various antimicrobial agents have been used to treat *Acanthamoeba* infection, but miltefosine should be included in combination therapy.

Keratitis The incidence of keratitis caused by *Acanthamoeba* has increased in the past 20 years, in part as a result of improved diagnosis. Earlier infections were associated with trauma to the eye and exposure to contaminated water. At present, most infections are linked to extended-wear contact lenses, and rare cases are associated with laser-assisted in situ keratomileusis (LASIK). Risk factors include the use of homemade saline, the wearing of lenses while swimming, and inadequate disinfection. Since contact lenses presumably cause microscopic trauma, early corneal findings may be nonspecific. The first symptoms usually include tearing and the painful sensation of a foreign body. Once infection is established, progression is rapid. The characteristic clinical sign is an annular, paracentral corneal ring representing a corneal abscess. Deeper corneal invasion and loss of vision may follow.

The differential diagnosis includes bacterial, mycobacterial, and herpetic infection. The irregular polygonal cysts of *Acanthamoeba* **(Fig. 230-4)** may be identified in corneal scrapings or biopsy material, and trophozoites can be grown on special media. Cysts are resistant to available drugs, and the results of medical therapy have been disappointing. Some reports have suggested partial responses to polyhexamethylene biguanide (0.2%) or propamidine isethionate (0.1%) eyedrops. Severe infections usually require keratoplasty.

BALAMUTHIA INFECTIONS

Balamuthia mandrillaris is a free-living ameba that was first identified in 1986 as the cause of a fatal infection in a mandrill baboon at the Wild Animal Park in San Diego, California. Since then more than 100 cases have been reported in the United States and 200 worldwide. The parasite has been isolated from soil and dust and is probably widespread in the environment. It is an important etiologic agent of granulomatous amebic encephalitis, cutaneous lesions, and sinus infections in humans. The potential risk factors for granulomatous amebic encephalitis identified by the California Encephalitis Project include young age, immunocompromising conditions, and Hispanic ethnicity. The infection likely starts with percutaneous or mucous membrane exposure and then spreads hematogenously to the brain and other organs—a pattern that explains the risk for transmission through organ transplantation. In 2009–2012, three clusters of organ transplant–transmitted *B. mandrillaris* infections were detected by recognition of severe unexpected illness in multiple recipients from the same donor after an incubation period of 17–24 days.

Frequently, *Balamuthia* affects immunocompetent individuals, in whom the course is typically subacute, with focal neurologic signs, fever, seizures, and headaches leading to death within 1 week to several months after onset. Skin lesions may occur on the face, trunk, or extremities. In addition to dust inhalation, inoculation of trophozoites or cysts from stagnant water may occur through open wounds or mucous membranes. Diagnosis relies on examination of CSF, which reveals mononuclear or neutrophilic pleocytosis, elevated protein levels, and normal to low glucose concentrations. Amebae are rarely isolated from CSF and require culture in the presence of cell monolayers. Multiple hypodense lesions are usually detected with imaging studies **(Fig. 230-5)**. The differential diagnosis includes tuberculomas **(Chap. 183)** and neurocysticercosis **(Chap. 242)**. Testing for *Balamuthia* is part of the multiplex PCR test from the CDC. Fluorescent antibodies for serology and immunohistochemistry also are available.

The nine surviving patients in the United States have been treated with a variety of drugs, including pentamidine, flucytosine,

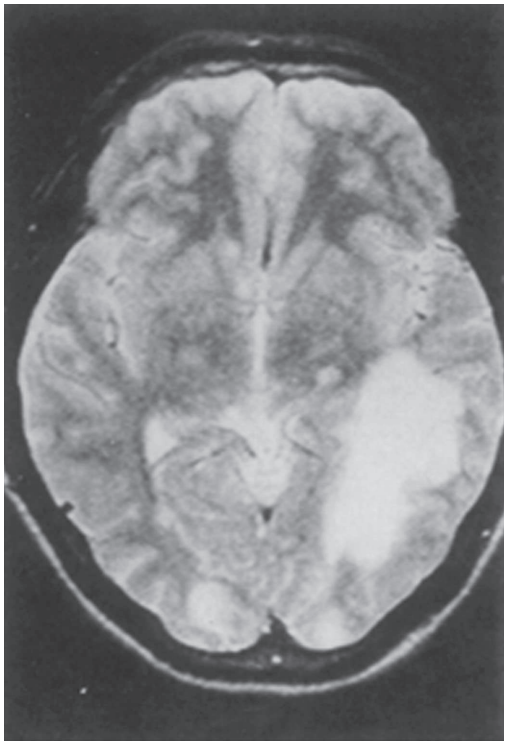

FIGURE 230-5 Brain MRI of amebic meningoencephalitis due to *Balamuthia mandrillaris*. A large lesion in the parieto-occipital lobe and other smaller lesions are seen. *(Courtesy of the Department of Radiology, UCSD Medical Center, San Diego.)*

sulfadiazine, and macrolides. The CDC recommends that miltefosine now be included, as for treatment of other free-living amebae. Clinicians should contact the CDC Emergency Operations Center at (770)-488-7100 for assistance in diagnosis and treatment.

231 Malaria

Elizabeth A. Ashley, Nicholas J. White

Humanity has but three great enemies: Fever, famine, and war; of these by far the greatest, by far the most terrible, is fever.

—William Osler, 1896

Malaria is a protozoan disease transmitted by the bite of infected female *Anopheles* mosquitoes and is the most important of the parasitic diseases of humans. In 2022, there were an estimated 249 million cases in 85 malaria-endemic countries and 608,000 deaths (i.e., ~1660 deaths each day). Two countries had an estimated 43% of these deaths: Nigeria (31%) and Democratic Republic of the Congo (12%). Malaria was eliminated from the United States, Canada, Europe, and Russia >50 years ago, but its prevalence rose in many parts of the tropics between 1970 and 2000. In response to this rise, there was substantial investment aimed at increasing access to accurate diagnosis, effective treatments, and insecticide-treated bed nets. Between 2000 and 2015, malaria mortality rates decreased dramatically as a result of highly effective control programs in several countries; since then, however, progress has reversed and estimated global case numbers, mainly in sub-Saharan Africa, have risen steadily. Meanwhile an increasing number of countries that had low malaria transmission are now targeting malaria elimination. This ambitious goal is threatened by increasing resistance to antimalarial drugs and insecticides.

Malaria remains today, as it has been for centuries, a heavy burden on tropical communities, a threat to nonendemic countries, and a danger to travelers.

ETIOLOGY AND PATHOGENESIS

Six species of the genus *Plasmodium* cause nearly all malarial infections in humans. These are *P. falciparum*, *P. vivax*, two morphologically identical sympatric species of *P. ovale* (*curtisi* and *wallikeri*), *P. malariae*, and—in Southeast Asia—the monkey malaria parasite *P. knowlesi* **(Table 231-1)**. Occasionally humans are also infected with the monkey parasites *P. simium* (South America) and *P. cynomolgi* (Southeast Asia). While almost all deaths are caused by falciparum malaria, *P. knowlesi* and occasionally *P. vivax* can also cause severe illness. Human infection begins when a female anopheline mosquito inoculates plasmodial *sporozoites* from its salivary glands during a blood meal **(Fig. 231-1)**. These microscopic motile forms of the malaria parasite are carried rapidly via the bloodstream to the liver, where they invade hepatic parenchymal cells and begin a period of asexual reproduction. By this amplification process (known as *intrahepatic* or *preerythrocytic schizogony*), a single sporozoite may produce from 10,000 to >30,000 daughter merozoites. These few swollen infected liver cells containing the hepatic schizonts eventually burst, discharging motile *merozoites* into the bloodstream. The merozoites then invade red blood cells (RBCs) to become *trophozoites* and, in nonimmune subjects, multiply 6- to 20-fold every 48 h (*P. knowlesi*, 24 h; *P. malariae*, 72 h). When the parasites reach densities of ~50/μL of blood (~100 million parasites in total in the blood of an adult), the symptomatic stage of the infection begins. In *P. vivax* and *P. ovale* infections, a proportion of the intrahepatic forms do not divide immediately but remain inert for a period ranging from 2 weeks to ≥1 year. These dormant forms, or *hypnozoites*, are the cause of the relapses that characterize infection with these species.

Attachment of merozoites to erythrocytes is mediated via a complex interaction with several different binding ligands and specific erythrocyte surface receptors. *P. falciparum* merozoites bind via

TABLE 231-1 Characteristics of *Plasmodium* Species Infecting Humans

CHARACTERISTIC	FINDING FOR INDICATED SPECIES				
	P. FALCIPARUM	*P. VIVAX*	*P. OVALE*[a]	*P. MALARIAE*	*P. KNOWLESI*
Duration of intrahepatic phase (days)	5.5	8	9	15	5.5
Number of merozoites released per infected hepatocyte	30,000	10,000	15,000	15,000	20,000
Approximate duration of erythrocytic cycle (h)	48	48	50	72	24
Red cell preference	Younger cells (but can invade cells of all ages)	Reticulocytes and cells up to 2 weeks old	Reticulocytes	Older cells	Younger cells
Morphology	Usually only ring forms; banana-shaped gametocytes	Irregularly shaped large rings and trophozoites; enlarged erythrocytes; Schüffner's dots	Infected erythrocytes, enlarged and oval with tufted ends; Schüffner's[b] dots	Band or rectangular forms of trophozoites common	Resembles *P. falciparum* (early trophozoites) or *P. malariae* (later trophozoites, including band forms)
Pigment color	Black	Yellow-brown	Dark brown	Brown-black	Dark brown
Ability to cause relapses	No	Yes	Yes	No	No

[a]Genomic studies have revealed *P. ovale* to be two sympatric species: *P. ovale curtisi* and *P. ovale wallikeri*, which are morphologically very similar but may have different incubation periods and latencies. [b]Also known as James's dots.

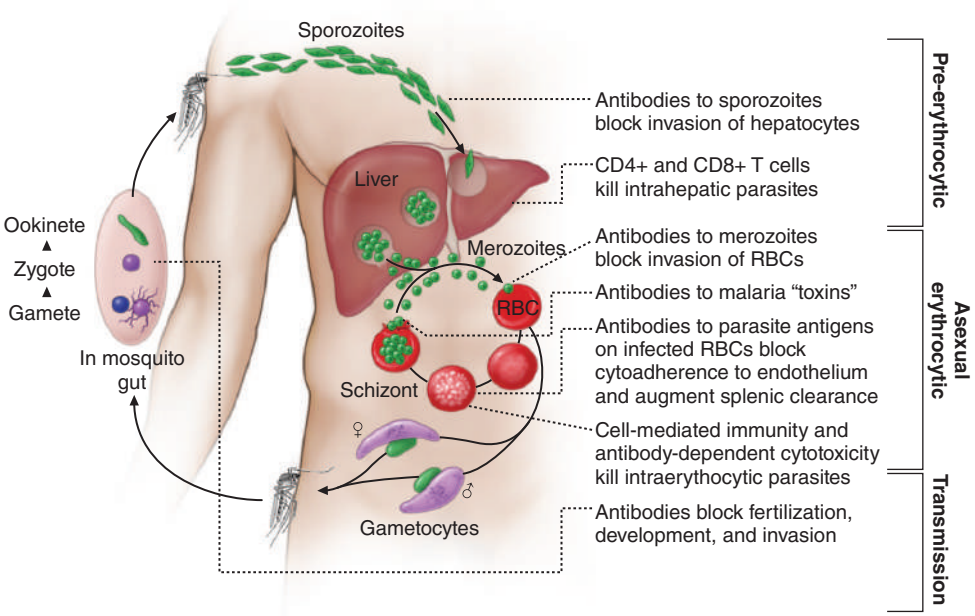

FIGURE 231-1 The malaria transmission cycle from mosquito to human and targets of immunity. In *Plasmodium vivax* and *P. ovale* infections some liver stage parasites remain dormant ("hypnozoites") and awake weeks or months later to cause relapses. RBC, red blood cell.

erythrocyte- binding antigen 175 to glycophorin A and via EBA-140 to glycophorin C. The other glycophorins (B and D) also contribute. The merozoite reticulocyte-binding protein homologue 5 (PfRh5) plays a critical role binding to red cell basigin (CD147, EMMPRIN).

P. vivax binds to receptors on developing erythrocytes. The Duffy blood-group antigen Fy^a or Fy^b plays an important role in invasion of *P. vivax* and *P. knowlesi*. Most West Africans and people with origins in that region have the Duffy-negative FyFy phenotype and are generally resistant to *P. vivax* malaria.

During the first few hours of intraerythrocytic development, the small "ring forms" of the different malaria species appear similar under light microscopy. As the trophozoites enlarge, species-specific characteristics become evident, malaria pigment (hemozoin) becomes visible, and the parasite assumes an irregular or ameboid shape. By the end of the intraerythrocytic life cycle, the parasite has consumed two-thirds of the RBC's hemoglobin and has grown to occupy most of the cell. It is now called a *schizont*. Multiple nuclear divisions have taken place (*schizogony* or *merogony*). The infected RBC then ruptures to release 6–30 daughter merozoites, each potentially capable of invading a new RBC and repeating the cycle. The disease in human beings is caused by the direct effects of the asexual parasite—RBC invasion and destruction—and by the host's reaction. Some of the blood-stage parasites develop into morphologically distinct, longer-lived sexual forms (*gametocytes*) that can transmit malaria. In falciparum malaria, a delay of several asexual cycles precedes this switch to gametocytogenesis. Female gametocytes typically outnumber males by 4:1. Immature (stage I to IV) gametocytes are sequestered preferentially in the bone marrow and are also found in the spleen, brain, and intestine.

After being ingested in the blood meal of a biting female anopheline mosquito, the male gametocyte exflagellates and divides rapidly into eight motile male gametes. These fuse with female gametocytes, undergoing two rounds of sexual division (meiosis) to form a zygote in the insect's midgut. This zygote matures into an ookinete, which penetrates and encysts in the mosquito's gut wall. The resulting oocyst expands by asexual division until it bursts to liberate myriad motile sporozoites, which then migrate in the hemolymph to the salivary gland of the mosquito to await inoculation into another human at the next feed, thus completing the parasite's life cycle.

EPIDEMIOLOGY

Malaria occurs throughout most of the tropical regions of the world (Fig. 231-2). *P. falciparum* predominates in Africa, New Guinea, and Hispaniola (i.e., the Dominican Republic and Haiti); *P. vivax* is more

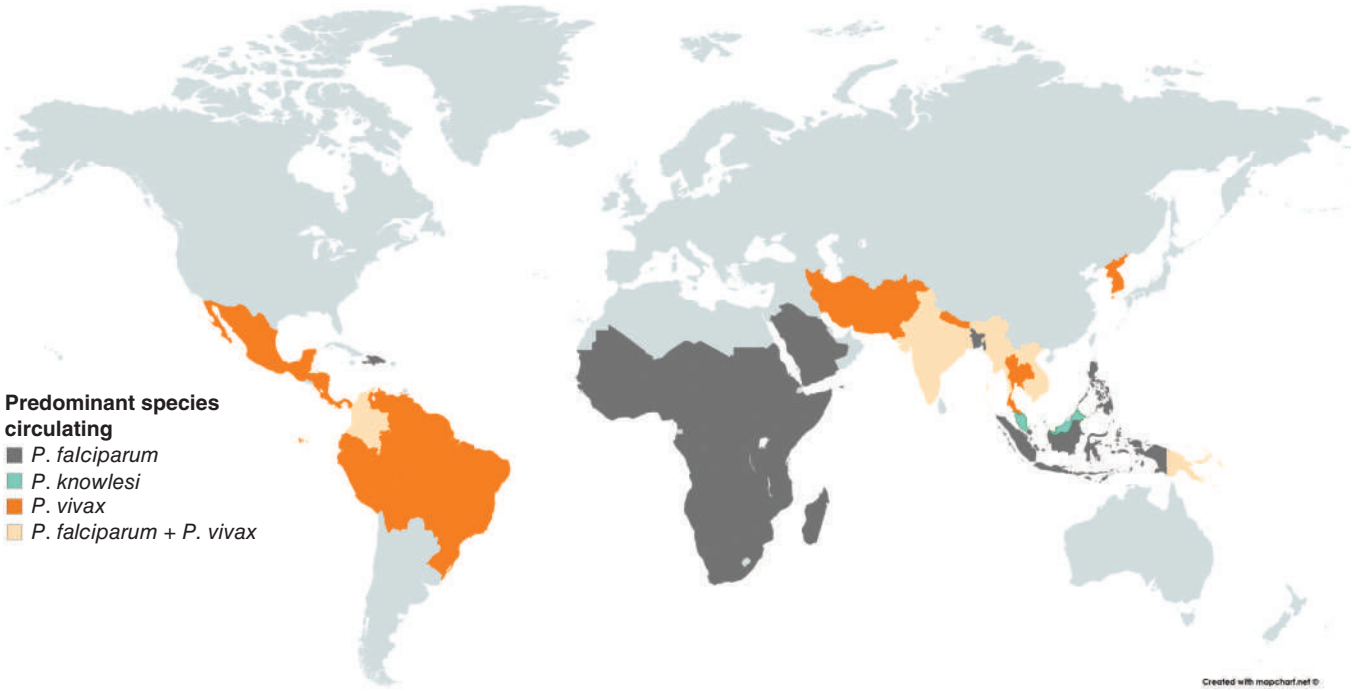

FIGURE 231-2 Malaria-endemic countries showing predominant *Plasmodium* species. *Plasmodium vivax* is common in the Horn of Africa and in Mauritania but relatively unusual elsewhere in the continent.

common in Central and South America and most of Asia. The prevalence of these two species is approximately equal in Oceania. *P. malariae* is found in most endemic areas, especially throughout sub-Saharan Africa, but is much less common. *P. ovale* is relatively unusual outside of Africa. In endemic areas, submicroscopic asymptomatic infections (detectable by polymerase chain reaction [PCR]) with all human malaria parasites are much more common than microscopy-detected infections. *P. knowlesi* causes human infections commonly on the island of Borneo and, to a lesser extent, elsewhere in Southeast Asia, where the main hosts, long-tailed and pig-tailed macaques, are found.

The epidemiology of malaria is complex and may vary considerably even within relatively small geographic areas. Endemicity traditionally has been defined in terms of rates of microscopy-detected parasitemia or palpable spleens in children 2–9 years of age and has been classified as hypoendemic (<10%), mesoendemic (11–50%), hyperendemic (51–75%), and holoendemic (>75%). In holo- and hyperendemic areas (e.g., certain regions of tropical Africa or coastal New Guinea) where there is intense *P. falciparum* transmission, people may sustain one or more infectious mosquito bites per week and are infected repeatedly throughout their lives. In such settings, malaria morbidity and mortality are substantial during early childhood. Immunity against disease is hard won in these areas following repeated symptomatic infections in childhood, but, if the child survives, infections become increasingly asymptomatic. These asymptomatic older children and adults are a major source of malaria transmission. As control measures progress and urbanization expands, environmental conditions become less conducive to malaria transmission, and all age groups may lose protective immunity and become susceptible to illness. Constant, frequent, year-round infection is termed *stable transmission*. In areas where transmission is low, erratic, or focal, full protective immunity is not acquired, and symptomatic disease may occur at all ages. This situation usually exists in hypoendemic areas and is termed *unstable transmission*. Even in stable transmission areas, there is often an increased incidence of symptomatic malaria during the rainy season coinciding with increased mosquito breeding and transmission. Malaria can behave like an epidemic disease in some areas, particularly those with unstable malaria, such as northern India (the Punjab region), the Horn of Africa, Rwanda, Burundi, southern Africa, and Madagascar. Epidemics may occur when changes in environmental, economic, or social conditions (e.g., heavy rains following drought or migration—usually of refugees or workers—from a nonmalarious region to an area of high transmission) are compounded by relaxation or breakdown in malaria control and prevention services caused by underinvestment, war, or civil disorder. Epidemics often result in high mortality rates among all age groups. The principal determinants of the epidemiology of malaria are the number (density), the human-biting habits, and the longevity of the anopheline mosquito vectors. More than 100 of the >400 anopheline species can transmit malaria, but the ~40 species that do so commonly vary considerably in their efficiency as malaria vectors. More specifically, the transmission of malaria is directly proportional to the density of the vector, the square of the number of human bites per day per mosquito, and the tenth power of the probability of the mosquito's surviving for 1 day. Mosquito longevity is particularly important as a determinant of malaria transmissibility because the parasite's development within the mosquito—from gametocyte ingestion to subsequent inoculation (*sporogony*)—lasts 8–30 days, depending on ambient temperature. In order to transmit malaria, the vector mosquito must therefore survive for >7 days. Sporogony is not completed at cooler temperatures—i.e., <16°C (<60.8°F) for *P. vivax* and <21°C (<69.8°F) for *P. falciparum*; thus, transmission does not occur below these temperatures or at high altitudes. Global warming is resulting in malaria transmission at higher altitudes than previously. The most effective mosquito vectors of malaria are those, such as the *Anopheles gambiae* species complex in Africa, that are long-lived, occur in high densities in tropical climates, breed readily, and bite humans in preference to other animals. The entomologic inoculation rate (i.e., the number of sporozoite-positive mosquito bites per person per year) is the most common measure of malaria transmission and varies from <1 in some parts of Latin America and Southeast Asia to >300 in parts of tropical Africa.

PATHOPHYSIOLOGY

ERYTHROCYTE CHANGES

After invading an erythrocyte, the growing malarial parasite progressively consumes and degrades intracellular proteins, principally hemoglobin. The potentially toxic heme is detoxified by lipid-mediated crystallization to biologically inert hemozoin (malaria pigment). The parasite also alters the RBC membrane by changing its transport properties, exposing cryptic surface antigens, and inserting new parasite-derived proteins. The RBC becomes more irregular in shape, more antigenic, and less deformable.

In *P. falciparum* infections, membrane protuberances appear on the erythrocyte's surface 12–15 h after cell invasion. These "knobs" extrude a high-molecular-weight, antigenically variant, strain-specific erythrocyte membrane adhesive protein (PfEMP1) that mediates attachment to receptors on venular and capillary endothelium (*cytoadherence*). Several vascular receptors have been identified; intercellular adhesion molecule 1 and endothelial protein C receptor are important in the brain, VAR2CSA (which binds chondroitin sulfate A) predominates in the placenta, and CD36 binds parasitized RBCs in most other organs. Erythrocytes containing more mature parasites stick inside and eventually block capillaries and venules. Infected RBCs may also adhere to uninfected RBCs (to form rosettes) and to other parasitized erythrocytes (agglutination). The processes of cytoadherence, rosetting, and agglutination are central to the pathogenesis of falciparum malaria. They result in the sequestration of infected RBCs in vital organs (particularly the brain), where they interfere with microcirculatory flow and metabolism. Sequestered *P. falciparum* parasites continue to develop out of reach of the principal host defense mechanism: splenic processing and filtration. As a consequence, only the younger ring forms of the asexual *P. falciparum* parasites circulate in the peripheral blood, and the level of peripheral parasitemia variably underestimates the true number of parasites within the body. In severe malaria, uninfected erythrocytes also become less deformable, which compromises their passage through the partially obstructed capillaries and venules and shortens their survival.

In the other human malarias, significant sequestration does not occur, and all stages of the parasite's development are evident on peripheral-blood smears. *P. vivax* and *P. ovale* show a marked predilection for young RBCs and *P. malariae* for old cells; these species produce a level of parasitemia that seldom exceeds 2%. In contrast, *P. falciparum* can invade erythrocytes of all ages and may be associated with very high parasite densities. Dangerously high parasite densities may also occur in *P. knowlesi* infections, with rapid increases as a result of the shorter (24-h) asexual life cycle.

HOST RESPONSE

Initially, the host responds to malaria infection by activating nonspecific defense mechanisms. Splenic immunologic and filtrative clearance functions are augmented, and the removal of both parasitized and uninfected erythrocytes is accelerated. The spleen also removes damaged ring-form parasites (a process known as "pitting") from within the red cell and returns the once-infected cells back to the circulation, where their survival is shortened. The parasitized cells escaping splenic removal are destroyed when the schizont ruptures. The material released induces monocyte/macrophage activation and the release of proinflammatory cytokines, which cause fever and other pathologic effects. Temperatures of ≥40°C (≥104°F) damage mature parasites; in untreated infections, the effect of such temperatures is to further synchronize the parasitic cycle, with eventual production of the regular fever spikes and rigors that originally characterized the different malarias. These regular fever patterns (*quotidian*, daily; *tertian*, every 2 days; *quartan*, every 3 days) are seldom seen today as patients receive prompt and effective antimalarial treatment.

The geographic distributions of the thalassemias, sickle cell disease, hemoglobins C and E, hereditary ovalocytosis, and glucose-6-phosphate dehydrogenase (G6PD) deficiency closely resemble that of falciparum malaria before the introduction of control measures. This similarity suggests that these genetic disorders confer protection

against death from falciparum malaria. HbA/S heterozygotes (sickle cell trait) have a sixfold reduction in the risk of dying from severe falciparum malaria and are correspondingly protected from the bacterial infections that complicate malaria. Hemoglobin S–containing RBCs impair parasite growth at low oxygen tensions, and *P. falciparum*–infected RBCs containing hemoglobin S or C exhibit reduced cytoadherence because of reduced surface presentation of the adhesin PfEMP1. Parasite multiplication in HbA/E heterozygotes is reduced at high parasite densities. In Melanesia, children with α-thalassemia have more frequent malaria (both vivax and falciparum) in the early years of life, which appears to protect them against severe disease. In Melanesian ovalocytosis and in Africans with the Dantu blood group, rigid erythrocytes resist merozoite invasion. G6PD deficiency provides some protection against severe *P. falciparum* infections but has a much stronger protective effect against *P. vivax* infections.

Nonspecific host defense mechanisms stop the infection's expansion, and the subsequent strain-specific immune response then controls the infection. Eventually, exposure to sufficient strains confers protection from high-level parasitemia and disease but not from infection (*premunition*). Asymptomatic parasitemia is very common among adults and older children living in regions with stable and intense malaria transmission (i.e., holo- or hyperendemic areas) and also in parts of low-transmission areas. Parasitemia in asymptomatic infections fluctuates in density but often averages ~5000/mL—which is just below the level of microscopy detection but sufficient to generate transmissible densities of gametocytes. Immunity is mainly specific for both the species and the strain of infecting malarial parasite. Both humoral immunity and cellular immunity are necessary for protection, but the mechanisms of each are incompletely understood (Fig. 231-1). Immune individuals have a polyclonal increase in serum levels of IgM, IgG, and IgA, although much of this antibody is unrelated to protection. Antibodies to a variety of parasite antigens presumably act in concert to limit in vivo replication of the parasite. In *P. falciparum* infections, the variant surface adhesin PfEMP1 is the most important of these antigens. Passive transfer of maternal antibody contributes to the partial protection of infants from severe malaria in the first months of life. This complex immunity to disease declines when a person lives outside an endemic area for several months or longer.

Several factors retard the development of cellular immunity to malaria. These factors include the absence of major histocompatibility antigens on the surface of infected RBCs, which precludes direct T-cell recognition; malaria antigen–specific immune unresponsiveness; and the enormous strain diversity of malarial parasites, along with the ability of the parasites to express variant immunodominant antigens on the erythrocyte surface that change during the course of infection. Parasites may persist in the blood for months or years (or, in the case of *P. malariae*, for decades) if treatment is not given. The complexity of the immune response in malaria, the sophistication of the parasites' evasion mechanisms, and the lack of a good in vitro correlate with clinical immunity have all slowed progress toward effective vaccines.

CLINICAL FEATURES

Malaria is a common cause of fever in tropical countries. Clinical diagnosis is notoriously unreliable. The first symptoms of malaria are nonspecific; the lack of a sense of well-being, headache, fatigue, abdominal discomfort, and muscle aches followed by fever are all similar to the symptoms of a minor viral illness. In some instances, a prominence of headache, chest pain, abdominal pain, cough, arthralgia, myalgia, or diarrhea may suggest another diagnosis. Although headache may be severe in malaria, the neck stiffness and photophobia of meningitis do not occur. While myalgia may be prominent, it is not usually as severe as in dengue fever, and the muscles are not tender as in leptospirosis or typhus. Nausea, vomiting, and orthostatic hypotension are common. The classic malarial paroxysms, in which fever spikes, chills, and rigors occur at regular intervals, are unusual and at presentation suggest infection (often relapse) with *P. vivax* or *P. ovale*. The temperature of nonimmune individuals and children often rises above 40°C (104°F), with tachycardia and sometimes delirium. Childhood febrile convulsions may occur with any of the malarias, but generalized seizures are associated specifically with falciparum malaria and may herald the development of encephalopathy (cerebral malaria). Many clinical abnormalities have been described in acute malaria, but most patients with uncomplicated infections have few abnormal physical findings other than fever, malaise, mild anemia, and (in some cases) a palpable spleen. Anemia is common among young children living in areas with stable transmission (e.g., much of West Africa) and increases in prevalence where resistance has compromised the efficacy of antimalarial drugs. Frequent vivax malaria relapse is an important cause of anemia in young children in some areas (e.g., on the island of New Guinea). In nonimmune individuals with acute malaria, the spleen takes several days to become palpable, but splenic enlargement is found in a high proportion of otherwise healthy individuals in malaria-endemic areas and reflects repeated infections. Slight enlargement of the liver is also common, particularly among young children. Jaundice may develop in patients with otherwise uncomplicated malaria and usually resolves over 1–3 weeks. Malaria is not associated with a rash. Petechial hemorrhages in the skin or mucous membranes—features of viral hemorrhagic fevers and leptospirosis—develop only very rarely in severe falciparum malaria, although thrombocytopenia is usual.

SEVERE FALCIPARUM MALARIA

Appropriately and promptly treated, uncomplicated falciparum malaria (i.e., where the patient can sit or stand unaided and can swallow medicines and food) carries a mortality rate of <0.1%. However, once vital-organ dysfunction occurs or the total proportion of erythrocytes infected increases to >2% (a level corresponding to $>10^{12}$ parasites in an adult), mortality risk rises steeply, depending on the immunity of the host. The major manifestations of severe falciparum malaria are shown in **Table 231-2**, and features indicating a poor prognosis are listed in **Table 231-3**.

Cerebral Malaria Coma is a characteristic and ominous feature of falciparum malaria and, even with treatment, has been associated with death rates of ~20% among adults and 15% among children. Any obtundation, delirium, or abnormal behavior in falciparum malaria should be taken very seriously. The onset of coma may be gradual or sudden following a convulsion.

Cerebral malaria manifests as a diffuse symmetric encephalopathy; focal neurologic signs are unusual. Although some passive resistance to head flexion may be detected, signs of meningeal irritation are absent. The eyes may be divergent, and bruxism and a pout reflex are common, but other primitive reflexes are usually absent. The corneal reflexes are preserved, except in deep coma. Muscle tone may be either increased or decreased. The tendon reflexes are variable, and the plantar reflexes may be flexor or extensor; the abdominal and cremasteric reflexes are absent. Flexor or extensor posturing may be seen. On routine fundoscopy, ~15% of patients have retinal hemorrhages; with pupillary dilation and indirect ophthalmoscopy, this figure increases to 30–40%. Papilledema (8% among children, rare among adults) and cotton wool spots (<5%) also occur. More specific funduscopic abnormalities **(Fig. 231-3)** include discrete spots of retinal opacification (30–60%) and decolorization of a retinal vessel or segment of vessel (occasional cases). Convulsions, which are usually generalized and often repeated, occur in ~10% of adults and up to 50% of children with cerebral malaria. More covert seizure activity is common, particularly among children, and may manifest as repetitive tonic–clonic eye movements or even hypersalivation. Whereas adults rarely (<3% of cases) suffer obvious neurologic sequelae, ~10% of children surviving cerebral malaria—especially those with hypoglycemia, severe anemia, repeated seizures, and deep coma—have residual neurologic deficits when they regain consciousness; hemiplegia, cerebral palsy, cortical blindness, deafness, and impaired cognition may all occur. The majority of these deficits improve markedly or resolve completely within 6 months. However, the prevalence of some other deficits increases over time; ~10% of children surviving cerebral malaria have a persistent language deficit. There may also be deficits in learning, planning and executive functions, attention, memory, and nonverbal functioning. The incidence of epilepsy is increased and life expectancy is decreased among these children.

TABLE 231-2 Manifestations of Severe Falciparum Malaria

SIGNS	MANIFESTATIONS
Major	
Unarousable coma/ cerebral malaria	Failure to localize or respond appropriately to noxious stimuli; coma persisting for >30 min after generalized convulsion; a Glasgow Coma Score <11, or in young children a Blantyre Coma Score of <3
Acidemia/acidosis	Arterial pH of <7.25, base deficit >8 meq/L, or plasma bicarbonate level of <15 mmol/L; venous lactate level of ≥5 mmol/L; manifests as labored deep breathing, often termed "respiratory distress"
Severe normochromic, normocytic anemia	Hematocrit of <15% or hemoglobin level of <50 g/L (<5 g/dL) with parasite density of >10,000/μL[a]
Renal failure	Serum or plasma creatinine level of >265 μmol/L (>3 mg/dL) or blood urea level of >20 μmol/L[b]
Pulmonary edema/ adult respiratory distress syndrome	Noncardiogenic pulmonary edema, often aggravated by overhydration; radiologically confirmed or oxygen saturation <92% on room air with a respiratory rate >30/ min, often with chest wall indrawing and crepitations on auscultation
Hypoglycemia	Plasma glucose level of <2.2 mmol/L (<40 mg/dL)
Hypotension/shock	Systolic blood pressure of <70 mmHg in children 1–5 years or <80 mmHg in adults; with evidence of impaired perfusion or capillary refill >2 s
Bleeding/ disseminated intravascular coagulation	Significant bleeding and hemorrhage from the gums, nose, and gastrointestinal tract and/or evidence of disseminated intravascular coagulation
Convulsions	More than two generalized seizures in 24 h; signs of continued seizure activity, sometimes subtle (e.g., tonic-clonic eye movements without limb or face movement)
Other	
Hemoglobinuria[c]	Macroscopic black, brown, or red urine; not associated with effects of oxidant drugs and red blood cell enzyme defects (such as G6PD deficiency)
Extreme weakness	Prostration; inability to sit unaided[d]
Hyperparasitemia	Parasitemia level of >5% in nonimmune patients (>10% in any patient)
Jaundice	Serum bilirubin level of >50 mmol/L (>3 mg/dL) if combined with a parasite density of >100,000/μL or other evidence of vital-organ dysfunction

[a]This is nonspecific and may include patients with chronic anemia; a parasitemia threshold of 100,000/μL is more specific for acute malarial anemia. [b]These are criteria for adults. Lower values reflect severe malaria in children. [c]Hemoglobinuria may also occur in uncomplicated malaria and in patients with G6PD deficiency, particularly if they take oxidant drugs such as primaquine. [d]In children who are normally able to sit.

Abbreviation: G6PD, glucose-6-phosphate dehydrogenase.

TABLE 231-3 Features Indicating a Poor Prognosis in Severe Falciparum Malaria

Clinical
Marked agitation
Hyperventilation (respiratory distress)
Low core temperature (<36.5°C; <97.7°F)
Bleeding
Deep coma
Repeated convulsions
Anuria
Shock
Laboratory
Biochemistry
Hypoglycemia (<2.2 mmol/L)
Hyperlactatemia (≥5 mmol/L)
Acidemia (arterial pH <7.25, base deficit >8 meq/L, or serum HCO_3 <15 mmol/L)
Elevated serum creatinine (>265 μmol/L)
Elevated total bilirubin (>50 μmol/L)
Elevated liver enzymes (AST/ALT 3 times upper limit of normal)
Elevated muscle enzymes (CPK ↑, myoglobin ↑)
Elevated urate (>600 μmol/L)
Hematology
Leukocytosis (>12,000/μL)
Severe anemia (PCV <10%)
Coagulopathy
Low platelet count (<50,000/μL)
Prolonged prothrombin time (>3 s)
Prolonged partial thromboplastin time
Decreased fibrinogen (<200 mg/dL)
Parasitology
Hyperparasitemia
Increased mortality at >100,000/μL
High mortality at >500,000/μL
>20% of parasites identified as pigment-containing trophozoites and schizonts
>5% of neutrophils contain visible malaria pigment

Note: Increased risk of concomitant bacteremia in adults if >20% parasitemia.

Abbreviations: ALT, alanine aminotransferase; AST, aspartate aminotransferase; CPK, creatine phosphokinase; PCV, packed cell volume.

Hypoglycemia Hypoglycemia, an important and common complication of severe malaria, is associated with a poor prognosis and is particularly problematic in children and pregnant women. Hypoglycemia in malaria results from both a failure of hepatic gluconeogenesis and an increase in the consumption of glucose by the host and, to a much lesser extent, the malaria parasites. Hypoglycemia may be compounded by quinine, a powerful stimulant of pancreatic insulin secretion, which is still sometimes used in endemic areas for the treatment of both severe and uncomplicated falciparum malaria. In severe disease, the clinical diagnosis of hypoglycemia is difficult: the usual physical signs (sweating, gooseflesh, tachycardia) are absent, and the neurologic impairment caused by hypoglycemia cannot be distinguished from that caused by malaria.

Acidosis Acidosis, resulting from accumulation of organic acids, is an important cause of death from severe malaria, which in adults is often compounded by renal impairment. Hypovolemia is not a major contributor to acidosis. Lactic acidosis is caused by the combination of anaerobic glycolysis in tissues where sequestered parasites interfere with microcirculatory flow, lactate production by the parasites, and a failure of hepatic and renal lactate clearance. Hyperlactatemia commonly coexists with hypoglycemia. Acids of gut origin are important contributors to acidosis. In children, ketoacidosis may also contribute. Hydroxyphenyllactic acid, α-hydroxybutyric acid, and β-hydroxybutyric acid concentrations are elevated. Acidotic breathing, sometimes called "respiratory distress," is a sign of poor prognosis. It is followed often by circulatory failure refractory to volume expansion or inotropic drug treatment and ultimately by respiratory arrest. Plasma concentrations of bicarbonate or lactate are the best biochemical prognosticators in severe malaria.

Noncardiogenic Pulmonary Edema Adults with severe falciparum malaria may develop noncardiogenic pulmonary edema (adult respiratory distress syndrome) even after several days of antimalarial therapy. The mortality rate is >80%. The pathogenesis is unclear. Pulmonary edema can be readily precipitated by overly vigorous administration of IV fluid. Noncardiogenic pulmonary edema can also develop in otherwise uncomplicated vivax malaria, where recovery is usual.

Renal Impairment Acute kidney injury is common in severe falciparum malaria. Oliguric renal failure requiring temporary renal replacement therapy is an important manifestation in adults but is unusual among children. The pathogenesis of renal failure is unclear but may be related to erythrocyte sequestration and agglutination interfering with renal microcirculatory flow and metabolism. Clinically and pathologically, this syndrome manifests as acute tubular

FIGURE 231-3 The eye in cerebral malaria: perimacular whitening and pale-centered retinal hemorrhages. *(Courtesy of N. Beare, T. Taylor, S. Harding, S. Lewallen, and M. Molyneux; with permission.)*

necrosis. Acute renal failure may occur simultaneously with other vital-organ dysfunction (in which case the mortality risk is high) or may progress as other disease manifestations resolve. In survivors, urine flow resumes in a median of 4 days, and serum creatinine levels return to normal in a mean of 17 days **(Chap. 321)**. Early dialysis or hemofiltration considerably improves the chances of survival, particularly in acute hypercatabolic renal failure.

Hematologic Abnormalities Anemia results from accelerated RBC removal by the spleen, obligatory RBC destruction at parasite schizogony, and ineffective erythropoiesis. In severe malaria, the deformability of both infected and uninfected RBCs is reduced. The degree of reduced deformability correlates with prognosis and with the development of anemia. Splenic clearance of all RBCs is increased. In nonimmune individuals and in areas with unstable transmission, anemia can develop rapidly and transfusion is often required. A hemoglobin of ≤3 g/dL on presentation is associated with increased mortality. Acute hemolytic anemia with massive hemoglobinuria ("blackwater fever") may occur. Hemoglobinuria may contribute to renal injury. Some patients with blackwater fever have G6PD deficiency, but in the majority of cases, it is unclear why massive hemolysis has occurred. In nonimmune patients, sudden hemolysis may follow many days after artesunate treatment of hyperparasitemia, usually as a result of relatively synchronous loss of once-parasitized "pitted" RBCs. As a consequence of repeated malarial infections, children in high-transmission areas are usually anemic and often develop severe anemia. This results from both shortened survival of uninfected RBCs and marked dyserythropoiesis. Anemia is a common consequence of antimalarial drug resistance, which results in repeated or continued infection.

Slight coagulation abnormalities are common in falciparum malaria, and mild thrombocytopenia is usual (a normal platelet count should question the diagnosis of malaria). Fewer than 5% of patients with severe malaria have significant bleeding with evidence of disseminated intravascular coagulation. Hematemesis from stress ulceration or acute gastric erosions may occur rarely.

Liver Dysfunction Mild hemolytic jaundice is common in malaria. Severe jaundice is associated with *P. falciparum* infections; is more common among adults than among children; and results from hemolysis, hepatocyte injury, and cholestasis. Liver failure does not occur. When accompanied by other vital-organ dysfunction (often renal impairment), liver dysfunction carries a poor prognosis. Hepatic dysfunction contributes to hypoglycemia, lactic acidosis, and impaired drug metabolism. Occasional patients with falciparum malaria may develop deep jaundice (with hemolytic, hepatic, and cholestatic components) without evidence of other vital-organ dysfunction, in which case the prognosis is good.

TABLE 231-4 Relative Incidence of Severe Complications of Falciparum Malaria

COMPLICATION	NONPREGNANT ADULTS	PREGNANT WOMEN	CHILDREN
Anemia	+	++	+++
Convulsions	+	+	+++
Hypoglycemia	+	+++	+++
Jaundice	+++	+++	+
Renal failure	+++	+++	+
Pulmonary edema	++	+++	+

Note: –, rare; +, infrequent; ++, frequent; +++, very frequent.

Other Complications HIV/AIDS and malnutrition predispose to more severe malaria in nonimmune individuals. Malaria anemia is worsened by concurrent infections with intestinal helminths, hookworm in particular. Approximately 6% of children diagnosed with severe malaria have concomitant bacteremia. In adults, the proportion is lower (<1%), except in those with very high parasite counts (>20% parasitemia). In areas of moderate and high malaria transmission, differentiating severe malaria from sepsis with incidental parasitemia in childhood is very difficult, and severe malaria is overdiagnosed. In endemic areas, *Salmonella* spp. bacteremia has been associated specifically with *P. falciparum* infections. Chest infections and catheter-associated urinary tract infections are common among patients who are unconscious for >3 days. Aspiration pneumonia may follow generalized convulsions. The frequencies of complications of severe falciparum malaria are summarized in **Table 231-4**.

MALARIA IN PREGNANCY

Malaria in early pregnancy causes fetal loss. In areas of high malaria transmission, falciparum malaria in primi- and secundigravid women is associated with low birth weight (average reduction, ~170 g) and consequently increased infant mortality rates. In general, infected mothers in areas of stable transmission remain asymptomatic despite intense accumulation of parasitized erythrocytes in the placental microcirculation. Maternal HIV infection predisposes pregnant women to more frequent and higher-density malaria infections, predisposes their newborns to congenital malarial infection, and exacerbates the reduction in birth weight associated with malaria.

In areas with unstable transmission of malaria, pregnant women are prone to severe infections and are particularly likely to develop high *P. falciparum* parasitemias complicated by anemia, hypoglycemia, and acute pulmonary edema. Fetal distress, premature labor, and stillbirth or low birth weight are common results. Fetal death is common in severe malaria. Congenital malaria occurs in <5% of newborns of infected mothers; its frequency and the level of parasitemia are related directly to the timing of maternal infection and the parasite density in maternal blood and in the placenta. *P. vivax* malaria in pregnancy is also associated with a reduction in birth weight (average, 110 g), but in contrast to falciparum malaria, this effect is more pronounced in multigravid than in primigravid women. About 300,000 women die in childbirth yearly, with most deaths occurring in low-income countries; maternal death from hemorrhage at childbirth is correlated with malaria-induced anemia.

MALARIA IN CHILDREN

Most of the estimated >600,000 deaths from falciparum malaria each year are in young African children. Convulsions, coma, hypoglycemia, metabolic acidosis, and severe anemia are relatively common among children with severe malaria, whereas deep jaundice, oliguric acute kidney injury, and acute pulmonary edema are unusual. Severely anemic children may present with labored deep breathing, which previously

has been attributed incorrectly to "anemic congestive cardiac failure" but is usually caused by metabolic acidosis. In general, children tolerate antimalarial drugs well and respond rapidly to treatment. Younger children, and in particular malnourished children, require higher body weight–adjusted antimalarial drug doses than older children or adults.

TRANSFUSION MALARIA

Malaria can be transmitted by blood transfusion, needlestick injury, or organ transplantation. The incubation period is often short because there is no preerythrocytic stage of development, and thus there are no relapses of *P. vivax* and *P. ovale* infections. The clinical features and management of these cases are the same as for naturally acquired infections, although primaquine is not needed for radical cure of vivax or ovale malaria as there are no liver stages.

CHRONIC COMPLICATIONS OF MALARIA

HYPERREACTIVE MALARIAL SPLENOMEGALY

Chronic or repeated malarial infections produce hypergammaglobulinemia; normochromic, normocytic anemia; and, in certain situations, splenomegaly. Some residents of malaria-endemic areas in tropical countries exhibit an abnormal immunologic response to repeated infections that is characterized by massive splenomegaly, hepatomegaly, marked elevations in serum IgM and malarial antibody titers, hepatic sinusoidal lymphocytosis, and (in Africa) peripheral B-cell lymphocytosis. This syndrome has been associated with the production of cytotoxic IgM antibodies to CD8+ T lymphocytes, antibodies to CD5+ T lymphocytes, and an increase in the ratio of CD4+ to CD8+ T cells. These events may lead to uninhibited B-cell production of IgM and the formation of cryoglobulins (IgM aggregates and immune complexes). This immunologic process stimulates lymphoid hyperplasia and clearance activity and eventually produces splenomegaly. Patients with hyperreactive malarial splenomegaly present with an abdominal mass or a dragging sensation in the abdomen and occasional sharp abdominal pains suggesting perisplenitis. There is usually anemia and some degree of pancytopenia (hypersplenism). In some cases, malaria parasites cannot be found in peripheral-blood smears by microscopy. Respiratory and skin infections are common and many patients die of overwhelming sepsis. Persons with hyperreactive malarial splenomegaly living in endemic areas should receive antimalarial chemoprophylaxis; the results are usually good. In nonendemic areas, antimalarial treatment is advised. Some cases have been mistaken for hematologic malignancy. However, in other cases refractory to therapy, clonal lymphoproliferation may develop, and this can evolve into a malignant lymphoproliferative disorder.

QUARTAN MALARIAL NEPHROPATHY

Chronic or repeated infections with *P. malariae* (and possibly with other malarial species) may cause soluble immune complex injury to the renal glomeruli, resulting in the nephrotic syndrome. Other unidentified factors must contribute to this process since only a very small proportion of infected patients develop renal disease. The histologic appearance is that of focal or segmental glomerulonephritis with splitting of the capillary basement membrane. Subendothelial dense deposits are seen on electron microscopy, and immunofluorescence reveals deposits of complement and immunoglobulins and *P. malariae* antigens are often visible. A coarse-granular pattern of basement membrane immunofluorescent deposits (predominantly IgG3) with selective proteinuria carries a better prognosis than a fine-granular, predominantly IgG2 pattern with nonselective proteinuria. Quartan nephropathy is mainly a disease of children and is rarely reported nowadays. It usually responds poorly to treatment with either antimalarial agents or glucocorticoids and cytotoxic drugs.

BURKITT'S LYMPHOMA AND EPSTEIN-BARR VIRUS INFECTION

It is possible that malaria-related immune dysregulation provokes infection with lymphoma viruses. Childhood Burkitt's lymphoma is strongly associated with Epstein-Barr virus (EBV) and with high transmission of *P. falciparum*. Chronic *P. falciparum* malaria drives large numbers of EBV-infected cells through the lymph node germinal centers and deregulates activation-induced cytidine deaminase, resulting in DNA damage, c-myc translocations, and sometimes lymphoma.

DIAGNOSIS OF MALARIA

When a patient in or from a malarious area presents with fever, thick and thin blood smears should be prepared and *examined immediately* to confirm the diagnosis and identify the species of infecting parasite **(Figs. 231-4 through 231-10)**. In general, if the blood smear is negative when examined by an experienced microscopist, the patient does not have malaria. If reliable microscopy is not available, a rapid test should be performed. Malaria is not a clinical diagnosis.

DEMONSTRATION OF THE PARASITE

The definitive diagnosis of malaria rests on the demonstration of asexual forms of the parasite in stained peripheral-blood smears. Of the Romanowsky stains, Giemsa at pH 7.2 is preferred; Field's, Wright's, or Leishman's stain can also be used. Staining of parasites with the fluorescent dye acridine orange allows more rapid diagnosis of malaria (but not speciation of the infection) in patients with low-level parasitemia.

Both thin (Figs. 231-4, 231-5, 231-10) and thick (Figs. 231-6, 231-7, 231-8, and 231-9) blood smears should be examined. The thin blood smear should be air-dried, fixed in anhydrous methanol, then stained; the RBCs in the tail of the film should then be examined under oil immersion (×1000 magnification). The density of parasitemia is expressed as the number of parasitized erythrocytes per 1000 RBCs. The thick blood film should be of uneven thickness. The smear should be dried thoroughly and stained without fixing. As many layers of

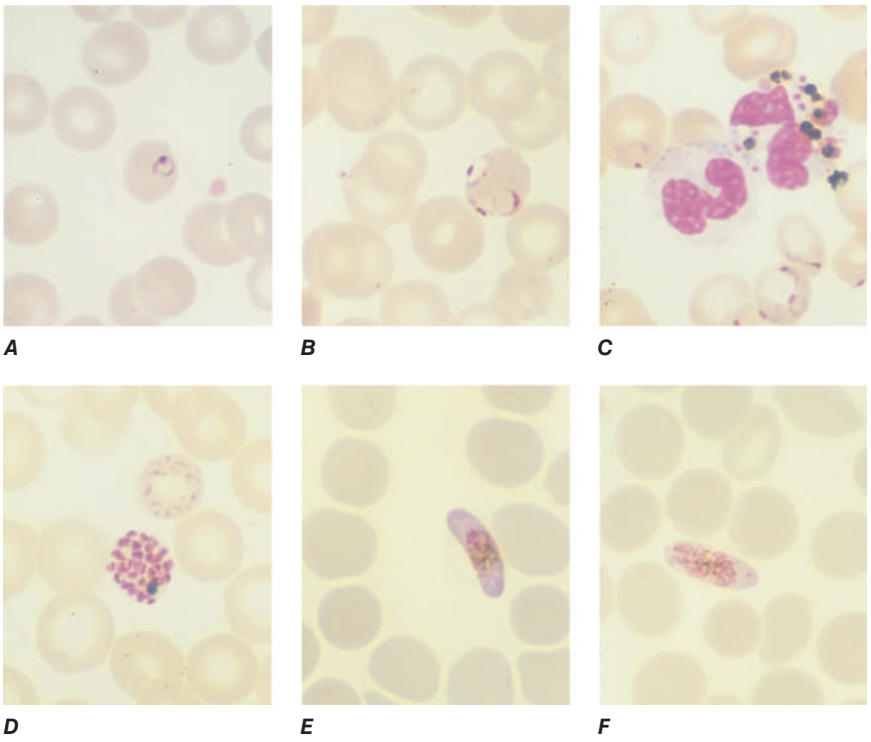

FIGURE 231-4 Thin blood films of *Plasmodium falciparum*. *A.* Young trophozoite. ***B.*** Old trophozoite. ***C.*** Trophozoites in erythrocytes and pigment in polymorphonuclear cells. ***D.*** Mature schizont. ***E.*** Female gametocyte. ***F.*** Male gametocyte. *(Reproduced from Bench Aids for the Diagnosis of Malaria Infections, 2nd ed, with the permission of the World Health Organization.)*

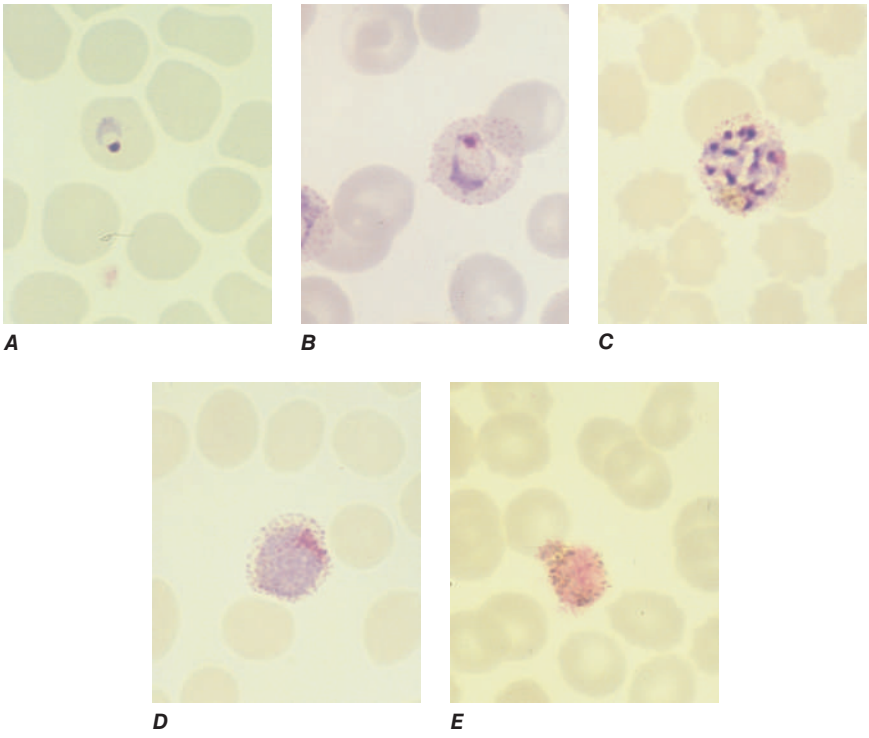

FIGURE 231-5 Thin blood films of *Plasmodium vivax*. *A.* Young trophozoite. ***B.*** Old trophozoite. ***C.*** Mature schizont. ***D.*** Female gametocyte. ***E.*** Male gametocyte. *(Reproduced from Bench Aids for the Diagnosis of Malaria Infections, 2nd ed, with the permission of the World Health Organization.)*

erythrocytes overlie one another and are lysed during the staining procedure, the thick film has the advantage of concentrating the parasites (by 40- to 100-fold compared with a thin blood film) and thus increasing diagnostic sensitivity. Both parasites and white blood cells (WBCs) are counted, and the number of parasites per unit volume is calculated from the total leukocyte count. Alternatively, a WBC count of 8000/μL is assumed. This figure is converted to the number of parasitized erythrocytes per microliter. A minimum of 200 WBCs should be counted under oil immersion. Interpretation of blood smears, particularly thick films, requires some experience because artifacts are common. Before a thick smear is judged to be negative, 100–200 fields should be examined. In high-transmission areas, the presence of up to 10,000 parasites/μL of blood may be tolerated without symptoms or signs in partially immune individuals. Thus, in these areas, the detection of low-density malaria parasitemia is sensitive but has low specificity in identifying malaria as the cause of illness. Because the prevalence of asymptomatic parasitemia is often high, low-density parasitemia is a common incidental finding in other conditions causing fever.

RAPID DIAGNOSTIC TESTS

Rapid, simple, sensitive, and specific antibody-based diagnostic stick or card tests that detect *P. falciparum*–specific histidine-rich protein 2 (PfHRP2), lactate dehydrogenase, or occasionally aldolase antigens in finger-prick blood samples have become the main method of malaria diagnosis in endemic areas **(Table 231-5)**. Some of these rapid diagnostic tests (RDTs) carry a second antibody (either pan-malaria or *P. vivax*–specific) and so distinguish falciparum malaria from the less dangerous malarias. PfHRP2-based RDTs may remain positive for several weeks after acute infection. This prolonged positivity is a disadvantage in high-transmission areas where infections are frequent but helps in the diagnosis of severe malaria in patients who have taken antimalarial drugs and cleared peripheral parasitemia but who still have a strongly positive PfHRP2 test. A major disadvantage of RDTs is that they do not quantify parasitemia. Widespread use of PfHRP2 RDTs has put strong selection pressure on *P. falciparum* populations in some areas, leading to an increased prevalence of mutant parasites with deletion of *PfHRP2/3* genes that are not detected by the current generation of PfHRP2-based tests. This is a particular problem in the horn of Africa but increasingly reported elsewhere.

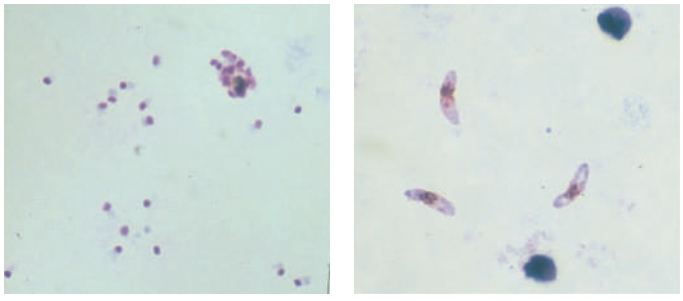

FIGURE 231-6 Thick blood films of *Plasmodium falciparum*. *A.* Trophozoites. ***B.*** Gametocytes. *(Reproduced from Bench Aids for the Diagnosis of Malaria Infections, 2nd ed, with the permission of the World Health Organization.)*

The relationship between parasite density and prognosis is complex and variable; in general, patients with $>10^5$ parasites/μL are at increased risk of dying, but nonimmune patients may die with much lower counts, and partially immune persons may tolerate parasite densities many times higher with only minor symptoms. In severe malaria, a poor prognosis is indicated by a predominance of more mature *P. falciparum* parasites (i.e., >20% of parasites with visible pigment) in the peripheral-blood film or by the presence of phagocytosed malarial pigment in >5% of neutrophils (an indicator of recent schizogony). In *P. falciparum* infections, gametocytemia peaks 1 week after the peak of asexual parasite densities. Because the mature gametocytes of *P. falciparum* (unlike those of other plasmodia) are not affected by most antimalarial drugs, their persistence does not mean there is drug resistance or a need to re-treat if a full course of appropriate treatment has been given. Phagocytosed malarial pigment seen inside peripheral-blood monocytes may provide a clue to recent infection if malaria parasites are not detectable. After parasite clearance, this intraphagocytic malarial pigment is often evident for several days in peripheral-blood films, and for longer in bone marrow aspirates or smears of fluid expressed after intradermal puncture.

Molecular diagnosis by PCR amplification of parasite nucleic acid is more sensitive than microscopy or rapid diagnostic tests for detecting malaria parasites and defining malarial species. PCR is used in reference centers but should not be used for primary diagnosis in endemic

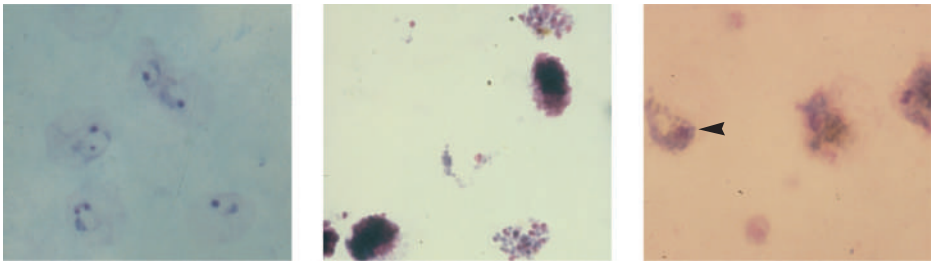

FIGURE 231-7 Thick blood films of *Plasmodium vivax*. *A.* Trophozoites. ***B.*** Schizonts. ***C.*** Gametocytes. *(Reproduced from Bench Aids for the Diagnosis of Malaria Infections, 2nd ed, with the permission of the World Health Organization.)*

areas as it is too sensitive. In epidemiologic surveys, ultrasensitive PCR detection (1000 times more sensitive than microscopy) has proved very useful in identifying asymptomatic infections as control and eradication programs drive parasite prevalences down to very low levels and in identifying residual "hot spots" of transmission. Serologic diagnosis with either indirect fluorescent antibody or enzyme-linked immunosorbent assays is useful for screening of prospective blood donors and may prove useful as a measure of transmission intensity in future epidemiologic studies. Serology has no place in the diagnosis of acute illness.

LABORATORY FINDINGS IN ACUTE MALARIA

Normochromic, normocytic anemia is usual. The leukocyte count is generally normal, although it may be raised in very severe infections. There is slight monocytosis, lymphopenia, and eosinopenia, with reactive lymphocytosis and eosinophilia in the weeks after acute infection. The platelet count is usually reduced to ~10^5/μL (a normal platelet count may point to another diagnosis). The erythrocyte sedimentation rate, plasma viscosity, and levels of C-reactive protein and other acute-phase proteins are elevated. Severe infections may be accompanied by prolonged prothrombin and partial thromboplastin times and by more severe thrombocytopenia. Antithrombin III levels are reduced even in mild infection. In uncomplicated malaria, plasma concentrations of electrolytes, blood urea nitrogen (BUN), and creatinine are usually normal. Findings in severe malaria may include metabolic acidosis, with low plasma concentrations of glucose, sodium, bicarbonate, phosphate, and albumin, together with elevations in lactate, BUN, creatinine (adjusted for age and body mass), urate, muscle and liver enzymes, and conjugated and unconjugated bilirubin. Hypergammaglobulinemia is usual in immune and semi-immune subjects living in malaria-endemic areas. Urinalysis generally gives normal results. In adults and children with cerebral malaria, the mean cerebrospinal fluid (CSF) opening pressure at lumbar puncture is ~160 mm H_2O; usually the CSF content is normal or there is a slight elevation of total protein level (<1.0 g/L [<100 mg/dL]) and cell count (<20/μL).

TREATMENT

Malaria

Patients with severe malaria and those unable to take oral drugs should receive parenteral antimalarial therapy immediately (Table 231-6). Antimalarial drug susceptibility testing can be performed but yields results too slowly to influence the choice of treatment. Molecular markers of resistance to various antimalarial drugs have been identified such as *dhfr* mutations (antifols), *Pfcrt* mutations (chloroquine), *Pfkelch13* mutations (artemisinin), *Pfpm1* or *Pfpm2* gene amplification (piperaquine) and *Pfmdr1*gene amplification (mefloquine), which are used in population surveillance studies.

The World Health Organization (WHO) recommends artemisinin-based combination therapy (ACT) as first-line treatment for uncomplicated *P. falciparum* malaria in malaria-endemic areas. An ACT comprises an artemisinin derivative (e.g., artesunate, artemether, or dihydroartemisinin), combined with a single partner drug from another antimalarial drug class in a fixed-dose coformulation. ACTs are also the recommended first-line treatment for *P. knowlesi* infections, and either chloroquine or an ACT is recommended for the other malarias. The choice of ACT depends on the likely sensitivity of the infecting parasites to the partner drug. ACTs may be unavailable in temperate countries, where treatment recommendations are limited to the registered available drugs. Despite increasing evidence of chloroquine resistance in *P. vivax* (from parts of Indonesia, Oceania, eastern and southern Asia, and Central and South America), chloroquine remains an effective treatment for *P. vivax* malaria in many areas and for *P. ovale* and *P. malariae* infections everywhere.

Artemisinin resistance in *P. falciparum* emerged in Southeast Asia in the late 2000s, where it was followed by piperaquine and mefloquine resistance in some areas. Significant artemisinin resistance is now prevalent throughout the Greater Mekong Subregion and has now emerged and spread in East Africa. As new antimalarials are still years away, it has been suggested that current ACTs should now combine two slowly eliminated partner drugs to provide mutual protection against resistance (triple ACTs). Falsified or substandard antimalarial drugs are sold in many Asian and African countries and may be the cause of treatment failures. Characteristics of antimalarial drugs are shown in Table 231-7.

SEVERE MALARIA

In large randomized controlled clinical trials, parenteral artesunate, a water-soluble artemisinin derivative, reduced severe falciparum malaria mortality rates by 35% in Asian adults and children and by 22.5% in African children compared with quinine treatment. Artesunate therefore is now the drug of choice for all patients with

TABLE 231-5 Standard Methods for the Diagnosis of Malaria[a]

METHOD	PROCEDURE	ADVANTAGES	DISADVANTAGES
Thick blood film[b]	Blood should be uneven in thickness but thin enough that the hands of a watch can be read through part of the spot. Stain dried, unfixed blood spot with Giemsa, Field's, or another Romanowsky stain. Count number of asexual parasites per 200 WBCs (or per 500 WBCs at low densities). Count and report gametocytes separately.[c]	Sensitive (0.001% parasitemia); species specific; inexpensive	Requires experience (artifacts may be misinterpreted as low-level parasitemia); underestimates true count
Thin blood film[d]	Stain fixed smear with Giemsa, Field's, or another Romanowsky stain. Count number of RBCs containing asexual parasites per 1000 RBCs. In severe malaria, assess stage of parasite development and count neutrophils containing malaria pigment.[e] Count and report gametocytes separately.[c]	Rapid; species specific; inexpensive; in severe malaria, provides prognostic information[e]	Insensitive (<0.05% parasitemia); uneven distribution of *P. vivax*, as enlarged infected red cells concentrate at leading edge
PfHRP2 dipstick or card test	A drop of blood is placed on the stick or card, which is then immersed in washing solutions. Monoclonal antibody capture of parasitic antigens reads out as a colored band.	Robust and relatively inexpensive; rapid; sensitivity similar to or slightly lower than that of thick films (~0.001% parasitemia)	Detects only *Plasmodium falciparum*; remains positive for weeks after high-density infections[f]; does not quantitate *P. falciparum* parasitemia; evasion of detection by certain strains due to polymorphisms/deletions in *HRP2/3* genes
Plasmodium LDH dipstick or card test	A drop of blood is placed on the stick or card, which is then immersed in washing solutions. Monoclonal antibody capture of parasitic antigens reads out as two colored bands. One band is genus specific (all malarias) or *P. vivax* specific, and the other band is specific for *P. falciparum.*	Rapid; sensitivity similar to or slightly lower than that of thick films for *P. falciparum* (~0.001% parasitemia)	May miss low-level parasitemia with *P. vivax*, *P. ovale*, and *P. malariae* and may not speciate these organisms; does not quantitate *P. falciparum* parasitemia; lower sensitivity for detection of *P. knowlesi*, which may be misidentified as *P. falciparum*
Microtube concentration methods with acridine orange staining	Blood is collected in a specialized tube containing acridine orange, anticoagulant, and a float. After centrifugation, which concentrates the parasitized cells around the float, fluorescence microscopy is performed.	Sensitivity similar or superior to that of thick films (~0.001% parasitemia); ideal for processing large numbers of samples rapidly	Does not speciate or quantitate; requires fluorescence microscopy

[a]Malaria cannot be diagnosed clinically with accuracy, but treatment should be started on clinical grounds if laboratory confirmation is likely to be delayed. In areas of the world where malaria is endemic and transmission rates are high, low-level asymptomatic parasitemia is common in otherwise healthy people. Thus, malaria may not be the cause of a fever in a parasitemic patient, although in this context, the presence of >10,000 parasites/μL (~0.2% parasitemia) does indicate that malaria is likely to be the cause. Antibody and polymerase chain reaction (PCR) tests have no role in the diagnosis of malaria except that PCR is increasingly used for genotyping and speciation in mixed infections and for detection of low-level parasitemia in asymptomatic residents of endemic areas. [b]Asexual parasites/200 WBCs × 40 = parasite count/μL (assumes a WBC count of 8000/μL). See Figs. 231-6 through 231-10. [c]*P. falciparum* gametocytemia may persist for days or weeks after clearance of asexual parasites. Gametocytemia without asexual parasitemia does not indicate active infection. [d]Parasitized RBCs (/1000) × hematocrit × 125.6 = parasite count/μL. See Figs. 231-4, 231-5 and 231-10. [e]The presence of >100,000 parasites/μL (~2% parasitemia) is associated with an increased risk of severe malaria, but some patients have severe malaria with lower counts. At any level of parasitemia, the finding that >50% of parasites are tiny rings (cytoplasm thickness less than half of nucleus width) carries a relatively good prognosis. In a severely ill patient, the presence of visible pigment in >20% of parasites or of phagocytosed pigment in >5% of polymorphonuclear leukocytes (indicating massive recent schizogony) carries a worse prognosis. [f]Persistence of PfHRP2 is a disadvantage in high-transmission settings, where many asymptomatic people have positive tests, but can be used to diagnostic advantage in low-transmission settings when a sick patient has previously received unknown treatment (which, in endemic areas, often consists of antimalarial drugs). In this situation, a positive PfHRP2 test indicates that the illness is falciparum malaria, even if the blood smear is negative.

Abbreviations: LDH, lactate dehydrogenase; PfHRP2, *P. falciparum* histidine-rich protein 2; RBCs, red blood cells; WBCs, white blood cells.

TABLE 231-6 Regimens for the Treatment of Malaria[a]

TYPE OF DISEASE OR TREATMENT	REGIMEN(S)
Uncomplicated Malaria	
Known chloroquine-sensitive strains of *Plasmodium vivax*, *P. malariae*, *P. ovale*, *P. falciparum*[b]	Chloroquine (10 mg of base/kg stat followed by 5 mg/kg at 12, 24, and 36 h *or* by 10 mg/kg at 24 h and 5 mg/kg at 48 h) *or* Amodiaquine (10–12 mg of base/kg qd for 3 days)
Radical treatment for *P. vivax or P. ovale* infection (prevention of relapse)	In addition to chloroquine or amodiaquine or ACT, primaquine (0.5 mg of base/kg qd in Southeast Asia and Oceania [total dose 7 mg/kg] and 0.25 mg/kg elsewhere [total dose 3.5 mg/kg]) should be given for 14 days to prevent relapse.[c] In mild G6PD deficiency, 0.75 mg of base/kg should be given once weekly for 8 weeks. Primaquine should not be given in severe G6PD deficiency. Single dose tafenoquine (adult dose 300 mg) is being introduced for radical cure in some areas alongside quantitative G6PD testing. Can be given only If G6PD levels are normal.
P. falciparum malaria	Artesunate[d,e] (4 mg/kg qd for 3 days) *plus* sulfadoxine (25 mg/kg)/pyrimethamine (1.25 mg/kg) as a single dose
	or
	Artesunate[d] (4 mg/kg qd for 3 days) *plus* amodiaquine (10 mg of base/kg qd for 3 days)[d,e]
	or Artemether-lumefantrine[d] (1.5/9 mg/kg bid for 3 days with food)
	or
	Artesunate[d] (4 mg/kg qd for 3 days) *plus* mefloquine (24–25 mg of base/kg—either 8 mg/kg qd for 3 days or 15 mg/kg on day 2 and then 10 mg/kg on day 3)[f]
	or
	DHA-piperaquine[d] (target dose: 4/24 mg/kg qd for 3 days in children weighing <25 kg and 4/18 mg/kg qd for 3 days in persons weighing ≥25 kg) *or* Artesunate-pyronaridine[d] (4/12 mg/kg qd for 3 days)
Second-line treatment/treatment of imported malaria (if other ACT not available)	Artesunate[e] (2 mg/kg qd for 7 days) *or* quinine (10 mg of salt/kg tid for 7 days) *plus 1 of the following 3:* Tetracycline[f] (4 mg/kg qid for 7 days) Doxycycline[f] (3 mg/kg qd for 7 days) Clindamycin (10 mg/kg bid for 7 days) *or* Atovaquone-proguanil (20/8 mg/kg qd for 3 days with food)
Severe Falciparum Malaria[g,h,i]	
	Artesunate[e] (2.4 mg/kg stat IV followed by 2.4 mg/kg at 12 and 24 h and then daily if necessary; for children weighing <20 kg, give 3 mg/kg per dose)
	or, if unavailable,
	Artemether[e] (3.2 mg/kg stat IM followed by 1.6 mg/kg qd)
	or, if unavailable,
	Quinine dihydrochloride (20 mg of salt/kg[j] infused over 4 h, followed by 10 mg of salt/kg infused over 2–8 h q8h[k])

[a]In endemic areas where malaria transmission is low, except in pregnant women and infants, a single dose of primaquine (0.25 mg of base/kg) should be added as a gametocytocide to all falciparum malaria treatments to prevent transmission. This is safe, even in G6PD deficiency. [b]Very few areas now have chloroquine-sensitive *P. falciparum* malaria. [c]Recent large studies indicate that these total doses can be condensed into 7-day primaquine regimens. [d]In areas where the partner drug to artesunate is known to be effective. Fixed-dose co-formulated combinations are available. The World Health Organization recommends artemisinin combination regimens as first-line therapy for falciparum malaria in all tropical countries and advocates use of fixed-dose combinations. [e]Artemisinin derivatives are not readily available in some temperate countries. [f] Tetracycline and doxycycline should not be given to pregnant women or to children <8 years of age. [g]Oral treatment should be substituted as soon as the patient recovers sufficiently to take fluids by mouth. [h]Artesunate is the drug of choice when available. The data from large studies in Southeast Asia showed a 35% lower mortality rate than with quinine, and very large studies in Africa showed a 22.5% reduction in mortality rate compared with quinine. The doses of artesunate in children weighing <20 kg should be 3 mg/kg. [i]Patients with severe malaria acquired in an area where artemisinin resistance has been confirmed should be given parenteral artesunate and quinine together at standard treatment doses. [j]A loading dose should not be given if therapeutic doses of quinine have definitely been administered in the previous 24 h. [k]Infusions can be given in 0.9% saline and 5–10% dextrose in water. Infusion rates for quinine should be carefully controlled.

Abbreviations: ACT, artemisinin combination therapy; DHA, dihydroartemisinin; G6PD, glucose-6-phosphate dehydrogenase.

severe malaria everywhere. Artesunate is given by IV injection but is also absorbed rapidly following IM injection. Artemether and the closely related drug artemotil (arteether) are oil-based formulations given by IM injection; they are erratically absorbed and do not confer the same survival benefit as artesunate. A rectal formulation of artesunate has been developed as a community-based prereferral treatment for patients in the rural tropics who cannot take oral medications. Prereferral administration of rectal artesunate has been shown to decrease mortality rates among severely ill children without access to immediate parenteral treatment. IV artesunate is approved by the U.S. Food and Drug Administration for the treatment of severe malaria and can be obtained from major drug distributors in the United States. Although parenteral quinine is steadily being replaced by parenteral artesunate in endemic areas, it may still have a small role in the treatment of presumed artemisinin-resistant severe falciparum malaria, where a precautionary approach is adopted and both artesunate and quinine are given together in full doses.

Severe falciparum malaria constitutes a medical emergency requiring intensive nursing care and careful management. Frequent evaluation of the patient's condition is essential. Adjunctive treatments such as high-dose glucocorticoids, urea, heparin, dextran, desferrioxamine, antibody to tumor necrosis factor α, high-dose phenobarbital (20 mg/kg), mannitol, or large-volume fluid or albumin boluses have proved either ineffective or harmful in clinical trials and should not be used. In acute renal failure or severe metabolic acidosis, hemofiltration or hemodialysis should be started as early as possible.

In severe malaria, parenteral antimalarial treatment should be started immediately, and in endemic areas, because of the difficulty in distinguishing sepsis from severe malaria, broad-spectrum antibiotics should also be started in children. Artesunate, given

TABLE 231-7 Properties of Antimalarial Drugs

DRUG(S)[a]	PHARMACOKINETIC PROPERTIES	ANTIMALARIAL ACTIVITY	MINOR TOXICITY	MAJOR TOXICITY
Quinine	Good oral and IM absorption (quinine); *Cl* and V_d reduced, but plasma protein binding (principally to α1 acid glycoprotein) increased (90%) in malaria; quinine $t_{1/2}$: 16 h in malaria, 11 h in healthy persons	Acts mainly on trophozoite blood stage; kills gametocytes of *P. vivax, P. ovale,* and *P. malariae* (but not *P. falciparum*); no action on liver stages	*Common:* cinchonism (tinnitus, high-tone hearing loss, nausea, vomiting, dysphoria, postural hypotension); ECG QT interval prolongation (usually by <10%). *Rare:* diarrhea, visual disturbance, rashes. *Note:* very bitter taste	*Common:* hypoglycemia. *Rare:* hypotension, blindness, deafness, cardiac arrhythmias, thrombocytopenia, hemolysis, hemolytic-uremic syndrome, vasculitis, cholestatic hepatitis, neuromuscular paralysis.
Chloroquine	Good oral absorption, very rapid IM and SC absorption; complex pharmacokinetics; enormous *Cl* and V_d (unaffected by malaria); blood concentration profile determined by distribution processes in malaria; $t_{1/2}$: 1–2 months. Active desethyl metabolite about 25% of parent drug concentrations	As for quinine, but acts slightly earlier in asexual cycle	*Common:* nausea, dysphoria, pruritus in dark-skinned patients, postural hypotension, ECG QT prolongation. *Rare:* accommodation difficulties, keratopathy, hypoglycemia, rash. *Note:* bitter taste but usually well tolerated	*Acute:* hypotensive shock (parenteral), cardiac arrhythmias, neuropsychiatric reactions. *Chronic:* retinopathy (cumulative dose, >100 g), skeletal and cardiac myopathy
Piperaquine	Adequate oral absorption, may be enhanced by fats; similar pharmacokinetics to chloroquine; $t_{1/2}$: 21–28 days	As for chloroquine; resistance has emerged in Southeast Asia	Occasional epigastric pain, diarrhea, ECG QT prolongation	None identified
Amodiaquine	Good oral absorption; largely converted to active metabolite desethylamodiaquine; $t_{1/2}$: 4–5 days	As for chloroquine, but more active against chloroquine-resistant *P. falciparum*	Nausea (tastes better than chloroquine), dysphoria, headache, bradycardia, ECG QT prolongation	Agranulocytosis; hepatitis, mainly with prophylactic use; should not be used with efavirenz
Primaquine	Complete oral absorption; active metabolite produced mainly via CYP2D6; $t_{1/2}$: 5–7 h	Radical cure; eradicates hepatic forms of *P. vivax* and *P. ovale;* kills *P. falciparum* gametocytes; kills developing liver stages of all species	Nausea, vomiting, diarrhea, abdominal pain, hemolysis, methemoglobinemia	Serious hemolytic anemia in severe G6PD deficiency; hemoglobinuria
Mefloquine	Adequate oral absorption; no parenteral preparation; $t_{1/2}$: 14–20 days (shorter in malaria)	As for quinine; resistance has emerged in Southeast Asia	Nausea, giddiness, dysphoria, fuzzy thinking, sleeplessness, nightmares, sense of dissociation	Neuropsychiatric reactions, convulsions, encephalopathy
Lumefantrine	Highly variable absorption related to fat intake; $t_{1/2}$: 3–4 days	As for quinine	None identified	None identified
Artemisinin and derivatives (artemether, artesunate)	Good oral absorption; good absorption of IM artesunate but slow and variable absorption of IM artemether; artesunate and artemether biotransformed to active metabolite dihydroartemisinin; all drugs eliminated very rapidly; $t_{1/2}$: <1 h	Broader stage specificity and more rapid than other drugs; no action on liver stages; kills all but fully mature gametocytes of *P. falciparum*	Reduction in reticulocyte count (but not anemia); neutropenia at high doses; in some cases, delayed anemia after treatment of severe malaria with hyperparasitemia	Anaphylaxis, urticaria, fever
Pyrimethamine	Good oral absorption, variable IM absorption; $t_{1/2}$: 4 days	For blood stages, acts mainly on mature forms; causal prophylactic	Well tolerated	Megaloblastic anemia, pancytopenia, pulmonary infiltration
Proguanil[b] (chloroguanide)	Good oral absorption; biotransformed to active metabolite cycloguanil; $t_{1/2}$: 16 h; biotransformation reduced by oral contraceptive use and in pregnancy	Causal prophylactic; not used alone for treatment	Well tolerated; mouth ulcers and rare alopecia	Megaloblastic anemia in renal failure
Atovaquone[b]	Highly variable absorption related to fat intake; $t_{1/2}$: 30–70 h	Acts mainly on trophozoite blood stage	None identified	None identified
Tetracycline, doxycycline[c]	Excellent absorption; $t_{1/2}$: 8 h for tetracycline, 18 h for doxycycline	Weak antimalarial activity; should not be used alone for treatment	Gastrointestinal intolerance, deposition in growing bones and teeth (tetracycline), photosensitivity, moniliasis, benign intracranial hypertension	Renal failure in patients with impaired renal function (tetracycline)
Pyronaridine	Rapid variable absorption, large V_d; $t_{1/2}$: 12–14 days	Acts mainly on trophozoite blood stage; kills gametocytes of *P. vivax, P. ovale,* and *P. malariae* (but not *P. falciparum*); no action on liver stages	Gastrointestinal intolerance, anemia, transient elevation of aminotransferases, hypoglycemia, headache	None identified
Arterolane	$t_{1/2}$: 3 h	Broad stage specificity; no action on liver stages; kills all but fully mature gametocytes of *P. falciparum*	Gastrointestinal intolerance, transient elevation of aminotransferases	None identified

[a]Several antimalarial drugs are formulated as different salts (e.g., phosphate, sulfate, hydrochloride) and are therefore prescribed as base equivalents. For example, chloroquine phosphate 250 salt contains 155 mg base equivalent. It is very important to check when prescribing that the correct dose is being given. [b]Atovaquone and proguanil are prescribed as a fixed-dose combination. This and proguanil alone should not be given if the estimated glomerular filtration rate is <30 mL/min. [c]Tetracycline and doxycycline should not be given to pregnant women or to children <8 years of age.

Abbreviations: Cl, systemic clearance; ECG, electrocardiogram; G6PD, glucose-6-phosphate dehydrogenase; V_d, total apparent volume of distribution.

by either IV or IM injection, is simple to administer, very safe, and rapidly effective. It does not require dose adjustments in liver dysfunction or renal failure. It should be used in pregnant women with severe malaria. If artesunate is unavailable and artemether or quinine is used, an initial loading dose must be given so that therapeutic concentrations are reached as soon as possible. Quinine causes dangerous hypotension if injected rapidly and so must be administered carefully by rate-controlled infusion only. If this approach is not possible, quinine may be given by deep IM injections into the anterior thigh. The optimal therapeutic range for quinine in severe malaria is not known with certainty, but total plasma concentrations of 8–15 mg/L for quinine are effective and do not cause serious toxicity. If the patient remains seriously ill or in acute renal failure for >2 days, maintenance doses of quinine should be reduced by 30–50% to prevent toxic accumulation of the drug. The initial dose should never be reduced. Convulsions should be treated promptly with IV (or rectal) benzodiazepines. The role of prophylactic anticonvulsants in children is uncertain. If respiratory support is not available, a full loading dose of phenobarbital (20 mg/kg) to prevent convulsions should *not* be given as it may cause respiratory arrest. Levetiracetam is the preferred anticonvulsant to control seizures.

When the patient is unconscious, the blood glucose level should be measured every 6 h for at least 24 h. All patients should receive a continuous infusion of dextrose, and blood concentrations ideally should be maintained above 4 mmol/L. Hypoglycemia (<2.2 mmol/L or 40 mg/dL) usually occurs within the first 24 h and should be treated immediately with bolus glucose. The parasite count and hematocrit should be measured every 6–12 h. Anemia develops rapidly. There is uncertainty as to the optimal thresholds for transfusion as there is some evidence that moderate anemia may be beneficial in a patient with severe malaria and vital organ dysfunction. It is recommended that if the hematocrit falls to <20%, whole blood (preferably fresh) or packed cells should be transfused slowly, with careful attention to circulatory status. In areas with higher malaria transmission, where blood for transfusion is in short supply, a threshold of 15% is widely used. Renal function should be checked at least daily. Children presenting with very severe anemia (hemoglobin <4 g/dL) and acidotic breathing require immediate blood transfusion. Management of fluid balance is difficult in severe malaria, particularly in adults, because of the thin dividing line between overhydration (leading to pulmonary edema) and underhydration (contributing to renal impairment). Fluid balance management is *different* from that in sepsis: fluid boluses are potentially dangerous in severe malaria. Nasogastric feeding should be delayed in nonintubated patients (for 60 h in adults and 36 h in children) to reduce the risk of aspiration pneumonia. As soon as the patient can take fluids, oral therapy should be substituted for parenteral treatment and a full 3-day course of ACT given. Mefloquine should be avoided as follow-on treatment for severe malaria because of the increased risk of post-malaria neurologic syndrome.

In areas of high transmission of both *P. falciparum* and *P. vivax* (the island of New Guinea), severe and potentially life-threatening anemia is common among children, and both species contribute. Elsewhere, severe vivax malaria may occur but is uncommon. Many patients have had comorbidities contributing to vital-organ dysfunction. Noncardiogenic pulmonary edema may occur.

P. knowlesi can cause severe disease associated with high parasite densities. Acute kidney injury, respiratory distress, and shock have all been described, but cerebral malaria does not occur. Treatment for severe vivax and knowlesi malaria should follow the recommendations given for falciparum malaria.

UNCOMPLICATED MALARIA

P. falciparum and *P. knowlesi* infections should be treated with an artemisinin-based combination because of their propensity for high parasite densities and severe disease. Infections with sensitive strains of *P. vivax*, *P. malariae*, and *P. ovale* should be treated either with an ACT or oral chloroquine (total dose, 25 mg of base/kg). The ACT regimens now recommended are safe and effective in adults, children, and pregnant women (all trimesters). The WHO recommends that artemether-lumefantrine should be given preferentially in the first trimester of pregnancy, if available, since there is the most experience with this drug. The rapidly eliminated artemisinin component is an artemisinin derivative (artesunate, artemether, or dihydroartemisinin) given for 3 days, and the partner drug is usually a more slowly eliminated antimalarial to which *P. falciparum* in the area is sensitive. Six ACT regimens are currently recommended by the WHO: artemether-lumefantrine, artesunate-mefloquine, dihydroartemisinin-piperaquine, artesunate-sulfadoxine-pyrimethamine, artesunate-amodiaquine, and artesunate-pyronaridine. In areas of low malaria transmission or to contain resistance spread, a single dose of primaquine (0.25 mg/kg) should be added to ACT as a *P. falciparum* gametocytocide to reduce the transmissibility of the infection. This low dose of primaquine is safe even in G6PD deficiency. Pregnant women should not be given primaquine. Atovaquone-proguanil is highly effective everywhere, although it is seldom used in endemic areas because of its high cost and the propensity for rapid emergence of resistance. Clinical recovery is slower after atovaquone-proguanil treatment than after ACT. Of great concern is the spread of artemisinin-resistant *P. falciparum* in Southeast Asia and East Africa. Infections with these resistant parasites are cleared slowly from the blood, with parasite clearance half-lives >5 h and clearance times typically exceeding 3 days. Cure rates with ACT have fallen to unacceptably low levels in some areas. Triple antimalarial combinations are under evaluation with promising results to date.

The 3-day ACT regimens are all well tolerated, although mefloquine is associated with increased rates of vomiting and dizziness. As second-line treatment for recrudescence following first-line therapy, a different ACT regimen may be given.

Patients should be monitored for vomiting for 1 h after the administration of any oral antimalarial drug. If there is vomiting, the dose should be repeated. Symptom-based treatment, with acetaminophen (paracetamol) administration, lowers fever and thereby reduces the patient's propensity to vomit these drugs. Minor central nervous system (CNS) reactions (nausea, dizziness, sleep disturbances) are common. The incidence of serious adverse neuropsychiatric reactions to mefloquine treatment is ~1 in 1000 in Asia but may be as high as 1 in 200 among African and white ethnic groups. Amodiaquine may also cause adverse CNS effects. All the antimalarial quinolines (chloroquine, piperaquine amodiaquine, mefloquine, and quinine) exacerbate the orthostatic hypotension associated with malaria, and all are tolerated better by children than by adults. Chloroquine, amodiaquine, and piperaquine all prolong ventricular repolarization (QT prolongation) but, at currently recommended doses, are not proarrhythmic. Pregnant women, young children, patients unable to tolerate oral therapy, and nonimmune individuals (e.g., travelers) with suspected malaria should be evaluated carefully and hospitalization considered. If there is any doubt as to the identity of the infecting malarial species, treatment for falciparum malaria should be given. A negative blood smear read by an experienced microscopist makes malaria very unlikely but does not rule it out completely; thick blood films should be checked again 1 and 2 days later to exclude the diagnosis. Nonimmune patients receiving treatment for malaria should have daily parasite counts performed to confirm reduction until the thick films are negative for asexual parasite stages. If the asexual parasitemia has not cleared by 7 days (and adherence is assured), second-line treatment should be administered.

To eradicate persistent liver stages and prevent relapse (radical treatment), primaquine (0.5 mg of base/kg in East Asia and Oceania and 0.25 mg/kg elsewhere) should be given once daily for 14 days to patients with *P. vivax* or *P. ovale* infection after laboratory tests for G6PD deficiency have proved negative. The same total dose may be given over 7 days. If the patient has a mild variant of G6PD deficiency, primaquine can be given in a

dose of 0.75 mg of base/kg (maximum, 45 mg) once weekly for 8 weeks. Pregnant women with vivax or ovale malaria should not be given primaquine but should receive suppressive prophylaxis with chloroquine (5 mg of base/kg per week) until 1 month after delivery, after which radical treatment can be given. The slowly eliminated 8-aminoquinoline tafenoquine has been registered in some countries (currently recommended adult dose 300 mg, which may be too low; dose-optimization studies are ongoing). This allows radical cure to be given in a single dose. The consequent risk of protracted hemolysis in G6PD deficiency, including in female heterozygotes who may test as normal with current G6PD screens (which detect <30–40% of normal enzyme activity), requires that all patients should have a quantitative test of G6PD activity before receiving tafenoquine. Only those with >70% of normal activity should receive the drug.

MANAGEMENT OF COMPLICATIONS OF MALARIA

Acute Renal Failure If plasma levels of BUN or age- and weight-adjusted creatinine rise despite adequate rehydration, fluid administration should be restricted to prevent volume overload. As in other forms of hypercatabolic acute kidney injury, renal replacement therapy is best performed early **(Chap. 321)**. Hemofiltration and hemodialysis are more effective than peritoneal dialysis and are associated with lower mortality risk. Some patients with renal impairment pass small volumes of urine sufficient to allow control of fluid balance; these cases can be managed conservatively if other indications for dialysis do not arise. Renal function usually improves within days, but full recovery may take weeks.

Acute Pulmonary Edema (Acute Respiratory Distress Syndrome) This syndrome is caused by increased pulmonary capillary permeability. Patients should be positioned with the head of the bed at a 45° elevation and should be given oxygen and IV diuretics. Positive-pressure ventilation should be started early if the immediate measures fail **(Chap. 316)**. Rarely, patients may require extracorporeal membrane oxygenation.

Hypoglycemia An initial slow injection of 20% dextrose (2 mL/kg over 10 min) should be followed by an infusion of 10% dextrose (0.10 g/kg per hour). The blood glucose level should be checked regularly thereafter as recurrent hypoglycemia is common, particularly among patients receiving quinine. In severely ill patients, hypoglycemia commonly occurs together with metabolic (lactic) acidosis and carries a poor prognosis.

Sepsis In malaria-endemic areas where a high proportion of children are parasitemic, it is usually impossible to distinguish severe malaria from bacterial sepsis with confidence. These children should be treated with both antimalarials and broad-spectrum antibiotics with activity against nontyphoidal *Salmonella* species from the outset. Ideally all patients with severe malaria should have blood cultures taken, and empirical antibiotics should also be given to adults with >20% parasitemia. Antibiotics should be considered for severely ill patients of any age who are not responding to antimalarial treatment or who deteriorate unexpectedly.

Other Complications Patients who develop spontaneous bleeding should be given fresh blood and IV vitamin K. Convulsions should be treated with IV or rectal benzodiazepines and, if necessary, respiratory support. Aspiration pneumonia should be suspected in any unconscious patient with convulsions, particularly with persistent hyperventilation; IV antimicrobial agents and oxygen should be administered, and pulmonary hygiene should be undertaken.

GLOBAL CONSIDERATIONS

The goal of global eradication of malaria remains a challenge. After substantial progress from 2000 to 2015, the global burden of malaria has been steadily increasing. Malaria eradication will require strong leadership, increased national commitment, and substantial international support. The two main tools used to control malaria are insecticide-treated bed nets (ITNs), previously shown to reduce all-cause mortality in African children by 20%, and the ACTs. Pyrethroid resistance and artemisinin resistance in Africa pose major threats to global malaria control. Newer ITNs combine pyrethroids with chlorfenapyr (a pyrrole insecticide) or pyriproxyfen (an insect growth regulator). New drugs to treat malaria are in development but still years away. Two very similar pre-erythrocytic vaccines (RTS,S/AS01 and RTS/matrix M) have been recommended by WHO for deployment. These vaccines provide relatively short-duration protection and are given to young children. Other challenges to malaria eradication include the widespread distribution of *Anopheles* breeding sites, the enormous number of infected persons, behavioral changes (to avoid ITN contact) in anopheline mosquito vectors, and inadequacies in human and material resources, infrastructure, and control programs. Eliminating vivax malaria is further hindered by the lack of a simple, safe, radical curative regimen. The animal reservoir of *P. knowlesi* presents another challenge to eradication of this species.

MALARIA PREVENTION

Malaria may be contained by judicious use of insecticides to kill the mosquito vector, rapid diagnosis, patient management, and—where effective and feasible—administration of intermittent preventive treatments, seasonal malaria chemoprevention, or chemoprophylaxis to high-risk groups such as pregnant women and young children. Indoor residual spraying with insecticides is practiced as part of an integrated vector control program in endemic countries, and a combination neonicotinoid-pyrethroid has been developed in an attempt to delay the emergence of insecticide resistance. Focal elimination of *P. falciparum* can be accelerated safely by mass treatment with slowly eliminated antimalarials such as dihydroartemisinin-piperaquine. In addition to the two malaria vaccines now available, an irradiated live sporozoite vaccine is in late-stage development, and research on many other vaccine candidates is ongoing.

PERSONAL PROTECTION AGAINST MALARIA

Simple measures to reduce the frequency of bites by infected mosquitoes in malarious areas are very important. These measures include the avoidance of exposure to mosquitoes at their peak feeding times (usually dusk to dawn) and the use of insect repellents containing 10–35% DEET (or, if DEET is unacceptable, 7% picaridin), suitable clothing, and ITNs or other insecticide-impregnated materials. Widespread use of bed nets treated with residual pyrethroids reduces the incidence of malaria in areas where vectors bite indoors at night.

CHEMOPROPHYLAXIS

(**Table 231-8**; *https://wwwnc.cdc.gov/travel/yellowbook/2020/travel-related-infectious-diseases/malaria*) Recommendations for malaria prophylaxis depend on knowledge of local patterns of drug sensitivity in *Plasmodium* species and the likelihood of acquiring malarial infection. Drugs effective against resistant *P. falciparum* should be used (atovaquone-proguanil, doxycycline, or mefloquine). Chemoprophylaxis is never entirely reliable, and malaria should always be considered in the differential diagnosis of fever in patients who have traveled to endemic areas, even if they are taking prophylactic antimalarial drugs.

Chemoprevention in Pregnancy Pregnant women planning to visit malarious areas should be warned about the potential risks and advised to avoid all nonessential travel. All pregnant women who live in endemic areas should be encouraged to attend regular antenatal clinics. Mefloquine is the only drug advised for pregnant women traveling to areas with drug-resistant malaria; this drug is generally considered safe in the second and third trimesters of pregnancy; the data on first-trimester exposure, although limited, are reassuring. Chloroquine and proguanil are regarded as safe, but there are now very few regions where these drugs can be recommended for protection. The safety of other prophylactic antimalarial agents in pregnancy has not been established. In endemic areas, intermittent preventive treatment in pregnancy (IPTp) involves giving treatment doses of sulfadoxine-pyrimethamine (SP) at each antenatal visit (maximum, once monthly) in the second and third trimesters of pregnancy. Women with HIV infection who are taking trimethoprim-sulfamethoxazole as prophylaxis should not

TABLE 231-8 Drugs Used in the Prophylaxis of Malaria[a]

DRUG	USAGE	ADULT DOSE	PEDIATRIC DOSE	COMMENTS
Atovaquone-proguanil (Malarone)	Prophylaxis in areas with chloroquine- or mefloquine-resistant *Plasmodium falciparum*	1 adult tablet PO[b]	5–8 kg: ½ pediatric tablet[c] daily ≥8–10 kg: ¾ pediatric tablet daily ≥10–20 kg: 1 pediatric tablet daily ≥20–30 kg: 2 pediatric tablets daily ≥30–40 kg: 3 pediatric tablets daily ≥40 kg: 1 adult tablet daily	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious areas and for 7 days after leaving such areas. Atovaquone-proguanil is contraindicated in persons with severe renal impairment (creatinine clearance rate, <30 mL/min). In the absence of data, it is not recommended for children weighing <5 kg, pregnant women, or women breast-feeding infants weighing <5 kg. Atovaquone-proguanil should be taken with food or a milky drink.
Chloroquine phosphate (Aralen and generic)	Prophylaxis only in the very few areas with chloroquine-sensitive *P. falciparum*[c] or areas with *P. vivax* only	300 mg of base (500 mg of salt) PO once weekly	5 mg of base/kg (8.3 mg of salt/kg) PO once weekly, up to maximum adult dose of 300 mg of base	Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious areas and for 4 weeks after leaving such areas. Chloroquine may exacerbate psoriasis.
Doxycycline (many brand names and generic)	Prophylaxis in areas with chloroquine- or mefloquine-resistant *P. falciparum*[d]	100 mg PO qd (except in pregnant women; see Comments)	≥8 years of age: 2 mg/kg PO qd, up to adult dose	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious areas and for 4 weeks after leaving such areas. Doxycycline is contraindicated in children aged <8 years and in pregnant women.
Hydroxychloroquine sulfate (Plaquenil)	An alternative to chloroquine for primary prophylaxis only in the very few areas with chloroquine-sensitive *P. falciparum*[d] or areas with *P. vivax* only	310 mg of base (400 mg of salt) PO once weekly	5 mg of base/kg (6.5 mg of salt/kg) PO once weekly, up to maximum adult dose of 310 mg of base	Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious areas and for 4 weeks after leaving such areas. Hydroxychloroquine may exacerbate psoriasis.
Mefloquine (Lariam and generic)	Prophylaxis in areas with chloroquine-resistant *P. falciparum*[d]	228 mg of base (250 mg of salt) PO once weekly	≤9 kg: 4.6 mg of base/kg (5 mg of salt/kg) PO once weekly >9–19 kg: ¼ tablet[e] once weekly >19–30 kg: ½ tablet once weekly >30–45 kg: ¾ tablet once weekly >45 kg: 1 tablet once weekly	Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious areas and for 4 weeks after leaving such areas. Mefloquine is contraindicated in persons allergic to this drug or related compounds (e.g., quinine and quinidine) and in persons with active or recent depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. Use with caution in persons with psychiatric disturbances or a history of depression. Mefloquine is not recommended for persons with cardiac conduction abnormalities.
Primaquine	For prevention of malaria in areas with mainly *P. vivax*	30 mg of base (52.6 mg of salt) PO qd	0.5 mg of base/kg (0.8 mg of salt/kg) PO qd, up to adult dose; should be taken with food	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious areas and for 7 days after leaving such areas. Primaquine is contraindicated in persons with G6PD deficiency. It is also contraindicated during pregnancy.
Primaquine	Terminal prophylaxis to decrease risk of relapses of *P. vivax* and *P. ovale*	30 mg of base (52.6 mg of salt) PO qd for 14 days after departure from the malarious area	0.5 mg of base/kg (0.8 mg of salt/kg), up to adult dose, PO qd for 14 days after departure from the malarious area	This therapy is indicated for persons who have had prolonged exposure to *P. vivax* and/or *P. ovale*. It is contraindicated in persons with G6PD deficiency as well as during pregnancy.

[a]Several antimalarial drugs are formulated as different salts (e.g., phosphate, sulfate, hydrochloride) and are therefore prescribed as base equivalents. For example, chloroquine phosphate 250 salt contains 155 mg base equivalent. It is very important to check when prescribing that the correct dose is being given. [b]An adult tablet contains 250 mg of atovaquone and 100 mg of proguanil hydrochloride. [c]A pediatric tablet contains 62.5 mg of atovaquone and 25 mg of proguanil hydrochloride. [d]Very few areas now have chloroquine-sensitive falciparum malaria. [e]One tablet contains 228 mg of base (250 mg of salt).

Abbreviation: G6PD, glucose-6-phosphate dehydrogenase.

Source: Centers for Disease Control and Prevention, *https://www.cdc.gov/malaria/travelers/index.html*.

be given concomitant SP. Dihydroartemisinin-piperaquine is being evaluated as an alternative. Children born to nonimmune mothers in malaria-endemic areas (usually expatriates moving to these areas) should receive prophylaxis from birth.

Chemoprevention for Children in Endemic Areas Seasonal malaria chemoprevention (SMC) involves giving monthly treatment doses of amodiaquine and SP to children (between 3 months and 5 years of age) in endemic areas of Africa. Originally designed for the intense 3- to 4-month rainy season malaria transmission period across the Sahel region of Africa, it is now introduced in other parts of Africa where malaria is less seasonal and more drug resistant, although its effectiveness there is not known. Hundreds of millions of doses are now dispensed annually. Perennial malaria chemoprevention (PMC) is a loosely described intervention involving giving treatment doses, usually of SP, to young children when they attend health services for immunizations or whenever convenient for control programs. It has replaced intermittent preventive treatment for infants. Children should not receive both SMC and PMC.

Chemoprevention in Travelers Travelers to a malaria-endemic region should start taking antimalarial drugs 2 days to 2 weeks before

departure so that any untoward reactions can be detected before travel and therapeutic antimalarial blood concentrations will be present if and when any infections develop (Table 231-8). Antimalarial prophylaxis should continue for 4 weeks after the traveler has left the endemic area, except if atovaquone-proguanil or primaquine has been taken; these drugs have significant activities against the liver stage of the infection (causal prophylaxis) and can be discontinued 1 week after departure from the endemic area. If suspected malaria develops while a traveler is abroad, obtaining a reliable diagnosis and antimalarial treatment locally is a top priority. Presumptive self-treatment for malaria with atovaquone-proguanil (for 3 consecutive days) or one of the artemisinin-based combinations can be considered under special circumstances; medical advice on self-treatment should be sought before departure for malaria-endemic areas and as soon as possible after illness begins. Every effort should be made to confirm the diagnosis.

Atovaquone-proguanil (3.75/1.5 mg/kg or 250/100 mg, daily adult dose) is a fixed-combination, once-daily prophylactic agent that is very well tolerated by adults and children. This combination is effective against all types of malaria, including multidrug-resistant falciparum malaria. Atovaquone-proguanil is best taken with food or a milky drink to optimize absorption. It is not recommended if the estimated glomerular filtration rate is <30 mL/min. There are insufficient data on safety for prophylaxis in pregnancy.

Mefloquine (250 mg of salt weekly, adult dose) has been widely used for malarial prophylaxis because it is usually effective against multidrug-resistant falciparum malaria and is reasonably well tolerated. Mefloquine has been associated with rare episodes of psychosis and seizures at prophylactic doses; these reactions are more frequent at the higher doses used for treatment. More common side effects with prophylactic mefloquine include mild nausea, dizziness, fuzzy thinking, disturbed sleep patterns, vivid dreams, dysphoria, and malaise. Mefloquine is contraindicated for use by travelers with known hypersensitivity and by persons with active or recent depression, anxiety disorder, psychosis, schizophrenia, another major psychiatric disorder, or seizures; it is not recommended for persons with cardiac conduction abnormalities, although the evidence that it is cardiotoxic is very weak. Daily administration of doxycycline (100 mg daily, adult dose) is an effective alternative to atovaquone-proguanil or mefloquine. Doxycycline is generally well tolerated but may cause vulvovaginal thrush, diarrhea, and photosensitivity and is not recommended for prophylaxis in children <8 years old or pregnant women, although evidence that it is harmful in children is lacking.

Chloroquine can no longer be relied upon to prevent *P. falciparum* infections but is still used to prevent and treat malaria due to the other human *Plasmodium* species and for *P. falciparum* malaria in Central American countries west and north of the Panama Canal and in Caribbean countries. Chloroquine-resistant *P. vivax* has been reported from parts of eastern Asia, Oceania, and Central and South America. High-level resistance in *P. vivax* is prevalent in Oceania and Indonesia. Chloroquine is generally well tolerated, although some patients cannot take it because of malaise, headache, visual symptoms (due to reversible keratopathy), gastrointestinal intolerance, alopecia, or pruritus. Chloroquine is considered safe in pregnancy. With chronic administration for >5 years, a characteristic dose-related retinopathy may develop, but this condition is rare at the doses used for antimalarial prophylaxis. Idiosyncratic or allergic reactions are also rare. Skeletal and/or cardiac myopathy is a potential problem with protracted prophylactic use, although it is more likely to occur at the high doses used in the treatment of rheumatoid arthritis. Neuropsychiatric reactions and skin rashes are unusual. Amodiaquine should not be used for weekly prophylaxis because continuous weekly use is associated with a high risk of agranulocytosis (~1 person in 2000) and hepatotoxicity (~1 person in 16,000). Chloroquine, amodiaquine, and piperaquine all cause moderate electrocardiograph QT prolongation but have not been associated with ventricular arrhythmias at therapeutic doses.

Primaquine (0.5 mg of base/kg or a daily adult dose of 30 mg taken with food), an 8-aminoquinoline compound, has proved safe and effective in the prevention of drug-resistant falciparum and vivax malaria in adults. Primaquine can be considered for adults (with the exception of pregnant women) who are intolerant to other recommended drugs. Abdominal pain can be prevented by taking primaquine with food. G6PD deficiency must be excluded before primaquine is prescribed. In the past, the dihydrofolate reductase inhibitors pyrimethamine and proguanil (chloroguanide) were administered widely, but the rapid selection of resistance in both *P. falciparum* and *P. vivax* has limited their use. Whereas antimalarial quinolines such as chloroquine (a 4-aminoquinoline) act only on the erythrocyte stage of parasitic development, the dihydrofolate reductase inhibitors (as well as atovaquone and primaquine) also inhibit preerythrocytic growth in the liver (causal prophylaxis) and development in the mosquito (sporontocidal activity). Proguanil is safe and well tolerated, although mouth ulceration occurs in ~8% of persons using this drug; it is considered safe for antimalarial prophylaxis in pregnancy. Prophylactic use of the combination of SP or amodiaquine is not recommended for weekly administration because of an unacceptable incidence of severe toxicity, principally exfoliative dermatitis and other skin rashes (SP) (incidence, 1 in 7000; fatal reactions, 1 in 18,000), agranulocytosis (amodiaquine), hepatitis, and pulmonary eosinophilia (both drugs).

Because of the increasing spread and intensity of antimalarial drug resistance, the Centers for Disease Control and Prevention (CDC) recommends that travelers and their providers consider their destination, type of travel, and current medications and health risks when choosing antimalarial chemoprophylaxis. There is an increasingly appreciated problem of falsified and substandard antimalarial drugs (and other medicines) on the shelves of pharmacies in Southeast Asia and sub-Saharan Africa; hence, travelers should purchase their preventive drugs from a reputable source before going to a malarious country. Consultation for the evaluation of prophylaxis failures or treatment of malaria can be obtained from state and local health departments and the CDC Malaria Hotline (770) 488-7788 or (855) 856-4713 [toll free]) or the CDC Emergency Operations Center (770-488-7100 [after hours]).

232 Babesiosis

Edouard Vannier, Jeffrey A. Gelfand

Babesiosis is an emerging infectious disease caused by protozoan parasites of the genus *Babesia* that invade and eventually lyse red blood cells (RBCs). Most cases occur in the United States during the summer months and are caused by *Babesia microti*, a species typically found in small rodents and transmitted by the deer tick, *Ixodes scapularis*. Symptoms are those of a flu-like illness. For most patients, a single standard course of atovaquone plus azithromycin is sufficient to achieve cure. Highly immunocompromised patients and asplenic individuals are at risk of persistent infection and should be treated for a longer duration. Adjunct red cell exchange can be useful for severe cases. In the absence of vaccine and chemoprophylaxis, persons at risk of severe babesiosis should minimize their exposure to ticks and, if possible, avoid endemic areas.

ETIOLOGY, EPIDEMIOLOGY, AND MODES OF TRANSMISSION

A few *Babesia* species have been implicated as etiologic agents of human babesiosis. These species use wild or domesticated mammals

as reservoir hosts and are maintained in their enzootic cycle by ticks. Humans are incidental, dead-end hosts. Most cases are reported from across the Northern Hemisphere; the predominant etiologic agent varies by continent.

United States • **GEOGRAPHIC DISTRIBUTION** Most cases (>95%) are caused by *B. microti* and are reported from the Northeast (Massachusetts, Rhode Island, Connecticut, Vermont, New Hampshire, Maine, New York, New Jersey) and the upper Midwest (Minnesota, Wisconsin) **(Fig. 232-1)**. Other *Babesia* species seldom cause disease. Symptomatic infection with *Babesia duncani* and *B. duncani*–type organisms has been reported from Washington State, Oregon, and California. Symptomatic infection with *Babesia divergens*–like organisms has been documented in the central states of Arkansas, Missouri, Michigan, and Kentucky and also in Washington State and Pennsylvania.

INCIDENCE Cases are reported weekly by state health departments to the Centers for Disease Control and Prevention (CDC) via the National Notifiable Diseases Surveillance System. In 2023, more than 3200 cases were reported from 33 of the 40 states in which babesiosis is notifiable. In 2011, when babesiosis became a nationally notifiable disease, 1126 cases were reported to the CDC. The increase in incidence over time is best explained by a greater density of ticks in highly endemic areas and by the northward expansion of these ticks. Although *B. microti* and *Borrelia burgdorferi* (the agent of Lyme disease; **Chap. 191**) are transmitted by the same tick species, the deer tick *I. scapularis*, the geographic expansion of babesiosis has lagged behind that of Lyme disease. This delay likely reflects the poor ecologic fitness of *B. microti* compared with that of *B. burgdorferi* and is consistent with the observation that *B. burgdorferi* helps maintain *B. microti* in their shared enzootic cycle. Other factors contributing to the rise in the incidence of babesiosis include greater exposure to ticks due to forest fragmentation in suburban areas and increased leisure activities in grassy or wooded areas.

MODES OF TRANSMISSION • **Tick Bite** *B. microti* is acquired primarily during the blood meal of an *I. scapularis* tick. Less than one-half (~45%) of patients recall a tick bite within the 8 weeks prior to symptom onset. Both nymphs and adult ticks can transmit *B. microti*; tick larvae are not infected because *B. microti* is not transmitted transovarially. Most cases (~90%) present from June through August because nymphs—the primary vector—are active from late spring to early summer. Patients who present in the fall may have acquired *B. microti* from an adult female tick. *B. duncani* and *B. divergens*–like organisms are thought to be transmitted by *Dermacentor albipictus* and *Ixodes dentatus* ticks, respectively.

Blood Transfusion More than 300 cases of transfusion-transmitted babesiosis (TTB) caused by *B. microti* have been reported. Most cases involve packed RBCs; a few have been attributed to frozen-deglycerolized RBCs and whole blood–derived platelets contaminated with RBCs but none to apheresis platelets. At the time of transfusion, the age of the refrigerated RBC units has ranged from 4 to 42 days, indicating that *B. microti* remains viable throughout the RBC unit's shelf life. Acellular blood components (plasma, cryoprecipitate) have not been implicated. TTB has occurred year-round because *B. microti* can persist for more than a year in untreated asymptomatic carriers. Given the seasonality of tick-borne babesiosis, two-thirds of the donations implicated in TTB cases have been obtained from June through October. Like that of tick-borne babesiosis, the incidence of TTB sharply increased during the first two decades of the millennium. In May 2020, the American Red Cross (ARC) began to test all blood donations collected in the 15 jurisdictions that account for 99% of tick-borne babesiosis cases and 95% of TTB cases. During the following 13 months, no suspected TTB cases were reported to the ARC. In contrast, from 2010 to 2017, *B. microti*–positive donations were linked to 81 TTB cases (~10 cases per year). Screening of the blood supply relies on the amplification of parasite 18S rRNA gene transcripts. In addition to *B. microti*, the Procleix Babesia

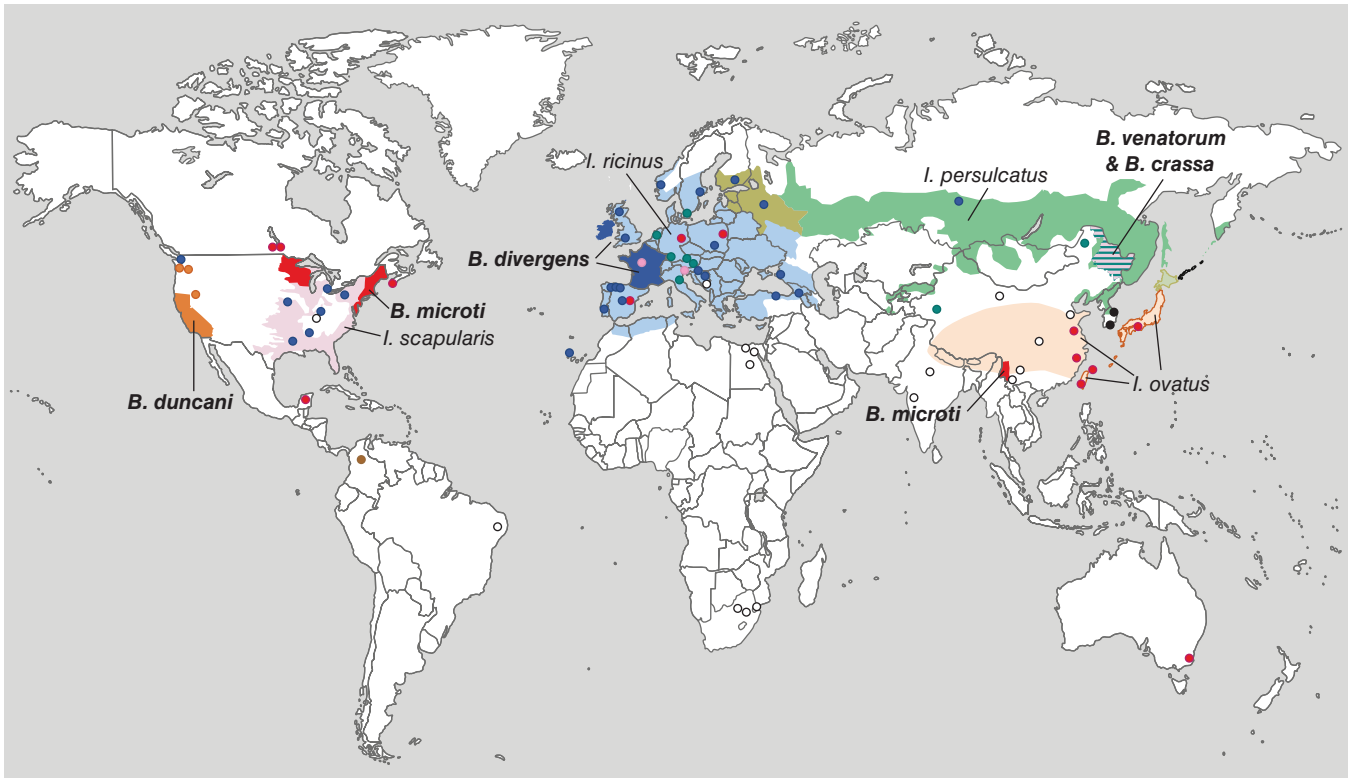

FIGURE 232-1 Geographic distribution of human babesiosis and associated tick vectors. Dark colors indicate areas where human babesiosis is endemic or sporadic (defined by ≥5 cases). Light colors indicate areas where tick vectors are present but human babesiosis is rare (<5 cases), undocumented, or absent. *Circles* depict single cases except in six locations (Colombia, Mexico, Montenegro, Poland, and the provinces of Gansu and Shandong in China) where all patients were diagnosed at one hospital or identified via survey in one location. Colors distinguish the etiologic agents: *red* for *Babesia microti*, *orange* for *B. duncani*, *blue* for *B. divergens* and *B. divergens–like*, *green* for *B. venatorum*, *pink* for *B. crassa–like*, *brown* for *B. bovis* and *B. bigemina*, and *black* for *B. motasi–like*. *White circles* depict cases caused by uncharacterized *Babesia* isolates or by isolates for which the full sequence of the 18S rRNA gene was not available or ruled out all of the *Babesia* species listed above. Asymptomatic infections and cases of travel-associated babesiosis are omitted.

Assay detects *B. duncani* and *B. divergens*, which have been implicated in a handful of TTB cases. The assay is exquisitely sensitive; the 95% limit of detection is 3 parasites per mL of blood for *B. microti* and *B. duncani*, and 2 parasites per mL of blood for *B. divergens*.

Vertical Transmission Passage of *B. microti* across the placenta has been documented but is rare. Symptoms typically develop during the third to the sixth week of life and often consist of fever accompanied by pallor and lethargy. Parasitemia at presentation has ranged from 2% to 5%. Both the neonate and the mother typically are seropositive for *B. microti* IgG antibody. Most cases of neonatal babesiosis, however, are acquired through blood transfusion or tick bite. Infants (<1 year of age) account for <1% of the annual number of cases of babesiosis reported to the CDC.

Solid Organ Transplantation This unusual mode of transmission has been highlighted in a single case report. Two patients received a diagnosis of babesiosis 8 weeks after transplantation of a kidney allograft obtained from a single donor who had received multiple transfusions shortly before his death. Corneas from the deceased donor were transplanted, but neither recipient was infected with *B. microti*; this outcome suggests that RBCs that had remained in the vasculature or fluids of the donated kidneys were the source of *B. microti*.

Risk Factors Most patients (~80%) who present with symptoms of babesiosis are ≥50 years. Those who are admitted to a hospital are a decade older (median age, 68 years) than those who are not (median age, 59 years). Aside from tick exposure and advanced age, major risk factors for severe babesiosis include asplenia and immunosuppression. Asplenia can be congenital, functional (e.g., due to celiac disease or hemoglobinopathies such as sickle cell disease and thalassemia), or acquired (due to splenectomy). Immunosuppression often is iatrogenic and associated with conditions such as autoimmune disorders, chronic inflammatory disorders, malignancies, or transplantation. Immunosuppression can be inherent in comorbidities such as X-linked agammaglobulinemia, common variable hypogammaglobulinemia, and HIV/AIDS. Risk factors for TTB include conditions that require transfusion of blood components, particularly RBCs.

Outside the United States Travel-associated babesiosis may become more common if, as anticipated, *Babesia* species continue to emerge worldwide (Fig. 232-1).

EUROPE More than 40 cases have been attributed to *B. divergens* since the index case was reported from Croatia in 1957. The infection is rarely diagnosed in immunocompetent individuals; most patients lack a spleen or have functional hyposplenism. Most cases occur in France and Ireland, particularly in regions with cattle farms. *B. divergens*, a parasite of cattle, is transmitted by the castor bean tick *Ixodes ricinus*. Other *Babesia* species rarely cause disease. *B. divergens*–like parasites have been implicated in 1 case on the Canary Islands and in another in western France. Five cases caused by *Babesia venatorum* have been reported from Italy, Austria, Germany, and Sweden. Two cases of infection with *Babesia crassa*–like organisms have been reported from Slovenia and western France. All 9 patients had been splenectomized. In Germany, a normosplenic patient with acute myeloid leukemia presumably acquired *B. microti* during the transfusion of whole blood–derived platelets. In eastern Poland, mild babesiosis caused by *B. microti* has occurred in normosplenic patients. *I. ricinus* is the vector for *B. microti* and *B. venatorum* and the presumed vector for *B. divergens*–like parasites. *Haemaphysalis concinna* is the likely vector for *B. crassa*–like organisms. *B. microti* is found in small rodents, *B. venatorum* in roe deer, and *B. crassa* in sheep. Rabbits are suspected reservoirs for *B. divergens*–like parasites.

ASIA *B. microti* was recognized as a human pathogen in Taiwan in the late 1990s. In the past decade, babesiosis has gained the status of emerging infectious disease in mainland China. In the northeastern province of Heilongjiang, *B. venatorum* and *B. crassa*–like organisms have caused mild disease in immunocompetent individuals, whereas antibodies specific for *B. microti* have been detected in blood donors. The taiga tick *Ixodes persulcatus* is a competent vector for *B. microti* and the presumed vector for *B. venatorum*. In this province, *B. crassa*–like organisms are found in *I. persulcatus* and *H. concinna* ticks. A case of *B. venatorum* infection was documented in a child residing in the northwestern Xinjiang Autonomous Region. Several cases of *B. microti* infection have been reported from southern China, mostly from Yunnan; two of the patients were co-infected with *Plasmodium* species, one with *P. falciparum* and the other with *P. vivax*.

The single case of babesiosis reported from Japan was acquired through blood transfusion and was caused by a *B. microti* organism that defines the Kobe lineage. Two cases have been reported from South Korea; both occurred in splenectomized individuals and were caused by *Babesia motasi*–like organisms, which are parasites of sheep and goats. In one case, *Haemaphysalis longicornis* was the presumed vector.

REMAINDER OF THE WORLD Three cases of babesiosis caused by *B. microti* have been reported from Canada: two from southern Manitoba and one from southern Nova Scotia. Asymptomatic *B. microti* infection has been detected in a few blood donors from southwestern Ontario. Babesiosis is a reportable disease in Manitoba and Quebec. In Yucatan, Mexico, four cases of febrile illness have been attributed to *B. microti*. Evidence that *Babesia bovis* and *Babesia bigemina* may cause human illness has come from Uraba, a region of Colombia where cattle ranching is important and malaria is endemic. In western India, the death of a young, splenectomized farmer was caused by a novel *Babesia* species. A fatal case of *B. microti* infection has been reported from New South Wales, Australia; the causative agent was likely imported.

CLINICAL MANIFESTATIONS

United States • ***B. MICROTI* INFECTION** Symptoms typically appear 1–4 weeks after the bite of an infected tick but 3–7 weeks (median, 37 days; range, 11–176 days) after transfusion of contaminated blood components. Patients experience a gradual onset of fatigue with or without malaise that is followed within days by fever and one or more of the following: chills, night sweats, headache, myalgia, and anorexia. Fever is persistent or intermittent and has reached 40.9°C (105.6°F). Less common symptoms include arthralgia, nausea, dry cough, neck stiffness, emotional lability, and sore throat. Diarrhea, vomiting, abdominal pain, and joint swelling are rare. Dark urine and jaundice raise the suspicion of severe hemolytic anemia and may be accompanied by shortness of breath.

On physical examination, fever is the salient feature. The skin may be pale or yellowish. A focal red rash, if present, denotes the site of the tick bite; an erythema migrans rash **(Fig. A1-8)** signifies concurrent Lyme disease **(Chap. 191)** or southern tick-associated rash illness (STARI) **(Chap. 190)**. Ecchymoses and petechiae are rare. Examination of the eyes may be remarkable for scleral icterus, which is consistent with severe hemolysis. Retinopathy with splinter hemorrhages and retinal infarcts are rare. Tenderness of the abdominal upper left quadrant suggests splenomegaly, which may be accompanied by hepatomegaly. Left-sided abdominal pain raises suspicion of splenic infarction or splenic rupture. Unexplained hypotension accompanied by tachycardia reinforces suspicion of splenic rupture. Splenic infarction and subcapsular hematoma can occur in the absence of splenic rupture. Splenic infarction and splenic rupture are confirmed by CT. Splenic infarcts appear as wedge-shaped hypodense lesions. A hyperdense fluid surrounding the spleen is consistent with hemoperitoneum caused by splenic rupture.

Severe babesiosis requires hospital admission. The median length of hospital stay is 4 days (interquartile range, 3–7). Severe babesiosis can be accompanied by one or several complications. The leading complication is acute renal failure (20%). The second most common complication is acute respiratory failure (7%). Less common complications include supraventricular arrhythmia, heart failure, disseminated intravascular coagulation, and shock. At least one transfusion of red blood cells is given to one of five patients hospitalized for babesiosis. Patients diagnosed >7 days after symptom onset are predisposed to severe complicated babesiosis, which has been defined as an illness requiring admission to an intensive care unit (ICU); an illness complicated

by acute respiratory distress syndrome, heart failure or shock; or an illness requiring dialysis, intubation or RBC exchange. Among clinical features, diarrhea and nausea or vomiting are strong predictors of severe babesiosis as just defined. Asplenia and autoimmune disorders predispose to severe disease, but underlying cardiac conditions do not. Concurrent Lyme disease does not decrease the risk of severe disease but has been associated with a lower risk for hospitalization; the implication is that a diagnosis of babesiosis should be considered in any patient diagnosed with Lyme disease.

Despite therapy, babesiosis can be fatal. Prior to the turn of the millennium, when clindamycin plus quinine was the regimen of choice for treatment of babesiosis, fatality rates ranging from 5% to 9% were reported. Since atovaquone plus azithromycin has become the first-line therapy, a fatal outcome is rare. Of the 7612 cases of babesiosis reported to the CDC in 2011–2015, 46 (0.6%) ended in death. Death is more frequent among those ≥65 years of age. A review of claims for 10,305 Medicare recipients who were diagnosed with babesiosis between 2006 and 2013 revealed that 1% had died within 30 days. Among those admitted to a hospital, the fatality rate was 3%. Fatality is high in immunocompromised patients (~20%) and those with splenic rupture or splenic infarction (6%).

OTHER BABESIA INFECTIONS The eight documented cases of *B. duncani* infection reported in the United States were moderate to severe; one patient died. Symptoms were similar to those evoked by *B. microti*. All seven patients infected with *B. divergens*–like organisms had been splenectomized and experienced a severe illness that required hospitalization; three died.

Global Considerations Most cases of *B. divergens* infection in Europe have occurred in individuals who lack a spleen or have functional hyposplenism. Symptoms develop suddenly and consist of fever (>41°C [>105.8°F]), headache, lumbar or abdominal pain, and dark urine. Jaundice and hemoglobinuria are common. Without immediate therapy, including immediate red cell exchange, patients often develop renal failure with or without acute respiratory distress or failure. In spleen-intact individuals, *B. divergens* infection typically evokes a mild illness. All 5 patients infected with *B. venatorum* in Europe had been splenectomized; their illness ranged from mild to severe, and none died. The 32 cases of *B. venatorum* infection reported from northeastern China occurred in spleen-intact residents. Symptoms were similar to those evoked by *B. microti*, although chills were rare. Seven patients were hospitalized for intermittent fever as high as 40°C. Only 4 patients were treated with clindamycin (without quinine); all 32 patients recovered. Cases of *B. crassa*–like infection reported from northeastern China also occurred in spleen-intact residents. Fever, fatigue, and myalgia were less common than among patients infected with *B. microti*, but headache was as common and nausea or vomiting more common. No patient was admitted to a hospital. Only 3 of the 31 patients were given clindamycin (without quinine); none died. In Europe, 2 cases of *B. crassa*–like infection occurred in splenectomized individuals and were severe. Neither ended in death, although 1 patient required intensive care. Cases of *B. motasi*–like infection in South Korea were severe; 1 patient died but the other recovered following clindamycin monotherapy.

PATHOGENESIS

Anemia RBC debris generated by hemolysis may accumulate in the kidney vasculature and cause renal failure. Free hemoglobin is rapidly complexed by haptoglobin. Once haptoglobin is depleted, the heme group is oxidized, released from hemoglobin, and complexed by hemopexin. Excessive hemolysis results in excess free hemoglobin, which scavenges and consumes nitric oxide, leading to thrombus formation and vascular inflammation. RBC lysis in small capillaries of the spleen may trigger localized necrosis, leading to splenic infarction. Exposed to oxidative stress, RBCs become poorly deformable and are filtered out by splenic macrophages as they attempt to pass through the red pulp. Erythrophagocytosis, along with the mounting of an immune response, contributes to splenomegaly and splenic rupture. Massive phagocytosis of RBCs, platelets, and white blood cells has led to hemophagocytic lymphohistiocytosis, a fatal condition. Persistent anemia, despite resolution of infection, has been attributed to autoantibodies that tag RBCs for clearance and may activate the complement system.

Inflammation Fever, chills, and sweats likely result from the systemic inflammatory response triggered by RBC lysis. Excessive inflammation promotes end-organ pathology, leading to renal and pulmonary compromise. The spleen is the immunodominant organ in babesiosis. This feature, along with the clearance of parasitized RBCs, explains why asplenia is a major risk factor for severe disease. Protective immunity involves $CD4^+$ T cells, particularly T_h1 cells, as revealed by high-grade parasitemia in mice depleted of $CD4^+$ T cells or treated with an interferon γ–neutralizing antibody. The importance of $CD4^+$ T cells is corroborated by the severity of babesiosis in patients with AIDS and in allograft recipients. In immunocompetent mice, Tfh cell expansion is accompanied with germinal center formation and antibody secretion. Although nearly every immunocompetent patient tests positive for *B. microti* antibody at diagnosis, a role for antibodies is uncertain. Persistent, relapsing babesiosis often occurs in patients treated with rituximab for a cancer or an autoimmune disorder; this observation suggests that B cells, and presumably antibodies, are critical for parasite clearance in some individuals.

DIAGNOSIS

A diagnosis of babesiosis should be considered for patients who experience symptoms compatible with babesiosis and may have been exposed to ticks in an endemic area, particularly from late spring to early fall, or were transfused with blood components, particularly packed RBCs, in the past 6 months. Given that *I. scapularis* ticks can be coinfected with *B. microti* and *B. burgdorferi*, babesiosis should be considered in any Lyme disease patient for whom symptoms worsen or do not abate within days or weeks of initiation of appropriate antibiotic therapy. Conversely, because one-half of patients diagnosed with babesiosis are infected with *B. burgdorferi*, a diagnosis of babesiosis should prompt a diagnostic evaluation for Lyme disease. Other tick-borne pathogens, although rarely implicated in cases of coinfection with *B. microti*, may be considered; these include *Anaplasma phagocytophilum* **(Chap. 192)** and *Borrelia miyamotoi* **(Chap. 190)**.

Routine Laboratory Testing The complete blood count often is remarkable for anemia. An elevated reticulocyte count signifies stress-induced erythropoiesis. Low levels of haptoglobin or elevated levels of lactate dehydrogenase are consistent with hemolysis. Severe anemia often is preceded by severe thrombocytopenia. The white blood cell (WBC) count is reduced, unchanged, or elevated. Elevated levels of alkaline phosphatase, aspartate aminotransferase, and alanine aminotransferase signify hepatocyte injury. Elevated total bilirubin levels result from hemolysis but may also denote hepatic compromise. Elevated levels of blood urea nitrogen and serum creatinine indicate renal compromise. Urinalysis may reveal excess urobilinogen, hemoglobinuria, and/or proteinuria. Given that babesiosis is an imitator of HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome, a diagnosis of babesiosis should be considered for pregnant women who are at risk of tick exposure and have laboratory abnormalities that define this syndrome.

There is no consensus on the use of a particular laboratory parameter as predictor of severe babesiosis. In a study of severe disease as defined above (see "Clinical Manifestations"), a total bilirubin level of >1.9 mg/dL was highly predictive of severe disease, whereas WBC counts of $<5 \times 10^3/\mu L$ were associated with a better prognosis. Parameters associated with severe disease also included WBC counts of $>10 \times 10^3/\mu L$ and creatinine levels of >1.2 mg/dL. An earlier study identified alkaline phosphatase levels of >125 IU/L and WBC counts of $>5 \times 10^3/\mu L$ as strong predictors of severe disease, in this case defined as a hospital stay of >2 weeks, an ICU stay of >2 days, or death.

Specific Testing A definitive diagnosis of babesiosis is made by microscopic examination of Giemsa-stained thin blood smears

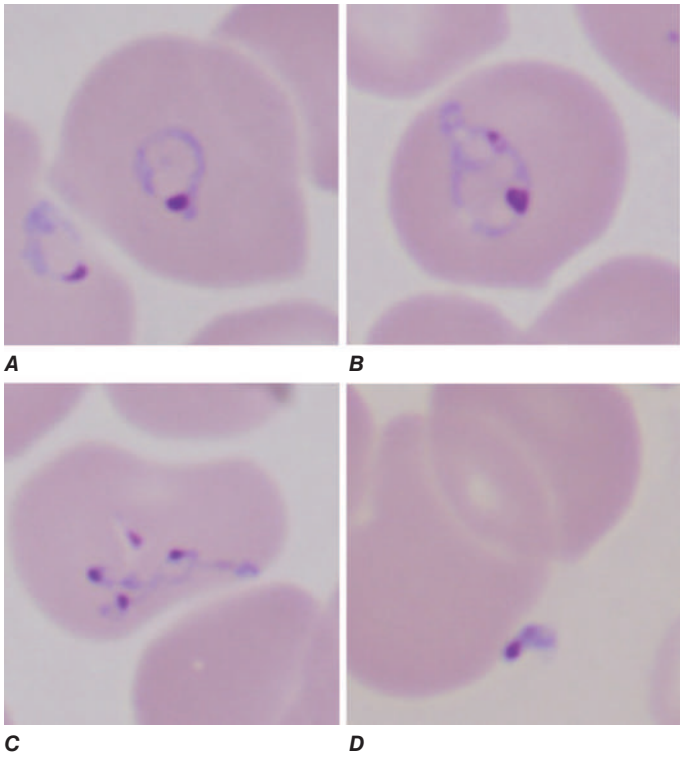

FIGURE 232-2 Giemsa-stained thin blood films showing *Babesia microti* parasites. *B. microti* is an obligate parasite of erythrocytes. Trophozoites may appear as ring forms (***A***) or as ameboid forms (***B***). Merozoites can be arranged in tetrads that are pathognomonic (***C***). Extracellular parasites can be noted (***D***), particularly when parasitemia is high. *(Reproduced with permission from E Vannier, PJ Krause: Human babesiosis. N Engl J Med 366:2397, 2012.)*

(Fig. 232-2) or amplification of *Babesia* DNA in blood. *Babesia* trophozoites appear round, oval, or ameboid. The ring form is most common and lacks the central brownish (hemozoin) deposit typical of *Plasmodium falciparum* late-stage trophozoites (see Fig. A2-1). For travelers who have returned from *P. falciparum*–endemic areas and reside in a *Babesia*-endemic area, a negative result in the BinaxNOW malaria test readily rules out falciparum malaria when microscopy cannot. The presence of extracellular merozoites, particularly when parasitemia is high, and the absence of gametocytes and schizonts also distinguish babesiosis from malaria. Merozoites are arranged in pairs and occasionally in tetrads (the "Maltese cross"). Tetrads are pathognomonic of babesiosis and can be seen in human erythrocytes infected with *B. microti*, *B. duncani*, *B. venatorum*, or *B. divergens*–like organisms. Parasitemia typically ranges from 0.1 to 10% in immunocompetent patients but has reached 30–40% in immunocompromised patients. Parasitemia of >4% is a risk factor for severe, complicated disease. Splenic complications, however, often occur in patients with low-grade parasitemia (median, 1%; range, 0.1–30%).

If parasites cannot be identified by microscopy and babesiosis is still suspected, amplification of *Babesia* DNA is recommended. Real-time polymerase chain reaction (PCR) assays, which amplify the parasite 18S rRNA gene, detect as few as 1–10 parasites/μL of blood. Use of a fluorescent probe allows for speciation of the causative agent. Real-time PCR is recommended for the monitoring of low-grade infection in patients at risk of relapsing babesiosis.

A single positive serologic result is not sufficient to establish a diagnosis of babesiosis because antibodies can persist for >1 year after the illness has resolved and the parasite has been cleared. An indirect fluorescent antibody test is most commonly used. For *B. microti*, IgM titers of ≥1:20 and IgG titers of ≥1:64 are considered positive. IgG titers of ≥1:1024 suggest active or recent infection. Antibodies to *B. microti* do not react with *B. duncani* or *B. divergens* antigen. Sera from patients infected with *B. venatorum* or *B. crassa*–like organisms react with *B. divergens* antigen.

TREATMENT

Babesiosis

MILD TO MODERATE *B. MICROTI* ILLNESS

Mild to moderate babesiosis caused by *B. microti* is treated with atovaquone plus azithromycin administered orally for 7–10 days. Dosages for adults and children are provided in **Table 232-1**. Symptoms usually abate within 48 h after initiation of therapy and resolve within 1–2 weeks. If symptoms persist despite therapy for babesiosis, initiating doxycycline while testing for *B. burgdorferi* or other tick-borne pathogens such as *A. phagocytophilum* and *B. miyamotoi* is essential. Fatigue may persist for weeks to months but does not warrant, on its own, that treatment be extended or resumed. Parasite DNA can be detected for as long as 3 months, but follow-up PCR testing is not recommended because relapse of infection in immunocompetent individuals is unlikely.

SEVERE *B. MICROTI* ILLNESS

First-Line Antimicrobial Therapy The preferred regimen for the treatment of severe babesiosis caused by *B. microti* is oral atovaquone plus IV azithromycin (Table 232-1). Use of this combination is supported by a retrospective study of 40 patients who were admitted for severe babesiosis, including 11 who were admitted to the ICU. All but 1 of the 40 patients improved following initiation of treatment with atovaquone plus azithromycin, and were discharged. Clindamycin plus quinine, the first regimen to ever bring cure to a babesiosis patient, is an alternative choice. Use of quinine is impeded by a risk for QTc prolongation and cinchonism, including tinnitus; these adverse events often require premature discontinuation. A prospective, nonblind, randomized clinical trial established that atovaquone plus azithromycin is as effective as clindamycin plus quinine in clearing *B. microti* parasites and resolving symptoms of non-life-threatening babesiosis. Adverse events were reported by 15% of patients treated with atovaquone plus azithromycin but 72% of patients treated with clindamycin plus quinine. No trial has compared the 2 regimens for treatment of severe babesiosis.

Intravenous azithromycin should be initiated at 500 mg/d, along with atovaquone. Laboratory parameters should be monitored daily until symptoms abate and parasitemia is <4%. Thereafter, azithromycin can be administered orally. If the patient has an intact spleen and is not immunocompromised, the dosage can be reduced to 250 mg/d. The regimen is administered for 7–10 days, but the duration should be extended if symptoms persist. If the patient is asplenic or immunocompromised, azithromycin should be maintained at 500 mg/d. Given the risk for prolonged or relapsing babesiosis in such patients, the regimen should be administered until symptoms have resolved and parasites are no longer seen on blood smear for at least 2 weeks.

Adjunct Exchange Transfusion RBC exchange (RCE) is recommended when parasitemia is high and the clinical status of the patient deteriorates in the context of complications such as severe hemolysis or critical organ dysfunction, particularly renal or pulmonary compromise. The primary purpose of RCE is to rapidly reduce parasite burden; RCE also corrects anemia. Plasma exchange seldom is used in severe, complicated babesiosis although it removes circulating inflammatory mediators and byproducts of hemolysis such as free hemoglobin, free heme, and unconjugated bilirubin. Therapeutic apheresis is performed in close consultation with transfusion medicine services.

The criteria for RCE are not strictly defined. It is common practice to initiate RCE when parasitemia is >10%, although no study has been conducted to identify the threshold above which RCE provides greatest benefit. A recent case series illustrates the limitation of using parasitemia as the sole criterion to initiate RCE in the hope of preventing death. In this study of 19 patients, pre-RCE parasitemia (mean, 12.9%; 95% confidence interval [CI], 9.4–16.4) was a predictor of post-RCE length of hospital stay but not of mortality;

***B. divergens* Infection[g]**	
Immediate complete exchange transfusion *plus* Clindamycin (600 mg q6–8h IV) *plus* Quinine (650 mg q8h PO)	Immediate complete exchange transfusion *plus* Clindamycin (7–10 mg/kg q6–8h IV; maximum, 600 mg/dose) *plus* Quinine (8 mg/kg q8h PO; maximum, 650 mg/dose)

[a]Treat for 7–10 days. [b]Treat for 7–10 days, but extend duration if symptoms persist. [c]For severely immunocompromised patients, antimicrobial therapy should be given for at least 6 consecutive weeks, including 2 final weeks during which parasites are no longer detected on blood smear. [d]If the risk of QTc prolongation or allergy associated with use of azithromycin is a concern, clindamycin can be substituted for azithromycin. For severely immunocompromised patients, IV clindamycin can be added to atovaquone plus azithromycin at initiation of treatment. [e]Clindamycin plus quinine is no longer the preferred regimen because quinine often is discontinued due to QTc prolongation or other side effects, including tinnitus. This regimen can be considered for cases that respond poorly to atovaquone plus azithromycin. [f]Other alternative regimens have been used successfully, as documented in a limited number of case reports. If quinine toxicity is a concern, atovaquone can be substituted for quinine. For cases that respond poorly to atovaquone plus azithromycin, atovaquone-proguanil can be added to the two-drug regimen or can be substituted for atovaquone. [g]A few cases of *B. divergens* infection in Europe have been treated successfully with atovaquone plus azithromycin or atovaquone-proguanil plus azithromycin.

this finding is consistent with the concept that end-organ dysfunction is a correlate of host inflammation rather than parasite burden. Post-RCE parasitemia (mean, 3.4%; 95% CI, 1.9–4.9) was associated neither with post-RCE length of hospital stay nor with mortality; this finding advocates against the use of repeat RCE. There was a trend toward an association between creatinine levels at admission and mortality, pointing to the greater benefit of RCE in patients with renal compromise. RCE has been withheld when the patient is stable and parasitemia has begun to resolve following initiation of antimicrobial therapy. In a study that compared 9 such patients with 19 patients who underwent RCE and received antimicrobial therapy, the two groups differed neither by the parasitemia at admission (mean, 11.0% vs 11.6%) nor by the time to parasitemia <1% (day 7 vs day 8).

Highly Immunocompromised Patients Patients are at risk for persistent, relapsing babesiosis when the immune response to *Babesia* is severely impaired. Major risk factors include asplenia, HIV/AIDS, and immunosuppressive regimens given for transplantation, an autoimmune disorder, or malignancy. Many of these regimens include rituximab or another B cell–depleting antibody. Antimicrobial therapy should be administered for at least 6 consecutive weeks, including 2 weeks beyond the first definitive negative PCR test for *B. microti*. Given the duration of treatment, atovaquone plus azithromycin is the preferred regimen. Azithromycin should be administered intravenously and initiated at 500 mg/d. Laboratory parameters should be monitored daily until symptoms abate and parasitemia is <4%. Thereafter, azithromycin can be administered orally, but the dosage should be maintained at 500 mg/d because lower dosages may promote antimicrobial resistance. Once the patient is no longer critically ill, routine laboratory testing can be performed every 2 to 3 days. When parasites are no longer observed on blood smear, real-time PCR should be used to monitor the infection. After discontinuation of therapy, close follow-up is recommended. If symptoms recur, blood smears and/or real-time PCR should be ordered.

Antimicrobial Resistance Parasitologic or clinical relapse has been documented in highly immunocompromised patients, particularly when antimicrobial therapy is interrupted or administered at a reduced dosage. Some patients who relapse while or after being treated with atovaquone plus azithromycin have been managed with clindamycin plus quinine (Table 232-1, footnote e). When quinine toxicity is a concern, clindamycin has been added to atovaquone plus azithromycin. An informed approach is to identify mutations that have arisen in the parasite genome and may explain antimicrobial resistance. Atovaquone targets the parasite cytochrome b (Cytb). When resistance to atovaquone is predicted to be partial, atovaquone-proguanil can be substituted for atovaquone (Table 232-1, footnote f). The rationale is that, as with *P. falciparum*, proguanil lowers the concentration of atovaquone required to collapse the mitochondrial membrane potential. Resistance to azithromycin has been attributed to missense mutations in the ribosomal protein subunit L4 gene (*RLP4*) and to a mutation in domain V of the 23S rRNA gene, which carries the peptidyl transferase activity of the parasite ribosome. Domain V is also the target of clindamycin. When resistance to azithromycin is explained by a mutation in *RPL4*, clindamycin can be substituted for azithromycin. A mutation in domain V that prevents binding of azithromycin and clindamycin precludes substitution of one for the other. Such mutation was recently identified in a patient who relapsed while being treated with a three-drug regimen that included azithromycin and clindamycin. Following initiation of tafenoquine at the loading dose of 600 mg (given over 3 consecutive days), parasitemia rapidly declined. Tafenoquine was administered along with atovaquone and proguanil. Maintenance therapy, which consisted of a 300-mg weekly dose of tafenoquine, was discontinued 5 weeks after the last positive *B. microti* PCR test. Tafenoquine, which acts by inducing reactive oxygen species, is well suited to substitute for drugs that target a particular gene product. Tafenoquine should not be prescribed to patients with glucose-6-phosphate dehydrogenase deficiency because their RBCs have reduced antioxidant capacity and would not sustain the oxidative stress caused by tafenoquine.

Splenic Rupture Splenic rupture typically occurs in young, healthy patients with low-grade parasitemia. If the patient is hemodynamically unstable, emergent splenectomy should be performed. If the patient is hemodynamically stable but bleeding persists, splenic arterial embolization should be considered. In the absence of hemoperitoneum, splenic rupture should be managed without surgery but with careful hemodynamic monitoring. Removal of the spleen leaves patients at risk for relapsing babesiosis or severe disease caused by other microorganisms.

OTHER *BABESIA* INFECTIONS

B. duncani and *B. divergens*–like infections typically have been treated with IV clindamycin (600 mg three or four times daily or 1200 mg twice daily) plus oral quinine (600–650 mg three times daily) for 7–10 days. RBC exchange is initiated for patients with severe hemolytic anemia and/or end-organ failure. In a recent case of severe *B. divergens*-like infection, a RBC exchange was performed and cure was achieved following a 2-week course of atovaquone plus azithromycin.

GLOBAL CONSIDERATIONS

In Europe, *B. divergens* infection is considered a medical emergency. The recommended approach is immediate, complete RCE combined with administration of clindamycin plus oral quinine (Table 232-1). Some cases have been cured with RCE and clindamycin monotherapy. Anemia may persist for >1 month and require blood transfusion. A severe case of *B. divergens* infection resolved during therapy with atovaquone plus azithromycin. A relapse in a spleen-intact individual was treated with atovaquone-proguanil plus azithromycin. The first-line therapy for *B. venatorum* infection in Europe has been IV or oral clindamycin plus quinine. In a patient intolerant to quinine, infection was cured after administration of atovaquone plus azithromycin. A pediatric case of mild *B. venatorum* infection in China was successfully treated by a standard course of atovaquone plus azithromycin.

PREVENTION

Given the lack of vaccine and chemoprophylaxis, individuals who reside in endemic areas, especially those at risk of severe babesiosis, should wear protective clothing, apply tick repellents to the skin and permethrin to clothing, and limit outdoor activities where ticks abound from May through October. The skin should be thoroughly examined after outdoor activities and ticks carefully removed with tweezers. As babesiosis continues to expand into new areas and because climate change has begun to reshape this expansion, physicians should be increasingly aware of this once neglected disease.

233 Leishmaniasis

Shyam Sundar

Encompassing a complex group of disorders, leishmaniasis is caused by unicellular eukaryotic obligatory intracellular protozoa of the genus *Leishmania* and primarily affects the host's reticuloendothelial system. *Leishmania* species produce widely varying clinical syndromes ranging from self-healing cutaneous ulcers to fatal visceral disease. These syndromes fall into three broad categories: visceral leishmaniasis (VL), cutaneous leishmaniasis (CL), and mucosal leishmaniasis (ML).

ETIOLOGY AND LIFE CYCLE

Leishmaniasis is caused by ~20 species of the genus *Leishmania* in the order Kinetoplastida and the family Trypanosomatidae **(Table 233-1)**. Several clinically important species are of the subspecies *Viannia*. The organisms are transmitted by phlebotomine sandflies of the genus *Phlebotomus* in the "Old World" (Asia, Africa, and Europe) and the genus *Lutzomyia* in the "New World" (the Americas). Transmission may be anthroponotic (i.e., the vector transmits the infection from infected humans to healthy humans) or zoonotic (i.e., the vector transmits the infection from an animal reservoir to humans). Human-to-human transmission via shared infected needles has been documented in IV drug users in the Mediterranean region. In utero transmission to the fetus occurs rarely.

Leishmania organisms occur in two forms: extracellular, flagellate promastigotes (length, 10–20 μm) in the sandfly vector and intracellular, nonflagellate amastigotes (length, 2–4 μm; **Fig. 233-1** in vertebrate hosts, including humans. Promastigotes are introduced through the proboscis of the female sandfly into the skin of the vertebrate host. Neutrophils predominate among the host cells that first encounter and take up promastigotes at the site of parasite delivery. The infected neutrophils may undergo apoptosis and release viable parasites that are taken up by macrophages, or the apoptotic cells may themselves be taken up by macrophages and dendritic cells. The parasites multiply as amastigotes inside macrophages, causing cell rupture with subsequent invasion of other macrophages. While feeding on infected hosts, sandflies pick up amastigotes, which transform into the flagellate form in the flies' posterior midgut and multiply by binary fission; the promastigotes then migrate to the anterior midgut and can infect a new host when flies take another blood meal.

EPIDEMIOLOGY

Leishmaniasis occurs in 99 countries—most of them developing—in tropical and temperate regions **(Fig. 233-2)**. More than 1 billion people live in areas endemic for leishmaniasis and are at risk of infection. An estimated 30,000 new cases of VL and more than 1 million new cases of CL occur annually. CL is common in South America, Africa, and Asia, whereas VL commonly occurs in East Africa, Brazil, and the Indian subcontinent. ML is limited to South America. The distribution of *Leishmania* is limited by the distribution of sandfly vectors.

VISCERAL LEISHMANIASIS

VL (also known as *kala-azar*, a Hindi term meaning "black fever") is caused by the *Leishmania donovani* complex, which includes *L. donovani* and *Leishmania infantum*; these species are responsible for anthroponotic and zoonotic transmission, respectively. East Africa now has the highest incidence of VL, followed by Brazil and the Indian subcontinent. In the Indian subcontinent (India, Nepal, and Bangladesh), where a VL elimination program has been implemented, VL incidence has markedly declined. In these three countries, the World Health Organization (WHO) recently announced the elimination of VL as a public health problem in Bangladesh and a steep decline in the incidence in Nepal, and India reported a 98.7% decline. Zoonotic VL is reported from all countries in the Middle East, Pakistan, and other countries from western Asia to China. Endemic foci also exist in the independent states of the former Soviet Union, mainly Georgia and Azerbaijan. In the Horn of Africa, Sudan, South Sudan, Ethiopia, Kenya, Uganda, and Somalia report VL. In Sudan and South Sudan, large outbreaks are thought to be anthroponotic, although zoonotic transmission also occurs. VL is rare in West and sub-Saharan Africa.

Mediterranean VL, long an established endemic disease due to *L. infantum*, has a large canine reservoir and was seen primarily in infants before the advent of HIV infection. In Mediterranean Europe, 70% of adult VL cases are associated with HIV co-infection. The combination is deadly because of the combined impact of the two infections on the immune system. IV drug users are at particular risk. Other forms of immunosuppression (e.g., that associated with organ transplantation) also predispose to VL. In the Americas, disease caused by *L. infantum* is endemic from Mexico to Argentina, but 90% of cases in the New World are reported from northeastern Brazil. After the introduction of highly active antiretroviral therapy, the incidence of HIV–VL co-infection declined significantly in Europe; however, ~30 and 5% of VL patients are co-infected with HIV in Ethiopia and India, respectively.

Immunopathogenesis The majority of individuals infected by *L. donovani* or *L. infantum* mount a successful immune response and control the infection, never developing symptomatic disease. Forty-eight hours after intradermal injection of killed promastigotes, these individuals exhibit delayed-type hypersensitivity (DTH) to leishmanial antigens in the leishmanin skin test (also called the Montenegro

skin test). Results in mouse models indicate that the development of acquired resistance to leishmanial infection is controlled by the production of interleukin (IL) 12 by antigen-presenting cells and the subsequent secretion of interferon (IFN) γ, tumor necrosis factor (TNF) α, and other proinflammatory cytokines by the T helper 1 (T_H1) subset of T lymphocytes. The immune response in patients developing active VL is complex; in addition to increased production of multiple proinflammatory cytokines and chemokines, patients with active disease have markedly elevated levels of IL-10 in serum as well as enhanced IL-10 mRNA expression in lesional tissues. A direct role for IL-10 in the pathology of VL in humans is supported by studies demonstrating that IL-10 blockade can enhance antigen-specific IFN-γ responses in whole blood from VL patients and IL-10 neutralization promotes parasitic killing. The main disease-promoting activity of IL-10 in VL may be to condition host macrophages for enhanced survival and growth of the parasite. IL-10 can render macrophages unresponsive to activation signals and inhibit killing of amastigotes by downregulating the production of TNF-α and nitric oxide. Multiple antigen-presentation functions of dendritic cells and macrophages are also suppressed by IL-10. Patients with such suppression do not have positive leishmanin skin tests, nor do their peripheral-blood mononuclear cells respond to leishmanial antigens in vitro. Organs of the reticuloendothelial system

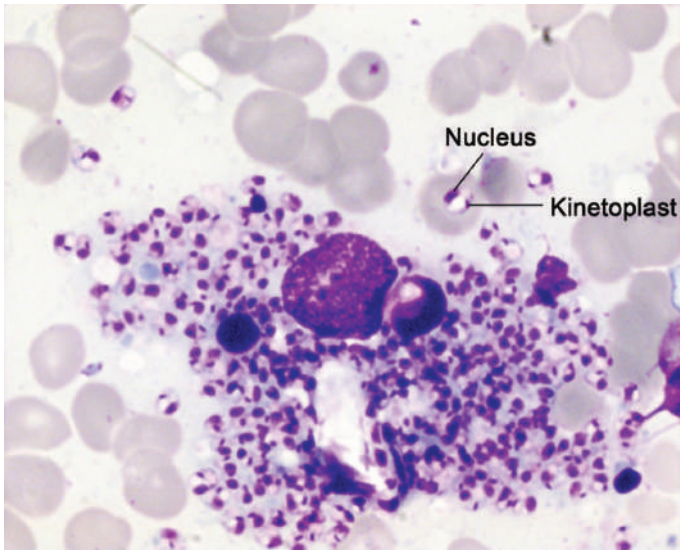

FIGURE 233-1 A macrophage with numerous intracellular amastigotes (2–4 μm) in a Giemsa-stained splenic smear from a patient with visceral leishmaniasis. Each amastigote contains a nucleus and a characteristic kinetoplast consisting of multiple copies of mitochondrial DNA. A few extracellular parasites are also visible.

are predominantly affected, with remarkable enlargement of the spleen, liver, and lymph nodes in some regions. The tonsils and intestinal submucosa are also heavily infiltrated with parasites. Bone marrow dysfunction results in pancytopenia.

Clinical Features On the Indian subcontinent and in the Horn of Africa, persons of all ages are affected by VL. In endemic areas of the Americas and the Mediterranean basin, immunocompetent infants and small children as well as immunodeficient adults are affected especially often. The incubation period is 2–3 months but may be up to 1 year or more. The most common presentation of VL is an abrupt onset of moderate- to high-grade fever associated with rigor and chills. Fever may continue for several weeks with decreasing intensity, and the patient may become afebrile for a short period before experiencing another bout of fever. The spleen may be palpable by the second week of illness and, depending on the duration of illness, may become hugely enlarged **(Fig. 233-3)**. Hepatomegaly (usually moderate) soon follows. Lymphadenopathy is common in most endemic regions of the world except the Indian subcontinent, where it is rare. Patients lose weight and feel weak, and the skin gradually develops dark discoloration due to hyperpigmentation that is most easily seen in brown-skinned individuals. In advanced illness, hypoalbuminemia may manifest as pedal edema and ascites. Anemia appears early and may become severe enough to cause congestive heart failure. Epistaxis, retinal hemorrhages, and gastrointestinal bleeding are associated with thrombocytopenia. Secondary infections such as pneumonia, tuberculosis, bacillary or amebic dysentery, and gastroenteritis are common. Herpes zoster, chickenpox, boils in the skin, and scabies may also occur. Untreated, the disease is fatal in most patients, including 100% of those with HIV co-infection.

Leukopenia and anemia occur early and are followed by thrombocytopenia. There is a marked polyclonal increase in serum immunoglobulins. Serum levels of hepatic aminotransferases are raised in a significant proportion of patients, and serum bilirubin levels are elevated occasionally. Renal dysfunction is uncommon.

Laboratory Diagnosis Demonstration of amastigotes in smears of tissue aspirates remains the gold standard for the diagnosis of VL (Fig. 233-1). The sensitivity of splenic smears is >95%, whereas smears of bone marrow (60–85%) and lymph node aspirates (50%) are less sensitive. Culture of tissue aspirates increases sensitivity. Splenic aspiration is invasive and may be dangerous in untrained hands. To circumvent these invasive procedures, several serologic techniques are currently used to detect antibodies to *Leishmania*. An enzyme-linked immunosorbent assay (ELISA) and the indirect immunofluorescent antibody test (IFAT) are used in sophisticated laboratories.

In the field, however, a rapid immunochromatographic test based on the detection of antibodies to a recombinant antigen (rK39) consisting of 39 amino acids conserved in the kinesin region of *L. infantum* is used worldwide. The test requires only a drop of fingerprick blood or serum, and the result can be read within 15 min. Except in East Africa (where both its sensitivity and specificity are lower), the sensitivity of the rK39 rapid diagnostic test (RDT) in immunocompetent individuals is ~98% and its specificity is ~90%. RDTs— based on a new synthetic polyprotein, rK28—performed better in Sudan, but are not available commercially. Since these antibody detection tests remain positive for years after cure, they cannot be used for measurement of cure or detection of relapse. Qualitative detection of leishmanial nucleic acid by polymerase chain reaction (PCR) and quantitative detection by

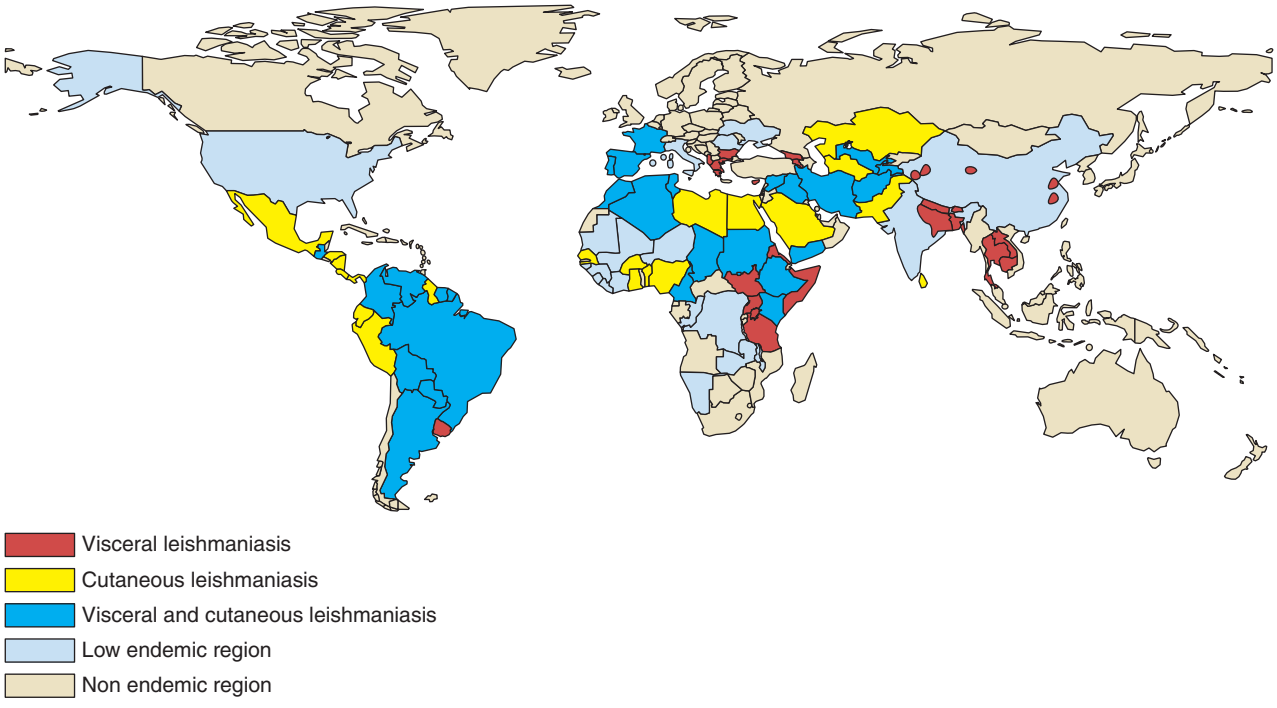

FIGURE 233-2 Worldwide distribution of human leishmaniasis.

FIGURE 233-3 A patient with visceral leishmaniasis has a hugely enlarged spleen visible through the surface of the abdomen. Splenomegaly is the most important feature of visceral leishmaniasis.

real-time PCR are highly sensitive and have the added advantage of species identification. However, because the capacity to perform these tests is confined to specialized laboratories, they are yet to be used for routine diagnosis of VL in endemic areas. Using blood samples, loop-mediated isothermal amplification (LAMP) of nucleic acids performs better compared with microscopy. A simple visual readout with minimum laboratory equipment requirements makes it attractive for point-of-care diagnostics for VL and post–kala-azar dermal leishmaniasis (PKDL), and it is likely to be used increasingly in the future.

Differential Diagnosis VL is easily mistaken for malaria. Other febrile illnesses that may mimic VL include typhoid fever, tuberculosis, brucellosis, schistosomiasis, and histoplasmosis. Splenomegaly due to portal hypertension, chronic myeloid leukemia, tropical splenomegaly syndrome, and (in Africa) schistosomiasis may also be confused with VL. Fever with neutropenia or pancytopenia in patients from an endemic region strongly suggests a diagnosis of VL; hypergammaglobulinemia in patients with long-standing illness strengthens the diagnosis. In nonendemic countries, a careful travel history is essential when any patient presents with fever.

TREATMENT

Visceral Leishmaniasis

GENERAL CONSIDERATIONS

Severe anemia should be corrected by blood transfusion, and other comorbid conditions should be managed promptly. Treatment of VL is complex because the optimal drug, dosage, and duration vary with the endemic region. Despite completing recommended treatment, some patients experience relapse (most often within 6–12 months), and prolonged follow-up is recommended. A pentavalent antimonial is the drug of choice in most endemic regions of the world, but there is widespread resistance to antimony in the Indian state of Bihar, where either amphotericin B (AmB)—deoxycholate or liposomal—or miltefosine is preferred. Dose requirements for AmB are lower in India than in the Americas, Africa, or the Mediterranean region. In Mediterranean countries, where cost is seldom an issue, liposomal AmB (LAmB) is the drug of choice. In immunocompetent patients, relapses are uncommon with AmB in its deoxycholate and lipid formulations. Antileishmanial therapy has recently evolved as new drugs and delivery systems have become available and resistance to antimonial compounds has emerged.

Except for AmB (deoxycholate and lipid formulations), antileishmanial drugs are available in the United States only from the Centers for Disease Control and Prevention Drug Service (telephone: 404-639-3670; email: drugservice@cdc.gov).

PENTAVALENT ANTIMONIAL COMPOUNDS

Two pentavalent antimonial (Sb^V) preparations are available: sodium stibogluconate (100 mg of Sb^V/mL) and meglumine antimoniate (85 mg of Sb^V/mL). The daily dose is 20 mg/kg by IV infusion or IM injection, and therapy continues for 28–30 days. Cure rates exceed 90% in Africa, the Americas, and most of the Old World but are <50% in Bihar, India, as a result of resistance. Adverse reactions to Sb^V treatment are common and include arthralgia, myalgia, and elevated serum levels of aminotransferases. Electrocardiographic changes are common. Concave ST-segment elevation is not significant, but prolongation of QT_c to >0.5 s may herald ventricular arrhythmia and sudden death. Chemical pancreatitis is common but usually does not require discontinuation of treatment; severe clinical pancreatitis occurs in immunosuppressed patients.

AMPHOTERICIN B

AmB (and its liposomal formulations) is currently used as a first-line drug in the Indian Subcontinent. Because of a better safety profile, LAmB is now the preferred drug of choice in other parts of the world, as well. Conventional AmB deoxycholate is administered in doses of 0.75–1.0 mg/kg on alternate days for a total of 15 infusions. Fever with chills is an almost universal adverse reaction to AmB infusions. Nausea and vomiting are also common, as is thrombophlebitis in the infused veins. Acute toxicities can be minimized by administration of antihistamines like chlorpheniramine and antipyretic agents like acetaminophen before each infusion. AmB can cause renal dysfunction and hypokalemia and, in rare instances, elicits hypersensitivity reactions, bone marrow suppression, and myocarditis, all of which can be fatal.

Several lipid formulations of AmB, developed to replace the deoxycholate formulation, are preferentially taken up by reticuloendothelial tissues. Because very little free drug is available to cause toxicity, a large amount of drug can be delivered over a short period. LAmB has been used extensively to treat VL in all parts of the world. With a terminal half-life of ~150 h, LAmB can be detected in the liver and spleen of animals for several weeks after a single dose. In addition to oral miltefosine (see below), this is the only drug approved by the U.S. Food and Drug Administration (FDA) for the treatment of VL; the regimen is 3 mg/kg daily on days 1–5, 14, and 21 (total dose, 21 mg/kg). However, the total-dose requirement for different regions of the world varies widely. In Asia, it is 10–15 mg/kg; in Africa, ~18 mg/kg; and in Mediterranean/American regions, ≥20 mg/kg. The daily dose is flexible (1–10 mg/kg). In a study in India, a single dose of 10 mg/kg cured infection in 96% of patients. This single-dose regimen is used in the elimination program in the Indian subcontinent. Adverse effects of LAmB are usually mild and include infusion reactions, backache, and occasional reversible nephrotoxicity.

PAROMOMYCIN

Paromomycin (aminosidine) is an aminocyclitol-aminoglycoside antibiotic with antileishmanial activity. Its mechanism of action

against *Leishmania* is yet to be established. Paromomycin is approved in India for the treatment of VL at an IM dose of 11 mg of base/kg daily for 21 days; this regimen produces a cure rate of 94.6%. However, the optimal dose has not been established in other endemic regions. Paromomycin is a relatively safe drug, but some patients develop hepatotoxicity, reversible ototoxicity, and (in rare instances) nephrotoxicity and tetany. Paromomycin, in combination with Sb^V, is used in sub-Saharan Africa.

MILTEFOSINE

Miltefosine, an alkylphosphocholine, is the first oral compound approved for the treatment of leishmaniasis in several endemic countries including the United States. This drug has a long half-life (150–200 h); its mechanism of action is not clearly understood. The recommended therapeutic regimens consist of 28 consecutive days of treatment in doses of 50 mg for patients weighing <25 kg, a twice-daily dose of 50 mg for patients weighing ≥25 kg, and 2.5 mg/kg for children 2–11 years of age. In children, allometric dosing has been suggested for adequate exposure to the drug. These regimens have resulted in a cure rate of ~94% in India. However, recent studies from the Indian subcontinent indicate a decline in the cure rate. Doses in other regions remain to be established. Because of its long half-life, miltefosine is prone to induce resistance in *Leishmania*. Its adverse effects include mild to moderate vomiting and diarrhea in 40 and 20% of patients, respectively; these reactions usually subside spontaneously after a few days. Rare instances of severe allergic dermatitis, hepatotoxicity, and nephrotoxicity have been reported. Because miltefosine is expensive and is associated with significant adverse events, it is best administered as directly observed therapy after meals to minimize the gastrointestinal adverse events, and to ensure completion of treatment and to minimize the risk of resistance induction. Because miltefosine is teratogenic in rats, its use is contraindicated during pregnancy and (unless contraceptive measures are strictly adhered to for at least 5 months after treatment) in women of childbearing age.

MULTIDRUG THERAPY

Multidrug therapy for leishmaniasis is likely to be preferred in the future. Its potential advantages in VL include (1) better compliance and lower costs associated with shorter treatment courses and decreased hospitalization, (2) less toxicity due to lower drug doses and/or shorter duration of treatment, and (3) a reduced likelihood that resistance to either agent will develop. In a study from India, one dose of LAmB (5 mg/kg) followed by miltefosine for 7 days, or paromomycin for 10 days, or both miltefosine and paromomycin simultaneously for 10 days (in their usual daily doses) produced a cure rate of >97% (all three combinations). In Africa, a combination of Sb^V and paromomycin given for 17 days was as effective and safe as Sb^V given for 30 days and is the preferred first-line treatment of VL. Recently, in a phase 3 trial from East Africa, this prevailing 17-day regimen was compared with combinations of paromomycin and miltefosine for 14 days as doses described above. The cure rates were similar, and this new combination has been proposed as an alternative to the standard 17-day regimen.

Prognosis of Treated VL Patients Recovery from VL is quick. Within a week after the start of treatment, defervescence, regression of splenomegaly, weight gain, and recovery of hematologic parameters are evident. With effective treatment, no parasites are recovered from tissue aspirates at the posttreatment evaluation. Continued clinical improvement over 12 months is suggestive of cure. A small percentage of patients (with the exact figure depending on the regimen used) relapse but respond well to retreatment with AmB or its lipid formulations.

VL in the Immunocompromised Host HIV/VL co-infection has been reported from 45 countries. Where both infections are endemic, VL behaves as an opportunistic infection in HIV-1-infected patients. HIV infection can increase the risk of VL development by several-fold in endemic areas. Co-infected patients usually show the classic signs of VL, but they may present with atypical features due to loss of immunity and involvement of unusual anatomic locations, e.g., infiltration of the skin, oral mucosa, gastrointestinal tract, lungs, and other organs. Serodiagnostic tests may be negative in up to 50% of patients. Parasites can be recovered from unusual sites such as bronchoalveolar lavage fluid and buffy coat. LAmB is the drug of choice for HIV/VL co-infection—both for primary treatment and for treatment of relapses. A total dose of 40 mg/kg, administered as 4 mg/kg on days 1–5, 10, 17, 24, 31, and 38, is considered optimal for the Americas and Mediterranean countries and is approved by the FDA, but most patients experience a relapse within 1 year. Recently, there has been a significant change in the WHO recommendations for treatment of HIV–VL co-infection in the Indian subcontinent and East Africa. LAmB infusions (total dose 30 mg/kg; 5 mg/kg on days 1, 3, 5, 7, 9, and 11) co-administered with oral miltefosine (100 mg/d for 14 days for the Indian subcontinent and 28 days for East Africa) should now be used to treat HIV–VL co-infection. AmB deoxycholate can also be used where LAmB is not accessible. Reconstitution of patients' immunity by antiretroviral therapy has led to a dramatic decline in the incidence of co-infection in the Mediterranean basin. In contrast, HIV–VL co-infection is on the rise in African and Asian countries. Ethiopia is worst affected: up to 30% of VL patients are also infected with HIV. Because restoration of the CD4+ T-cell count to >200/μL does decrease the frequency of relapse, antiretroviral therapy (in addition to antileishmanial therapy) is a cornerstone of the management of HIV–VL co-infection. Secondary prophylaxis with pentamidine or lipid AmB has been shown to delay relapses, but no regimen has been established as optimal.

Post–Kala-Azar Dermal Leishmaniasis On the Indian subcontinent and in Sudan and other East African countries, 2–50% of patients develop skin lesions concurrent with or after the cure of VL. Most common are hypopigmented macules, papules, and/or nodules or diffuse infiltration of the skin and sometimes of the oral mucosa. The African and Indian diseases differ in several respects; important features of PKDL in these two regions are listed in **Table 233-2**, and disease in an Indian patient is depicted in **Fig. 233-4**.

In PKDL, parasites are scanty in hypopigmented macules but may be seen and cultured more easily from nodular lesions. Cellular infiltrates are heavier in nodules than in macules. Lymphocytes are the dominant cells; next most common are histiocytes and plasma cells. In about half of cases, epithelioid cells—scattered individually or forming compact granulomas—are seen. The diagnosis is based on history, clinical findings supported by demonstration of parasites in the slit skin smears, or by demonstrating parasitic DNA in PCR. Sensitivity of skin smears is quite low, and positive serology does not help as it remains positive for several years after the cure of VL. Indian PKDL was treated with prolonged courses (up to 120 days) of pentavalent antimonials. This prolonged course was toxic and frequently led to noncompliance.

TABLE 233-2 Clinical, Epidemiologic, and Therapeutic Features of Post–Kala-Azar Dermal Leishmaniasis: East Africa and the Indian Subcontinent

FEATURE	EAST AFRICA	INDIAN SUBCONTINENT
Most affected country	Sudan and South Sudan	Bangladesh
Incidence among patients with VL	~50%	5–15%
Interval between VL and PKDL	During VL to 6 months	6 months to 3 years
Age distribution	Mainly children	Any age
History of prior VL	Yes	Not necessarily
Rashes of PKDL in presence of active VL	Yes	No
Treatment	Sodium stibogluconate for 2–3 months	Miltefosine for 12 weeks
Natural course	Spontaneous cure in majority of patients	Spontaneous cure rarely

Abbreviations: PKDL, post–kala-azar dermal leishmaniasis; VL, visceral leishmaniasis.

FIGURE 233-4 Post–kala-azar dermal leishmaniasis in an Indian patient. Note nodules of varying size involving the entire face. The face is erythematous, and the surface of some of the large nodules is discolored.

The alternative—three to four 20-day courses of AmB spread over several months—is expensive and unacceptable for most patients. Except for cosmetic reasons, these patients do not have any physical limitation, and thus motivation for such long and arduous treatment is very low. This leads to either no or incomplete treatment. In the Indian subcontinent, the currently recommended regimen is oral miltefosine for 12 weeks, in the usual daily doses. Though initially cure rates were high, a decline in its efficacy is now being reported in some studies. Furthermore, there are reports of ocular toxicity with this regimen in 3.7% of patients. The efficacy of either LAmB alone (20 mg/kg) or in combination with miltefosine (for 3 weeks) in PKDL has been recently tested in the Indian subcontinent; the efficacy was greater than 80% with both regimens. In East Africa, a majority of patients experience spontaneous healing. In those with persistent lesions, the response to 60 days of treatment with a pentavalent antimonial is good.

CUTANEOUS LEISHMANIASIS

CL can be broadly divided into Old World and New World forms. Old World CL caused by *Leishmania tropica* is anthroponotic and is confined to urban or suburban areas throughout its range. Zoonotic CL is most commonly due to *Leishmania major*, which naturally parasitizes several species of desert rodents that act as reservoirs over wide areas of the Middle East, Africa, and central Asia. Local outbreaks of human disease are common. Major outbreaks currently affect Afghanistan, Syria, Iraq, Lebanon, and Turkey in association with refugees and population movement. CL is increasingly seen in tourists and military personnel on mission in CL-endemic regions of countries and as a co-infection in HIV-infected patients. *Leishmania aethiopica* is restricted to the highlands of Ethiopia, Kenya, and Uganda, where it is a natural parasite of hyraxes. New World CL is mainly zoonotic and is most often caused by *Leishmania mexicana, Leishmania (Viannia) panamensis*, and *Leishmania amazonensis*. A wide range of forest animals act as reservoirs, and human infections with these species are predominantly rural. As a result of extensive urbanization and deforestation, *Leishmania (Viannia) braziliensis* has adapted to peridomestic and urban animals, and CL due to this organism is increasingly becoming an urban disease. In the United States, a few cases of CL have been acquired indigenously in Texas.

Immunopathogenesis As in VL, the proinflammatory (T_H1) response in CL may result in either asymptomatic or subclinical infection. However, in some individuals, the immune response causes ulcerative skin lesions, the majority of which heal spontaneously, leaving a scar. Healing is usually followed by immunity to reinfection with that species of parasite.

Clinical Features A few days or weeks after the bite of a sandfly, a papule develops and grows into a nodule that ulcerates over weeks or months. The base of the ulcer, which is usually painless, consists of necrotic tissue and crusted serum, but secondary bacterial infection sometime occurs. The margins of the ulcer are raised and indurated. Lesions may be single or multiple and vary in size from 0.5 to >3 cm **(Fig. 233-5)**. Lymphatic spread and lymph gland involvement may be palpable and may precede the appearance of the skin lesion. There may be satellite lesions, especially in *L. major* and *L. tropica* infections. The lesions usually heal spontaneously after 2–15 months. Lesions due to *L. major* and *L. mexicana* tend to heal rapidly, whereas those due to *L. tropica* and parasites of subspecies *Viannia* heal more slowly. In CL caused by *L. tropica*, new lesions—usually scaly, erythematous papules and nodules—develop in the center or periphery of a healed sore, a condition known as *leishmaniasis recidivans*. Lesions of *L. mexicana* and *Leishmania (Viannia) peruviana* closely resemble those seen in the Old World; however, lesions on the pinna of the ear are common, chronic, and destructive in the former infections. *L. mexicana* is responsible for chiclero's ulcer, the so-called self-healing sore of Mexico. CL lesions on exposed body parts (e.g., the face and hands), permanent scar formation, and social stigmatization may cause anxiety and depression and may affect the quality of life of CL patients.

Differential Diagnosis A typical history (an insect bite followed by the events leading to ulceration) in a resident of or a returning traveler from an endemic zone, strongly suggests CL. Cutaneous tuberculosis, fungal infections, leprosy, sarcoidosis, and malignant ulcers are sometime mistaken for CL.

Laboratory Diagnosis Demonstration of amastigotes in material obtained from a lesion remains the diagnostic gold standard. Microscopic examination of slit skin smears, aspirates, or biopsies of the lesion is used for detection of parasites. Culture of smear or biopsy material may yield *Leishmania*. PCR or LAMP is more sensitive than

FIGURE 233-5 Cutaneous leishmaniasis in a Bolivian child. There are multiple ulcers resulting from several sandfly bites. The edges of the ulcers are raised. *(Courtesy of P. Desjeux, Retired Medical Officer, World Health Organization, Geneva, Switzerland.)*

microscopy and culture and allows identification of *Leishmania* to the species level. Quantitative PCR may be used to monitor treatment responses. This information is important in decisions about therapy because responses to treatment can vary with the species.

TREATMENT

Cutaneous Leishmaniasis

Although lesions heal spontaneously in the majority of cases, their spread or persistence indicates that treatment may be needed. One or a few small lesions due to "self-healing species" can be treated with topical agents. Systemic treatment is required for lesions over the face, hands, or joints; multiple lesions; large ulcers; lymphatic spread; New World CL with the potential for development of ML; and CL in HIV-co-infected patients.

A pentavalent antimonial is the first-line drug for all forms of CL and is used in a dose of 20 mg/kg for 20 days. The exceptions to this rule are CL caused by *Leishmania (Viannia) guyanensis*, for which pentamidine isethionate is the drug of choice (two injections of 4 mg of salt/kg separated by a 48-h interval), and CL due to *L. aethiopica*, which responds to paromomycin (16 mg/kg daily) but not to antimonials. Relapses usually respond to a second course of treatment. In Peru, topical imiquimod (5–7.5%) plus parenteral antimonials have been shown to cure CL more rapidly than antimonials alone. Azoles and triazoles have been used with mixed responses in both Old and New World CL but have not been adequately assessed for this indication in clinical trials. In *L. major* infection, oral fluconazole (200 mg/d for 6 weeks) resulted in a higher rate of cure than placebo (79% vs 34%) and also cured infection faster. Adverse effects include gastrointestinal symptoms and hepatotoxicity. Ketoconazole (600 mg/d for 28 days) is 76–90% effective in CL due to *L. (V.) panamensis* and *L. mexicana* in Panama and Guatemala.

Orally administered miltefosine makes it very attractive and is a major advancement in the treatment of CL. Miltefosine has been used in CL in doses of 2.5 mg/kg for 28 days. This agent is effective against *L. major* infections. Recent Pan American Health Organization guidelines recommend intralesional pentavalent antimonials in patients with localized CL caused by *L. braziliensis* and *L. amazonensis*. There is a strong recommendation for oral miltefosine treatment for New World CL where *L. panamensis, L. mexicana, L. guyanensis*, and *L. braziliensis* are the species involved. Overall, there has been a tilt toward the use of miltefosine in CL and ML instead of antimonials, both in the New and Old Worlds. In Brazil, miltefosine cured 71% of patients with *L. (V.) guyanensis* infection. Other drugs, such as dapsone, allopurinol, rifampin, azithromycin, and pentoxifylline, have been used either alone or in combinations, but most of the relevant studies have had design limitations that preclude meaningful conclusions.

Small lesions (≤3 cm in diameter) may conveniently be treated weekly until cure with an intralesional injection of a pentavalent antimonial at a dose adequate to blanch the lesion (0.2–2.0 mL). An ointment containing 15% paromomycin sulfate, either alone or with 0.5% gentamicin or 12% methylbenzonium chloride, cured 70–82% of lesions due to *L. major* in 20 days and may be suitable for lesions caused by other species. Heat therapy with an FDA-approved radiofrequency generator and cryotherapy with liquid nitrogen have also been used successfully.

Diffuse Cutaneous Leishmaniasis (DCL) DCL is a rare form of leishmaniasis caused by *L. amazonensis* and *L. mexicana* in South and Central America and by *L. aethiopica* in Ethiopia and Kenya. DCL is characterized by the lack of a cell-mediated immune response to the parasite, the uncontrolled multiplication of which thus continues unabated. The DTH response does not develop, and lymphocytes do not respond to leishmanial antigens in vitro. DCL patients have a polarized immune response with high levels of immunosuppressive cytokines, including IL-10, transforming growth factor (TGF) β, and IL-4, and low concentrations of IFN-γ. Profound immunosuppression leads to widespread cutaneous disease. Lesions may initially be confined to the face or a limb but spread over months or years to other areas of the skin. They may be symmetrically or asymmetrically distributed and include papules, nodules, plaques, and areas of diffuse infiltration. These lesions do not ulcerate. The overlying skin is usually erythematous in pale-skinned patients. The lesions are teeming with parasites, which are therefore easy to recover. DCL does not heal spontaneously and is difficult to treat. If relapse and drug resistance are to be prevented, treatment should be continued for some time after lesions have healed and parasites can no longer be isolated. In the New World, repeated 20-day courses of pentavalent antimonials are given, with an intervening drug-free period of 10 days. Miltefosine has been used for several months with a good initial response. Combinations should be tried. In Ethiopia, a combination of paromomycin (14 mg/kg per day) and sodium stibogluconate (10 mg/kg per day) is effective.

MUCOSAL LEISHMANIASIS

The subgenus *Viannia* is widespread from the Amazon basin to Paraguay and Costa Rica and is responsible for deep sores and for ML (Table 233-1). In *L. (V.) braziliensis* infections, cutaneous lesions may be simultaneously accompanied by mucosal spread of the disease or followed by spread years later. ML is typically caused by *L. (V.) braziliensis* and rarely by *L. amazonensis*, *L. (V.) guyanensis*, and *L. (V.) panamensis*. Young men with chronic lesions of CL are at particular risk. Overall, ~3% of infected persons develop ML. Not every patient with ML has a history of prior CL. ML is almost entirely confined to the Americas. In rare cases, ML may also be caused by Old World species like *L. major, L. infantum* (*L. chagasi*), or *L. donovani*.

Immunopathogenesis and Clinical Features The immune response is polarized toward a T_H1 response, with marked increases of IFN-γ and TNF-α and varying levels of T_H2 cytokines (IL-10 and TGF-β). Patients have a stronger DTH response with ML than with CL, and their peripheral-blood mononuclear cells respond strongly to leishmanial antigens. The parasite spreads via the lymphatics or the bloodstream to mucosal tissues of the upper respiratory tract. Intense inflammation leads to destruction, and severe disability ensues. Lesions in or around the nose or mouth (espundia; **Fig. 233-6**) are the typical presentation of ML. Patients usually provide a history of self-healed CL preceding ML by 1–5 years. Typically, ML presents as nasal stuffiness and bleeding followed by destruction of nasal cartilage, perforation of the nasal septum, and collapse of the nasal bridge. Subsequent involvement of the pharynx and larynx leads to difficulty in swallowing and phonation. The lips, cheeks, and soft palate may also be affected. Secondary bacterial infection is common, and aspiration pneumonia may be fatal. Despite the high degree of T_H1 immunity and the strong DTH response, ML does not heal spontaneously.

Laboratory Diagnosis Tissue biopsy is essential for identification of parasites, but the rate of detection is poor unless PCR techniques are used. The strongly positive DTH response fails to distinguish between past and present infection.

TREATMENT

Mucosal Leishmaniasis

The regimen of choice is a pentavalent antimonial agent administered at a dose of 20 mg of Sb^V/kg for 30 days. Patients with ML require long-term follow-up with repeated oropharyngeal and nasal examination. With failure of therapy or relapse, patients may receive another course of an antimonial but then become unresponsive, presumably because of resistance in the parasite. In this situation, AmB should be used. An AmB deoxycholate dose totaling 25–45 mg/kg is appropriate. There are no controlled trials of LAmB, but administration of 2–3 mg/kg for 20 days is considered adequate. Miltefosine (2.5 mg/kg for 28 days) cured 71% of ML patients in Bolivia. The more extensive the disease, the worse is the prognosis; thus, prompt, effective treatment and regular follow-up are essential.

FIGURE 233-6 Mucosal leishmaniasis in a Brazilian patient. There is extensive inflammation around the nose and mouth, destruction of the nasal mucosa, ulceration of the upper lip and nose, and destruction of the nasal septum. *(Courtesy of R. Dietz, Universidade Federal do Espírito Santo, Vitória, Brazil.)*

PREVENTION OF LEISHMANIASIS

No vaccine is available for humans for any form of leishmaniasis, although several candidates are in early phases of development. Inoculation with live *L. major* ("leishmanization") is practiced in Iran; 80% of recipients were protected, according to one report. Anthroponotic leishmaniasis is controlled by case finding, treatment, and vector control with insecticide-impregnated bed nets and curtains and residual insecticide spraying. Control of zoonotic leishmaniasis is more difficult. Use of insecticide-impregnated collars for dogs, treatment of infected domestic dogs, and culling of street dogs are measures that have been used with uncertain efficacy to prevent transmission of *L. infantum*. In Brazil, canine vaccines have been found to promote a decrease in the human and canine incidence of zoonotic VL. Two vaccines, Leishmune and LeishTec, are licensed in Brazil; Leishmune provides significant protection to vaccinated dogs. CaniLeish and LetiFend are the two licensed canine vaccines approved for use in Europe. Personal prophylaxis with bed nets and repellants may reduce the risk of CL infections in the New World.

234 Chagas Disease and African Trypanosomiasis

François Chappuis, Yves Jackson

Myriads of protozoan parasites of the genus *Trypanosoma* infect plants and animals worldwide. Among these, three are of clinical significance for humans: *T. cruzi* causes Chagas disease, and *T. brucei gambiense* and *T. brucei rhodesiense* cause human African trypanosomiasis (HAT), which is also known as "sleeping sickness." Despite obvious differences in their geographic distribution, parasitic life cycle, clinical presentation, treatment, and outcome, these vector-borne diseases are archetypal examples of neglected tropical diseases. More broadly, these infectious diseases affect neglected populations of the lowest socioeconomic class who have limited access to care and who live either in remote rural areas of low- or middle-income tropical/subtropical countries or in urban areas of both endemic and nonendemic countries. Most drugs to treat these conditions are several decades old, their availability is limited, and their efficacy and/or safety is suboptimal.

Other trypanosome species (e.g., *T. congolense* and *T. evansi*) predominantly cause nonhuman zoonoses and only occasionally cause illness in humans.

CHAGAS DISEASE (AMERICAN TRYPANOSOMIASIS)

DEFINITION

First described in 1909 by Carlos Chagas, Chagas disease (American trypanosomiasis) is a zoonosis caused by the flagellated protozoan *T. cruzi*. After a frequently asymptomatic acute phase, 30–40% of patients develop potentially life-threatening chronic cardiomyopathy and/or digestive tract dysfunction over decades. Acute reactivation may occur in immunocompromised patients. Chagas disease imposes an important human and social burden in Latin America and has recently spread outside its natural boundaries to become a global public health problem. The vast majority of affected individuals are unaware of being infected and do not have access to appropriate clinical management and counseling.

TRANSMISSION

Vectorial Transmission *T. cruzi* infection is primarily a zoonosis transmitted to a range of wild and domestic mammals by blood-sucking triatomine bugs. Sylvatic, peridomiciliary, and intradomiciliary vectorial cycles sometimes overlap. Over a large geographic area in the Americas (from northern Argentina to the southern United States), most human infections are intradomiciliary, arising from a triatomine bite during nighttime sleep. Feces released by triatomines during a blood meal contain the infective metacyclic form of *T. cruzi* that enters the human body through cutaneous breaks, mucosae, or conjunctivae. Despite some laboratory research showing the potential for transmission by bedbugs, there is no evidence that bedbugs actually transmit *T. cruzi* to humans.

Nonvectorial Transmission Other modes of transmission can cause infection in both endemic and nonendemic regions. *T. cruzi* can be transmitted congenitally from mother to newborn, by transfusion of blood products, by tissue or organ transplantation, or by ingestion of contaminated food or drink. Congenital infection occurs in 1–10% of newborns of infected mothers. The risk of infection from contaminated blood products is low (1.7% overall, 13% for platelet recipients, and close to 0 for recipients of red blood cells and plasma). Transmission by infected organ and tissue transplants mostly affects heart, liver, and kidney recipients. Oral transmission is increasingly reported after ingestion of contaminated food (berries) or drinks (fruit or sugar cane juice) and occasionally causes outbreaks.

EPIDEMIOLOGY

An estimated 6–7 million people are infected by *T. cruzi*, including >1 million individuals with chronic cardiomyopathy. However, the true global burden of Chagas disease is in fact uncertain. The highest numbers of infected individuals reside in Argentina, Brazil, and Mexico; the prevalence is highest in Bolivia (6.1%), Argentina (3.6%), and Paraguay (2.1%). In highly endemic regions of these countries, the prevalence may exceed 40%. Formerly restricted to poor rural populations, the distribution of cases—and, to some extent, *T. cruzi* transmission—has progressively extended to cities in the context of rapid urbanization and rural migration. A recent history of migration from a rural area is the main risk factor in urban settings.

Overall, the prevalence and incidence of Chagas disease have sharply declined in recent decades because of improved housing and socioeconomic conditions as well as public health interventions, including regional vector-control initiatives, implementation of systematic screening of blood products, and improved detection of congenital transmission. Several countries have been declared free of domiciliary transmission as a result of sustained residual insecticide-spraying campaigns. This progress is threatened by adaptation of the vector to the periurban environment, its resurgence in areas where spraying has been discontinued, the development of resistance to pyrethroid insecticides, and the persistence of peridomiciliary transmission. A growing number of localized outbreaks are being reported in previously stable areas, with the Amazon basin particularly at risk.

Chagas disease distribution has expanded to nonendemic countries in the context of increased global travel, with cases reported more frequently in North America, Western Europe, Australia, and Japan. The United States harbors up to 300,000 cases, mostly among immigrants from Central America. In addition, sporadic vector-borne infections occur in the southern states. Western Europe has an estimated 68,000–123,000 cases, and Japan and Australia a few thousand cases. Despite the implementation of blood bank screening and of some dedicated medical programs, only a small proportion of cases have been identified and properly managed to date. A low level of awareness among health care professionals and difficulties experienced by some groups in accessing care appear to be major drivers. At-risk migrant communities are frequently subject to factors that render them socially, legally, or economically vulnerable. Moreover, the cultural perception of Chagas as a disease embedded in poverty can create a social stigma that complicates its management at the community level. In contrast to immigrants, international tourists visiting endemic countries are at very low risk of being infected, whether by reduviid bug bites or by other routes, and reports of Chagas disease in travelers are rare.

PATHOLOGY

Several *T. cruzi* strains have been identified. These strains have partially overlapping transmission cycles and geographic distributions, but no definitive evidence supports an association of certain strains with specific clinical manifestations or with variation in disease severity. The rarity of digestive tract involvement north of the Amazon basin suggests that specific parasitic and host genetic factors may influence the disease course. The pathogenesis of Chagas disease results from the complex interactions between the pathogen and the host immune response. Many questions about the relative importance of these interactions, including the role of autoimmune mechanisms, remain unanswered. After local penetration of trypomastigotes, parasites rapidly enter the bloodstream and disseminate through the body, infecting a wide range of nucleated cells in which they differentiate into amastigotes **(Fig. 234-1)**. The innate immune response triggered by parasite mucins and DNA leads to a predominantly T helper 1 response. The production of various proinflammatory cytokines and the activation of CD8+ T lymphocytes reduce parasitemia to a subpatent level within 4–8 weeks, a point marking the end of the acute phase.

Immune evasion mechanisms allow persistent low-intensity proliferation of amastigotes and their release into the bloodstream, with subsequent infection of potentially all types of nucleated cells—notably cardiac, skeletal, and smooth-muscle cells. Mechanisms that have been postulated to determine the pathogenic evolution toward cardiomyopathy include the parasites' persistence and the host's inability to downregulate the initial immune response, resulting in cell-mediated damage and an imbalance of T helper 1 and 2 responses with excessive production of proinflammatory cytokines. Secondary mechanisms, such as microcirculation abnormalities and dysautonomia, also may influence the progression of tissue damage. Genome-wide association studies suggest that genetic variation may contribute to cardiomyopathy development.

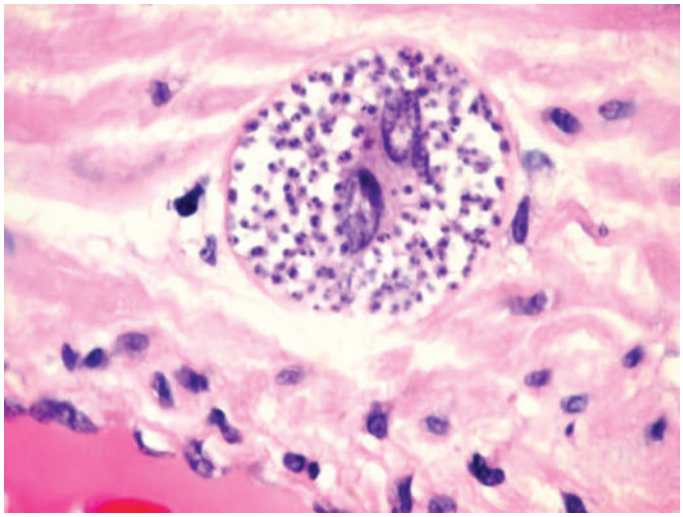

FIGURE 234-1 A cluster of *Trypanosoma cruzi* amastigotes with an inflammatory infiltrate in the placenta of a congenitally infected newborn infant.

In the myocardium, chronic inflammation results in cellular destruction and the development of fibrosis leading to a segmental loss of contractility and dilation of the chambers, with the associated risk of left ventricle apical aneurism. Focal hypoperfusion and tissue damage are sources of ventricular arrhythmias, while scarring lesions mostly affect the conduction system. Autonomic cell destruction leads to vagal and sympathetic denervation whose exact clinical significance remains to be clarified.

T. cruzi appears to have a direct toxic effect on digestive tract intramural autonomic ganglion cells. Over time, the loss of neural cells affects muscular tone, leading to motility disorders and ultimately to organ dilation (megaviscera syndrome). The esophagus and colon are primarily affected, but lesions may occur along the whole digestive tract. Inadequate relaxation of the lower esophageal sphincter causes symptoms of achalasia, whereas damage to the colon ultimately mimics Hirschsprung's disease, with severe constipation and the risk of volvulus and toxic dilation.

Factors reducing the cellular immune response, such as HIV infection, posttransplantation immunosuppressive therapies, or hematologic malignancies, may increase intracellular replication of amastigotes, with increased parasitemia (reactivation). Lesions develop predominantly in the central nervous system (CNS), the heart, and the skin. Among HIV-positive patients, the risk of reactivation is ~20% in the absence of antiretroviral therapies and occurs when the CD4+ T cell count falls to <100/μL. Clinically manifest *T. cruzi* reactivation is an AIDS-defining opportunistic infection.

CLINICAL MANIFESTATIONS

The clinical manifestations of *T. cruzi* infection vary greatly among individuals. The infection course is divided into two phases that are associated with different clinical features, duration, and prognosis **(Table 234-1)**. The acute phase remains undetected and undiagnosed in most individuals. While 5–10% of these early infections spontaneously resolve without treatment, *T. cruzi* persists for life in most individuals (the chronic phase); 60–70% of these individuals never develop apparent tissue damage (the indeterminate form), but the remaining 30–40% progress toward detectable organ damages of variable severity over decades (the determinate form). These chronic complications include cardiac (20–30%), digestive (5–20%), or mixed (5–10%) disorders. There

TABLE 234-1 Characteristics of the Stages of *Trypanosoma cruzi* Infection

PHASE OR SETTING	CONTEXT	ONSET OF FIRST SYMPTOMS	CLINICAL MANIFESTATIONS	DURATION	PROGNOSIS
Acute (congenital)	~5% risk of maternal transmission to newborn	At birth or weeks after delivery	>90% asymptomatic; rare lymphadenopathy, hepatosplenomegaly, jaundice, respiratory distress, growth retardation	2–8 weeks	Favorable when infant is born alive; unknown rate of in utero or neonatal death
Acute	Vector-borne transmission; oral transmission (ingestion of contaminated food/drinks); blood product transfusion; tissue/organ transplantation	1–2 weeks after vectorial transmission; may be sooner (days) after oral transmission or later (months) after transfusion/transplantation	>90% asymptomatic or mild febrile illness; local swelling at inoculation site (eyelid [Romaña sign] or skin [chagoma]); polyadenopathy; splenomegaly; myocarditis, hepatitis, and encephalitis more frequent with oral transmission	4–8 weeks	Mortality: 0.1–5% with oral transmission or myocarditis/encephalitis
Chronic (indeterminate form)	Balanced immune response after acute phase subsides	No symptoms	Normal clinical examination and ECG result	Lifelong or until determinate phase	No attributable mortality
Chronic (determinate form)	Predominant inflammatory response (in cardiomyopathy only)	Years to decades after initial infection	Dyspnea, chest pain, palpitation, syncope, sudden death, stroke, dysphagia, regurgitation, constipation, fecaloma, volvulus, peripheral neuropathy	Chronic	5-year mortality: 2–63%, depending on extent of cardiac damage; most important causes of death: cardiac failure and sudden death, followed by stroke
Acute (reactivation)	Severe immunosuppression	Variable	Myocarditis, erythema nodosum, panniculitis, *Toxoplasma*-like focal brain lesion, meningoencephalitis	Variable	Mortality depends on rapidity of diagnosis and treatment and on underlying conditions

Abbreviation: ECG, electrocardiography.

is no predictor of evolution toward clinical manifestations during the chronic phase. In patients with cardiomyopathy, bundle branch blocks are usually the first signs and may cause no symptoms for years until more severe conduction system disease, arrhythmias, and left ventricular dysfunction occur. Advanced cardiac damage entails a worse prognosis than other cardiomyopathies—notably, ischemic heart disease.

APPROACH TO THE PATIENT

Chagas Disease (American Trypanosomiasis)

More than 90% of infections go undiagnosed, and cases are frequently identified at a late stage once chronic complications develop. The vast majority of *T. cruzi*–infected individuals are asymptomatic (i.e., in the indeterminate form of the chronic phase). An awareness of potential Chagas disease is important for general practitioners as well as for physicians from various specialties, including gastroenterologists, cardiologists, neurologists, obstetricians, pediatricians, and infectious disease specialists. Outside endemic areas, screening for Chagas disease should be proposed when any Latin American individual has evocative symptoms and signs, including abnormalities on electrocardiography (ECG) or increased risk of (1) *T. cruzi* infection (Chagas disease in the mother or other family members; origins in a highly endemic country or area; history of unscreened blood transfusion in Latin America); (2) transmission to others (e.g., via pregnancy or blood or organ donation); or (3) reactivation (current or pending immunosuppression). Screening of the relatives of an index case may identify additional cases.

DIAGNOSIS AND STAGING

Diagnostic Confirmation Diagnostic strategies depend on the clinical phase (Table 234-2). Detection of circulating parasites by microscopy of the blood after concentration (e.g., by the Strout method, microhematocrit) or by nucleic acid–based assay (polymerase chain reaction [PCR]) is the best diagnostic approach when the parasitemia level is high—i.e., during the acute phases, including reactivation. Once parasitemia becomes undetectable by microscopy (a point marking the end of the acute phase), diagnosis relies on immunologic tests that detect anti–*T. cruzi* IgG. The most common techniques include a conventional or recombinant enzyme-linked immunosorbent assay (ELISA) and immunofluorescence assays. Two positive serologic tests using different techniques and targeting different antigens confirm the diagnosis of Chagas disease during the chronic phase. In the presence of discordant serologic results, a third serologic test is warranted. Some of the immunochromatographic rapid diagnostic tests on the market have sufficient sensitivity and specificity to be used as first-line screening tests where laboratory facilities are not easily accessible. If the rapid diagnostic test result is positive, at least one conventional serologic assay is necessary to confirm infection.

Diagnosis of congenital infection relies on examination of cord and/or peripheral blood by microscopy or PCR during the first days or weeks of life. A test conducted after 4 weeks of age is most accurate: PCR earlier in life may be falsely positive, likely because of the passage of *T. cruzi* DNA fragments from the mother to the child. If results are negative, serologic tests should be performed at 9 months of age, once maternal antibodies have been cleared.

During the chronic phase, the limited sensitivity (50–80%) of conventional PCR restricts its usefulness for primary diagnosis; however, PCR can document therapeutic failure if it yields positive results after the completion of treatment. In the United States, the Centers for Disease Control and Prevention (CDC) provides reference laboratory testing (see contact information in the treatment section).

TABLE 234-2 Diagnostic Procedures of Choice for Clinical Stages of *T. cruzi* Infection

STAGE	TECHNIQUE OF CHOICE	SAMPLE	DIAGNOSTIC CRITERIA
Acute	Microscopy after concentration, PCR	Peripheral blood, cerebrospinal or other body fluids	Positivity in one test
Acute (early congenital during first 9 months of life)	Microscopy after concentration, PCR	Cord or peripheral blood	Positivity in one test
Chronic (indeterminate and determinate forms)	Serology	Peripheral blood	Positivity in two tests with different techniques and antigens
Reactivation	Microscopy after concentration, PCR	Peripheral blood, cerebrospinal or other body fluids	Positivity with evidence of increasing parasitemia on serial samples or extremely high parasite load

Abbreviation: PCR, polymerase chain reaction.

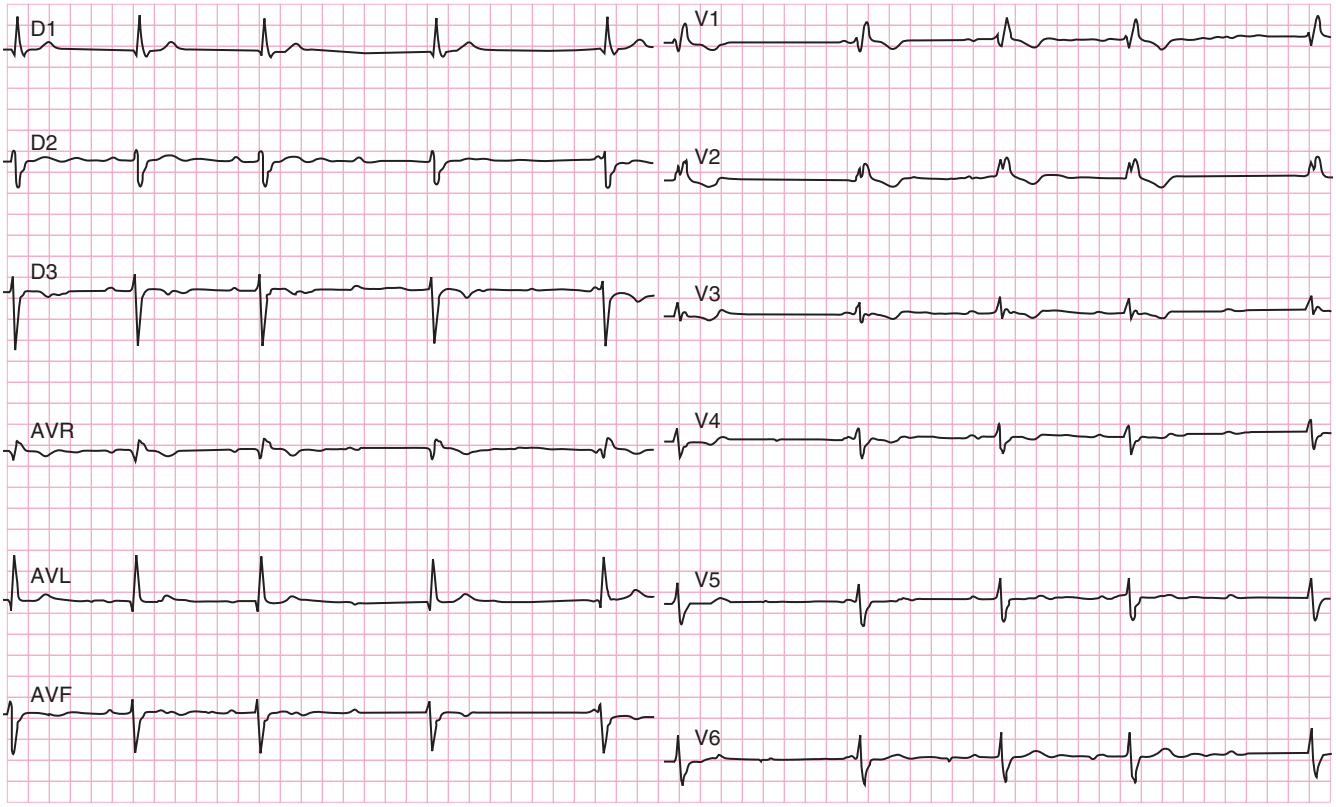

FIGURE 234-2 Electrocardiogram of a 43-year-old patient shows bradycardia with high-grade atrioventricular blocks.

Disease Staging Once *T. cruzi* infection is confirmed, clinicians should assess the presence of complications and concomitant factors that may influence the course of the disease. The initial evaluation includes a thorough cardiac, neurologic, and digestive history and a clinical examination. Twelve-lead ECG with a 30-s strip is a good screening test for Chagas-associated cardiomyopathy. The most frequently found abnormalities are right bundle branch block, left anterior fascicular block, ventricular premature beats, repolarization disorders, Q waves, and low QRS voltage **(Fig. 234-2)**. An abnormal ECG result or the presence of suggestive cardiac symptoms warrants further investigation. Echocardiography and the 24-h Holter test are the preferred methods for assessment of chamber dilation, apical aneurysm, ventricular dysfunction, and arrhythmias. Depending on the findings, the workup can be supplemented by MRI or electrophysiologic studies. Gastroenterologic investigations are performed in patients with suggestive symptoms, such as dysphagia and severe constipation. Barium esophagography and enema are first-line diagnostic procedures, which can be supplemented by esophageal manometry. Megacolon is diagnosed when the sigmoid or descending colon diameter is ≥6.5 cm.

Comorbidities, including other cardiovascular risk factors, immunosuppressive conditions, and other chronic infections (e.g., with *Strongyloides stercoralis* or HIV) should be investigated.

TREATMENT

Chagas Disease (American Trypanosomiasis)

ETIOLOGIC TREATMENT

Only two drugs, benznidazole and nifurtimox **(Table 234-3)**, have shown persistent efficacy against *T. cruzi* infection when administered for ≥30 days. While these drugs have been used since the early 1970s, many questions remain about their mode of action and efficacy at the different stages of infection. The treatment goal depends on the clinical stage; the overall objectives are to cure patients who have recent infection or reactivation, to reduce morbidity, and to prevent transmission at later stages. Treatment is most effective during the acute (including congenital) phase and the early chronic phase (i.e., in patients <18 years of age), with a 60–100% cure rate. The efficacy of treatment during the indeterminate form of the chronic phase in patients >18 years old is not known; however, treatment may protect against the development of cardiac damage later in life and eliminate the risk of vertical transmission when given before conception. In adults with chronic cardiomyopathy, benznidazole has no impact on disease progression and mortality risk. Neither benznidazole nor nifurtimox is effective against

TABLE 234-3 Chagas Treatment Regimens and Adverse Reactions to Benznidazole and Nifurtimox

DRUG	REGIMEN	DURATION	ADVERSE EVENTS IN ADULTS (FREQUENCY)	PREMATURE DISCONTINUATION (RATE)
Benznidazole	Age <12 years: 5–7.5 mg/kg per day in 2 doses Age >12 years: 5 mg/kg per day in 2 doses	30–60 days	Allergic dermatitis (29–50%), anorexia and weight loss (5–40%), paresthesia (0–30%), peripheral neuropathy (0–30%), nausea and vomiting (0–5%), leukopenia and thrombocytopenia (<1%)	7–20%
Nifurtimox	Age <10 years: 15–20 mg/kg per day in 3 or 4 doses Age 11–16 years: 12.5–15 mg/kg per day in 3 or 4 doses Age >16 years: 8–10 mg/kg per day in 3 or 4 doses	60–90 days	Anorexia and weight loss (50–81%), nausea and vomiting (15–50%), abdominal discomfort (12–40%), headaches (13–70%), dizziness and vertigo (12–33%), anxiety and depression (10–49%), insomnia (10–54%), myalgia (13–30%), peripheral neuropathy (2–5%), memory loss (6–14%), leukopenia (<1%)	6–44%

digestive complications. Treatment is contraindicated during pregnancy and in advanced renal or hepatic failure. Preferred regimens and drug tolerance vary with age. Adverse events are more frequent among adults, who are therefore at increased risk of premature treatment discontinuation (Table 234-3). As benznidazole seems better tolerated than nifurtimox in adults, it is the recommended first-line drug in this age range. Close (e.g., weekly) clinical and biologic monitoring is necessary during treatment. While treatment is usually prescribed for 60 days, the optimal duration remains a matter of debate, with a growing interest in shorter courses.

Treatment should be undertaken for all children, women of child-bearing age, patients in the acute phase, and patients with reactivation. Given the uncertainties about the impact of treatment, the decision to treat patients >18 years old who have the indeterminate form of the chronic phase should be made on an individual basis after discussing the pros and cons with the patient. A negative pregnancy test is mandatory before initiating treatment, as the recommended drugs have not been proven to be safe in pregnancy. The efficacy of second-line treatment (e.g., nifurtimox after failure with benznidazole) has not been evaluated to date.

The limited efficacy of current regimens and the understanding that living parasites are a driver of immunopathologic processes have fueled interest in novel therapeutic approaches. These include the addition of immunomodulatory interventions to antiparasitic treatment and the use of combinations of antiparasitic drugs. Information on drugs can be obtained through the CDC (Parasitic Diseases Public Inquiries line [404-718-4745] or chagas@cdc.gov), or the CDC Emergency Operations Center (770-488-7100). The U.S. Food and Drug Administration has approved the use of benznidazole for treatment of children 2–12 years and nifurtimox for those 0–17 years of age, and in older patients based on clinical decision.

NONETIOLOGIC TREATMENT

The management of Chagas cardiomyopathy generally follows the management guidelines for heart failure, conduction disturbances, or ventricular arrhythmia of other etiologies. Given the high risk of sudden death, early initiation of treatment with amiodarone or implantation of a cardioverter defibrillator should be considered in the presence of pathologic electrophysiologic abnormalities. Anticoagulation is recommended for primary and secondary prevention of cardioembolic events in the presence of an intramural thrombus or apical aneurysm. Strict control of other cardiovascular risk factors is warranted. Chagas cardiomyopathy is a prominent indication for heart transplantation in Latin America; some evidence indicates that the results are better than in cardiomyopathy of other etiologies. Posttransplantation immunosuppression requires close monitoring, given the high risk of reactivation.

Treatment of digestive dysmotility includes dietary counseling and meals rich in fiber and hydration, with smaller portions eaten more frequently. Drugs releasing the lower esophageal sphincter (e.g., nifedipine or isosorbide dinitrate before meals), pneumatic balloon dilatation, or laparoscopic myotomy improve upper gastrointestinal symptoms in the early stage. Use of botulinum toxin is effective but requires repeated injections. Laxatives and enemas alleviate chronic constipation in most patients. Surgery is indicated in patients with distressing symptoms that are refractory to medical treatment.

CLINICAL FOLLOW-UP

Defining the optimal cure after treatment remains very challenging and is a crucial topic of research. While the search for biomarkers (including through proteomics) to identify early indicators of treatment response holds some promise, serologic follow-up remains the cornerstone of posttreatment monitoring in the acute phase. In the chronic phase, there is no assay of proven value for documentation of response. The time needed for negative seroconversion after treatment indeed depends on the duration of infection. The interval is short (usually months, sometimes up to 2 years) when infection is treated during the acute (including congenital) phase. In contrast, decades are required in adults infected during childhood. A positive result in a posttreatment PCR indicates treatment failure, but a negative result cannot be interpreted because of the low sensitivity of PCR during the chronic phase. The status of patients with negative PCR results but persistent positive serology is therefore uncertain, but these patients should be considered potentially infective as long as serologic tests continue to yield positive results. All patients, treated or not, should be regularly monitored. The basic yearly assessment includes history-taking for detection of new symptoms, clinical examination, and 12-lead ECG.

PREVENTION

In the absence of a vaccine, preventive measures—primary (prevention of *T. cruzi* transmission), secondary (avoidance of complications), and tertiary (reduction of morbidity and mortality)—are necessary. Screening of blood donations is being progressively implemented in endemic areas and in countries to which high-risk groups are immigrating, and screening should be extended to organ donation. When sustained over prolonged periods, vector control is an effective and cost-effective strategy to curb intradomiciliary transmission. Insecticide-impregnated bed nets (as used for malaria) provide individual protection against reduviid bug bites. Screening of child-bearing-age and pregnant Latin American migrant women has been highly cost-effective in Spain, although the cost per case detected varies with the prevalence of infection in the targeted population. Early identification of cases through passive and active screening of the population at risk, along with provision of treatment, may reduce the risk of complications and secondary transmission, particularly congenital transmission. Finally, identification and treatment of cardiac complications and prevention of cardioembolic events at an early stage positively influence the disease course.

GLOBAL CONSIDERATIONS

With its geographic expansion, Chagas disease has become a global health issue, predominantly affecting vulnerable people on four continents. Yet, as with other neglected tropical diseases, progress against Chagas is limited by a lack of research and development and a lack of financial and political commitment. For example, the production and registration of existing drugs, and access to them, are still problematic in many countries, including the United States. Difficulties in research on and development of new drugs are compounded by the lack of financial incentives. The future of Chagas disease is likely to be influenced by global phenomena. Climatic changes, population aging, increasing prevalence of noncommunicable comorbidities (e.g., diabetes, hypertension) in low- and middle-income countries, and increasing use of immunosuppressive drugs are likely to impact the epidemiology, clinical course, and burden of Chagas disease. To tackle these challenges, clinical, public health, and policy interventions need to be scaled up and improved in areas of high or hidden prevalence (e.g., in the Chaco Region of Argentina, Bolivia, and Paraguay and in Mexico, Western Europe, and the United States, respectively).

HUMAN AFRICAN TRYPANOSOMIASIS (SLEEPING SICKNESS)

DEFINITION

HAT is a life-threatening illness caused by infection with extracellular protozoan parasites that are transmitted by tsetse flies in sub-Saharan Africa. *T. b. gambiense* and *T. b. rhodesiense* are the two pathogenic subspecies affecting humans; their epidemiologic and clinical features largely differ.

EPIDEMIOLOGY

The geographic range of HAT is restricted to sub-Saharan Africa in line with the distribution of its vector, the tsetse fly (*Glossina* species; **Fig. 234-3**). HAT due to *T. b. gambiense* is endemic in 24 countries of western and central Africa. Between 1999 and 2020, the number of reported cases fell by 98% (from 27,862 to 565) as a result of successful control measures based on systematic screening of populations at

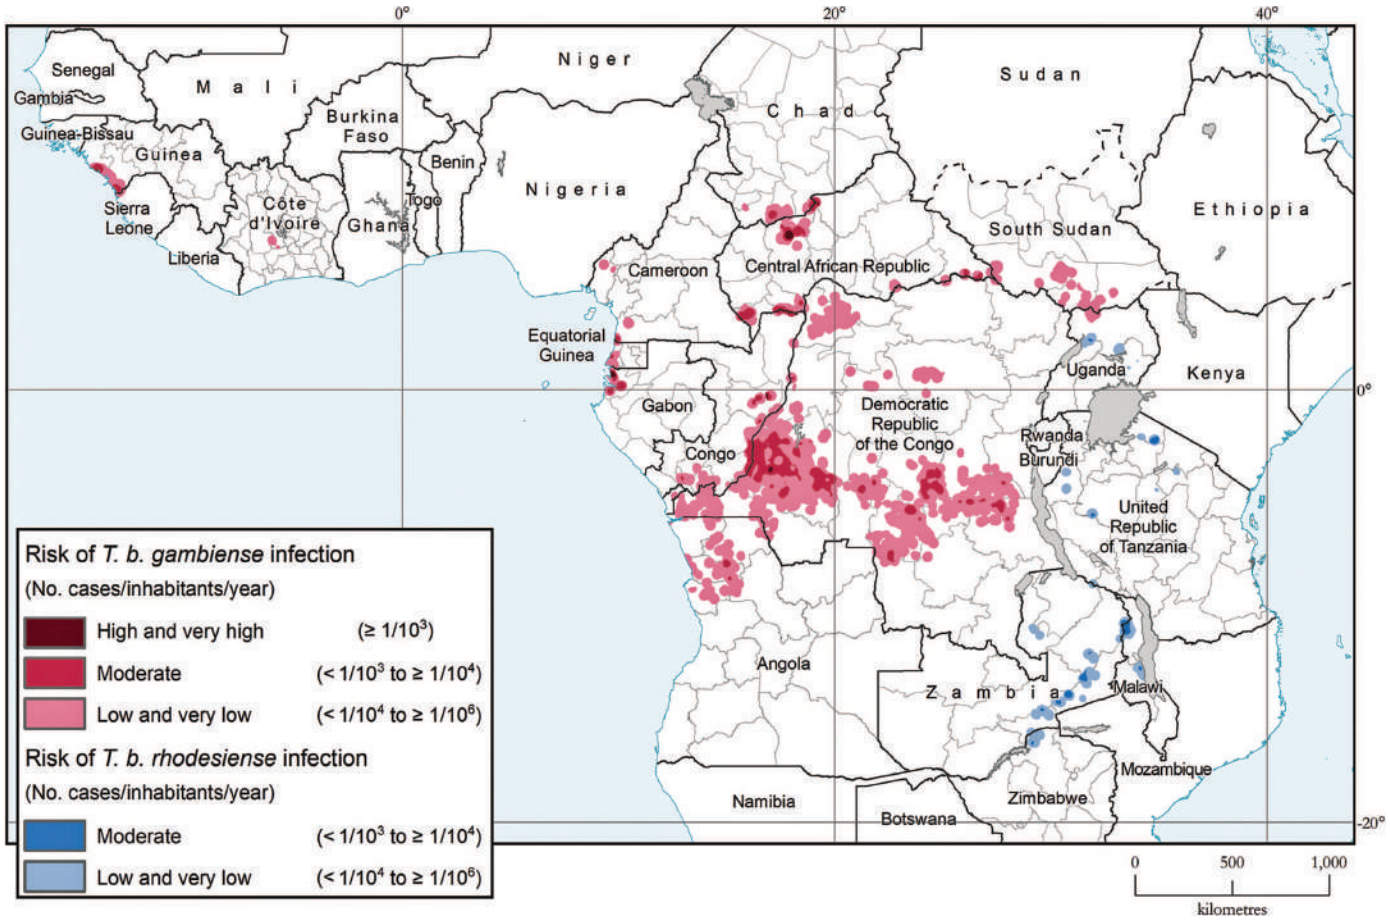

FIGURE 234-3 Areas at risk for human African trypanosomiasis, 2016–2020. *(Reproduced from Franco JR et al: The elimination of human African trypanosomiasis: Achievements in relation to WHO road map targets for 2020. PLoS Negl Trop Dis 2022; 16(1): e0010047, Figure 4.)*

risk, diagnostic confirmation, and treatment of infected individuals. During the same period, the number of reported cases of HAT due to *T. b. rhodesiense* fell by 84% (from 619 to 98) in the 10 disease-endemic countries of eastern and southeastern Africa. However, the ratio of reported to unreported cases remains uncertain for disease caused by both species. In 2020, most cases of *T. b. gambiense* HAT were reported by the Democratic Republic of the Congo (DRC; 70%), whereas Malawi reported most of the cases caused by *T. b. rhodesiense* (91%). The geographic distributions of *T. b. gambiense* and *T. b. rhodesiense* do not overlap, but the two species are present in distinct regions of Uganda. A roadmap for HAT elimination as a public health problem by 2020 was mapped out by the World Health Organization (WHO) with two primary indicators: the number of cases reported annually (target: <2000; reached since 2018) and the area at risk reporting ≥1 case/10,000 people/year (target: reduction of 90% by 2016–2020 compared with the 2000–2004 baseline; 83% reduction reached in 2020). The next goal set by WHO is the global elimination of transmission by 2030.

Humans are the predominant reservoir of *T. b. gambiense*. Rare cases of vertical (in utero) or transfusional transmission have been reported, but almost all patients are infected by the bite of tsetse flies during their daily activities along or near rivers, where the flies live and reproduce. In contrast, *T. b. rhodesiense* causes zoonosis in a variety of wild and domesticated animals (e.g., antelopes and cattle, respectively), which act as reservoirs. Humans are infected by *T. b. rhodesiense* via tsetse bites in woodland savannah. Honey gatherers, game park rangers, poachers, and firewood collectors are particularly at risk. Imported cases of HAT are occasionally diagnosed among African immigrants and other travelers. While long-term travelers (>30 days) are at increased risk of *T. b. gambiense* HAT, most imported cases of *T. b. rhodesiense* HAT are seen in short-term travelers, typically following visits to game parks.

PATHOLOGY AND PATHOGENESIS

T. b. rhodesiense and *T. b. gambiense*, unlike other trypanosome species, can infect humans because they resist lytic factors in human serum—namely, apolipoprotein L-1 (*APOL1*). Human *APOL1* variants are prevalent in individuals of African ancestry, conferring protection against livestock trypanosome species, but at the cost of increasing the likelihood of chronic kidney disease. The serum resistance–associated protein is responsible for resistance in *T. b. rhodesiense*, whereas other mechanisms, notably involving the *T. b. gambiense*–specific glycoprotein (TgsGP) gene, are used by *T. b. gambiense*.

Trypanosomes are transmitted to humans by the tsetse bite, proliferate, and induce a local inflammatory reaction that is sometimes clinically apparent as a chancre. Trypanosomes then disseminate into the hematolymphatic system, with lymph nodes becoming enlarged after infiltration by mononuclear cells and lymphocytes. The degree of enlargement of the liver and spleen is usually mild to moderate, with infiltration by mononuclear cells as a prominent feature. Trypanosomes multiply in the blood, but their presence and density vary. This variation is mainly due to a cyclic immune-evasion process, whereby the parasite population can be decimated by the host's immune response until the reemergence of offspring parasites that express a different variant surface glycoprotein to which the immune system is temporarily blind. Each trypanosome genome encodes a repertoire of ~1000 variant surface glycoproteins between which the parasites can switch genetically. Trypanosomes also multiply in extravascular tissues during the first stage of illness. The skin, skeletal muscles, serous membranes (peritoneum, pleurae, and pericardium), and heart can be involved, with interstitial infiltration of mononuclear cells and vasculitis evident on microscopic examination. Myocarditis and pericarditis with myocardial degeneration and interstitial hemorrhage are common features of *T. b. rhodesiense* infection.

The CNS is invaded weeks to months (*T. b. rhodesiense*) or months to years (*T. b. gambiense*) after initial infection. This invasion corresponds to the second stage of HAT, which is defined by the presence of trypanosomes or mononuclear cells in the cerebrospinal fluid (CSF). The white matter is predominantly affected, with perivascular proliferation of astrocytes, microglial cells, and Mott's (morular) cells that contain IgM in intracellular vacuoles. The location of white-matter lesions in the brain correlates with the main neurologic clinical features. The cerebral cortex and neurons are spared until the terminal stages of illness. Because reversible inflammatory lesions predominate over the irreversible destruction of tissue, neuropsychiatric symptoms and signs resolve partially or completely during or after treatment of second-stage HAT.

APPROACH TO THE PATIENT

Human African Trypanosomiasis

HAT is usually lethal in the absence of treatment. Therefore, early diagnosis is crucial; physicians should include HAT in the differential diagnosis of several clinical syndromes when a patient has traveled or lived in at-risk sub-Saharan African countries, and obtaining a thorough recent and remote travel history from the patient is a prerequisite for diagnosis. In particular, HAT due to *T. b. gambiense* should be suspected in patients with persistent and intermittent fever or headaches, progressive neuropsychiatric disorders, and biologic signs of systemic inflammation, even if the last exposure occurred several years previously. HAT due to *T. b. rhodesiense* should be suspected in patients with an acute febrile illness and a recent exposure to tsetse flies in an eastern African country, especially if diagnostic tests for malaria are negative.

CLINICAL MANIFESTATIONS

The clinical presentations of *T. b. gambiense* and *T. b. rhodesiense* HAT usually differ. *T. b. gambiense* HAT is a slowly evolving illness with a long incubation period (months to years) and a prolonged disease course. In contrast, *T. b. rhodesiense* HAT is an acute febrile illness with a short (<3-week) incubation period and a shorter (weeks to months) disease course. There are exceptions to this classic pattern. Acute forms of *T. b. gambiense* HAT have been reported, especially among travelers, and chronic forms of *T. b. rhodesiense* HAT occur in the southern range of its geographic distribution (e.g., Zambia and Malawi). Trypano-resistance (i.e., self-resolving first-stage infections) and trypano-tolerance (i.e., the long-term persistence of parasites [e.g., in the skin] without clinical features of disease) have been reported for *T. b. gambiense*. Concomitant HIV co-infection does not seem to predispose individuals to an increased risk of HAT, and the impact of the virus on the clinical presentation of HAT is not known.

T. b. gambiense The occurrence of trypanosomal chancre is reported in a sizeable proportion of travelers, but very rarely in patients living in endemic areas, where the nonpurulent, painful, and itchy nodule can easily be confused with a lesion caused by the bite of another arthropod. The chancre spontaneously disappears in 1–3 weeks.

SYSTEMIC FEATURES After an asymptomatic incubation period that usually lasts for weeks or months but occasionally lasts for years, patients may present with irregular and remittent fever, sometimes accompanied by fatigue, malaise, and myalgia. Fever is more frequent among travelers than among natives, but the absence of fever in no way rules out the disease. Circinate or serpiginous rashes, commonly called trypanids, can occur on the trunk and on proximal parts of the extremities. Trypanids are almost impossible to detect on dark skin and have been reported only in Caucasians. Pruritus is a common but nonspecific symptom that affects up to half of patients during the second stage. Painless edema of the face and extremities occasionally occurs during the first phase.

Enlarged lymph nodes—a classic sign of HAT—are detected in 38–85% of patients at both disease stages. Cervical palpation is essential in patients with suspected HAT. The lateroposterior cervical group (Winterbottom sign) and the supraclavicular group are most commonly affected. Lymph nodes are movable, soft initially, harder later, and painless. A variable proportion of patients present with mild to moderate hepatomegaly and splenomegaly. Signs of myocarditis and pericarditis are occasionally detected by ECG and echocardiography but are usually clinically silent. Symptoms of HAT may mimic hypothyroidism or adrenal insufficiency, but thyroid and adrenal function tests yield normal results. Loss of libido, impotence, and amenorrhea, with decreased levels of testosterone and estradiol, are common in second-stage patients and are most likely caused by dysfunction of the hypothalamic–pituitary axis.

NEUROPSYCHIATRIC FEATURES Most patients with second-stage illness have no or only mild specific neuropsychiatric symptoms and signs, which, when they develop, tend to do so late in the disease course. In contrast, some nonspecific features, such as headaches and mood and behavioral changes, are present in both disease stages but become more permanent and severe during the second stage. As mentioned earlier, HAT is commonly called "sleeping sickness" because of various sleep disturbances (daytime somnolence, nocturnal insomnia) that are more pronounced late in the second stage. Dysregulation of the daily sleep/wake cycle and fragmentation of sleeping patterns are characteristic. Depending on the area of the brain affected, various neurologic syndromes also can develop, including disorders that are pyramidal-related (e.g., motor weakness, rare instances of hemiplegia), extrapyramidal-related (e.g., rigidity, paratonia), and cerebellar-related (e.g., ataxia, abnormal gait). Fine tremor, resting myoclonus, and abnormal (athetoid or choreic) movements also have been reported. Mental disorder is a key feature of HAT and can easily be misdiagnosed as primary psychiatric illness. Common presentations are antisocial or aggressive behavior, mood disorders (e.g., irritability, indifference), apathy or hyperactivity, and depression or psychosis (e.g., delirium, hallucinations). In the final stage of illness, decreased consciousness, dementia, and sometimes epilepsy are present, leading to coma, bed sores, aspiration pneumonia, or other bacterial infections and ultimately to death.

T. b. rhodesiense The clinical presentation of *T. b. rhodesiense* HAT can be similar to that of *T. b. gambiense* HAT in areas (e.g., Zambia, Malawi) that characteristically harbor specific parasite genotypes and host factors. The typical acute form with an incubation period of <3 weeks generally occurs in the northern range of the disease's distribution (e.g., Tanzania, Uganda) and in travelers. The initial trypanosomal chancre is clinically similar to that seen in *T. b. gambiense* HAT but is more common, especially among travelers.

SYSTEMIC FEATURES Fever can be high and occurs in both first- and second-stage patients, often in association with headaches and with diffuse myalgia and arthralgia. Pruritus and edema of the face and legs can be present. Lymphadenopathies have been reported in variable proportions in both disease stages and predominately affect the submandibular, axillary, and inguinal regions. Mild to moderate hepatomegaly and splenomegaly are documented in a minority of patients. Myocarditis and pericarditis appear to influence clinical course and outcome, even though clinical features of cardiac failure or arrhythmia have not been prominent findings in large case series. In contrast, conduction abnormalities, with various degrees of atrioventricular block, have been reported in travelers. Sepsis-like features, with disseminated intravascular coagulation and multiple-organ failure, can occur in the terminal stage.

NEUROPSYCHIATRIC FEATURES Neuropsychiatric symptoms and signs in *T. b. rhodesiense* HAT are reported with varying frequency but overall are similar to those described above for *T. b. gambiense* HAT. The notable exception in *T. b. rhodesiense* disease is a more rapid evolution toward coma and death.

DIAGNOSIS

The clinical and biologic features of *T. b. gambiense* and *T. b. rhodesiense* HAT—anemia, thrombocytopenia, elevated levels of C-reactive protein and IgM—are not sufficiently specific, and current drug regimens are not sufficiently practical to allow the initiation of treatment solely on the basis of suspicion. Diagnostic confirmation is therefore required in all patients.

T. b. gambiense The diagnosis of *T. b. gambiense* HAT is based on a three-step approach: screening, diagnostic confirmation, and staging.

SCREENING Immunologic (serologic) methods constitute the preferred screening tool. The card agglutination test for trypanosomiasis (CATT) has been used in most endemic areas for several decades. The test reagent contains stained, freeze-dried trypanosomes of selected variable-antigen types. If specific antibodies are present in the patient's blood or serum, agglutination can be seen with the naked eye. The sensitivity of the CATT on undiluted blood or serum is 69–100% (>90% in most studies), with some regional variation; its specificity is 84–99%. The CATT and associated equipment (e.g., a rotator) are manufactured and distributed by the Institute of Tropical Medicine in Antwerp, Belgium, but are not widely available outside endemic areas. In recent years, lateral flow tests have been developed and commercialized, first based on whole parasites and later on recombinant antigens. Their diagnostic performance is comparable to that of the CATT. Other serologic test formats (ELISA, immunofluorescence, indirect hemagglutination) are available in some reference laboratories in both endemic and nonendemic countries.

DIAGNOSTIC CONFIRMATION The microscopic observation of trypanosomes in the lymph, blood, skin, or CSF confirms the diagnosis. Direct observation of motile trypanosomes on a wet preparation of lymph obtained by cervical lymph node puncture is simple and cheap but has limited sensitivity (50–65% in most studies). Trypanosomes can be found in the blood but often occur at low densities. Therefore, stained thin and thick blood smears have very low sensitivity. Sensitivity is improved (to 40–60% in most studies) with the microhematocrit centrifugation technique, which is based on microscopic examination of the buffy coat after centrifugation of four to six microhematocrit tubes. The most sensitive method (~90%) is the miniature anion-exchange centrifugation technique, which is based on the visualization of trypanosomes in eluate after the passage of a large volume (500 μL) of blood through an anion-exchange column and subsequent centrifugation. Trypanosomes can also be visualized on microscopic examination of skin biopsies, even when parasites have not been visualized in the blood or lymph node.

STAGING Staging is based on the examination of CSF obtained by lumbar puncture. Second-stage HAT is defined by the presence in CSF of a raised leukocyte count (>5/μL) and/or of trypanosomes. The latter can be detected in the cell-counting chamber or, preferably, after centrifugation of the CSF. Staging is no longer an obligatory step in settings where fexinidazole is used as first-line treatment for both first- and second-stage HAT patients, except for young children (<6 years or weighing <20 kg) and for patients with neuropsychiatric symptoms and signs consistent with severe HAT, i.e., mental confusion, abnormal behavior, logorrhea, anxiety, ataxia, tremor, motor weakness, speech impairment, abnormal gait or movements, or seizures (see "Treatment," below).

Several molecular methods based on PCR or loop-mediated isothermal amplification have been developed, mostly based on the detection of multiple-copy DNA targets of the Trypanozoon group (to which *T. brucei* belongs) or the single-copy TgsGP gene of *T. b. gambiense*. None of these methods has been fully validated for diagnostic purposes, and a positive result of their application to blood should be interpreted as suspected rather than confirmed HAT. Molecular methods applied to CSF (to detect biomarkers) have not proved more accurate than classic methods for staging and have yielded false-positive results in a substantial proportion of cases.

T. b. rhodesiense The diagnosis of *T. b. rhodesiense* HAT is usually simpler because parasites are more numerous in body fluids. They can occasionally be visualized in a chancre aspirate. In light of the lack of available serologic tests and the high sensitivity of parasite detection methods in blood, wet mounts, thin/thick smears **(Fig. 234-4)**, and the microhematocrit or other concentration techniques are used for both screening and confirmation. Because the modalities of treatment of *T. b. rhodesiense* are stage dependent, staging remains an obligatory step, and the definition and methods used are the same as for *T. b. gambiense* HAT.

TREATMENT

Human African Trypanosomiasis

The management of HAT is based on general supportive therapy (e.g., rehydration, pain management), treatment of concomitant infections (e.g., malaria, pneumonia), and antiparasitic treatment. The modalities of antitrypanosomal treatment depend on the *Trypanosoma* species, the stage of illness, and the presence of contraindications **(Table 234-4)**.

T. B. GAMBIENSE

Fexinidazole, a nitroimidazole compound, is the first effective oral treatment against HAT. It is administered with food for 10 days, divided into a 4-day loading phase and a 6-day maintenance phase. It is highly effective (>95% cure rate) in patients with first-stage and nonsevere second-stage HAT, the latter being defined as <100 leukocytes/μL in the CSF. Fexinidazole is associated with a lower cure rate (87%) in patients with severe second-stage (≥100 leukocytes/μL in the CSF) HAT. The most relevant adverse reactions reported in clinical trials are vomiting, headache, and neuropsychiatric disorders (e.g., insomnia, anxiety, agitation). Fexinidazole is contraindicated in patients with hepatic insufficiency or at increased risk of QT interval prolongation. In the absence of safety and efficacy data, it remains contraindicated in small children (<6 years and/or weighing <20 kg).

Pentamidine isethionate is highly effective (>95%) against first-stage *T. b. gambiense* HAT and is an excellent alternative to fexinidazole when the latter is contraindicated or not available. It is generally well tolerated and can therefore be administered in peripheral health care centers in endemic countries **(Fig. 234-5)**. Hypotension after injection is common but generally mild. Hypoglycemia or hyperglycemia occasionally occurs, but permanent diabetes is very rare. Severe adverse events, such as acute pancreatitis and anaphylaxis, occur extremely rarely.

Nifurtimox–eflornithine combination therapy is very effective (>95% cure rate) and safe in patients with second-stage HAT, including patients with severe (≥100 leukocytes/μL in the CSF) illness. Common adverse reactions include gastrointestinal disturbances (nausea, vomiting, abdominal pain), headache, anorexia, and reversible bone marrow toxicity (anemia, leukopenia). Convulsions and psychosis are reported in <5% of patients.

Acoziborole, administered orally as a single-dose treatment (three tablets), cured >95% of 208 patients age >15 years with first- and second-stage HAT. Provided that its efficacy and safety is confirmed in a higher number of individuals, acoziborole could become the preferred treatment for *T. b. gambiense* HAT in the future.

TABLE 234-4 Treatment of Human African Trypanosomiasis (HAT)

DISEASE AND STAGE	FIRST-LINE TREATMENT: DRUG(S) AND ROUTE	FIRST-LINE TREATMENT: DOSE AND DURATION	ALTERNATIVE TREATMENT
***T. b. gambiense* HAT**			
First stage	Fexinidazole PO	≥35 kg: 1800 mg for 4 days, followed by 1200 mg for 6 days 20–34 kg: 1200 mg for 4 days, followed by 600 mg for 6 days[a]	Pentamidine isethionate IM or IV[b]: 4 mg/kg per day for 7 days
Nonsevere second stage (6–99 leukocytes/μL in the cerebrospinal fluid [CSF])	Fexinidazole PO	≥35 kg: 1800 mg for 4 days, followed by 1200 mg for 6 days 20–34 kg: 1200 mg for 4 days, followed by 600 mg for 6 days[a]	Eflornithine: 200 mg/kg bid for 7 days *plus* Nifurtimox: 5 mg/kg tid for 10 days
Severe second stage (≥100 leukocytes/μL in the CSF)	Eflornithine IV + nifurtimox PO	Eflornithine: 200 mg/kg bid for 7 days Nifurtimox: 5 mg/kg tid for 10 days	Fexinidazole: ≥35 kg: 1800 mg for 4 days, followed by 1200 mg for 6 days 20–34 kg: 1200 mg for 4 days, followed by 600 mg for 6 days[a]
***T. b. rhodesiense* HAT**			
First stage	Suramin IV	4–5 mg/kg on day 1 followed by 5 weekly injections of 20 mg/kg (e.g., days 3, 10, 17, 24, 31)[c]	Pentamidine isethionate IM or IV[b]: 4 mg/kg per day for 7 days
Second stage	Melarsoprol IV	2.2 mg/kg per day for 10 days	—

[a]Fexinidazole should not be administered in children <6 years and weighing <20 kg. [b]For IV administration, slow infusion (60–120 min) should be used. [c]The maximal dose is 1 g per injection; the drug should be diluted in distilled water.

T. B. RHODESIENSE

Suramin has been used for >90 years and remains the first-line treatment for first-stage *T. b. rhodesiense* HAT. Common adverse events are pyrexia and nephrotoxicity, which is usually mild and reversible but necessitates surveillance of albuminuria and renal function before each dose.

Because eflornithine is ineffective against *T. b. rhodesiense*, melarsoprol, an arsenic-based derivative, remains in use for second-stage *T. b. rhodesiense* HAT. Reactive encephalopathy is a life-threatening adverse event that occurs in 5–18% of patients, with an associated mortality rate of 10–70%. The efficacy of concomitant high-dose prednisolone to prevent reactive encephalopathy in patients with *T. b. rhodesiense* HAT is not known. Other severe but less frequent adverse reactions to melarsoprol include exfoliative dermatitis, bloody diarrhea, peripheral neuropathy, renal dysfunction, and liver toxicity. Phlebitis is common, as is soft tissue necrosis if the drug is accidentally given paravenously.

The 10-day fexinidazole oral treatment regimen (see above for *T. b. gambiense* HAT) was recently studied as an alternative to suramin and melarsoprol in Malawi and Uganda. Fexinidazole was administered in 45 patients with first-stage (n = 10) and second-stage (n = 35) patients and cured 43 (96%).

FIGURE 234-5 Intramuscular injection of pentamidine by a nurse in a village health center, Province Orientale, Democratic Republic of the Congo.

PROGNOSIS

Provided that treatment guidelines are properly followed, >95% of patients with first-stage and second-stage *T. b. gambiense* HAT are definitively cured with fexinidazole, pentamidine, and nifurtimox–eflornithine combination therapy. The overall case–fatality rate is <1% except in very advanced cases. Because relapses can occur long after completion of treatment, follow-up visits are advised every 6 months for at least 2 years. If clinical features of HAT are present, both blood and CSF examinations are indicated. Patients with second-stage *T. b. rhodesiense* HAT are at a 5–10% risk of dying during or after melarsoprol treatment, but relapses are very rare.

GLOBAL CONSIDERATIONS

The elimination of sleeping sickness as a public health problem has been achieved, thanks to increased control activities run by national control programs and nongovernmental medical organizations, improved funding, and the end of several civil wars (e.g., in Angola) in the past 20 years. Funding for research, development, and implementation of improved diagnostic (e.g., rapid diagnostic tests), therapeutic (e.g., oral drugs), and vector control tools remains crucial to sustain recent achievements and to move on to the next objective, i.e., the global elimination of transmission by 2030.

235 *Toxoplasma* Infections

Kami Kim

DEFINITION

Toxoplasmosis is caused by infection with the obligate intracellular parasite *Toxoplasma gondii*. Acute infection acquired after birth is typically asymptomatic, but some immunocompetent individuals can present with systemic or ocular disease. Acute infection is thought to result in the lifelong chronic persistence of cysts in the host's tissues. The classic presentation of toxoplasmosis is encephalitis in immunocompromised individuals (especially HIV-positive individuals or transplant recipients) in whom latent infection has reactivated. Among the clinical manifestations of the disease are lymphadenopathy, encephalitis, myocarditis, pneumonitis, and retinitis. Congenital toxoplasmosis is an infection of newborns that results from the transplacental passage of parasites from an infected mother to the fetus. These infants may be asymptomatic at birth, but many children later manifest signs and symptoms, including chorioretinitis, strabismus, epilepsy, and psychomotor retardation. Toxoplasmosis can also present as acute disease (typically chorioretinitis) associated with food- or waterborne sources.

ETIOLOGY

T. gondii is an intracellular coccidian that infects both birds and mammals. Up to a third of the world's population is thought to be infected latently with this organism. There are two distinct stages in the life cycle that are transmissible to humans **(Fig. 235-1)**. Tissue cysts that contain bradyzoites are transmitted in undercooked meat. After an intermediate host (e.g., a human, mouse, sheep, pig) ingests the cyst, it is rapidly digested by the acidic-pH gastric secretions. Sporulated oocysts that contain sporozoites are products of the sexual cycle in feline intestines and acquired by ingestion of food or water contaminated with infected cat feces. Bradyzoites or sporozoites are released, enter the intestinal epithelium, and transform into rapidly dividing tachyzoites. The tachyzoites can infect and replicate in all mammalian cells except red blood cells. The parasite actively penetrates the cell and forms a parasitophorous vacuole. Parasite replication continues within the vacuole. After the parasites reach a critical mass, intracellular signaling within the host and the parasite results in parasite egress from the vacuole. The host cell is destroyed, and the released tachyzoites infect adjoining cells. Parasites can disseminate throughout the body as free tachyzoites or within phagocytic cells in the bloodstream or via lymphatics. Tachyzoites actively invade host cells and can cross epithelial and endothelial barriers.

The tachyzoite replication cycle within an infected organ causes cytopathology and clinical symptoms. Most tachyzoites are eliminated by the host's humoral and cell-mediated immune responses. Tissue cysts containing bradyzoites develop 7–10 days after systemic tachyzoite infection. These tissue cysts occur in various host organs but persist principally within the central nervous system (CNS) and muscle. The development of this chronic stage completes the asexual portion of the life cycle. Active infection in the immunocompromised host is usually due to the spontaneous release of encysted parasites that undergo rapid transformation into tachyzoites within the CNS that cannot be contained by the immune system.

The *sexual* stage in the life cycle takes place in the cat (the definitive host) and is defined by the formation of oocysts within the feline host intestine. This enteroepithelial cycle begins with the ingestion of the bradyzoite tissue cysts and, after several intermediate stages, culminates in the production of gametes. Gamete fusion produces a zygote, which envelops itself in a rigid wall and is secreted in the feces as an unsporulated oocyst. After 2–3 days of exposure to air at ambient temperature, the noninfectious oocyst sporulates to produce eight sporozoite progeny. The sporulated oocyst can be ingested by an intermediate host. It is in the intermediate host that *T. gondii* completes its life cycle.

Sporulated oocysts are environmentally hardy and very infectious; they are thought to be sources of waterborne outbreaks such as those reported in Victoria (British Columbia, Canada) and in South America. In the Northern Hemisphere, *T. gondii* strains are predominantly of three genotypes. Strains found in South and Central America are more virulent than those from the Northern Hemisphere, are frequently of the type I virulent genotype or atypical genotypes, and are more likely to be associated with symptomatic disease, usually ocular posterior uveitis. Ocular toxoplasmosis should be considered in a person from Central or South America with ocular symptoms and retinal abnormalities. Severe disease, including sepsis, fever of unknown origin, and pneumonia, has been reported and should be considered in a patient with travel history to South or Central America. There have been reports of outbreaks in North America among individuals who have ingested undercooked game, especially venison, and these strains appear more virulent as the attack rate is often high. Prevalence of *T. gondii* in Africa suggests *T. gondii* infection is common and that some strains may also be quite virulent.

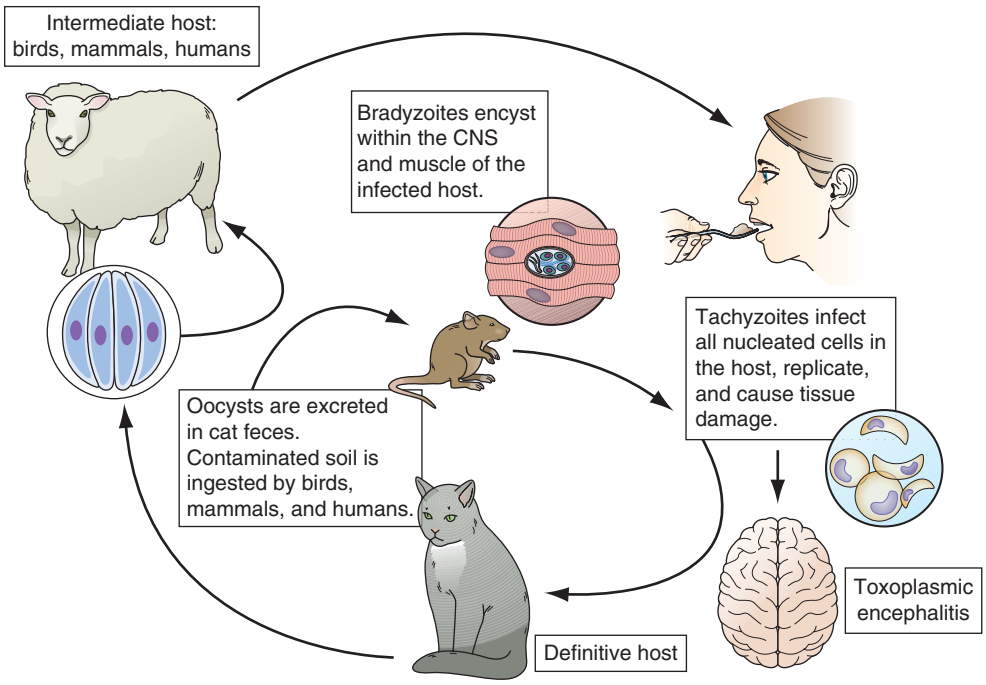

FIGURE 235-1 Life cycle of *Toxoplasma gondii*. The cat is the definitive host in which the sexual phase of the cycle is completed. Oocysts shed in cat feces can infect a wide range of animals, including birds, rodents, grazing domestic animals, and humans. The bradyzoites found in the muscle of food animals may infect humans who eat insufficiently cooked meat products, particularly lamb and pork. Although human disease can take many forms, congenital infection and encephalitis from reactivation of latent infection in the brains of immunosuppressed persons are the most important manifestations. CNS, central nervous system. *(Courtesy of Dominique Buzoni-Gatel, Institut Pasteur, Paris.)*

EPIDEMIOLOGY

T. gondii infects a wide range of mammals and birds. Its seroprevalence depends on the locale and the age of the population. Generally, hot arid climatic conditions are associated with a low prevalence of infection. In the United States and most European

countries, the seroprevalence increases with age and exposure. In the United States, seroprevalence has steadily decreased, with 11% of individuals >6 years old having serologic evidence of *Toxoplasma* exposure in a 2011–2014 survey, with foreign-born Americans having a higher rate of seroprevalence. In most other regions of the world, the seroprevalence is higher, with a seroprevalence as high as 78% reported in Brazil. Because of increased awareness of foodborne infections, the prevalence of seropositivity has decreased worldwide over the past two decades, although it remains very high in Central and South America.

TRANSMISSION

Oral Transmission Most cases of human *Toxoplasma* infection are thought to be acquired by the oral route. Transmission can be attributable to ingestion of sporulated oocysts from contaminated soil, food, or water. During acute feline infection, a cat may excrete as many as 100 million oocysts per day. These sporozoite-containing oocysts are highly infectious and may remain viable for many years in soil or water. Humans infected during an oocyst-transmitted infection develop stage-specific antibodies to the oocyst/sporozoite.

Children and adults also acquire infection from tissue cysts containing bradyzoites. Undercooking or insufficient freezing of meat is an important source of infection in the developed world. Toxoplasmosis has been associated with eating raw or undercooked food including ground beef, lamb, or venison or drinking unpasteurized goat milk. More recent epidemiologic studies have associated acute infections with ingestion of untreated water or shellfish (oysters, mussels, and clams).

Transmission via Blood or Organs In addition to being transmitted orally, *T. gondii* can be transmitted directly from a seropositive donor to a seronegative recipient in a transplanted heart, heart–lung, kidney, liver, or pancreas. Viable parasites can be cultured from refrigerated anticoagulated blood, which may be a source of infection in individuals receiving blood transfusions. *T. gondii* reactivation has been reported in bone marrow, hematopoietic stem cell, and liver transplant recipients as well as in individuals with AIDS. Finally, laboratory personnel can be infected after contact with contaminated needles or glassware or with infected tissue.

Transplacental Transmission On average, about one-third of all women who acquire infection with *T. gondii* during pregnancy transmit the parasite to the fetus; the remainder give birth to normal, uninfected babies. Of the various factors that influence fetal outcome, gestational age at the time of infection is the most critical (see below). Recrudescent maternal infection is rarely the source of congenital disease, although rare cases of transmission by immunocompromised women (e.g., those infected with HIV or those receiving high-dose glucocorticoids) have been reported. Thus, women who are seropositive before pregnancy usually are protected against acute infection and do not give birth to congenitally infected neonates.

There is essentially no risk for congenital infection if the mother becomes infected ≥6 months before conception. If infection is acquired <6 months before conception, the likelihood of transplacental infection increases as the interval between infection and conception decreases. Women with documented acute toxoplasmosis should be counseled to use appropriate measures to prevent pregnancy for 6 months after infection. In pregnancy, if the mother becomes infected during the first trimester, the incidence of transplacental infection is lowest (~15%), but the disease in the neonate is most severe. If maternal infection occurs during the third trimester, the incidence of transplacental infection is greatest (65%), but the infant is usually asymptomatic at birth. Infected infants who are normal at birth may have a higher incidence of learning disabilities and chronic neurologic sequelae than uninfected children. Only a small proportion (20%) of women infected with *T. gondii* develop clinical signs of infection. Often the diagnosis is first appreciated when routine postconception serologic tests show evidence of specific antibody. Chronic toxoplasmosis has not been thought to affect pregnancy, but there have been recent studies suggesting a greater incidence of adverse pregnancy outcomes without evidence of reactivated toxoplasmosis. The lingering effects of chronic infection are controversial (see below) and an area of ongoing investigation.

PATHOGENESIS

Upon the host's ingestion of either tissue cysts containing bradyzoites or oocysts containing sporozoites, the parasites are released from the cysts by the digestive process. Bradyzoites are resistant to the effect of pepsin and invade the host's gastrointestinal tract. Within enterocytes (or other gut-associated cells), the parasites undergo morphologic transformation, giving rise to invasive tachyzoites. From the gastrointestinal tract, parasites disseminate to a variety of organs, particularly lymphatic tissue, skeletal muscle, myocardium, retina, placenta, and the CNS. At these sites, the parasite infects host cells, replicates, and invades the adjoining cells. In this fashion, the hallmarks of the infection develop: cell death and focal necrosis surrounded by an acute inflammatory response.

In the immunocompetent host, both the humoral and the cellular immune responses control infection; parasite virulence and tissue tropism may be strain specific. Tachyzoites are sequestered by a variety of immune mechanisms, including induction of parasiticidal antibody, activation of macrophages with radical intermediates, production of interferon γ (IFN-γ), and stimulation of CD8+ cytotoxic T lymphocytes. These antigen-specific lymphocytes are capable of killing both extracellular parasites and target cells infected with parasites. As tachyzoites are cleared from the acutely infected host, tissue cysts containing bradyzoites begin to appear, usually within the CNS, skeletal muscle, and the retina. *Toxoplasma* secretes signaling molecules into infected host cells, and these molecules modulate host gene expression, host metabolism, and host immune response. It was initially thought that cysts with bradyzoites are not eliminated by the immune system, but more recent studies in the murine model indicate that both CD8+ T cells and alternatively activated macrophages are able to kill cysts in vivo. The ability to eliminate cysts may depend on the genetic background of the infected host as well as the parasite genotype that initially infected the host.

Immunocompromised or fetal hosts lack the immune factors necessary to control the spread of tachyzoite infection. This altered immune state allows the persistence of tachyzoites and gives rise to progressive focal destruction in affected organs (i.e., necrotizing encephalitis, pneumonia, and myocarditis).

It is thought that all infected individuals have persistent infection with cysts containing bradyzoites with lifelong infection remaining subclinical. Although bradyzoites are in a slow metabolic phase, bradyzoites can replicate, and cysts do rupture within the CNS. These subclinical cycles of cyst ruptures followed by development of new bradyzoite-containing cysts are the probable source of recrudescent infection in immunocompromised individuals and the most likely stimulus for the persistence of antibody titers in the immunocompetent host.

The persistence of toxoplasmosis has been hypothesized to be a contributing factor to a variety of neuropsychiatric conditions, including schizophrenia and bipolar disease, but the contribution of chronic toxoplasmosis to human disease remains controversial. In rodents, chronic *T. gondii* infection has significant effects on behavior, increasing predation. Epidemiologic studies such as the National Health and Nutrition Examination Survey (NHANES) study show a correlation between *T. gondii* seropositivity and a number of chronic diseases, including diabetes and cognitive dysfunction.

PATHOLOGY

Cell death and focal necrosis due to replicating tachyzoites induce an intense mononuclear inflammatory response in any tissue or cell type infected. Tachyzoites rarely can be visualized by routine histopathologic staining of these inflammatory lesions. However, immunofluorescent staining with parasitic antigen–specific antibodies can reveal the organism. In contrast to the inflammatory process caused by tachyzoites, bradyzoite-containing cysts cause inflammation only at the early stages of development. Once the cysts reach maturity, the inflammatory process is blunted, and the cysts remain relatively immunologically quiescent within the brain matrix until they rupture.

Lymph Nodes During acute infection, lymph node biopsy demonstrates characteristic findings, including follicular hyperplasia and irregular clusters of tissue macrophages with eosinophilic cytoplasm. Granulomas rarely are evident in these specimens. Although tachyzoites are not usually visible, parasites can be demonstrated by subinoculation of infected tissue into mice, with resultant disease, or by PCR. PCR amplification of DNA fragments of *Toxoplasma* genes is effective and sensitive in establishing lymph node infection by tachyzoites.

Eyes In the eye, infiltrates of monocytes, lymphocytes, and plasma cells may produce uni- or multifocal lesions. Granulomatous lesions and retinochoroiditis can be observed in the posterior chamber after acute necrotizing retinitis. Other ocular complications include iridocyclitis, cataracts, and glaucoma. *T. gondii* is the most common cause of posterior uveitis in immunocompetent individuals and ocular toxoplasmosis is a common clinical presentation in outbreaks.

Central Nervous System During CNS involvement, both focal and diffuse meningoencephalitis can be documented, with evidence of necrosis and microglial nodules. Necrotizing encephalitis in patients without AIDS is characterized by small diffuse lesions with perivascular cuffing in contiguous areas. In the AIDS population, polymorphonuclear leukocytes may be present in addition to monocytes, lymphocytes, and plasma cells. Cysts containing bradyzoites frequently are found contiguous with the necrotic tissue border. As a consequence of antiretroviral therapy (ART) for AIDS, the incidence of toxoplasmosis has decreased in the developed world. The incidence of toxoplasmosis in underresourced settings is not known due to lack of diagnostic infrastructure but is likely to be higher than in the United States, particularly in regions of the world with populations with large numbers of untreated patients living with HIV.

Lungs and Heart Among patients with AIDS who die of toxoplasmosis, 40–70% have involvement of the lungs and heart. Interstitial pneumonitis can develop in neonates and immunocompromised patients and rarely in immunocompetent individuals. Thickened and edematous alveolar septa infiltrated with mononuclear and plasma cells are apparent. This inflammation may extend to the endothelial walls. Tachyzoites and bradyzoite-containing cysts have been observed within the alveolar membrane. Superimposed bronchopneumonia can be caused by other microbial agents. Cysts and aggregates of parasites in cardiac muscle tissue are evident in patients with AIDS who die of toxoplasmosis. Focal necrosis surrounded by inflammatory cells is associated with hyaline necrosis and disrupted myocardial cells. Pericarditis is associated with toxoplasmosis in some patients.

Gastrointestinal Tract Rare cases of human gastrointestinal tract infection with *T. gondii* have presented as ulcerations in the mucosa. Acute infection in certain strains of inbred mice (C57BL/6) results in lethal ileitis within 7–9 days. This inflammatory bowel disease has been recognized in several other mammalian species, including pigs and nonhuman primates.

Other Sites Pathologic changes during disseminated infection are similar to those described for the lymph nodes, eyes, and CNS. In patients with AIDS, the skeletal muscle, pancreas, stomach, and kidneys can be involved, with necrosis, invasion by inflammatory cells, and (rarely) tachyzoites detectable by routine staining. Large necrotic lesions may cause direct tissue destruction. In addition, secondary effects from acute infection of these various organs, including pancreatitis, myositis, and glomerulonephritis, have been reported.

HOST IMMUNE RESPONSE

Acute *Toxoplasma* infection evokes a cascade of protective immune responses in the immunocompetent host. *Toxoplasma* enters the host at the gut mucosal level and evokes a mucosal immune response that includes the production of antigen-specific secretory IgA. Titers of serum IgA antibody directed at the tachyzoite surface antigen p30/SAG1 are a useful marker for congenital and acute toxoplasmosis.

Within the host, *T. gondii* rapidly induces detectable levels of both IgM and IgG serum antibodies. Monoclonal gammopathy of the IgG class can occur in congenitally infected infants. IgM levels may be increased in newborns with congenital infection. The polyclonal IgG antibodies evoked by infection are parasiticidal in vitro in the presence of serum complement and are the basis for the Sabin-Feldman dye test. However, cell-mediated immunity is the major protective response evoked by the parasite during host infection. Macrophages are activated after phagocytosis of antibody-opsonized parasites. If the parasite is not phagocytosed and enters the macrophage, monocytes, or dendritic cells by active penetration, these "Trojan horses" represent a mechanism for transport and dissemination to distant organs. *Toxoplasma* stimulates a robust interleukin (IL) 12 response by human dendritic cells.

The CD4+ and CD8+ T-cell responses are antigen-specific and further stimulate the production of a variety of important lymphokines that expand the T-cell and natural killer cell repertoire. *T. gondii* is a potent inducer of a T_H1 phenotype, with IL-12 and IFN-γ playing an essential role in the control of the parasites' growth in the host. Regulation of the inflammatory response is at least partially under the control of a T_H2 response that includes the production of IL-4 and IL-10 in seropositive individuals. Human T-cell clones of both the CD4+ and the CD8+ phenotypes are cytolytic against parasite-infected macrophages. These T-cell clones produce cytokines that are "microbistatic." IL-18, IL-7, and IL-15 upregulate the production of IFN-γ and may be important during acute and chronic infection. The effect of IFN-γ may be paradoxical, with stimulation of a host downregulatory response as well.

Although *T. gondii* infection is believed to be recrudescent in patients with AIDS or other immunocompromised states, antibody titers are not useful in establishing reactivation or in following the activity of infection. An absence of positive serologies suggests an alternative diagnosis, although AIDS patients may have borderline positive or low serologies and transplant patients treated with immunosuppressive agents including those specific for B cells may become seronegative. T cells from AIDS patients with reactivation of toxoplasmosis fail to secrete both IFN-γ and IL-2. This alteration in the production of these critical immune cytokines contributes to the persistence of infection. *Toxoplasma* infection develops late in the course of AIDS (CD4+ count <100/μL), when the loss of T cell–dependent protective mechanisms, particularly CD8+ T cells, becomes most pronounced.

CLINICAL MANIFESTATIONS

In persons whose immune systems are intact, acute toxoplasmosis is usually asymptomatic and self-limited. This condition can go unrecognized in 80–90% of adults and children with acquired infection. The asymptomatic nature of this infection makes diagnosis difficult in mothers infected during pregnancy. In contrast, the wide range of clinical manifestations in congenitally infected children includes severe neurologic complications such as hydrocephalus, microcephaly, intellectual disability, and chorioretinitis. If prenatal infection is severe, multiorgan failure and subsequent intrauterine fetal death can occur. In children and adults, chronic infection can persist throughout life, with little consequence to the immunocompetent host.

Toxoplasmosis in Immunocompetent Patients The most common manifestation of acute toxoplasmosis is cervical lymphadenopathy. The nodes may be single or multiple, are usually nontender, are discrete, and vary in firmness. Lymphadenopathy also may be found in suboccipital, supraclavicular, inguinal, and mediastinal areas. Generalized lymphadenopathy occurs in 20–30% of symptomatic patients. Between 20 and 40% of patients with lymphadenopathy also have headache, malaise, fatigue, and fever (usually with a temperature of <40°C [<104°F]). A smaller proportion of symptomatic individuals have myalgia, sore throat, abdominal pain, maculopapular rash, meningoencephalitis, and confusion.

Rare complications associated with infection in the normal immune host include pneumonia, myocarditis, encephalopathy, pericarditis, and polymyositis. These manifestations are often associated with more virulent parasitic genotypes/strains. Signs and symptoms associated with acute infection usually resolve within several weeks, although

the lymphadenopathy may persist for some months. In one epidemic, toxoplasmosis was diagnosed correctly in only 3 of the 25 patients who consulted physicians. If toxoplasmosis is considered in the differential diagnosis, routine laboratory and serologic screening should precede node biopsy.

In North America and Europe, there are three predominant genotypes, but strains are more genetically diverse in Central and South America. Genotypes of *T. gondii* prevalent in South America are more virulent than those typically seen in North America or Europe. These genotypes may be associated with acute or recurrent ocular disease in immunocompetent individuals and have also been associated with pneumonitis and a fulminant sepsis picture in immunologically normal individuals. Thus, a detailed history, particularly regarding travel and countries of residence, is critical for establishing a diagnosis. Individuals from South or Central America may have frequent recurrences of ocular toxoplasmosis that may require treatment and suppressive therapy.

The results of routine laboratory studies are usually unremarkable except for minimal lymphocytosis, an elevated erythrocyte sedimentation rate, and a nominal increase in serum aminotransferase levels. Evaluation of cerebrospinal fluid (CSF) in cases with evidence of encephalopathy or meningoencephalitis shows an elevation of intracranial pressure, mononuclear pleocytosis (10–50 cells/mL), a slight increase in protein concentration, and (occasionally) an increase in the gamma globulin level. PCR amplification of the *Toxoplasma* DNA target sequence in CSF is specific for active toxoplasmosis, but not sensitive. PCR of ocular fluid or bronchoalveolar lavage may also be positive in those with ocular or pulmonary toxoplasmosis, respectively. The CSF of chronically infected individuals is normal.

Infection of Immunocompromised Patients Patients with AIDS, transplant patients, and those receiving immunosuppressive therapy for lymphoproliferative disorders are at greatest risk for developing acute toxoplasmosis. Toxoplasmosis has also been reported after treatment with antibodies to tumor necrosis factor. The infection may be due either to reactivation of latent infection or to acquisition of parasites from exogenous sources such as blood or transplanted organs. In individuals with AIDS, >95% of cases of *Toxoplasma* encephalitis (TE) are believed to be due to recrudescent infection. In most of these cases, encephalitis develops when the CD4+ T-cell count falls below 100/μL. In immunocompromised hosts, the disease may be rapidly fatal if untreated. Thus, accurate diagnosis and initiation of appropriate therapy are necessary to prevent fulminant infection.

Toxoplasmosis is a principal opportunistic infection of the CNS in persons with AIDS. Individuals with AIDS who are seropositive for *T. gondii* are at high risk for encephalitis. Before the advent of highly effective ART, about one-third of the 15–40% of adult AIDS patients in the United States who were latently infected with *T. gondii* developed TE. TE may still be a presenting infection in individuals who are unaware of their positive HIV status.

Individuals may be at relatively high risk for reactivation after allogeneic hematopoietic stem cell transplantation (HSCT), particularly if complicated by graft-versus-host reaction. Weekly PCR screening of blood from patients seropositive prior to HSCT is recommended, although not all centers routinely monitor HSCT patients for toxoplasmosis. Screening *Toxoplasma* serologies (donor and recipient) before transplantation identifies patients potentially at risk for reactivated toxoplasmosis. Serologies should be performed prior to initiation of immunosuppressive agents.

The signs and symptoms of acute toxoplasmosis in immunocompromised patients principally involve the CNS **(Fig. 235-2)**. More than 50% of patients with clinical manifestations have intracerebral involvement. Clinical findings at presentation range from nonfocal to focal dysfunction. CNS findings include encephalopathy, meningoencephalitis, and mass lesions. Patients may present with altered mental status (75%), fever (10–72%), seizures (33%), headaches (56%), and focal neurologic findings (60%), including motor deficits, cranial nerve palsies, movement disorders, dysmetria, visual-field loss, and aphasia. Patients who present with evidence of diffuse cortical dysfunction develop evidence of focal neurologic disease as infection progresses. This altered condition is due not only to the necrotizing encephalitis caused by direct invasion by the parasite but also to secondary effects, including vasculitis, edema, and hemorrhage. The onset of infection can range from an insidious process over several weeks to an acute presentation with fulminant focal deficits, including hemiparesis, hemiplegia, visual-field defects, localized headache, and focal seizures.

Although lesions can occur anywhere in the CNS, the areas most often involved appear to be the brainstem, basal ganglia, pituitary gland, and corticomedullary junction. Brainstem involvement gives rise to a variety of neurologic dysfunctions, including cranial nerve palsy, dysmetria, and ataxia. With basal ganglion infection, patients may develop hydrocephalus, choreiform movements, and choreoathetosis. *Toxoplasma* usually causes encephalitis, and meningeal involvement is uncommon. CSF findings may be unremarkable or may include a modest increase in cell count and in protein—but not glucose—concentration.

Cerebral toxoplasmosis must be differentiated from other opportunistic infections or tumors in the CNS of AIDS patients. The differential diagnosis includes herpes simplex encephalitis, cryptococcal meningitis, progressive multifocal leukoencephalopathy, and primary CNS lymphoma. Involvement of the pituitary gland can give rise to panhypopituitarism and hyponatremia from inappropriate secretion of vasopressin (antidiuretic hormone). HIV-associated neurocognitive disorder (HAND) may present as cognitive impairment, attention loss, and altered memory. Brain biopsy in patients who have been treated for TE but who continue to exhibit neurologic dysfunction often fails to identify organisms.

Autopsies of *Toxoplasma*-infected patients have demonstrated the involvement of multiple organs, including the lungs, gastrointestinal tract, pancreas, skin, eyes, heart, and liver. *Toxoplasma* pneumonia can be confused with *Pneumocystis* pneumonia. Respiratory involvement usually presents as dyspnea, fever, and a nonproductive cough and may rapidly progress to acute respiratory failure with hemoptysis, metabolic acidosis, hypotension, and (occasionally) disseminated intravascular coagulation. Histopathologic studies demonstrate necrosis and a mixed cellular infiltrate. The presence of organisms is a helpful diagnostic indicator, but organisms can also be found in healthy tissue. Infection of the heart is usually asymptomatic but can be associated with cardiac tamponade or biventricular failure. Infections of the gastrointestinal tract and the liver have been documented.

Congenital Toxoplasmosis Between 400 and 4000 infants born each year in the United States are affected by congenital toxoplasmosis. Acute infection in mothers acquiring *T. gondii* during pregnancy is usually asymptomatic; most women are diagnosed via prenatal serologic screening. Infection of the placenta leads to hematogenous

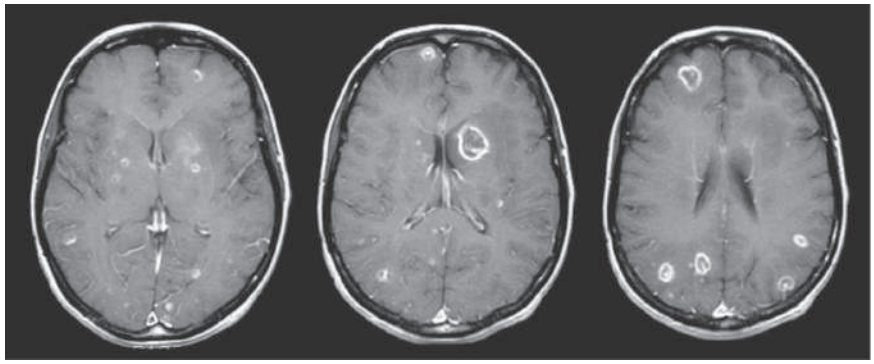

FIGURE 235-2 Toxoplasmic encephalitis in a 36-year-old patient with AIDS. The multiple lesions are demonstrated by magnetic resonance imaging scanning (T1-weighted with gadolinium enhancement). *(Courtesy of Clifford Eskey, Dartmouth Hitchcock Medical Center, Hanover, NH; with permission.)*

infection of the fetus. As gestation proceeds, the proportion of fetuses that become infected increases, but the clinical severity of the infection declines. Although infected children may initially be asymptomatic, the persistence of *T. gondii* can result in reactivation and clinical disease—most frequently chorioretinitis—decades later. Factors associated with relatively severe disabilities include delays in diagnosis and in initiation of therapy, neonatal hypoxia and hypoglycemia, profound visual impairment (see "Ocular Infection," below), uncorrected hydrocephalus, and increased intracranial pressure. If treated appropriately, upward of 70% of children have normal developmental, neurologic, and ophthalmologic findings at follow-up evaluations. Treatment for 1 year with pyrimethamine, a sulfonamide, and folinic acid is tolerated with minimal toxicity (see "Treatment," below).

Ocular Infection Infection with *T. gondii* is estimated to cause 35% of all cases of chorioretinitis in the United States and Europe. It was formerly thought that the majority of cases of ocular disease were due to congenital infection. Ocular toxoplasmosis in immunocompetent individuals occurs more commonly than was previously appreciated and has been associated with outbreaks traced to oocyst contamination of soil or water in Victoria (British Columbia) and in South America. Outbreaks have also been reported in North America after ingestion of undercooked venison.

A variety of ocular manifestations are documented, including blurred vision, scotoma, photophobia, and eye pain. Macular involvement occurs, with loss of central vision, and nystagmus is secondary to poor fixation. Involvement of the extraocular muscles may lead to disorders of convergence and to strabismus. Ophthalmologic examination should be undertaken in newborns with suspected congenital infection. As the inflammation resolves, vision improves, but episodic flare-ups of chorioretinitis, which progressively destroy retinal tissue and lead to glaucoma, are common. The ophthalmologic examination reveals yellow-white, cotton-like patches with indistinct margins of hyperemia. As the lesions age, white plaques with distinct borders and black spots within the retinal pigment become more apparent. Lesions usually are located near the posterior pole of the retina; they may be single but are more commonly multiple. Congenital lesions may be unilateral or bilateral and show evidence of massive chorioretinal degeneration with extensive fibrosis. Surrounding these areas of involvement are a normal retina and vasculature. In patients with AIDS, retinal lesions are often large, with diffuse retinal necrosis, and include both free tachyzoites and cysts containing bradyzoites. Toxoplasmic chorioretinitis may be a prodrome to the development of encephalitis.

TABLE 235-1 Differential Laboratory Diagnosis of Toxoplasmosis

CLINICAL SETTING	ALTERNATIVE DIAGNOSIS	DISTINGUISHING CHARACTERISTICS
Mononucleosis syndrome	Epstein-Barr virus infection	Serology/PCR
	Cytomegalovirus infection	PCR/viral load/serology
	HIV infection	Serology/antigen/viral load
	Bartonella infection (cat-scratch disease)	Biopsy (PCR or culture)/serology
	Lymphoma	Biopsy
Congenital infection	Cytomegalovirus infection	PCR
	Herpes simplex virus infection	PCR
	Rubella virus infection	Serology
	Syphilis	Serology
	Listeriosis	Bacterial culture
Chorioretinitis in immunocompetent individual	Tuberculosis	Bacterial culture/PCR
	Syphilis	Serology
	Histoplasmosis	Serology/culture/antigen
Chorioretinitis in AIDS patient	Cytomegalovirus infection	Characteristic exam
	Syphilis	Serology
	Herpes simplex virus infection	PCR
	Varicella-zoster virus infection	PCR
	Fungal infection	PCR/culture
CNS lesions in AIDS patient	Lymphoma or metastatic tumor	Tissue biopsy
	Brain abscess	Culture/biopsy
	Progressive multifocal leukoencephalopathy	PCR for JC virus
	Fungal infection	Antigen/PCR/biopsy/culture
	Mycobacterial infection	PCR/biopsy/culture

Abbreviations: CNS, central nervous system; PCR, polymerase chain reaction.

DIAGNOSIS

Tissue and Body Fluids The differential diagnosis of acute toxoplasmosis can be made by appropriate culture, serologic testing, and PCR (Table 235-1). PCR is the mainstay for detection of organisms in tissue or biological fluids, but a negative PCR does not rule out toxoplasmosis. Isolation or PCR of *T. gondii* from the patient's body fluids (blood, CSF, or bronchoalveolar lavage) reflects acute infection, whereas isolation from biopsied tissue is an indication only of the presence of tissue cysts and should not be misinterpreted as evidence of acute toxoplasmosis. Persistent parasitemia in patients with latent, asymptomatic infection is rare. Histologic examination of lymph nodes may suggest the characteristic changes described above. Demonstration of tachyzoites in lymph nodes establishes the diagnosis of acute toxoplasmosis. Histologic demonstration of cysts containing bradyzoites confirms prior infection with *T. gondii* but may represent latent rather than acute infection.

Serology Serologic testing has become the routine method of diagnosis. Diagnosis of acute infection with *T. gondii* can be established by detection of the simultaneous presence of IgG and IgM antibodies to *Toxoplasma* in serum. The presence of circulating IgA favors the diagnosis of an acute infection. The Sabin-Feldman dye test, the indirect fluorescent antibody test, and the enzyme-linked immunosorbent assay (ELISA) all measure circulating IgG antibody to *Toxoplasma*. Positive IgG titers (>1:10) can be detected as early as 2–3 weeks after infection. These titers usually peak at 6–8 weeks and decline slowly to a new baseline level that persists for life. Antibody avidity increases with time and can be useful in difficult cases during pregnancy for establishing when infection may have occurred. The serum IgM titer should be measured in concert with the IgG titer to better establish the time of infection; either the double-sandwich IgM-ELISA or the IgM-immunosorbent assay (IgM-ISAGA) should be used. Both assays are specific and sensitive, with fewer false-positive results than other commercial tests. The double-sandwich IgA-ELISA is more sensitive than the IgM-ELISA for detecting congenital infection in the fetus and newborn. Although a negative IgM result with a positive IgG titer indicates distant infection, IgM can persist for >1 year and should not necessarily be considered a reflection of acute disease. If acute toxoplasmosis is suspected, a more extensive panel of serologic tests can be performed. In the United States, testing is available at the Remington Laboratory for Specialty Diagnostics (*https://www.sutterhealth.org/services/lab-pathology/toxoplasma-serology-laboratory*).

Molecular Diagnostics Molecular approaches can directly detect *T. gondii* in biologic samples independent of the serologic response. Results obtained with PCR have high specificity and clinical utility in the diagnosis of toxoplasmosis but may only be available in specialty laboratories. While very specific, depending on the body fluid type tested, the sensitivity of PCR of body fluids may be low, so diagnostic algorithms typically incorporate serologic testing of blood

or body fluids. Real-time PCR, if available, can provide quantitative results. Molecular epidemiologic studies with polymorphic markers have been useful in correlating clinical signs and symptoms of disease with different *T. gondii* genotypes that may vary in virulence. Next-generation sequencing approaches (metagenomics) of blood or body fluids are often useful, particularly in immunocompromised individuals.

The Immunocompetent Adult or Child For the patient who presents with lymphadenopathy only, a positive IgM titer is an indication of acute infection—and an indication for therapy, if clinically warranted (see "Treatment," below). The serum IgM titer should be determined again in 3 weeks. An elevation in the IgG titer without an increase in the IgM titer suggests that infection is present but is not acute. If there is a borderline increase in either IgG or IgM, the titers should be reassessed in 3–4 weeks.

The Immunocompromised Host A presumptive clinical diagnosis of TE in patients with AIDS is based on clinical presentation, history of exposure (as evidenced by positive serology), and radiologic evaluation. To detect latent infection with *T. gondii*, HIV-infected persons should be tested for IgG antibody to *Toxoplasma* soon after HIV infection is diagnosed. When these criteria are used, the predictive value is as high as 80%. More than 97% of patients with AIDS and toxoplasmosis have IgG antibody to *T. gondii* in serum. IgM serum antibody usually is not detectable. Although IgG titers do not correlate with active infection, serologic evidence of infection almost always precedes the development of TE. It is therefore important to determine the *Toxoplasma* antibody status of all patients infected with HIV. Antibody titers may range from negative to 1:1024 in patients with AIDS and TE. Fewer than 3% of patients have no demonstrable antibody to *Toxoplasma* at diagnosis of TE.

Patients with TE have focal or multifocal abnormalities demonstrable by computed tomography (CT) or magnetic resonance imaging (MRI). Neuroradiologic evaluation should include double-dose contrast CT of the head. By this test, single and frequently multiple contrast-enhancing lesions (<2 cm) may be identified. MRI usually demonstrates multiple lesions located in both hemispheres, with the basal ganglia and corticomedullary junction most commonly involved; MRI provides a more sensitive evaluation of the efficacy of therapy than does CT (Fig. 235-2). These findings are not pathognomonic of *Toxoplasma* infection, because 40% of CNS lymphomas are multifocal and 50% are ring-enhancing. For both MRI and CT scans, the rate of false-negative results is ~10%. The finding of a single lesion on an MRI scan increases the likelihood of primary CNS lymphoma (in which solitary lesions are four times more likely than in TE) and strengthens the argument for the performance of a brain biopsy. A therapeutic trial of anti-*Toxoplasma* medications is frequently used to assess the diagnosis. Treatment of presumptive TE with pyrimethamine plus sulfadiazine or clindamycin results in quantifiable clinical improvement in >50% of patients by day 3. Leucovorin is administered to prevent bone marrow toxicity. By day 7, >90% of treated patients show evidence of improvement. In contrast, if patients fail to respond or have lymphoma, clinical signs and symptoms worsen by day 7. Patients in this category require brain biopsy with or without a change in therapy. This procedure can now be performed by a stereotactic CT-guided method that reduces the potential for complications. Brain biopsy for *T. gondii* identifies organisms in 50–75% of cases. PCR amplification of CSF may also confirm toxoplasmosis or suggest alternative diagnoses (Table 235-1), such as progressive multifocal leukoencephalopathy (JC virus positive) or primary CNS lymphoma (Epstein-Barr virus positive).

CT and MRI with contrast are currently the standard diagnostic imaging tests for TE. As in other conditions, the radiologic response may lag behind the clinical response. Resolution of lesions may take from 3 weeks to 6 months. Some patients show clinical improvement despite worsening radiographic findings.

Congenital Infection The issue of concern when a pregnant woman has evidence of recent *T. gondii* infection is whether the fetus is infected. PCR analysis of the amniotic fluid has replaced fetal blood sampling. Serologic diagnosis is based on the persistence of IgG antibody or a positive IgM titer after the first week of life (a time frame that excludes placental leak). The IgG determination should be repeated every 2 months. An increase in IgM beyond the first week of life is indicative of acute infection. Up to 25% of infected newborns may be seronegative and have normal routine physical examinations. Thus, assessment of the eye and the brain, with ophthalmologic testing, CSF evaluation, and radiologic studies, is important in establishing the diagnosis.

Ocular Toxoplasmosis The serum antibody titer may not correlate with the presence of active lesions in the fundus, particularly in cases of congenital toxoplasmosis. In general, a positive IgG titer (measured in undiluted serum if necessary) in conjunction with typical lesions establishes the diagnosis. If lesions are atypical and the serum antibody titer is in the low-positive range, the diagnosis is presumptive. The parasitic antigen–specific polyclonal IgG assay as well as parasite–specific PCR may facilitate the diagnosis. PCR of ocular samples has better yield than PCR of blood, but negative PCR does not rule out the diagnosis. Diagnosis may also be established by ocular fluid Western blot or comparison of ocular fluid antibody with blood antibody (Goldmann-Witmer coefficient). The clinical diagnosis of ocular toxoplasmosis can be supported in 60–90% of cases by laboratory tests, depending on the time of anterior chamber puncture and the panel of antibody analyses used.

TREATMENT

Toxoplasmosis

CONGENITAL INFECTION

Congenitally infected neonates are treated with daily oral pyrimethamine (1 mg/kg) and sulfadiazine (100 mg/kg) with folinic acid for 1 year. Depending on the signs and symptoms, prednisone (1 mg/kg per day) may be used for congenital infection. Some U.S. states and some countries routinely screen pregnant women (France, Austria) and/or newborns (Denmark, Massachusetts). Management and treatment regimens vary with the country and the treatment center. Most experts use spiramycin to treat pregnant women who have acute toxoplasmosis early in pregnancy and use pyrimethamine/sulfadiazine/folinic acid to treat women who seroconvert after 18 weeks of pregnancy or in cases of documented fetal infection. Studies suggest that treatment during pregnancy decreases the severity of infection. Many women who are infected in the first trimester elect termination of pregnancy. Those who do not terminate pregnancy are offered prenatal antibiotic therapy to reduce the frequency and severity of *Toxoplasma* infection in the infant. The optimal duration of treatment for a child with asymptomatic congenital toxoplasmosis is not clear, although most clinicians in the United States would treat the child for 1 year in light of cohort investigations conducted by the National Collaborative Chicago-Based, Congenital Toxoplasmosis Study.

INFECTION IN IMMUNOCOMPETENT PATIENTS

Immunologically competent adults and older children who have only lymphadenopathy do not require specific therapy unless they have persistent, severe symptoms. Patients with ocular toxoplasmosis are usually treated for 6 weeks with pyrimethamine plus either sulfadiazine or clindamycin and sometimes with prednisone. Trimethoprim-sulfamethoxazole (TMP-SMX) can also be given if pyrimethamine cannot be obtained (5 mg/kg bid based on TMP). Treatment should be supervised by an ophthalmologist familiar with *Toxoplasma* disease. Ocular disease can be self-limited without treatment, but therapy is typically considered for lesions that are severe or close to the fovea or optic disc. Prolonged treatment with TMP-SMX prevents recurrences of ocular toxoplasmosis while on treatment and is often considered in individuals with frequent flares

in a 1- to 2-year period. Flares are more common in individuals who have acquired infection in South America. Whether treatment improves long-term visual outcomes is unclear. Other clinical presentations of toxoplasmosis in immunocompetent individuals are treated 2–4 weeks with duration and decision to treat based upon response and severity of clinical symptoms.

INFECTION IN IMMUNOCOMPROMISED PATIENTS

Clinical Treatment Immunocompromised patients, such as patients with AIDS and/or transplant recipients, should be treated for acute toxoplasmosis as toxoplasmosis is rapidly fatal if untreated. The recommended treatment is pyrimethamine (200 mg load, 50 mg/d if <60 kg, 75 mg/d if >60 kg) plus sulfadiazine (1000 mg qid for <60 kg; 1500 mg qid >60 kg) plus leucovorin (10–25 mg/d) to reduce hematologic toxicity for a minimum of 6 weeks. In cases of sulfa intolerance, clindamycin (600 mg qid) can be substituted. TMP-SMX (5 mg/kg of TMP, 25 mg/kg SMX bid) appears to be an effective alternative for treatment of TE in resource-poor settings where the preferred combination of pyrimethamine plus sulfadiazine is not available. Pyrimethamine is very expensive in the United States, so many clinicians prescribe TMP-SMX if pyrimethamine cannot be obtained. Most experts continue to prefer pyrimethamine plus sulfadiazine because of better synergy between the drugs and fewer clinical failures relative to TMP-SMX.

Primary Prophylaxis in AIDS The incidence of TE has declined as the survival of patients with HIV infection has increased through the use of ART. The incidence of TE in underresourced settings is unknown because serologic testing and imaging are not available. AIDS patients who are seropositive for *T. gondii* and who have a CD4+ T lymphocyte count of <100/μL should receive prophylaxis against TE.

The daily dose of TMP-SMX (one double-strength tablet qd) recommended for prophylaxis of *Pneumocystis jirovecii* pneumonia (PJP; formerly *Pneumocystis carinii* or PCP) is effective against TE. If patients cannot tolerate TMP-SMX, the recommended alternative is dapsone-pyrimethamine, which likewise is effective against PJP. Atovaquone with or without pyrimethamine also can be considered. Prophylactic monotherapy with dapsone, pyrimethamine, azithromycin, clarithromycin, or aerosolized pentamidine is probably insufficient.

Discontinuing Primary Prophylaxis Prophylaxis against TE can be discontinued in HIV-positive patients who have responded to ART and whose CD4+ T lymphocyte count has been >200/μL for 3 months. Although patients with CD4+ T lymphocyte counts of <100/μL are at greatest risk for developing TE, the risk that this condition will develop when the count has increased to 100–200/μL has not been established. Thus, prophylaxis should be discontinued when the count has increased to >200/μL. Prophylaxis should be recommenced if the CD4+ T lymphocyte count again decreases to <100–200/μL.

Individuals who have completed initial therapy for TE should receive treatment indefinitely until immune reconstitution, with a CD4+ T-cell count of >200/μL, is achieved with ART. Combination therapy with pyrimethamine plus sulfadiazine plus leucovorin is effective. An alternative to sulfadiazine in this regimen is clindamycin or TMP-SMX.

Discontinuing Secondary Prophylaxis (Long-Term Maintenance Therapy) Patients receiving secondary prophylaxis for TE are at low risk for recurrence when they have completed initial therapy for TE, remain asymptomatic, and have evidence of restored immune function. Individuals with HIV infection should have a CD4+ T lymphocyte count of >200/μL for at least 6 months after combined ART (cART). A repeat MRI brain scan is recommended. Secondary prophylaxis should be reintroduced if the CD4+ T lymphocyte count decreases to <200/μL.

Prophylaxis in Allogeneic HSCT or Solid Organ Transplant The incidence of toxoplasmosis is lower in seropositive allogeneic HSCT given TMP-SMX prophylaxis, so prophylaxis should be given after engraftment for at least 6 months with weekly PCR monitoring performed after transplant. TMP-SMX regimens will prevent both toxoplasmosis and *P. jirovecii*.

PREVENTION

Seronegative immunocompromised or pregnant persons should be counseled regarding sources of *Toxoplasma* infection. The chances of primary infection with *Toxoplasma* can be reduced by not eating undercooked meat and by avoiding oocyst-contaminated material (i.e., a cat's litter box). Specifically, lamb, beef, pork, and venison should be cooked to an internal temperature of 63°C (145°F) measured in the thickest portion of the cut and rested for 3 min. Ground meat should be cooked to 71°C (145°F), whereas poultry should be cooked to 74°C (165°F). Hands should be washed thoroughly after work in the garden, and all fruits and vegetables should be washed. Freezing meat to –20°C (–4°F) also kills cysts. Ingestion of raw shellfish is a risk factor for toxoplasmosis, given that the filter-feeding mechanism of clams and mussels concentrates oocysts.

If the patient owns a cat, the litter box should be cleaned or changed daily, preferably by an HIV-negative, nonpregnant person; alternatively, patients should wash their hands thoroughly after changing the litter box. Litter boxes should be changed daily if possible, as freshly excreted oocysts will not have sporulated and will not be infectious. Patients should be encouraged to keep their cats inside and not to adopt or handle stray cats. Cats should be fed only canned or dried commercial food or well-cooked table food, not raw or undercooked meats. Patients need not be advised to part with their cats or to have their cats tested for toxoplasmosis. Ideally, blood intended for transfusion into *Toxoplasma*-seronegative immunocompromised individuals should be screened for antibody to *T. gondii*. Although such serologic screening is not routinely performed, seronegative women should be screened for evidence of infection several times during pregnancy if they are exposed to environmental conditions that put them at risk for infection with *T. gondii*. HIV-positive individuals should adhere closely to these preventive measures.

Acknowledgment

The author would like to acknowledge Dr. Lloyd Kasper for his numerous contributions to our understanding of the pathogenesis of toxoplasmosis and his essential role in preparation of this chapter for prior editions.

236 Protozoal Intestinal Infections and Trichomoniasis

Peter F. Weller, Edward T. Ryan

PROTOZOAL INFECTIONS

GIARDIASIS

Giardia duodenalis (also known as *G. lamblia* or *G. intestinalis*) is a cosmopolitan protozoal parasite that inhabits the small intestines of humans and other mammals. Giardiasis is one of the most common parasitic diseases in both developed and developing countries worldwide, causing both endemic and epidemic intestinal disease and diarrhea. In resource-constrained areas with limited access to adequate sanitation and safer water, prevalence rates of giardiasis may be 20–40%, especially among young children.

Life Cycle and Epidemiology (Fig. 236-1) Infection follows the ingestion of environmentally hardy cysts, which excyst in the small intestine, releasing flagellated trophozoites (Fig. 236-2) that multiply by binary fission. *Giardia* remains a pathogen of the proximal small bowel and does not disseminate hematogenously. Trophozoites remain free in the lumen or attach to the mucosal epithelium by means of a ventral sucking disk. As a trophozoite encounters altered conditions, it forms a morphologically distinct cyst, which is the stage of the parasite usually found in the feces. Trophozoites may be present and even predominate in loose or watery stools, but it is the resistant cyst that survives outside the body and is responsible for transmission. Cysts do not tolerate heating or desiccation, but they do remain viable for months in cold fresh water. The number of cysts excreted varies widely but can approach 10^7 per gram of stool.

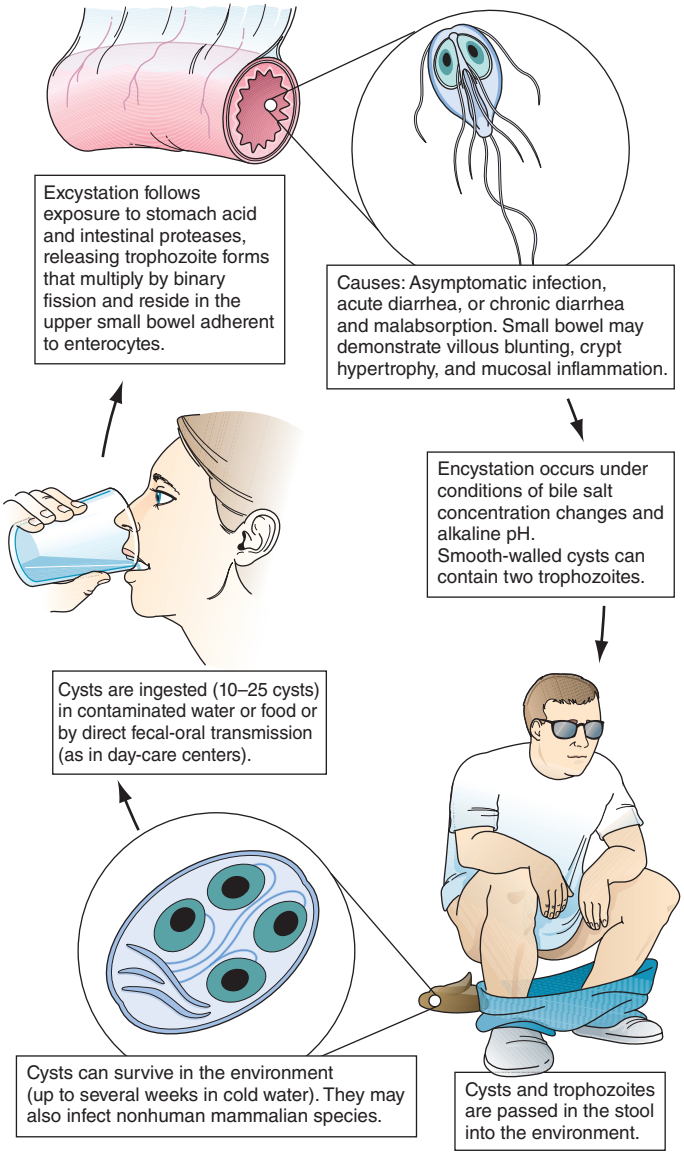

FIGURE 236-1 Life cycle of *Giardia*. *(Reproduced with permission from RL Guerrant et al [eds]: Tropical Infectious Diseases: Principles, Pathogens and Practice, 2nd ed. Elsevier, 2006.)*

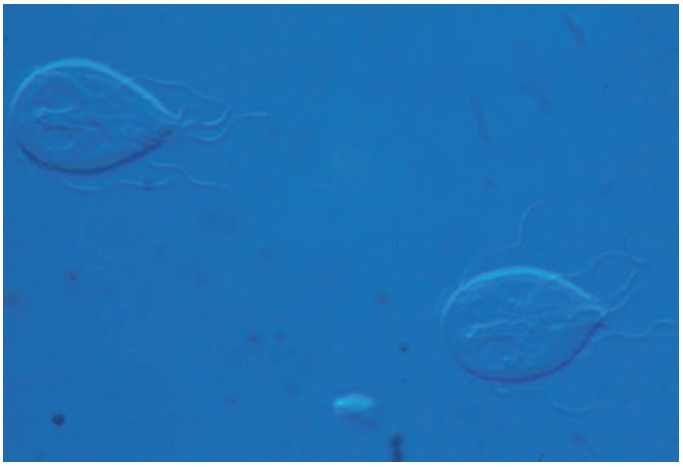

FIGURE 236-2 Flagellated, binucleate *Giardia* trophozoites.

Ingestion of as few as 10 cysts is sufficient to cause infection in humans. Because cysts are infectious when excreted, person-to-person transmission occurs where fecal hygiene is poor. Giardiasis is especially prevalent in day-care centers; person-to-person spread also takes place in other institutional settings with poor fecal hygiene and during anal–oral contact. If food is contaminated with *Giardia* cysts after cooking or preparation, foodborne transmission can occur. Waterborne transmission accounts for episodic infections (e.g., in campers and travelers) and for major epidemics in metropolitan areas. Surface water, ranging from mountain streams to large municipal reservoirs, can become contaminated with fecally derived *Giardia* cysts. The efficacy of water as a means of transmission is enhanced by the small infectious inoculum of *Giardia*, the prolonged survival of cysts in cold water, and the resistance of cysts to killing by routine chlorination methods that are adequate for controlling bacteria. Viable cysts can be eradicated from water by either boiling or filtration.

In the United States, *Giardia* (like *Cryptosporidium*; see below) can cause waterborne epidemics of gastroenteritis. *Giardia* is common in developing countries, and infections may be acquired by travelers.

There are several recognized genotypes or assemblages of *G. duodenalis*. Human infections are due to assemblages A and B, whereas other assemblages are more common in other animals, including cats and dogs. Like beavers from reservoirs implicated in epidemics, dogs and cats have been found to be infected with assemblages A and B; this finding suggests both that these animals may have been infected from human sources and that they might be sources of further human infections.

Giardiasis, like cryptosporidiosis, creates a significant economic burden because of the costs incurred in the installation of water filtration systems required to prevent waterborne epidemics, in the management of epidemics that involve large communities, and in the evaluation and treatment of endemic infections.

Pathophysiology The reasons that some, but not all, infected patients develop clinical manifestations and the mechanisms by which *Giardia* causes alterations in small-bowel function are largely unknown. Although trophozoites adhere to the epithelium, they are not invasive but may elicit apoptosis of enterocytes, epithelial barrier dysfunction, and epithelial cell malabsorption and secretion.

TABLE 236-1 Diagnosis of Intestinal Protozoal Infections

PARASITE	STOOL O+P	FECAL ACID-FAST STAIN	FECAL ANTIGEN IMMUNOASSAYS	FECAL NAATS	OTHER

Cystoisospora	±	+		+	
Cyclospora	±	+		+	
Dientamoeba	±		+	+	
Balantidium	+				
Microsporidia	–			+	Special fecal stains, tissue biopsies

Abbreviations: DFA, direct immunofluorescence assay; NAATs, nucleic acid amplification tests; O+P, conventional ova and parasites.

Consequent lactose intolerance and, in a minority of infected adults and children, significant malabsorption are clinical signs of the loss of epithelial brush-border enzyme activities. In most infections, the morphology of the bowel is unaltered; however, in chronically infected, symptomatic patients, the histopathologic findings (including flattened villi) and the clinical manifestations at times resemble those of tropical sprue and gluten-sensitive enteropathy. The pathogenesis of diarrhea in giardiasis is not known.

The natural history of *Giardia* infection varies markedly. Infections may be asymptomatic, transient, recurrent, or chronic. *G. duodenalis* parasites vary genotypically, and such variations might contribute to different courses of infection. Parasite as well as host factors may be important in determining the course of infection and disease. Both cellular and humoral responses develop in human infections, but their precise roles in disease pathogenesis and/or control of infection are unknown. Because patients with hypogammaglobulinemia suffer from prolonged, severe infections that are poorly responsive to treatment, humoral immune responses appear to be important. The greater susceptibilities of the young than of the old and of newly exposed persons than of chronically exposed populations suggest that at least partial protective immunity may develop.

Clinical Manifestations Disease manifestations of giardiasis range from asymptomatic carriage to fulminant diarrhea and malabsorption. Most infected persons are asymptomatic, but in epidemics, the proportion of symptomatic cases may be higher. Symptoms may develop suddenly or gradually. In persons with acute giardiasis, symptoms develop after an incubation period that lasts at least 5–6 days and usually 1–3 weeks. Prominent early symptoms include diarrhea, abdominal pain, bloating, belching, flatus, nausea, and vomiting. Although diarrhea is common, upper intestinal manifestations such as nausea, vomiting, bloating, and abdominal pain may predominate. The duration of acute giardiasis is usually >1 week, although diarrhea often subsides. Individuals with chronic giardiasis may present with or without having experienced an antecedent acute symptomatic episode. Diarrhea is not necessarily prominent, but increased flatus, loose stools, sulfurous belching, and (in some instances) weight loss occur. Symptoms may be continual or episodic and may persist for years. Some persons who have relatively mild symptoms for long periods recognize the extent of their discomfort only in retrospect. Fever, the presence of blood and/or mucus in the stools, and other signs and symptoms of colitis are uncommon and suggest a different diagnosis or a concomitant illness. Symptoms tend to be intermittent yet recurring and gradually debilitating, in contrast with the acute disabling symptoms associated with many enteric bacterial infections. Because of the less severe illness early on and the propensity for chronic infections, patients may seek medical advice late in the course of the illness; however, disease can be severe, resulting in malabsorption, weight loss, growth retardation in children, and dehydration. A number of extraintestinal manifestations have been described, such as urticaria, anterior uveitis, and arthritis; whether these are caused by giardiasis or concomitant processes is unclear.

Giardiasis can be severe in patients with hypogammaglobulinemia and can complicate other preexisting intestinal diseases, such as that occurring in cystic fibrosis. In patients with AIDS, *Giardia* can cause enteric illness that is refractory to treatment.

Diagnosis (Table 236-1) Giardiasis is diagnosed by detection of parasite antigens in the feces, by identification of cysts in the feces or of trophozoites in the feces or small intestines, or by nucleic acid amplification tests (NAATs). Cysts are oval and measure 8–12 μm × 7–10 μm. Mature cysts characteristically contain four nuclei. Trophozoites are pear-shaped, dorsally convex, flattened parasites with two nuclei and four pairs of flagella (Fig. 236-2). The diagnosis is sometimes difficult to establish. Direct examination of fresh or properly preserved stools as well as concentration methods can be used. Because cyst excretion is variable and may be undetectable at times, repeated examination of stool, sampling of duodenal fluid, and biopsy of the small intestine may be required to detect the parasite. Tests for parasitic antigens in stool are often more sensitive than or comparable to microscopic examination, are easier to perform, have a more rapid turn-around time, are often cost-comparable, and are often the first-line test in many institutions. NAATs are also highly sensitive.

TREATMENT

Giardiasis

Cure rates with metronidazole (250–500 mg thrice daily for 5 days) are usually >90%. Tinidazole (2 g once by mouth) may be more effective than metronidazole. Nitazoxanide (500 mg twice daily for 3 days) is an alternative agent for treatment of giardiasis. Paromomycin, an oral aminoglycoside that is not well absorbed, can be given to symptomatic pregnant patients, although information is limited on how effectively this agent eradicates infection. Albendazole and mebendazole also can be used as alternative agents, although their efficacy is lower than that of single-dose tinidazole. Quinacrine, secnidazole, ornidazole, and furazolidone are other alternative agents that have demonstrated some efficacy.

Almost all patients respond to therapy and are cured, although some with chronic giardiasis experience delayed resolution of symptoms after eradication of *Giardia*. For many of the latter patients, residual symptoms probably reflect delayed regeneration of intestinal brush-border enzymes. Continued infection should be documented by stool examinations before treatment is repeated. Patients who remain infected after repeated treatments should be evaluated for reinfection through family members, close personal contacts, and environmental sources as well as for hypogammaglobulinemia. In cases refractory to multiple treatment courses, prolonged therapy with metronidazole (750 mg thrice daily for 21 days) or therapy with varied combinations of multiple agents has been successful.

Prevention Giardiasis can be prevented by consumption of uncontaminated food and water and by personal hygiene during the provision of care for infected children. Boiling or filtering potentially contaminated water prevents infection.

CRYPTOSPORIDIOSIS

The coccidian parasite *Cryptosporidium* causes diarrheal disease that is self-limited in immunocompetent human hosts but can be severe in persons with AIDS or other forms of immunodeficiency. Two species

of *Cryptosporidium*, *C. hominis* and *C. parvum*, cause most human infections.

Life Cycle and Epidemiology *Cryptosporidium* species are widely distributed in the world. In resource-constrained areas, cryptosporidiosis is the second most common cause of moderate to severe diarrhea during the first two years of life (following rotavirus). Cryptosporidiosis is acquired by the consumption of oocysts (50% infectious dose: ~10–100 *C. hominis/parvum* oocysts in nonimmune individuals), which excyst to liberate sporozoites that in turn enter and infect intestinal epithelial cells. The parasite's further development involves both asexual and sexual cycles, which produce forms capable of infecting other epithelial cells and of generating oocysts that are passed in the feces. *Cryptosporidium* species infect a number of animals, and *C. parvum* can spread from infected animals to humans. Since oocysts are immediately infectious when passed in feces, person-to-person transmission takes place in day-care centers and among household contacts and medical providers. Waterborne transmission (especially that of *C. hominis*) accounts for infections in travelers and for common-source epidemics. Oocysts are quite hardy and resist killing by routine chlorination. Both drinking water and recreational water (e.g., pools, waterslides) have been increasingly recognized as sources of infection.

Pathophysiology Although intestinal epithelial cells harbor cryptosporidia in an intracellular vacuole, the means by which secretory diarrhea is elicited remain uncertain. No characteristic pathologic changes are found by biopsy. The distribution of infection can be spotty within the principal site of infection, the small bowel. Cryptosporidia are found in the pharynx, stomach, and large bowel of some patients and at times in the respiratory tract. Especially in patients with AIDS, involvement of the biliary tract can cause papillary stenosis, sclerosing cholangitis, or cholecystitis.

Clinical Manifestations Asymptomatic infections can occur in both immunocompetent and immunocompromised hosts. In immunocompetent persons, symptoms develop after an incubation period of ~1 week and consist principally of watery nonbloody diarrhea, sometimes in conjunction with abdominal pain, nausea, anorexia, fever, and/or weight loss. In these hosts, the illness usually subsides after 1–2 weeks. In contrast, in immunocompromised hosts (especially those with AIDS and CD4+ T-cell counts <100/μL), diarrhea can be chronic, persistent, and remarkably profuse, causing clinically significant fluid and electrolyte depletion. Stool volumes may range from 1 to 25 L/d. Weight loss, wasting, and abdominal pain may be severe. Biliary tract involvement can manifest as mid-epigastric or right-upper-quadrant pain.

Diagnosis (Table 236-1) Evaluation starts with fecal examination for small oocysts, which are smaller (4–5 μm in diameter) than the fecal stages of most other parasites. Because conventional stool examination for ova and parasites (O+P) does not detect *Cryptosporidium*, specific testing must be requested. Detection is enhanced by evaluation of stools (obtained on multiple days) by several techniques, including modified acid-fast and direct immunofluorescent stains and enzyme immunoassays. NAATs also are useful. Cryptosporidia can also be identified by light and electron microscopy at the apical surfaces of intestinal epithelium from biopsy specimens of the small bowel and, less frequently, the large bowel.

TREATMENT

Cryptosporidiosis

Nitazoxanide, approved by the U.S. Food and Drug Administration (FDA) for the treatment of cryptosporidiosis, is available in tablet form for adults (500 mg twice daily for 3 days) and as an elixir for children. This agent has not been effective for the treatment of immunosuppressed patients or HIV-infected patients, in whom improved immune status due to antiretroviral therapy can lead to amelioration of cryptosporidiosis. Otherwise, treatment includes supportive care with replacement of fluids and electrolytes and administration of antidiarrheal agents. Biliary tract obstruction may require papillotomy or T-tube placement. Prevention requires minimizing exposure to infectious oocysts in human or animal feces. Use of submicron water filters may minimize acquisition of infection from drinking water.

CYSTOISOSPORIASIS

The coccidian parasite *Cystoisospora belli* (formerly referred to as *Isospora belli*) causes human intestinal disease. Infection is acquired by the consumption of oocysts, after which the parasite invades intestinal epithelial cells and undergoes both sexual and asexual cycles of development. Oocysts excreted in stool are not immediately infectious but must undergo further maturation.

Although *C. belli* infects many animals, little is known about the epidemiology or prevalence of this parasite in humans. It is most common in tropical and subtropical countries. Acute infections can begin abruptly with fever, abdominal pain, and watery nonbloody diarrhea and can last for weeks or months. In patients who have AIDS or are immunocompromised for other reasons, infections often are not self-limited but rather resemble cryptosporidiosis, with chronic, profuse watery diarrhea. Eosinophilia, which is not found in other enteric protozoan infections, may be detectable in immunocompetent hosts. The diagnosis (Table 236-1) is usually made by detection of the large (~25 μm) oocysts in stool by modified acid-fast staining. Oocyst excretion may be low-level and intermittent; if repeated stool examinations are unrevealing, sampling of duodenal contents by aspiration or small-bowel biopsy (often with electron microscopic examination) may be necessary. NAATs are effective newer diagnostic tools.

TREATMENT

Cystoisosporiasis

Trimethoprim-sulfamethoxazole (TMP-SMX, 160/800 mg two times daily for 7–10 days; and, for HIV-infected patients, then continuing three times daily for 3–4 weeks) is effective. For patients intolerant of sulfonamides, pyrimethamine (50–75 mg/d) or ciprofloxacin 500 mg two times a day can be used. Relapses can occur in persons with AIDS and necessitate maintenance therapy with TMP-SMX (160/800 mg three times per week).

CYCLOSPORIASIS

Cyclospora cayetanensis, a cause of diarrheal illness, is globally distributed: illness due to *C. cayetanensis* has been reported in the United States, Asia, Africa, Latin America, and Europe. The epidemiology of this parasite has not yet been fully defined, but waterborne transmission and foodborne transmission (e.g., by basil, sweet peas, and imported raspberries) have been recognized. The full spectrum of illness attributable to *Cyclospora* has not been delineated. Some infected patients may be without symptoms, but many have diarrhea, flulike symptoms, and flatulence and belching. The illness can be self-limited, can wax and wane, or, in many cases, can involve prolonged diarrhea, anorexia, and upper gastrointestinal symptoms, with sustained fatigue and weight loss in some instances. Diarrheal illness may persist for >1 month. *Cyclospora* can cause enteric illness in patients infected with HIV.

The parasite is detectable in epithelial cells of small-bowel biopsy samples and elicits secretory diarrhea by unknown means. The absence of fecal blood and leukocytes indicates that disease due to *Cyclospora* is not caused by destruction of the small-bowel mucosa. The diagnosis (Table 236-1) can be made by detection of spherical 8- to 10-μm oocysts in the stool, although routine stool O+P examinations are not sufficient. Specific fecal examinations must be requested to detect the oocysts, which are variably acid-fast and are fluorescent when viewed with ultraviolet light microscopy. NAATs are sensitive. Cyclosporiasis should be considered in the differential diagnosis of prolonged diarrhea, with or without a history of travel by the patient to other countries.

TREATMENT

Cyclosporiasis

Cyclosporiasis is treated with TMP-SMX (160/800 mg twice daily for 7–10 days). HIV-infected patients may require longer treatment courses, may experience relapses after treatment, and thus may require longer-term suppressive maintenance therapy. Nitazoxanide and ciprofloxacin may be alternative agents in patients unable to receive TMP-SMX.

MICROSPORIDIOSIS

Microsporidia are obligate intracellular spore-forming protozoa that infect many animals and cause disease in humans, especially as opportunistic pathogens in AIDS. Microsporidia are members of a distinct phylum, Microspora, which contains hundreds of genera and thousands of species. The various microsporidia are differentiated by their developmental life cycles, ultrastructural features, and molecular taxonomy based on ribosomal RNA. The complex life cycles of the organisms result in the production of infectious spores (Fig. 236-3). Currently, at least 17 species of microsporidia are recognized as causes of human disease, most commonly of the genera *Enterocytozoon* and *Encephalitozoon*. Although some microsporidia are probably prevalent causes of self-limited or asymptomatic infections in immunocompetent patients, little is known about how microsporidiosis is acquired.

Microsporidiosis is most common among patients with AIDS, less common among patients with other types of immunocompromise, and rare among immunocompetent hosts. In patients with AIDS, intestinal infections with *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* are recognized to contribute to chronic diarrhea and wasting; these infections have been found in 10–40% of patients with chronic diarrhea. Both organisms have been found in the biliary tracts of patients with cholecystitis. *E. intestinalis* may also disseminate to cause fever, diarrhea, sinusitis, cholangitis, and bronchiolitis. In patients with AIDS, *Encephalitozoon hellem* has caused superficial keratoconjunctivitis as well as sinusitis, respiratory tract disease, and disseminated

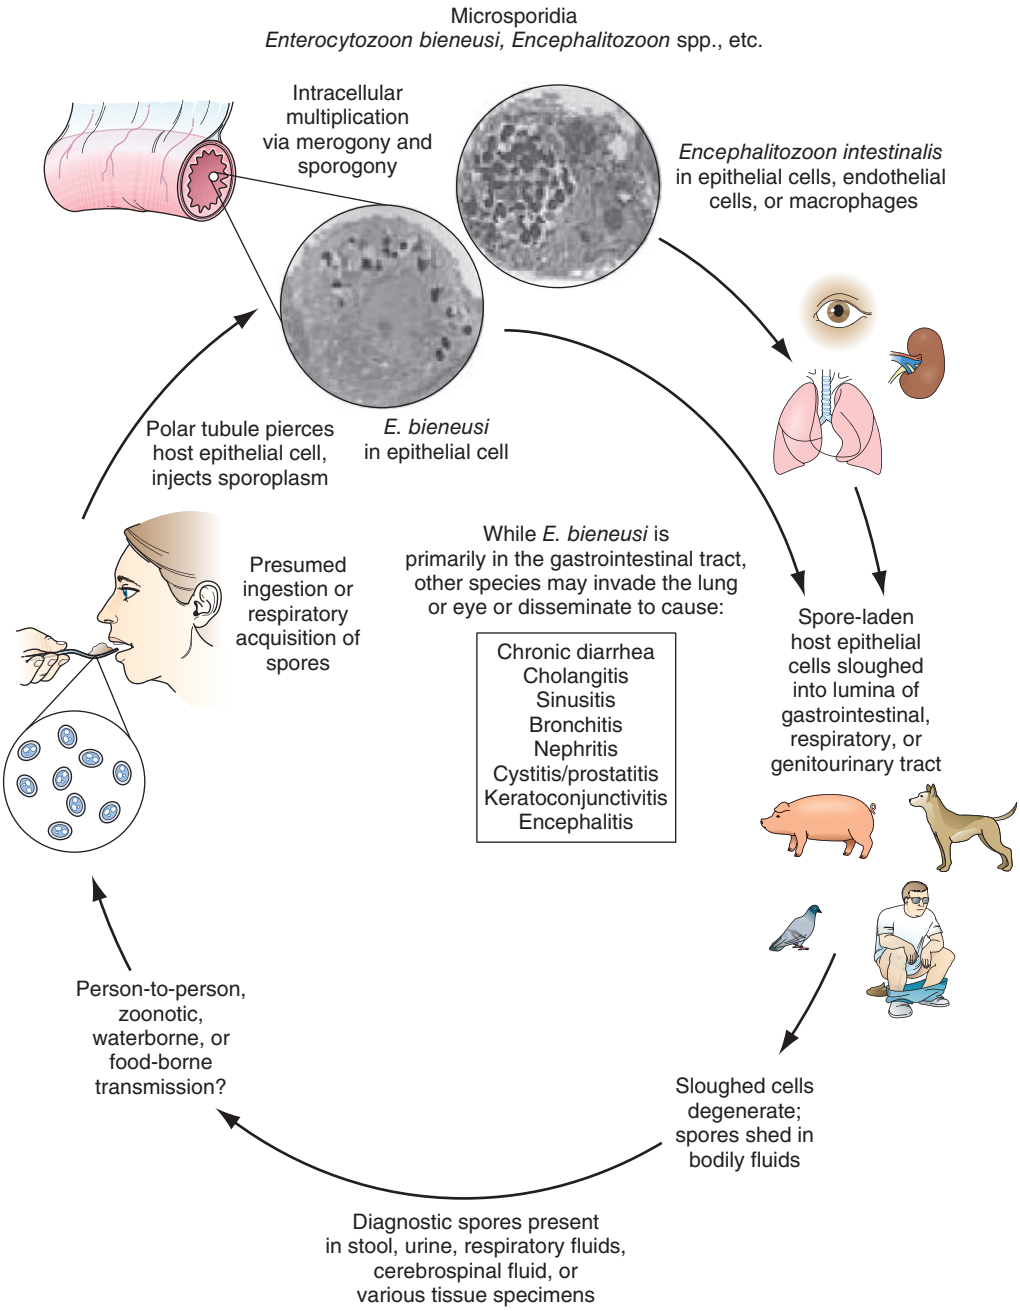

FIGURE 236-3 Life cycle of microsporidia. *(Reproduced with permission from RL Guerrant et al [eds]: Tropical Infectious Diseases: Principles, Pathogens and Practice, 2nd ed. Elsevier 2006.)*

infection. Myositis due to *Pleistophora* has been documented. *Nosema*, *Vittaforma*, and *Microsporidium* have caused stromal keratitis associated with trauma in immunocompetent patients.

Microsporidia are small gram-positive organisms with mature spores measuring 0.5–2 μm × 1–4 μm. Diagnosis of microsporidial infections in tissue often requires electron microscopy, although intracellular spores can be visualized by light microscopy with hematoxylin and eosin, Giemsa, or tissue Gram's stain. Light microscopy with a modified trichrome stain or fluorescent assays can be used on stool, tissue, or urine. NAATs are useful for diagnosis and speciation. Definitive therapies for microsporidial infections remain to be established. For superficial keratoconjunctivitis due to *E. hellem*, *E. cuniculi*, *E. intestinalis*, and *E. bieneusi*, topical therapy with fumagillin suspension has shown promise **(Chap. 229)**. For enteric infections with *E. intestinalis* in HIV-infected patients, therapy with albendazole may be efficacious **(Chap. 229)**.

OTHER INTESTINAL PROTOZOA

Balantidiasis *Balantidium coli* is a large ciliated protozoal parasite that can produce a spectrum of large-intestinal disease analogous to amebiasis. The parasite is widely distributed in the world. Since it infects pigs, cases in humans are more common where pigs are raised. Infective cysts can be transmitted from person to person and through water, but many cases are due to the ingestion of cysts derived from porcine feces in association with slaughtering, with use of pig feces for fertilizer, or with contamination of water supplies by pig feces.

Ingested cysts liberate trophozoites, which reside and replicate in the large bowel. Many patients remain asymptomatic, but some have persisting intermittent diarrhea, and a few develop more fulminant dysentery. In symptomatic individuals, the pathology in the bowel—both gross and microscopic—is similar to that seen in amebiasis, with varying degrees of mucosal invasion, focal necrosis, and ulceration. Balantidiasis, unlike amebiasis, only rarely spreads hematogenously to other organs. The diagnosis is made by detection of the parasite in stool or sampled colonic tissue. Tetracycline (500 mg four times daily for 10 days) is an effective therapeutic agent. Metronidazole is an alternative agent.

Blastocystosis *Blastocystis hominis* is an organism of uncertain pathogenicity. Some patients who pass *B. hominis* in their stools are asymptomatic, whereas others have diarrhea and associated intestinal symptoms. Diligent evaluation reveals other potential bacterial, viral, or protozoal causes of diarrhea in some but not all patients with symptoms. Because the pathogenicity of *B. hominis* is uncertain and because therapy for *Blastocystis* infection is neither specific nor uniformly effective, patients with prominent intestinal symptoms should be fully evaluated for other infectious causes of diarrhea. If diarrheal symptoms associated with *Blastocystis* are prominent, metronidazole (500–750 mg thrice daily for 5–10 days) or tinidazole (2 g once) can be tried. Alternative agents include paromomycin, TMP-SMX, and nitazoxanide.

Dientamoebiasis *Dientamoeba fragilis* is unique among intestinal protozoa in that it has a trophozoite stage but not a cyst stage. How trophozoites survive to transmit infection is not known. When symptoms develop in patients with *D. fragilis* infection, they are generally mild and include intermittent diarrhea, abdominal pain, and anorexia. The diagnosis is made by the detection of trophozoites in stool; the lability of these forms accounts for the greater yield when fecal samples are preserved immediately after collection. NAATs are more sensitive than fecal microscopy. Paromomycin (25–35 mg/kg per day in three doses for 7 days) or metronidazole (500–750 mg three times daily for 10 days) is appropriate for treatment. Tetracycline, doxycycline, tinidazole, secnidazole, and ornidazole are alternative agents.

Sarcocystosis Humans can be the definitive or dead-end intermediate host for *Sarcocystis* spp. sarcocystoses are zoonotic infections. Humans can act as definitive hosts (the host in which a parasite completes its sexual life cycle) following consumption of undercooked beef or pork that contain the protozoa *Sarcocystis hominis* or *S. suihominis*, respectively. In this setting, humans can develop intestinal symptoms including nausea, vomiting, and diarrhea that is often self-resolving within a few days. Human intestinal infection can result in transient shedding of infectious oocysts that are consumed by cattle or pigs in the environment, and in these hosts the protozoa encyst in muscle tissue, allowing completion of the life cycle when these tissues are consumed by humans. Separately, humans can develop a transient myositis with peripheral eosinophilia following ingestion of oocysts of *S. nesbitti* shed by snakes. Intestinal sarcocystosis can be detected by stool examination, although oocysts are not usually detectable during the diarrheal phase. Intestinal sarcocystosis is self-limited and treated supportively.

TRICHOMONIASIS

Various species of trichomonads can be found in the mouth (in association with periodontitis) and occasionally in the gastrointestinal tract. *Trichomonas vaginalis*—one of the most prevalent protozoal parasites in the United States—is a pathogen of the genitourinary tract and a major cause of symptomatic vaginitis **(Chap. 141)**.

Life Cycle and Epidemiology *T. vaginalis* is a pear-shaped, actively motile organism that measures about 10 × 7 μm, replicates by binary fission, and inhabits the lower genital tract of females and the urethra and prostate of males. There are 2–3 million infections each year in the United States. While the organism can survive for a few hours in moist environments and could be acquired by direct contact, person-to-person venereal transmission accounts for virtually all cases of trichomoniasis. Its prevalence is greatest among persons with multiple sexual partners and among those with other sexually transmitted diseases **(Chap. 141)**.

Clinical Manifestations Many men infected with *T. vaginalis* are asymptomatic, although some develop urethritis and a few have epididymitis or prostatitis. In contrast, infection in women, which has an incubation period of 5–28 days, is more often symptomatic and manifests with malodorous vaginal discharge (often yellow), vulvar erythema and itching, dysuria or urinary frequency (in 30–50% of patients), and dyspareunia. These manifestations, however, do not clearly distinguish trichomoniasis from other types of infectious vaginitis.

Diagnosis Detection of motile trichomonads by microscopic examination of wet mounts of vaginal or prostatic secretions has been the conventional means of diagnosis. Although this approach provides an immediate diagnosis, its sensitivity for the detection of *T. vaginalis* is only ~50–60% in routine evaluations of vaginal secretions. Direct immunofluorescent antibody staining is more sensitive (70–90%) than wet-mount examinations. *T. vaginalis* can be recovered from the urethra of both males and females and is detectable in males after prostatic massage. NAATs are highly sensitive and specific for urine and for endocervical and vaginal swabs from women and often considered first-line diagnostics.

TREATMENT

Trichomoniasis

Metronidazole (either a single 2-g dose or 500-mg doses twice daily for 7 days), tinidazole (a single 2-g dose) or secnidazole (a single 2-g dose) is effective. All sexual partners must be treated concurrently to prevent reinfection, especially from asymptomatic males. In males with persistent symptomatic urethritis after therapy for nongonococcal urethritis, metronidazole therapy should be considered for possible trichomoniasis. Alternatives to metronidazole for treatment during pregnancy are not readily available. Reinfection often accounts for apparent treatment failures, but strains of *T. vaginalis* exhibiting high-level resistance to metronidazole have been encountered. Treatment of these resistant infections with higher oral doses, parenteral doses, or concurrent oral and vaginal doses of metronidazole or with tinidazole has been successful.

Section 19 Helminthic Infections

237 Introduction to Helminthic Infections

Peter F. Weller, Edward T. Ryan

The word *helminth* is derived from the Greek *helmins* ("parasitic worm"). Helminthic worms are highly prevalent and, depending on the species, may exist as free-living organisms or as parasites of plant or animal hosts. The parasitic helminths have co-evolved with specific mammalian and other host species. Accordingly, most helminthic infections are restricted to nonhuman hosts, and only rarely do these zoonotic helminths accidentally cause human infections.

Helminthic parasites of humans belong to two phyla: Nemathelminthes, which includes nematodes (roundworms), and Platyhelminthes, which includes cestodes (tapeworms) and trematodes (flukes). Helminthic parasites of humans reside within the human body and hence are the cause of true infections. In contrast, parasites of other genera that reside only on mucocutaneous surfaces of humans (e.g., the parasites causing myiasis and scabies) are considered to represent infestations rather than infections.

Helminthic parasites differ substantially from protozoan parasites in several respects. First, protozoan parasites are unicellular organisms, whereas helminthic parasites are multicellular worms that possess differentiated organ systems. Second, helminthic parasites have complex life cycles that require sequential stages of development outside the human host. Thus, most helminths do not complete their replication within the human host; rather, they develop to a certain stage within the mammalian host and, as part of their obligatory life cycle, must mature further outside that host. During the "extra-human" stages of their life cycle, helminths exist either as free-living organisms or as parasites within another host species and thereafter mature into new developmental stages capable of infecting humans. Thus, with only two exceptions (*Strongyloides stercoralis* and *Capillaria philippinensis*, which are capable of internal human reinfections), increases in the number of adult helminths (i.e., the "worm burden") within the human host require repeated exogenous reinfections. In the case of protozoan parasites, a brief, even singular exposure (e.g., a single mosquito bite transmitting malaria) may lead rapidly to intense parasite loads and overwhelming infections; in contrast, for all but the two helminths noted above, increases in worm burden require multiple and usually ongoing exposures to infectious forms, such as ingestion of eggs of intestinal helminths or waterborne exposures to infectious cercariae of *Schistosoma mansoni*. This requirement is germane both to the consideration of helminthic infections in individuals and to ongoing global efforts to interrupt and/or minimize the acquisition of helminthic infections by humans.

Third, helminthic infections have a predilection toward stimulation of host immune responses that elicit eosinophilia within human tissues and blood. The many protozoan infections characteristically do not elicit eosinophilia in infected humans, with only three exceptions (two intestinal protozoan parasites, *Cystoisospora belli* and *Dientamoeba fragilis*, and tissue-borne *Sarcocystis* species). The magnitude of helminth-elicited eosinophilia tends to correlate with the extent of tissue invasion by larvae or adult helminths. For example, in several helminthic infections, including acute schistosomiasis (Katayama syndrome), paragonimiasis, and hookworm and *Ascaris* infections, eosinophilia is most pronounced during the early phases of infection, when migrations of infecting larvae and progression of subsequent developmental stages through the tissues are greatest. In established infections, local eosinophilia is often present around helminths in tissues, but blood eosinophilia may be intermittent, mild, or absent. In helminthic infections in which parasites are well contained within tissues (e.g., echinococcal cysts) or confined within the lumen of the intestinal tract (e.g., adult *Ascaris* or tapeworms), eosinophilia is usually absent.

NEMATODES

Nematodes are nonsegmented roundworms. Species of nematodes are remarkably diverse and abundant in nature. Among the many thousands of nematode species, few are parasites of humans. Most nematodes are free-living, and these species have variably evolved to survive in diverse ecologic niches, including saltwater, freshwater, or soil. The well-studied organism *Caenorhabditis elegans* is a free-living nematode. Nematodes can be either beneficial or deleterious parasites of plants. Parasitic nematodes have co-evolved with specific mammalian hosts and have no capacity to live their full life cycles in other hosts. Uncommonly, humans are exposed to infectious stages of nonhuman nematode parasites, and the resultant zoonotic nematode infections can elicit inflammatory and immune responses as larval forms migrate and die in the unsuitable human host. Examples include pulmonary coin lesions due to mosquito-transmitted infections with the dog heartworm *Dirofilaria immitis*; eosinophilic meningoencephalitis due to ingested eggs of the raccoon ascarid *Baylisascaris procyonis*; and eosinophilic meningitis due to ingestion of larvae of the rat lungworm *Angiostrongylus cantonensis*.

Nematode parasites of humans include worms that reside in the intestinal tract or localize in extraintestinal vascular or tissue sites. Roundworms are sexually dimorphic, with separate male and female forms that copulate to produce offspring (except for *S. stercoralis*, whose adult females are hermaphroditic in the human intestinal tract). Depending on the species, fertilized females release either larvae or eggs containing larvae. Nematodes have five developmental stages: an adult stage and four sequential larval stages. These parasites characteristically are surrounded by a durable outer cuticular layer. Nematodes

have a nervous system; a muscular system, including muscle cells under the cuticle; and a developed intestinal tract, including an oral cavity and an elongated gut that ends in an anal pore. Adults may range in size from minute to >1 meter in length (with *Dracunculus medinensis*, for example, at the long end of this spectrum).

Humans acquire infections with nematode parasites by various routes, depending on the parasitic species. Ingestion of eggs passed in human feces is a major global health problem with many of the intestinal helminths (e.g., *Ascaris lumbricoides*). In other species, infecting larvae penetrate skin exposed to fecally contaminated soil (e.g., *S. stercoralis*, hookworms) or traverse the skin after the bite of infected insect vectors (e.g., filariae). Some nematode infections are acquired by consumption of specific animal-derived foods (e.g., trichinellosis from raw or undercooked pork or wild carnivorous mammals). As noted above, only two nematodes, *S. stercoralis* and *C. philippinensis*, can internally reinfect humans; thus, for all other nematodes, any increases in worm burden must be due to continued exogenous reinfections.

CESTODES

Tapeworms are the cestode parasites of humans. Adult tapeworms are elongated, segmented, hermaphroditic flatworms that reside in the intestinal lumen or, in their larval forms, may live in extraintestinal tissues. Tapeworms include a head (*scolex*) and a number of attached segments (*proglottids*). The worms attach to the intestinal tract via their scolices, which may possess suckers, hooks, or grooves. The scolex is the site of formation of new proglottids. Tapeworms do not have a functional gut tract; rather, each tapeworm segment passively and actively obtains nutrients through its specialized surface tegument. Mature proglottids possess both male and female sex organs, but insemination usually occurs between adjacent proglottids. Fertilized proglottids release eggs that are passed in the feces. When ingested by an intermediate host, an egg releases an oncosphere that penetrates the gut and develops further in tissues as a cysticercus. Humans acquire infection by ingesting animal tissues that contain cysticerci, and the resultant tapeworms develop and reside in the proximal small bowel (e.g., *Taenia solium*, *T. saginata*). Alternatively, if humans ingest eggs of these cestodes that have been passed in human or animal feces, oncospheres develop and can cause space-occupying extraintestinal cystic lesions in tissues; examples include cysticercosis due to *T. solium* and hydatid disease due to species of *Echinococcus*.

TREMATODES

Trematodes of medical importance include blood flukes, intestinal flukes, and tissue flukes. Adult flukes are often leaf-shaped flatworms. Oral and/or ventral suckers help adult flukes maintain their positions in situ. Flukes have an oral cavity but no distal anal pore. Nutrients are obtained both through their integument and by ingestion into the blind intestinal tract. Flukes are hermaphroditic except for blood flukes (schistosomes), which are sexually dimorphic. Eggs are passed in human feces (*Fasciola*, *Fasciolopsis*, *Clonorchis*, *Schistosoma japonicum*, *S. mansoni*), urine (*Schistosoma haematobium*), or sputum and feces (*Paragonimus*). Expelled eggs release miracidia—usually in water—that infect specific snail species. Within snails, parasites multiply and cercariae are released. Depending on the species, cercariae can penetrate the skin (schistosomes) or can develop into metacercariae that can be ingested with plants (e.g., watercress for *Fasciola*) or with fish (*Clonorchis*) or crabs (*Paragonimus*).

CONCLUSION

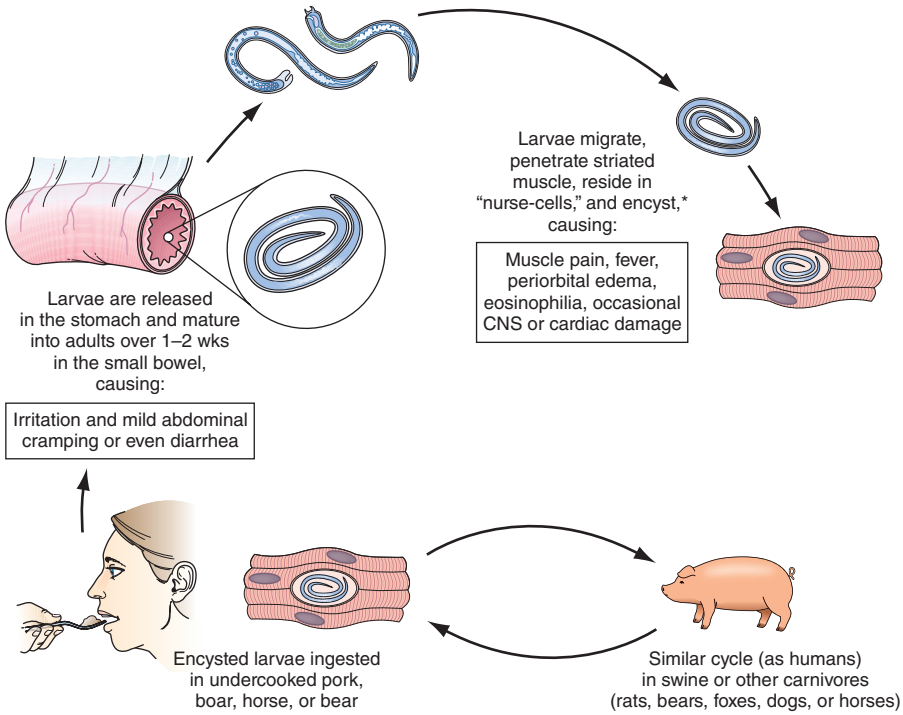
Many of the so-called neglected tropical diseases are due to helminthic infections. The health impacts of many helminthic infections are varied and are based on the frequent need for repeated exposures to increase the worm burdens in infected humans. In global regions where exposures to specific helminths occur even in childhood (e.g., fecally derived intestinal nematodes, mosquito-transmitted filariae, or waterborne snail-transmitted schistosomes), the morbidities in infected individuals can include nutritional, developmental, cognitive, and functional impairments. Ongoing global mass-treatment programs are currently aimed at diminishing the local intensity of infection and prevalences of specific helminths and their consequent impacts on the health of local populations.

238 Trichinellosis and Other Tissue Nematode Infections

Peter F. Weller, Edward T. Ryan

Nematodes are elongated, symmetric roundworms. Parasitic nematodes of medical significance may be broadly classified as either predominantly intestinal or tissue nematodes. The intestinal nematodes are covered in **Chap. 239**; filarial tissue-dwelling nematodes and *Dracunculus medinensis* infection are both covered in **Chap. 240**. This chapter covers the tissue nematodes that cause trichinellosis, visceral and ocular larva migrans, cutaneous larva migrans, cerebral angiostrongyliasis, and gnathostomiasis. All of these zoonotic infections result from incidental exposure to infectious nematodes. The clinical symptoms of these infections are due largely to invasive larval stages that (except in the case of *Trichinella*) do not reach maturity in humans.

TRICHINELLOSIS



Trichinellosis develops after the ingestion of meat containing cysts of *Trichinella* (e.g., pork or other meat from a carnivore/omnivore). Although most infections are mild and asymptomatic, heavy infections can cause severe enteritis, periorbital edema, myositis, and (infrequently) death.

Life Cycle and Epidemiology At least nine species of *Trichinella* and 13 genotypes are recognized as causes of infection in humans. Two species are distributed worldwide: *T. spiralis*, which is found in a great variety of carnivorous and omnivorous animals, and *T. pseudospiralis*, which is found in mammals and birds. *T. nativa* is present in Arctic and subarctic regions and infects bears, foxes, and walruses; *T. nelsoni* is found in equatorial eastern Africa, where it is common among felid predators and scavengers such as hyenas and bush pigs; and *T. britovi* is found in Europe, western Africa, and western Asia among carnivores but not among domestic swine. *T. murrelli* is present in wild animals in North American and Japan. *T. papuae* is found in Papua New Guinea, Thailand, Taiwan, and Cambodia in domestic and feral pigs and in saltwater crocodiles and turtles. *T. zimbabwensis* is present in crocodiles in Tanzania. *T. patagoniensis* is found in cougars in South America.

After human consumption of trichinous meat, encysted larvae are liberated by digestive acid and proteases **(Fig. 238-1)**. The larvae invade the small-bowel mucosa and mature into adult worms. After ~1 week, female worms release newborn larvae that migrate via the circulation to striated muscle. The larvae of all species except *T. pseudospiralis*, *T. papuae*, and *T. zimbabwensis* then encyst by inducing a radical transformation in the muscle cell architecture. Host immune responses may help to expel intestinal adult worms but have few deleterious effects on muscle-dwelling larvae.

Human trichinellosis classically has been caused by the ingestion of infected pork products and thus can occur in almost any location where the meat of domestic or wild swine is eaten. Increasingly, human trichinellosis has also been acquired from the meat of other animals, including dogs (in parts of Asia and Africa), horses (in Italy and France), and bears and walruses (in northern regions). Although cattle and horses (being herbivores) are not natural hosts of *Trichinella*, beef and horse meat have been implicated in outbreaks when contaminated or adulterated with trichinous pork or perhaps following ingestion of fodder contaminated with meat parts from naturally infected animals. Approximately 10–20 cases of trichinellosis are reported annually in the United States, down from 400–500 cases per year in the 1940s, largely reflecting the impact of control programs targeting education, pig-raising, and the processing and freezing of pork. Consumption of wild game (especially bear and walrus meat) now accounts for the majority of cases reported each year in North America. Most mild cases probably remain undiagnosed.

Pathogenesis and Clinical Features Clinical symptoms of trichinellosis arise from the successive phases of parasite enteric invasion,

T. papuae, T. zimbabwensis, and *T. pseudospiralis* do not encyst.

FIGURE 238-1 Life cycle of *Trichinella spiralis* (cosmopolitan); *nelsoni* (equatorial Africa); *britovi* (Europe, western Africa, western Asia); *nativa* (Arctic); *murrelli* (North America); *papuae* (Papua New Guinea); *zimbabwensis* (Tanzania); and *pseudospiralis* (cosmopolitan). CNS, central nervous system. *(Reproduced with permission from RL Guerrant et al [eds]: Tropical Infectious Diseases: Principles, Pathogens and Practice, 2nd ed. Elsevier, 2006.)*

larval migration, and muscle encystment (Fig. 238-1). Most light infections (those with <10 larvae per gram of muscle) are asymptomatic, whereas heavy infections (which can involve >50 larvae per gram of muscle) can be life-threatening. An initial enteric phase due to release of ingested muscle larvae may elicit diarrhea, abdominal pain, constipation, and nausea during the first weeks after infection.

Symptoms due to larval migration and muscle invasion begin to appear in the second week after infection. The migrating *Trichinella* larvae provoke a marked local and systemic hypersensitivity reaction, with fever and eosinophilia. Periorbital and facial edema is common, as are hemorrhages in the subconjunctivae, retina, and nail beds ("splinter" hemorrhages). A maculopapular rash, headache, cough, dyspnea, or dysphagia sometimes develops. Myocarditis with tachyarrhythmias or heart failure—and, less commonly, encephalitis or pneumonitis—may develop and accounts for most deaths of patients with trichinellosis.

Upon onset of larval encystment in muscle 2–3 weeks after infection, symptoms of myositis with myalgias, muscle edema, and weakness develop, usually overlapping with the inflammatory reactions to migrating larvae. The most commonly involved muscle groups include the extraocular muscles; the biceps; and the muscles of the jaw, neck, lower back, and diaphragm. Peaking ~3 weeks after infection, symptoms subside only gradually during a prolonged convalescence. Uncommon infections with *T. pseudospiralis*, whose larvae do not encapsulate in muscles, elicit a prolonged polymyositis-like illness.

Laboratory Findings and Diagnosis Blood eosinophilia develops in >90% of patients with symptomatic trichinellosis and may peak at a level of >50% 2–4 weeks after infection. Serum levels of muscle enzymes, including creatine phosphokinase, are elevated in most symptomatic patients. Patients should be questioned thoroughly about their consumption of pork or wild animal meat and about illness in other individuals who ate the same meat. A presumptive clinical diagnosis can be based on fevers, eosinophilia, periorbital edema, and myalgias after a suspect meal. A rise in the titer of parasite-specific antibody, which usually does not occur until after the third week of infection, confirms the diagnosis. Alternatively, a definitive diagnosis requires surgical biopsy of at least 1 g of involved muscle; the yields are highest near tendon insertions in symptomatic muscles. The fresh muscle tissue should be compressed between glass slides and examined microscopically **(Fig. 238-2)** because larvae may be missed by examination of routine histopathologic sections alone.

TREATMENT

Trichinellosis

Most lightly infected patients recover uneventfully with bed rest, antipyretics, and analgesics. Glucocorticoids like prednisone **(Table 238-1)** are beneficial for severe myositis and myocarditis. Mebendazole and albendazole are active against enteric stages of the parasite, but their efficacy against encysting/encysted larvae has not been conclusively demonstrated.

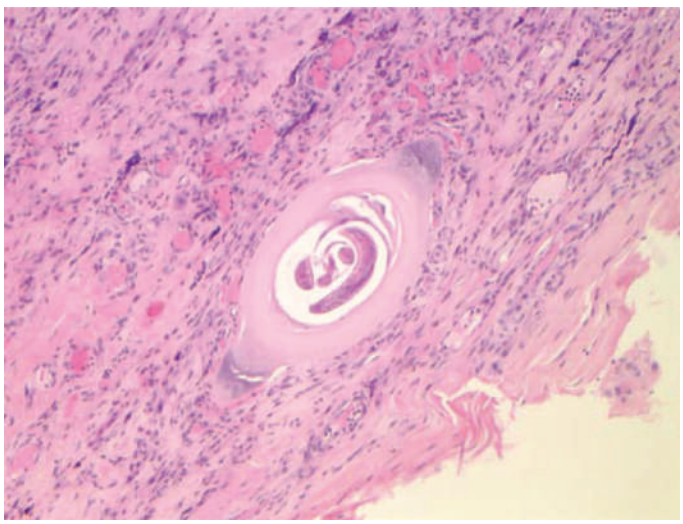


FIGURE 238-2 *Trichinella* larva encysted in a characteristic hyalinized capsule in striated muscle tissue. *(CDC/Wadsworth Center, New York State Department of Health.)*

TABLE 238-1 Therapy for Tissue Nematode Infections

INFECTION	SEVERITY	TREATMENT
Trichinellosis	Mild	Supportive
	Moderate	Albendazole (400 mg bid × 10–14 days) *or*
		Mebendazole (200–400 mg tid × 3 days, then 500 mg tid × 10 days)
	Severe	Add glucocorticoids (e.g., prednisone, 1 mg/kg qd × 5 days)
Visceral larva migrans	Mild to moderate	Supportive
	Severe	Glucocorticoids (as above)
	Ocular	Not fully defined; albendazole (800 mg bid for adults, 400 mg bid for children) with glucocorticoids × 5–20 days has been effective
Cutaneous larva migrans		Ivermectin (single dose, 200 μg/kg) *or*
		Albendazole (200 mg bid × 3 days)
Angiostrongyliasis	Mild to moderate	Supportive Not fully defined: albendazole (15 mg/kg per day in two divided doses × 14 days) with glucocorticoids (as above)
	Severe	Not fully defined: albendazole (15 mg/kg per day in two divided doses × 14 days) with glucocorticoids (as above)
Gnathostomiasis		Ivermectin (200 μg/kg per day × 2 days)[a] *or*
		Albendazole (400 mg bid × 21 days)[a]

[a]These agents may have efficacy for cutaneous gnathostomiasis; their use in neurologic and ocular gnathostomiasis is less certain and may be detrimental. Steroids are often given during neurologic and ocular gnathostomiasis.

Prevention Larvae are usually killed by cooking pork until it is no longer pink or by freezing it at −15°C for 3 weeks. However, Arctic *T. nativa* larvae in walrus or bear meat are relatively resistant and may remain viable despite freezing.

VISCERAL AND OCULAR LARVA MIGRANS

Visceral larva migrans is a syndrome caused by nematodes that are normally parasitic for nonhuman host species. In humans, these nematode larvae do not develop into adult worms but instead migrate through host tissues and elicit eosinophilic inflammation. The most common form of visceral larva migrans is toxocariasis due to larvae of the canine ascarid *Toxocara canis*; the syndrome is due less commonly to the feline ascarid *T. cati* and even less commonly to the pig ascarid *Ascaris suum*. Rare cases with eosinophilic meningoencephalitis have been caused by the raccoon ascarid *Baylisascaris procyonis*.

Life Cycle and Epidemiology The canine roundworm *T. canis* is distributed among dogs worldwide. Ingestion of infective eggs by dogs is followed by liberation of *Toxocara* larvae, which penetrate the gut wall and migrate intravascularly into canine tissues, where most remain in a developmentally arrested state. During pregnancy, some larvae resume migration in bitches and infect puppies prenatally (through transplacental transmission) or after birth (through suckling). Thus, in lactating bitches and puppies, larvae return to the intestinal tract and develop into adult worms, which produce eggs that are released in the feces. Eggs must undergo embryonation over several weeks to become infectious. Humans acquire toxocariasis mainly by ingesting soil/sand—such as found in public parks and playgrounds—contaminated by dog or cat feces that contains infective *T. canis* eggs.

Pathogenesis and Clinical Features Clinical disease most commonly afflicts preschool children. After humans ingest *Toxocara* eggs, the larvae hatch and penetrate the intestinal mucosa, from which they are carried by the circulation to a wide variety of organs and tissues. The larvae invade the liver, lungs, central nervous system (CNS), and other sites, provoking intense local eosinophilic granulomatous responses. The degree of clinical illness depends on larval number and tissue distribution, reinfection, and host immune responses. Most light infections are asymptomatic and may be evidenced only by blood eosinophilia. Characteristic symptoms of visceral larva migrans include fever, malaise, anorexia and weight loss, cough, wheezing, and rashes. Hepatosplenomegaly is common. These features may be accompanied by extraordinary peripheral eosinophilia at levels that may approach 90%. Uncommonly, seizures or behavioral disorders develop. Rare deaths are due to severe neurologic, pneumonic, or myocardial involvement.

The ocular form of the larva migrans syndrome occurs when *Toxocara* larvae invade the eye. An eosinophilic granulomatous mass, most commonly in the posterior pole of the retina, develops around the entrapped larva. The retinal lesion can mimic retinoblastoma in appearance, and mistaken diagnosis of the latter condition can lead to unnecessary enucleation. The spectrum of eye involvement also includes endophthalmitis, uveitis, and chorioretinitis. Unilateral visual disturbances, strabismus, and eye pain are the most common presenting symptoms. In contrast to visceral larva migrans, ocular toxocariasis usually develops in older children or young adults with no history of pica; these patients seldom have eosinophilia or visceral manifestations.

Diagnosis In addition to eosinophilia, leukocytosis and hypergammaglobulinemia may be evident in visceral larva migrans; these attributes are often absent in ocular larva migrans. Transient pulmonary infiltrates are apparent on chest x-rays of about one-half of patients with symptoms of pneumonitis. The clinical diagnosis can be confirmed by an enzyme-linked immunosorbent assay for toxocaral antibodies, although this assay may be negative in ocular larva migrans. Stool examination for parasite eggs is worthless in toxocariasis, since the larvae do not develop into egg-producing adults in humans.

TREATMENT

Visceral and Ocular Larva Migrans

The vast majority of *Toxocara* infections are self-limited and resolve without specific therapy. In patients with severe myocardial, CNS, or pulmonary involvement, glucocorticoids may be employed to reduce inflammatory complications. Available anthelmintic drugs, including mebendazole and albendazole, have not been shown conclusively to alter the course of larva migrans, although most individuals with moderate to severe visceral larva migrans receive albendazole with concomitant steroids (Table 238-1). Treatment of ocular disease is not fully defined, but the administration of steroids (to decrease ocular inflammation) and albendazole has been effective. Control measures include prohibiting dog excreta in public parks and playgrounds, deworming dogs, and preventing pica in children.

CUTANEOUS LARVA MIGRANS

Cutaneous larva migrans ("creeping eruption") is a serpiginous skin eruption caused by burrowing larvae of animal hookworms, usually the dog and cat hookworm *Ancylostoma braziliense*. The larvae hatch from eggs passed in dog and cat feces and mature in the soil. Humans become infected after skin contact with soil in areas frequented by dogs and cats. Cutaneous larva migrans is prevalent among children and travelers in regions with warm humid climates.

After larvae penetrate the skin, erythematous lesions form along the tortuous tracks of their migration along the dermal-epidermal junction; the larvae advance several centimeters in a day. The intensely pruritic lesions may occur anywhere on the body and can be numerous if the patient has lain on the ground. Vesicles and bullae may form. The animal hookworm larvae do not mature in humans and, without treatment, will die after an interval ranging from weeks to a couple of months, with resolution of skin lesions. The diagnosis is made on clinical grounds. Skin biopsies only rarely detect diagnostic larvae. Symptoms can be alleviated by ivermectin or albendazole (Table 238-1).

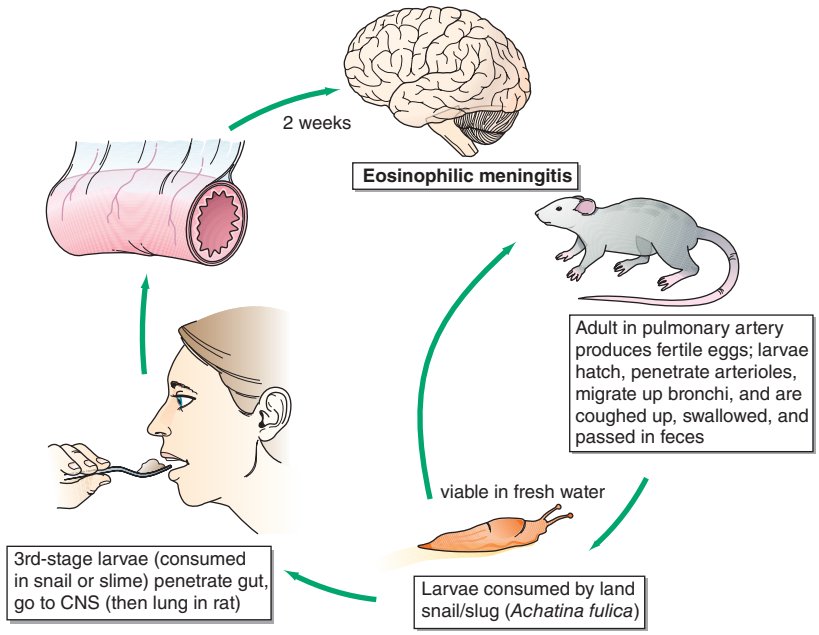

FIGURE 238-3 Life cycle of *Angiostrongylus cantonensis* (rat lung worm) found in Southeast Asia and the Pacific Basin as well as on Caribbean islands, in countries of Central and South America, and in the southern United States. CNS, central nervous system. *(Reproduced with permission from RL Guerrant et al [eds]: Tropical Infectious Diseases: Principles, Pathogens and Practice, 2nd ed. Elsevier, 2006.)*

ANGIOSTRONGYLIASIS

Angiostrongylus cantonensis, the rat lungworm, is the most common cause of human eosinophilic meningitis **(Fig. 238-3)**.

Life Cycle and Epidemiology This infection occurs principally in Southeast Asia and the Pacific Basin (including Hawaii) but has spread to other areas of the world, including the Caribbean islands, countries in Central and South America, and the southern United States. *A. cantonensis* larvae produced by adult worms in the rat lung migrate to the gastrointestinal tract and are expelled with the feces. They develop into infective larvae in land snails and slugs. Humans acquire the infection by ingesting raw infected mollusks; vegetables contaminated by mollusk slime; or crabs, freshwater shrimp, and certain marine fish that have themselves eaten infected mollusks. The larvae then migrate to the brain.

Pathogenesis and Clinical Features The parasites eventually die in the CNS, but not before initiating pathologic consequences that, in heavy infections, can result in permanent neurologic sequelae or death. Migrating larvae cause marked local eosinophilic inflammation and hemorrhage, with subsequent necrosis and granuloma formation around dying worms. Clinical symptoms develop 2–35 days after the ingestion of larvae, typically at about 2 weeks. Patients usually present with an insidious or abrupt excruciating frontal, occipital, or bitemporal headache. Neck stiffness, nausea and vomiting, and paresthesias are also common. Fever, cranial and extraocular nerve palsies, seizures, paralysis, and lethargy are uncommon.

Laboratory Findings Examination of cerebrospinal fluid (CSF) is mandatory in suspected cases and usually reveals an elevated opening pressure, a white blood cell count of 150–2000/μL, and an eosinophilic pleocytosis of >20%. The protein concentration is usually elevated and the glucose level normal. The larvae of *A. cantonensis* are only rarely seen in CSF. Peripheral-blood eosinophilia may be mild. The diagnosis is generally based on the clinical presentation of eosinophilic meningitis together with a compatible epidemiologic history. Serologic tests are sometimes available in endemic regions, although they have not been standardized and may be negative at onset of clinical symptoms. A polymerase chain reaction assay that detects *A. cantonensis* DNA in CSF or other tissues is available, including through the U.S. Centers for Disease Control and Prevention (CDC) and the Hawaii Department of Public Health in the United States.

TREATMENT

Angiostrongyliasis

Many individuals with eosinophilic meningitis from angiostrongyliasis improve with supportive therapy alone. Steroids are often given to decrease inflammation. Specific chemotherapy is of uncertain benefit and should never be given without steroids to prevent exacerbation of inflammatory brain lesions; when given, albendazole is usually employed. (Table 238-1). Repeated lumbar punctures with removal of CSF can assist with symptom relief. In most patients, cerebral angiostrongyliasis has a self-limited course, and recovery is complete. The infection may be prevented by adequately cooking snails, crabs, and prawns and inspecting vegetables for mollusk infestation. Other parasitic or fungal causes of eosinophilic meningitis in endemic areas may include gnathostomiasis (see below), paragonimiasis **(Chap. 241)**, schistosomiasis **(Chap. 241)**, neurocysticercosis **(Chap. 242)**, and coccidioidomycosis **(Chap. 219)**.

A separate species of *Angiostrongylus*, *A. costaricensis*, can inhabit the mesenteric arteries of humans, causing an eosinophilic inflammatory mass in abdominal viscera. *A. costaricensis* is a zoonosis (rat–mollusk/slug life cycle) found in the New World, especially Latin America, and occurs following ingestion of slugs or raw produce contaminated by slug slime. Diagnosis is most commonly made at the time of surgical excision, which is often curative.

GNATHOSTOMIASIS

Infection of human tissues with larvae of *Gnathostoma spinigerum* can cause eosinophilic meningoencephalitis, migratory cutaneous swellings, or invasive masses of the eye and visceral organs.

Life Cycle and Epidemiology Human gnathostomiasis occurs in many countries and is notably endemic in Southeast Asia and parts of China and Japan. In nature, the mature adult worms parasitize the gastrointestinal tract of dogs and cats. First-stage larvae hatch from eggs passed into water and are ingested by *Cyclops* species (water fleas). Infective third-stage larvae develop in the flesh of many animal species (including fish, frogs, eels, snakes, chickens, and ducks) that have eaten either infected *Cyclops* or another infected second intermediate host. Humans typically acquire the infection by eating raw or undercooked

fish or poultry. Raw fish dishes, such as *som fak* in Thailand and *sashimi* in Japan, account for many cases of human gnathostomiasis. Some cases in Thailand result from the local practice of applying frog or snake flesh as a poultice.

Pathogenesis and Clinical Features Clinical symptoms are due to the aberrant migration of a single larva into cutaneous, visceral, neural, or ocular tissues. After invasion, larval migration may cause local inflammation, with pain, cough, or hematuria accompanied by fever and eosinophilia. Painful, itchy, migratory swellings may develop in the skin, particularly in the distal extremities or periorbital area. Cutaneous swellings usually last ~1 week but often recur intermittently over many years. Larval invasion of the eye can provoke a sight-threatening inflammatory response. Invasion of the CNS results in eosinophilic meningitis with myeloencephalitis, a serious complication due to ascending larval migration along a large nerve tract. Patients characteristically present with agonizing radicular pain and paresthesias in the trunk or a limb, which are followed shortly by paraplegia. Cerebral involvement, with focal hemorrhages and tissue destruction, is often fatal.

Diagnosis and Treatment Cutaneous migratory swellings with marked peripheral eosinophilia, supported by an appropriate geographic and dietary history, generally constitute an adequate basis for a clinical diagnosis of gnathostomiasis. However, patients may present with ocular or cerebrospinal involvement without antecedent cutaneous swellings. In the latter case, eosinophilic pleocytosis is demonstrable (usually along with hemorrhagic or xanthochromic CSF), but worms are almost never recovered from CSF. Computed tomography or magnetic resonance imaging of the brain during neuronal gnathostomiasis often demonstrates cerebral hemorrhage from the destructive migration of the parasite. Surgical removal of the parasite from subcutaneous or ocular tissue, though rarely feasible, is both diagnostic and therapeutic. Albendazole or ivermectin may be helpful, especially for cutaneous gnathostomiasis (Table 238-1). At present, cerebrospinal involvement is managed with supportive measures and generally with a course of glucocorticoids; the role of albendazole or ivermectin is uncertain and could be detrimental. Gnathostomiasis can be prevented by adequate cooking of fish and poultry in endemic areas.

239 Intestinal Nematode Infections

David J. Diemert, Thomas B. Nutman

More than one billion individuals worldwide are infected with one or more species of intestinal nematode. **Table 239-1** summarizes biologic and common clinical features of infections due to the major intestinal parasitic nematodes. These parasites are most common in regions with inadequate sanitation and disposal of fecal waste, particularly in resource-limited countries in the tropics and subtropics, although they have also been seen with increasing frequency among immigrants and refugees to developed countries. Although intestinal nematode infections are not usually fatal, they contribute to malnutrition, impaired physical and cognitive development, and diminished work capacity. It is interesting that these helminth infections may protect some individuals from allergic diseases. Humans may on occasion be infected with nematode parasites that ordinarily infect animals; these zoonotic infections produce diseases such as trichostrongyliasis, anisakiasis, capillariasis, and abdominal angiostrongyliasis.

Intestinal nematodes are roundworms that range in length from 1 mm to many centimeters when mature (Table 239-1). Their life cycles are complex and highly varied; some species, including *Strongyloides stercoralis* and *Enterobius vermicularis*, can be transmitted directly from person to person, while others, such as *Ascaris lumbricoides*, *Trichuris trichiura,* and the hookworms, require a soil phase for development. Because most helminth parasites cannot fully complete their life cycle within the same human host, heavy burdens of adult worms require repeated exposure to the parasite in its infectious stage, whether larva or egg. Hence, clinical disease, as opposed to asymptomatic (or subclinical) infection, generally develops only with repeated exposure and is typically related to infection intensity. In children with marginal nutritional status, intestinal helminth infections may impair growth and development. Eosinophilia and elevated serum IgE antibody levels are features of many helminth infections, the latter particularly when the helminth life cycle involves tissue migration such as *A. lumbricoides, S. stercoralis,* or the hookworms. Significant protective immunity to intestinal nematodes appears not to develop in humans.

ASCARIASIS

A. lumbricoides is the largest intestinal nematode parasite of humans, reaching up to 40 cm in length. Most infected individuals have low worm burdens and are asymptomatic. Clinical disease arises from larval migration in the lungs or the effects of adult worms in the intestines.

Life Cycle Adult worms live in the lumen of the small intestine. Mature female *Ascaris* worms are extraordinarily fecund, each producing over 200,000 eggs a day that are expelled within feces. Ascarid eggs, which are remarkably resistant to environmental stresses, become infective after several weeks of maturation in warm, moist soil and can remain infective for years. After infective eggs are swallowed, gastric acid dissolves their protective outer layer, releasing larvae into the intestine that invade the mucosa, migrate through the circulation to the lungs, penetrate into the alveoli, ascend the bronchial tree, and return—through swallowing—to the small intestine, where they develop into adult worms. The time between initial infection and egg detection in the feces is typically between 2 and 3 months. Adult worms live for 1–2 years.

Epidemiology *Ascaris* is widely distributed in tropical and subtropical regions as well as in other humid areas in more temperate regions of the world. Transmission typically occurs through fecally contaminated soil and is due either to inadequate treatment of sewage or to the use of human feces as fertilizer. With their propensity for poorer oral hygiene, younger children are most often affected. Infection outside endemic areas, though uncommon, can occur when eggs on transported produce are ingested.

TABLE 239-1 Major Human Intestinal Parasitic Nematodes

FEATURE	PARASITIC NEMATODE				
	ASCARIS LUMBRICOIDES (ROUNDWORM)	*NECATOR AMERICANUS, ANCYLOSTOMA DUODENALE, ANCYLOSTOMA CEYLANICUM* (HOOKWORM)	*STRONGYLOIDES STERCORALIS*	*TRICHURIS TRICHIURA* (WHIPWORM)	*ENTEROBIUS VERMICULARIS* (PINWORM)

[a]Time from infection to egg production by mature female worm. [b]Assumed but no evidence base in humans.

Clinical Features During the lung phase of larval migration, ~9–12 days after egg ingestion, patients may develop an irritating nonproductive cough and burning substernal discomfort that is aggravated by coughing or deep inspiration. Dyspnea and blood-tinged sputum are less common. Fever can occur. Eosinophilia develops during this symptomatic phase and subsides slowly over weeks. Chest imaging may reveal rounded infiltrates a few millimeters to several centimeters in size that are hallmarks of eosinophilic pneumonitis (Löffler's syndrome). These infiltrates may be transient and intermittent, clearing after several weeks. Where there is seasonal transmission of the parasite such as on the Arabian peninsula, seasonal pneumonitis with eosinophilia may develop in previously infected and sensitized hosts.

In light infections, adult worms in the small intestine usually cause no symptoms. In heavier infections, a large bolus of entangled worms can cause pain and small-bowel obstruction, sometimes complicated by perforation, intussusception, or volvulus. Obstruction is more common in children due to their having intestinal lumens of narrow diameter. Single worms may cause disease when they migrate into aberrant sites. A large worm can enter and occlude the biliary tree, causing biliary colic, cholecystitis, cholangitis, pancreatitis, or (rarely) intrahepatic abscesses. Migration of an adult worm up the esophagus can provoke coughing or vomiting up the worm. In highly endemic areas, intestinal and biliary ascariasis can rival acute appendicitis as a cause of surgical acute abdomen.

Laboratory Findings Most cases of ascariasis can be diagnosed by microscopic detection of characteristic *Ascaris* eggs (65 × 45 µm) in fecal samples, although increasingly, polymerase chain reaction (PCR) of worm DNA extracted from stool is being used in research and some clinical settings. Occasionally, patients present after passing an adult worm—identifiable by its large size and smooth cream-colored surface—in the stool or, much less commonly, through the mouth or nose. During the early transpulmonary migratory phase, when eosinophilic pneumonitis occurs, larvae can be found in sputum or gastric aspirates before diagnostic eggs appear in the stool. The eosinophilia that is prominent during this early stage usually decreases to minimal levels in established infection. Adult worms may be visualized, occasionally serendipitously, on contrast radiographic studies of the gastrointestinal tract. A plain abdominal film may reveal masses of worms in gas-filled loops of bowel in patients with intestinal obstruction. Pancreaticobiliary worms can be detected by ultrasound and endoscopic retrograde cholangiopancreatography; the latter method has been used to extract biliary *Ascaris* worms.

TREATMENT

Ascariasis

Ascariasis should always be treated to prevent potentially serious complications. Albendazole (400 mg once), mebendazole (100 mg twice daily for 3 days or 500 mg once), pyrantel pamoate (11 mg/kg once with a maximum dose not to exceed 1 g), ivermectin (150–200 µg/kg once), and moxidectin (8 mg once) are effective. These medications are contraindicated in pregnancy, however. Mild diarrhea and abdominal pain are uncommon side effects of these agents.

Partial intestinal obstruction should be managed with nasogastric suction, IV fluid administration, and instillation of piperazine through the nasogastric tube, although complete obstruction and its severe complications require immediate surgical intervention.

HOOKWORM

Three species (*Necator americanus, Ancylostoma duodenale*, and *Ancylostoma ceylanicum*) are responsible for most human hookworm infections. Most infected individuals are asymptomatic. Hookworm disease develops from a combination of factors—heavy worm burden, prolonged duration of infection, and inadequate iron intake—and results in iron-deficiency anemia and, on occasion, hypoproteinemia.

Life Cycle Adult hookworms, which are ~1 cm long, use buccal teeth (*Ancylostoma*) or cutting plates (*Necator*) to attach to the small-bowel mucosa where they secrete enzymes that enable them to invade submucosal tissues and ingest blood and villous tissue. Female adult hookworms produce thousands of eggs daily. The eggs are deposited with feces in soil, where rhabditiform larvae hatch and develop over a 1-week period into infectious filariform larvae. Infective larvae penetrate the skin and reach the lungs by way of the bloodstream. There they invade alveoli and ascend the airways to the larynx before being swallowed and reaching the small intestine. The prepatent period from skin penetration to appearance of eggs in the feces is ~6–8 weeks, but it may be longer with *Ancylostoma* spp. Less commonly, larvae of *Ancylostoma* spp., if swallowed orally, can survive and develop directly into adult worms that parasitize the intestinal mucosa. Adult hookworms may survive over a decade but usually live ~6–8 years for *A. duodenale* and 2–5 years for *N. americanus*.

Epidemiology Over 400 million people are infected with hookworms worldwide. Whereas *N. americanus* is the predominant species throughout the tropics and subtropics, *A. duodenale* is more geographically restricted to areas of North Africa and northern Asia. *A. ceylanicum* is much less common than the other two species and is mainly found in Southeast Asia. Age prevalence studies have shown a constant increase in hookworm prevalence throughout childhood and into adulthood. Older children have the greatest intensity of hookworm infection; however, in rural areas where fields are fertilized with human feces, older working adults also may be heavily infected.

Clinical Features Most hookworm infections are of light intensity and therefore are clinically asymptomatic. Infective larvae may provoke a pruritic maculopapular rash ("ground itch") at the site of skin penetration as well as serpiginous tracks of subcutaneous migration (similar to those of cutaneous larva migrans; **Chap. 238**) in previously sensitized hosts. Larvae migrating through the lungs occasionally cause mild transient pneumonitis, but this condition develops less frequently in hookworm infection than in ascariasis. In the early intestinal phase, infected persons may develop epigastric pain, abdominal bloating, and other abdominal symptoms accompanied by eosinophilia. The major consequence of chronic hookworm infection is iron deficiency. Symptoms are minimal if iron stores are adequate, but undernourished individuals develop symptoms of progressive iron-deficiency anemia and hypoproteinemia, including fatigue, weakness, and shortness of breath.

Laboratory Findings The diagnosis is established by the finding of characteristic 40 × 60 μm oval hookworm eggs in the feces. Stool concentration techniques may be required to detect light infections. Eggs of the three species are indistinguishable by light microscopy, whereas PCR provides significant improvement in species-specific diagnosis, although this remains a research tool that is not available in commercial laboratories. In a stool sample that is not fresh, hookworm eggs may have hatched to release rhabditiform larvae, which must be differentiated from those of *S. stercoralis*. Hypochromic microcytic anemia, occasionally with eosinophilia or hypoalbuminemia, is characteristic of hookworm disease.

TREATMENT

Hookworm Infection

Hookworm infection can be treated with several safe and effective anthelmintic drugs, including albendazole (400 mg once daily for 3 days) and mebendazole (500 mg once daily or 100 mg twice daily for 3 days). Mild iron-deficiency anemia can often be treated with oral iron supplementation alone. Severe hookworm disease with protein loss and malabsorption necessitates nutritional support and oral iron replacement along with deworming. There is significant concern that the benzimidazoles (mebendazole and albendazole) are becoming much less effective against human hookworms.

Ancylostoma caninum* and *Ancylostoma braziliense *A. caninum*, the canine hookworm, has been identified as a cause of human eosinophilic enteritis, especially in northeastern Australia. In this rare zoonotic infection, adult hookworms attach to the small intestine (where they may be visualized by endoscopy) and elicit abdominal pain and intense local eosinophilia. Treatment with mebendazole (100 mg twice daily for 3 days) or albendazole (400 mg once) or endoscopic removal is effective. Both of these animal hookworm species can cause cutaneous larva migrans ("creeping eruption"; **Chap. 238**).

STRONGYLOIDIASIS

S. stercoralis is distinguished by its ability—unique among helminths (except for *Capillaria*; see below)—to complete its life cycle and replicate within a human host. This capacity permits ongoing cycles of autoinfection as infective larvae are internally produced that can develop into egg-producing adult worms without exiting the host. Infection with *S. stercoralis* can thus persist for decades without further exposure to exogenous infective larvae. In immunocompromised hosts, large numbers of invasive *Strongyloides* larvae can disseminate widely and can be fatal.

Life Cycle In addition to a parasitic life cycle in the human host, *Strongyloides* can undergo a free-living cycle of development in the soil **(Fig. 239-1)**. This adaptability facilitates the parasite's survival in the absence of mammalian hosts. Rhabditiform larvae passed in feces can transform into infectious filariform larvae either directly or after a free-living phase of development. Humans acquire *S. stercoralis* when filariform larvae in fecally contaminated soil penetrate the skin or mucous membranes. The larvae then travel through the bloodstream to the lungs, where they break into the alveolar spaces, ascend the bronchial tree, are swallowed, and thereby reach the small intestine. There the larvae mature into adult worms that embed in the mucosa of the proximal small bowel. The minute (1- to 2-mm long) parasitic adult female worms reproduce by parthenogenesis; adult males do not exist in the human host. Eggs hatch in the intestinal mucosa, releasing rhabditiform larvae that migrate to the lumen and pass with the feces into soil. Alternatively, rhabditiform larvae in the bowel can develop directly into filariform larvae that penetrate the colonic wall or perianal skin and enter the circulation to repeat the migration that establishes ongoing internal reinfection.

Epidemiology *S. stercoralis* is spottily distributed in tropical areas and other warm, humid regions and is common in Southeast Asia, sub-Saharan Africa, and Brazil. In the United States, the parasite is endemic in parts of the Southeast and is found in immigrants, refugees, travelers, and military personnel who have lived in endemic areas.

Clinical Features In uncomplicated strongyloidiasis, many patients are asymptomatic or have mild cutaneous and/or abdominal symptoms. Recurrent urticaria, often involving the buttocks, is the most common cutaneous manifestation. Larvae migrating in the skin can elicit a pathognomonic serpiginous eruption known as *larva currens*. This pruritic, raised, erythematous lesion advances as rapidly as 10 cm/h along the course of larval migration. Adult parasites burrow into the duodenojejunal mucosa and can cause abdominal (usually midepigastric) pain, which resembles peptic ulcer disease except that

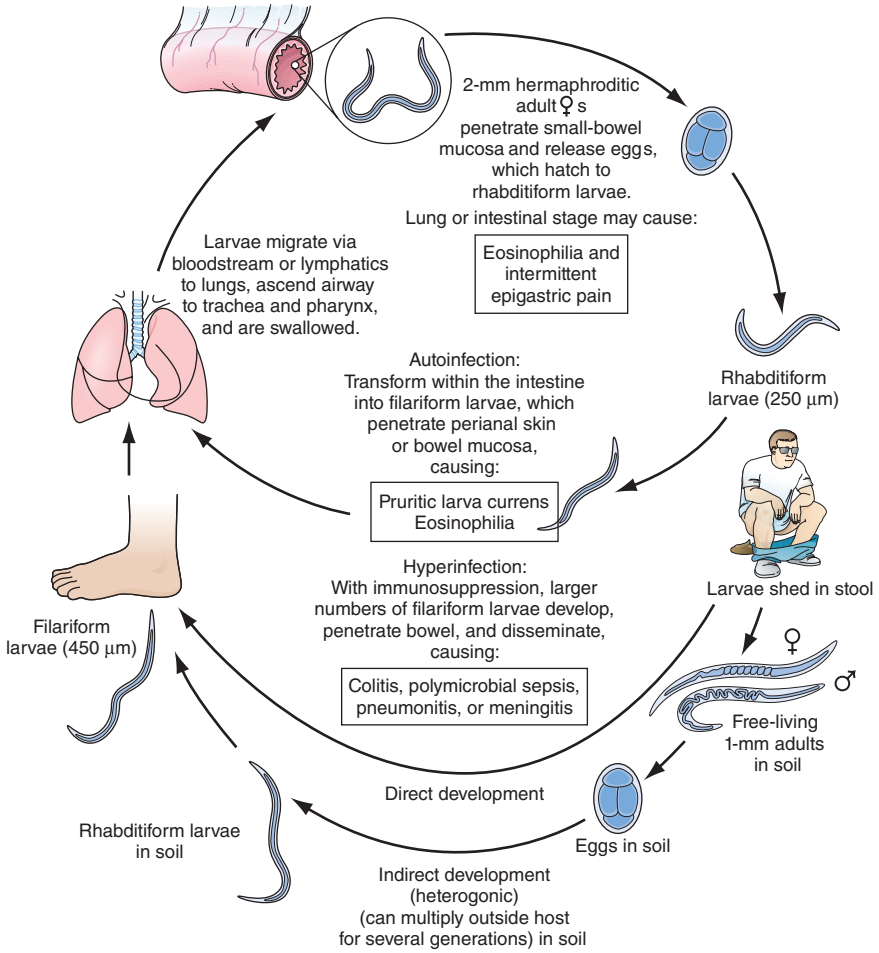

FIGURE 239-1 Life cycle of *Strongyloides stercoralis*. *(Reproduced with permission from RL Guerrant et al [eds]: Tropical Infectious Diseases: Principles, Pathogens and Practice, 2nd ed. Elsevier, 2006.)*

it is aggravated by food ingestion. Nausea, watery diarrhea, abdominal bloating, occult gastrointestinal bleeding, and weight loss can occur. Small-bowel obstruction may develop with early, heavy infection. Pulmonary symptoms are rare in uncomplicated strongyloidiasis. Eosinophilia is common, with levels fluctuating over time.

The ongoing autoinfection cycle of *S. stercoralis* is normally constrained by the host's immune system. Impairment of host cell-mediated immunity, especially with high-dose glucocorticoid therapy and less commonly with other immunosuppressive medications, or associated with infection with human T-cell lymphotropic virus type 1 (HTLV-1), may lead to hyperinfection and the generation of large numbers of filariform larvae. Colitis, enteritis, or malabsorption may develop. Hyperinfection can also lead to disseminated strongyloidiasis, characterized by larvae invading not only gastrointestinal tissues and the lungs but also the central nervous system, skin, peritoneum, liver, and kidneys. Moreover, bacteremia may develop because of the spread of enteric flora through disrupted mucosal barriers. Gram-negative sepsis, pneumonia, or meningitis may complicate or dominate the clinical course. Eosinophilia is often absent in severely infected patients. Disseminated strongyloidiasis, particularly in patients with unsuspected infection who are taking glucocorticoids, has a high mortality rate.

Diagnosis In uncomplicated strongyloidiasis, visualizing rhabditiform larvae by light microscopic examination of a fecal sample is diagnostic. Rhabditiform larvae are ~250 μm long, with a short buccal cavity that distinguishes them from hookworm larvae. In uncomplicated infections, few larvae are passed and single stool examinations detect only about one-third of cases. Serial examinations and the use of the agar plate detection method improve the sensitivity of stool diagnosis. Again, PCR has begun to be used more widely and provides increased diagnostic sensitivity. In hyperinfection, a single microscopy-based stool examination is usually positive given the large number of larvae being produced. *Strongyloides* larvae may also be found by sampling of the duodenojejunal contents by aspiration or biopsy. An enzyme-linked immunosorbent assay for serum antibodies to antigens of *Strongyloides* is a sensitive method for diagnosing uncomplicated infections. Such serologic testing should be performed for patients with prior potential exposure, especially those with eosinophilia and/or those who may be starting glucocorticoid therapy or undergoing solid organ transplantation. In disseminated strongyloidiasis, filariform larvae are easily detected in stool as well as in samples obtained from sites of potential larval migration, including sputum, bronchoalveolar lavage fluid, or surgical drainage fluid.

TREATMENT

Strongyloidiasis

Even in the asymptomatic state, strongyloidiasis must be treated because of the potential for subsequent hyperinfection and fatal dissemination. Ivermectin (200 μg/kg daily for 2 days) is more effective than albendazole (400 mg daily for 3 days). Decreases in eosinophil count and antibody titer indicate a response to treatment. For disseminated strongyloidiasis, treatment with ivermectin should be extended for at least 14 days after fecal examinations have become negative. In potentially immunocompromised hosts, the course of ivermectin should be repeated 2 weeks after initial treatment. Ivermectin has been successfully given per rectum in those unable to take ivermectin orally and can be given parenterally (using veterinary preparations) through single-patient expanded access protocols.

TRICHURIASIS

Most infections with *Trichuris trichiura* are asymptomatic, but heavy infections may cause gastrointestinal symptoms. Like the other soil-transmitted helminths, whipworm is distributed globally in the tropics and subtropics and is most common among poor children from resource-limited regions of the world.

Life Cycle Adult *Trichuris* worms reside in the colon and cecum, their thin anterior portions embedded in the superficial mucosa. Thousands of eggs laid daily by adult female worms pass with the feces and mature in the soil. After ingestion, infective eggs hatch in the duodenum, releasing larvae that mature before migrating to the large bowel. The entire cycle takes ~3 months, and adult worms may live for several years.

Clinical Features Most individuals infected with *T. trichiura* have no symptoms or eosinophilia. Heavy infections may result in anemia, abdominal pain, anorexia, and bloody or mucoid diarrhea resembling inflammatory bowel disease. Rectal prolapse can result from massive infections in children due to protracted tenesmus. Moderately heavy *T. trichiura* burdens also contribute to impaired physical growth.

Diagnosis and Treatment The characteristic 50 × 20 μm lemon-shaped *T. trichiura* eggs are readily detected on microscopic examination of stool. Adult worms, which are 3–5 cm long, are occasionally seen on proctoscopy. PCR is being used increasingly in settings where it is available. Albendazole (400 mg daily for 3 days) or mebendazole (100 mg twice daily for 3 days) is safe and moderately effective for treatment. The addition of ivermectin (200 μg/kg daily for 3 doses) to either benzimidazole drug increases cure rates significantly.

ENTEROBIASIS (PINWORM)

E. vermicularis is more common in temperate climates than in the tropics. In the United States, ~40 million persons are infected with pinworms, with most cases occurring in children.

Life Cycle and Epidemiology Adult *Enterobius* worms are ~5–10 mm long and dwell in the cecum. Gravid female worms migrate nocturnally out of the anus to the perianal region where they release up to 10,000 immature eggs each. The eggs become infective within hours and are transmitted by hand-to-mouth passage. From ingested eggs, larvae hatch and mature into adults. This life cycle takes ~1 month, and adult worms survive for ~2 months. Autoinfection results from perianal scratching and transport of infective eggs on the fingers or under the nails to the mouth. Retroinfection can also occur by larvae released from embryonated eggs on the perianal skin migrating back into the rectum. Because of the ease of person-to-person spread, pinworm infections are common among family members.

Clinical Features Most pinworm infections are asymptomatic. Perianal pruritus is the cardinal symptom. The itching, which is often worse at night as a result of the nocturnal emergence of female worms, may lead to excoriation and bacterial superinfection. Heavy infections have been associated with abdominal pain, weight loss, and rarely acute appendicitis. Uncommonly, pinworms may migrate into the female genital tract, causing vulvovaginitis and pelvic or peritoneal granulomas. Eosinophilia is uncommon.

Diagnosis Since pinworm eggs are not released in feces, the diagnosis cannot be made by conventional fecal ova and parasite microscopy. Instead, eggs are detected by the application of clear cellulose acetate tape to the perianal region in the morning. After the tape is transferred to a slide, microscopic examination can detect pinworm eggs, which are oval, measure 55 × 25 μm, and are flattened along one side.

TREATMENT

Enterobiasis

Infected children and adults should be treated with mebendazole (100 mg once), albendazole (400 mg once), or pyrantel pamoate (11 mg/kg once), with the same treatment repeated after 2 weeks because the drugs do not kill eggs or early-stage larvae. Treatment of household members is recommended to eliminate asymptomatic reservoirs of potential reinfection. Linens and clothing should be washed in hot water followed by a hot dryer to kill deposited eggs.

TRICHOSTRONGYLIASIS

Trichostrongylus species, which are normally parasites of herbivorous animals, occasionally infect humans, particularly in Asia, Africa, and Australia. Humans acquire the infection by accidentally ingesting *Trichostrongylus* larvae on contaminated leafy vegetables. The larvae do not migrate in humans but mature directly into adult worms in the small bowel. The pathology caused by these worms is similar to hookworm, although they ingest far less blood. Most infected persons are asymptomatic, but heavy infections may give rise to mild anemia and eosinophilia. In stool examinations, *Trichostrongylus* eggs resemble hookworm eggs but are larger (85 × 115 μm). Treatment consists of mebendazole, albendazole, or pyrantel pamoate **(Chap. 229)**.

ANISAKIASIS

Anisakiasis is a gastrointestinal infection caused by the accidental ingestion in uncooked saltwater fish of nematode larvae belonging to the family Anisakidae. The incidence of anisakiasis in the United States has increased as a result of the growing popularity of raw fish dishes. Most cases occur in Japan, the Netherlands, and Chile, where raw fish—sashimi, pickled green herring, and ceviche, respectively—are national culinary staples. Anisakid nematodes parasitize large sea mammals such as whales, dolphins, and seals. As part of a complex parasitic life cycle involving marine food chains, infectious larvae migrate to the musculature of a variety of fish species that serve as intermediate hosts. Both *Anisakis simplex* and *Pseudoterranova decipiens* have been implicated in human anisakiasis, but an identical gastric syndrome may be caused by the red larvae of eustrongylid parasites of fish-eating birds.

When humans consume infected raw or undercooked fish, live larvae may be coughed up within 48 h. Alternatively, larvae may immediately penetrate the mucosa of the stomach. Within hours, violent upper abdominal pain accompanied by nausea and occasionally vomiting ensues, mimicking an acute abdomen. The diagnosis can be established by direct visualization on upper endoscopy, outlining of the worm by contrast radiographic studies, or histopathologic examination of extracted tissue. Extraction of the burrowing larvae during endoscopy is curative. In addition, larvae may pass to the small bowel, where they penetrate the mucosa and provoke a vigorous eosinophilic granulomatous response. Symptoms may appear 1–2 weeks after the infective meal, with intermittent abdominal pain, diarrhea, nausea, and fever resembling the manifestations of Crohn's disease. Ingestion of *Anisakis*-derived proteins through consumption of fish meat containing *Anisakis* parasites can elicit allergic gastrointestinal and even anaphylactic responses.

Anisakid eggs are not found in the stool since the larvae do not mature in humans. Serologic tests have been developed but are not widely available.

Anisakid larvae in saltwater fish are killed by cooking to 60°C, freezing at –20°C for 3 days, or commercial blast freezing, but usually not by salting, marinating, or cold smoking. No medical treatment is available; surgical or endoscopic removal should be undertaken.

CAPILLARIASIS

Intestinal capillariasis is caused by ingestion of raw fish infected with *Capillaria philippinensis*. Subsequent autoinfection can lead to a severe wasting syndrome. The disease occurs in the Philippines and Thailand and, on occasion, elsewhere in Asia. The natural life cycle of *C. philippinensis* involves fish from fresh and brackish water. When humans eat infected raw fish, the larvae mature in the intestine into adult worms, which produce invasive larvae that cause intestinal inflammation and villus loss and can develop into new adult worms without leaving the human host. Capillariasis has an insidious onset

with nonspecific abdominal pain and watery diarrhea. If untreated, repeated rounds of autoinfection can lead to protein-losing enteropathy, severe malabsorption, and ultimately death from cachexia, cardiac failure, or superinfection. The diagnosis is made by identifying characteristic peanut-shaped (20 × 40 μm) eggs on microscopic examination of stool. Severely ill patients require hospitalization and supportive therapy in addition to prolonged anthelmintic treatment with albendazole (400 mg twice daily for 10 days) or mebendazole (500 mg daily for 20 days; **Chap. 229**).

ABDOMINAL ANGIOSTRONGYLIASIS

Abdominal angiostrongyliasis is primarily a disease of children living in Latin America. The zoonotic parasite *Angiostrongylus costaricensis* causes eosinophilic ileocolitis after the ingestion of contaminated vegetation. *A. costaricensis* normally parasitizes the cotton rat and other rodents, with slugs and snails serving as intermediate hosts. Humans become infected by accidentally ingesting infective larvae in mollusk slime deposited on fruits and vegetables; children are at highest risk. The larvae penetrate the gut wall and migrate to mesenteric arterioles, where they develop into adult worms. Eggs deposited in the gut wall provoke an intense eosinophilic granulomatous reaction, and adult worms may cause mesenteric arteritis, thrombosis, or frank bowel infarction. Symptoms may mimic those of appendicitis, including abdominal pain and tenderness, fever, vomiting, and a palpable mass in the right iliac fossa. Leukocytosis and eosinophilia are prominent. CT with contrast typically shows inflamed bowel, often with concomitant obstruction, but a definitive diagnosis is usually made histologically after partial bowel resection. Pathologic examination reveals a thickened bowel wall with eosinophilic granulomas surrounding the *Angiostrongylus* eggs. In nonsurgical cases, the diagnosis rests solely on clinical grounds because larvae and eggs cannot be detected in the stool and serologic tests are not available. Medical therapy for abdominal angiostrongyliasis is of uncertain efficacy. Careful observation and surgical resection for severe symptoms are the mainstays of treatment.

240 Filarial and Related Infections

Philip J. Budge, Thomas B. Nutman

Filarial worms are nematodes that dwell in the subcutaneous tissues and the lymphatics. Eight filarial species infect humans **(Table 240-1)**; of these, four—*Wuchereria bancrofti*, *Brugia malayi*, *Onchocerca volvulus*, and *Loa loa*—are responsible for most symptomatic filarial infections. Filarial parasites, which infect an estimated 170 million persons worldwide, are transmitted by specific species of mosquitoes or other arthropods and have a complex life cycle, including insect-borne infective larval stages and adult worms that reside in either lymphatic or subcutaneous tissues of humans. The offspring of adults are microfilariae, which, depending on their species, are 200–250 μm long and 5–7 μm wide, may or may not be enveloped in a loose sheath, and either circulate in the blood or migrate through the skin (Table 240-1). To complete the life cycle, microfilariae are ingested by the arthropod vector and develop over 1–2 weeks into new infective larvae. Adult worms live for many years, whereas microfilariae survive for 3–36 months. The intracellular bacterial endosymbiont *Wolbachia* has been found in all stages of *Brugia*, *Wuchereria*, *Mansonella*, and *Onchocerca* species and has become a target for antifilarial chemotherapy.

Usually, infection is established only with repeated, prolonged exposures to infective larvae. Since the clinical manifestations of filarial diseases develop relatively slowly, these infections should be considered chronic, with possible long-term debilitating effects. The nature, severity, and timing of clinical manifestations in patients with filarial infections who are native to endemic areas and have lifelong exposure may differ significantly from those who are travelers or who have recently moved to these areas. Characteristically, filarial disease is more acute and intense in newly exposed individuals than in natives of endemic areas.

LYMPHATIC FILARIASIS

Lymphatic filariasis is caused by *W. bancrofti*, *B. malayi*, or *Brugia timori*. The threadlike adult parasites reside in afferent lymphatics or lymph nodes, where they may remain viable for more than two decades.

EPIDEMIOLOGY

W. bancrofti, the most widely distributed filarial parasite of humans, affects an estimated 51 million people and is found throughout the tropics and subtropics, including Asia and the Pacific Islands, Africa, areas of South America, and the Caribbean basin. Humans are the only definitive host for the parasite. Generally, the subperiodic form is found only in the Pacific Islands; elsewhere, *W. bancrofti* is nocturnally periodic. Nocturnally periodic forms of microfilariae are scarce in peripheral blood by day and increase at night, whereas subperiodic forms are present in peripheral blood at all times and reach maximal levels in the afternoon. Natural vectors for *W. bancrofti* are *Culex* mosquitoes in urban settings and *Anopheles* or *Aedes* mosquitoes in rural areas.

Brugian filariasis due to *B. malayi* occurs primarily in eastern India, Indonesia, Malaysia, and the Philippines. *B. malayi* also has two forms distinguished by the periodicity of microfilaremia. The more common nocturnal form is transmitted in areas of coastal rice fields, while the subperiodic form is found in forests. *B. malayi* naturally infects cats as well as humans. The distribution of *B. timori* is limited to the islands of southeastern Indonesia.

PATHOLOGY

The principal pathologic changes of lymphatic filariasis result from inflammatory damage to the lymphatics, which is typically caused by adult worms and not by microfilariae. Adult worms live in afferent lymphatics or sinuses of lymph nodes and cause lymphatic dilation and thickening of the vessel walls. The infiltration of plasma cells,

eosinophils, and macrophages in and around the infected vessels, along with endothelial and connective tissue proliferation, leads to tortuosity of the lymphatics and damaged or incompetent lymph valves. Lymphedema and chronic stasis changes with hard or brawny edema develop in the overlying skin. These consequences of filarial infection are due both to the direct effects of the worms and to the host's inflammatory response to the parasite. Inflammatory responses are believed to cause the granulomatous and proliferative processes that precede total lymphatic obstruction. It is thought that the lymphatic vessel remains patent as long as the worm remains viable, and that the death of the worm leads to enhanced granulomatous reactions and fibrosis. Lymphatic obstruction results, and despite collateralization, lymphatic function is compromised.

CLINICAL FEATURES

The most common presentations of the lymphatic filariases are asymptomatic (or subclinical) microfilaremia, hydrocele **(Fig. 240-1)**, acute adenolymphangitis (ADL), and chronic lymphatic disease. In areas where *W. bancrofti* or *B. malayi* is endemic, most infected individuals have few overt clinical manifestations of filarial infection despite the presence of circulating microfilariae in the peripheral blood. Although they may be clinically asymptomatic, virtually all persons with *W. bancrofti* or *B. malayi* microfilaremia have some degree of subclinical disease that includes microscopic hematuria and/or proteinuria, dilated (and tortuous) lymphatics (visualized by imaging), and—in men with *W. bancrofti* infection—scrotal lymphangiectasia (detectable by ultrasound). Despite these findings, most individuals appear to remain clinically asymptomatic for years; in relatively few does the infection progress to either acute or chronic disease.

FIGURE 240-1 Hydrocele associated with *Wuchereria bancrofti* infection.

ADL is characterized by high fever, lymphatic inflammation (lymphangitis and lymphadenitis), and transient local edema. The lymphangitis is retrograde, extending peripherally from the lymph node draining the area where the adult parasites reside. Regional lymph nodes are often enlarged, and the entire lymphatic channel can become indurated and inflamed. Concomitant local thrombophlebitis can occur as well. In brugian filariasis, a single local abscess may form along the involved lymphatic tract and subsequently rupture to the surface. The lymphadenitis and lymphangitis can involve both the upper and lower extremities in both bancroftian and brugian filariasis, but involvement of the genital lymphatics occurs almost exclusively with *W. bancrofti* infection. This genital involvement can be manifested by funiculitis, epididymitis, and scrotal pain and tenderness. In endemic areas, another type of acute disease—dermatolymphangioadenitis (DLA)—is recognized as a syndrome that includes high fever, chills, myalgias, and headache. Edematous inflammatory plaques clearly demarcated from normal skin are seen. Vesicles, ulcers, and hyperpigmentation also may be noted. There is often a history of trauma, burns, irradiation, insect bites, punctiform lesions, or chemical injury. Entry lesions, especially in the interdigital area, are common. DLA is often diagnosed as cellulitis.

If lymphatic damage progresses, transient lymphedema can develop into lymphatic obstruction and the permanent changes associated with elephantiasis **(Fig. 240-2)**. Brawny edema follows early pitting edema, the subcutaneous tissues thicken, and hyperkeratosis occurs. Fissuring of the skin develops, as do hyperplastic changes. Superinfection of these poorly vascularized tissues becomes a problem. In bancroftian filariasis, in which genital involvement is common, hydroceles may develop (Fig. 240-1); in advanced stages, this condition may evolve into scrotal lymphedema and scrotal elephantiasis. Furthermore, if there is obstruction of the retroperitoneal lymphatics, increased renal lymphatic pressure leads to rupture of the renal lymphatics and the development of chyluria, which is usually intermittent and most prominent in the morning.

FIGURE 240-2 Elephantiasis of the lower extremity associated with *Wuchereria bancrofti* infection.

The clinical manifestations of filarial infections in travelers or transmigrants who have recently entered an endemic region are distinctive. Given a sufficient number of bites by infected vectors, usually over a 3- to 6-month period, recently exposed patients can develop acute lymphatic or scrotal inflammation with or without urticaria and localized angioedema. Lymphadenitis of epitrochlear, axillary, femoral, or inguinal lymph nodes is often followed by evolving retrograde lymphangitis. Acute attacks are short-lived and are not usually accompanied by fever. With prolonged exposure to infected mosquitoes, these attacks, if untreated, become more severe and lead to permanent lymphatic inflammation and obstruction.

DIAGNOSIS

A definitive diagnosis can be made only by detection of the parasites and hence can be difficult. Adult worms localized in lymphatic vessels or nodes are largely inaccessible. Microfilariae can be found in blood, in hydrocele fluid, or (occasionally) in other body fluids. Such fluids can be examined microscopically, either directly or—for greater sensitivity—after concentration of the parasites by the passage of fluid through a polycarbonate cylindrical-pore filter (pore size, 3 μm) or by the centrifugation of fluid fixed in 2% formalin (Knott's concentration technique). The timing of blood collection is critical and should be based on the periodicity of the microfilariae in the endemic region involved. Many infected individuals do not have microfilaremia, and definitive diagnosis in such cases can be difficult. Assays for circulating antigens of *W. bancrofti* permit the diagnosis of microfilaremic and cryptic (amicrofilaremic) infection. Two tests are commercially available: an enzyme-linked immunosorbent assay (ELISA) and a rapid-format lateral flow assay. Both assays have sensitivities of 93–100% and specificities approaching 100%, although false positives can occur in individuals infected with *Loa loa* (see "Loiasis" below). There are currently no tests for circulating antigens in brugian filariasis.

Polymerase chain reaction (PCR)–based assays for DNA of *W. bancrofti* and *B. malayi* in blood have been developed. A number of studies indicate that the sensitivity of this diagnostic method is equivalent to or greater than that of parasitologic methods.

In cases of suspected lymphatic filariasis, examination of the scrotum, the lymph nodes, or (in female patients) the breast by means of high-frequency ultrasound in conjunction with Doppler techniques may result in the identification of motile adult worms within dilated lymphatics **(Video 240-1)**. Worms may be visualized in the lymphatics of the spermatic cord in up to 80% of men infected with *W. bancrofti*. Live adult worms have a distinctive pattern of movement within the lymphatic vessels (termed the *filarial dance sign*). Radionuclide lymphoscintigraphic imaging of the limbs reliably demonstrates widespread lymphatic abnormalities in both subclinical microfilaremic persons and those with clinical manifestations of lymphatic pathology. Although of potential utility in the delineation of anatomic changes associated with infection, lymphoscintigraphy is unlikely to assume primacy in the diagnostic evaluation of individuals with suspected infection; it is principally a research tool, although it has been used more widely for assessment of lymphedema of any cause. Eosinophilia and elevated serum concentrations of IgE and antifilarial antibody support the diagnosis of lymphatic filariasis. There is, however, extensive cross-reactivity between filarial antigens and antigens of other helminths. Of note, *W. bancrofti*– and *B. malayi*–specific antigens have been identified and are now available for use in rapid diagnostic tests with specificities of >98%. However, seropositivity cannot be equated with active infection: residents of endemic areas can become sensitized to filarial antigens through exposure to infective mosquitoes without having patent filarial infections.

The ADL associated with lymphatic filariasis must be distinguished from thrombophlebitis, infection, and trauma. Retrograde evolution is a characteristic feature that helps distinguish filarial lymphangitis from ascending bacterial lymphangitis. Chronic filarial lymphedema must also be distinguished from the lymphedema of malignancy, postoperative scarring, trauma, chronic edematous states, and congenital lymphatic system abnormalities.

TREATMENT

Lymphatic Filariasis

With newer definitions of clinical syndromes in lymphatic filariasis and new tools to assess clinical status (e.g., ultrasound, lymphoscintigraphy, circulating filarial antigen assays, PCR), approaches to treatment based on infection status can be considered.

Orally administered diethylcarbamazine (DEC; 6 mg/kg daily for 12 days), which has both macro- and microfilaricidal properties, remains the drug of choice for the treatment of active lymphatic filariasis (defined by microfilaremia, antigen positivity, or adult worms on ultrasound), although albendazole (400 mg twice daily by mouth for 21 days) also has demonstrated macrofilaricidal efficacy. A 4- to 6-week course of oral doxycycline (targeting the intracellular *Wolbachia*) also has significant macrofilaricidal activity, as does DEC/albendazole used daily for 7 days. The addition of DEC to a 3-week course of doxycycline is also efficacious in lymphatic filariasis.

Regimens that combine single doses of albendazole (400 mg) with either DEC (6 mg/kg) or ivermectin (200 μg/kg) all have a sustained microfilaricidal effect and are the mainstay of programs for the eradication of lymphatic filariasis in Africa (albendazole/ivermectin) and elsewhere (albendazole/DEC) (see "Prevention and Control," below). More recently, a regimen using single doses of the three major antifilarial drugs (albendazole/DEC/ivermectin) has been shown to sustain microfilarial clearance out to at least 2 years.

As already mentioned, a growing body of evidence indicates that, although they may be asymptomatic, virtually all persons with *W. bancrofti* or *B. malayi* microfilaremia have some degree of subclinical disease (hematuria, proteinuria, abnormalities on lymphoscintigraphy). Thus, early treatment of asymptomatic persons who have microfilaremia is recommended to prevent further lymphatic damage. For ADL, supportive treatment (including the administration of antipyretics and analgesics) is recommended, as is antibiotic therapy if secondary bacterial infection is likely. Similarly, because

lymphatic disease is associated with the presence of adult worms, treatment with DEC is recommended for microfilaria-negative carriers of adult worms.

In persons with chronic manifestations of lymphatic filariasis, treatment regimens that emphasize hygiene, prevention of secondary bacterial infections, and physiotherapy have gained wide acceptance for morbidity control. These regimens are similar to those recommended for lymphedema of most nonfilarial causes and are known by a variety of names, including *complex decongestive physiotherapy* and *complex lymphedema therapy*. Hydroceles (Fig. 240-1) can be managed surgically. With chronic manifestations of lymphatic filariasis, drug treatment should be reserved for individuals who have evidence of active infection; however, in some settings, a 6-week course of doxycycline has been shown to provide improvement in filarial lymphedema irrespective of disease activity.

Side effects of DEC treatment in infected individuals may include fever, chills, arthralgias, headaches, nausea, and vomiting. Both the development and the severity of these reactions are directly related to the number of microfilariae circulating in the bloodstream. The adverse reactions may represent either an acute hypersensitivity reaction to the antigens being released by dead and dying parasites or an inflammatory reaction induced by the intracellular *Wolbachia* endosymbionts freed from their intracellular niche.

Ivermectin has a side effect profile similar to that of DEC when used in lymphatic filariasis. In patients infected with *L. loa* who have high levels of microfilaremia, DEC—like ivermectin (see "Loiasis," below)—can elicit severe encephalopathic complications. When used in single-dose regimens for the treatment of lymphatic filariasis, albendazole is associated with relatively few side effects.

PREVENTION AND CONTROL

To protect themselves against filarial infection, individuals must avoid contact with infected mosquitoes by using personal protective measures, including bed nets, particularly those impregnated with insecticides such as permethrin. Mass drug administration (MDA) is the current approach to elimination of lymphatic filariasis as a public health problem. The underlying tenet of this approach is that mass annual distribution of antifilarial chemotherapy—albendazole with either DEC (for all areas except those where onchocerciasis is co-endemic; see section on onchocerciasis treatment, below) or ivermectin or with both ivermectin and DEC (triple-drug therapy)—will profoundly suppress microfilaremia. If the suppression is sustained, then transmission can be interrupted.

Created by the World Health Organization in 1997, the Global Programme to Eliminate Lymphatic Filariasis is based on mass administration of single annual doses of DEC plus albendazole in non-African regions and of albendazole plus ivermectin in Africa. Available information from late 2022 indicated that >935 million persons in 68 countries had thus far participated. Not only has lymphatic filariasis been eliminated in some defined areas, but collateral benefits—avoidance of disability and treatment of intestinal helminths and other conditions (e.g., scabies and louse infestation)—also have been noted. The strategy of the global program is being refined, and attempts are being made to integrate this effort with other mass-treatment strategies (e.g., deworming programs, malaria control, and trachoma control) in an integrated control strategy.

TROPICAL PULMONARY EOSINOPHILIA

Tropical pulmonary eosinophilia (TPE) is a distinct syndrome that develops in some individuals infected with the lymphatic-dwelling filarial species. Most cases have been reported from India, Pakistan, Sri Lanka, Brazil, Guyana, and Southeast Asia; the decreasing incidence of TPE in the past decade probably reflects global MDA efforts.

CLINICAL FEATURES

The main features include a history of residence in filaria-endemic regions, paroxysmal cough and wheezing (usually nocturnal and probably related to the nocturnal periodicity of microfilariae), weight loss, low-grade fever, lymphadenopathy, and pronounced blood eosinophilia (>3000 eosinophils/μL). Chest x-rays or computed tomography (CT) scans may be normal but generally show increased bronchovascular markings. Diffuse miliary lesions or mottled opacities may be present in the middle and lower lung fields. Tests of pulmonary function show restrictive abnormalities in most cases and obstructive defects in half. Characteristically, total serum IgE levels (4–40 KIU/mL) and antifilarial antibody levels are markedly elevated.

PATHOLOGY

In TPE, microfilariae and parasite antigens are rapidly cleared from the bloodstream by the lungs. The clinical symptoms result from allergic and inflammatory reactions elicited by the cleared parasites. In some patients, trapping of microfilariae in other reticuloendothelial organs can cause hepatomegaly, splenomegaly, or lymphadenopathy. A prominent, eosinophil-enriched, intra-alveolar infiltrate is common, and with it comes the release of cytotoxic proinflammatory eosinophil granule proteins that may mediate some of the pathology seen in TPE. In the absence of successful treatment, interstitial fibrosis can lead to progressive pulmonary damage.

DIFFERENTIAL DIAGNOSIS

TPE must be distinguished from asthma, Löffler's syndrome, allergic bronchopulmonary aspergillosis, allergic granulomatosis with polyangiitis (eosinophilic granulomatosis with polyangiitis or Churg-Strauss syndrome), other systemic vasculitides (most notably, periarteritis nodosa), chronic eosinophilic pneumonia, and the hypereosinophilic syndromes (HESs).

TREATMENT

Tropical Pulmonary Eosinophilia

DEC is used at a daily dosage of 4–6 mg/kg for 14 days. Symptoms usually resolve within 3–7 days after the initiation of therapy. Relapse, which occurs in ~12–25% of cases (sometimes after an interval of several years), requires re-treatment.

ONCHOCERCIASIS

EPIDEMIOLOGY

Onchocerciasis ("river blindness") is caused by the filarial nematode *O. volvulus*, which infects an estimated 37 million individuals in 31 countries worldwide. The majority of individuals infected with *O. volvulus* live in the equatorial region of Africa extending from the Atlantic coast to the Red Sea. In the Americas, the only remaining countries with isolated foci are Venezuela and Brazil. The infection is also found in Yemen.

ETIOLOGY

Infection in humans begins with the deposition of infective larvae on the skin by the bite of an infected blackfly. The larvae develop into adults, which are typically found in subcutaneous nodules. About 7 months to 3 years after infection, the gravid female releases microfilariae that migrate out of the nodule and throughout the tissues, concentrating in the dermis. Infection is transmitted to other persons when a female fly ingests microfilariae from the host's skin and these microfilariae then develop into infective larvae. Adult *O. volvulus* females and males are ~40–60 cm and ~3–6 cm in length, respectively. The life span of adults can be as long as 18 years, with an average of ~9 years. Because the blackfly vector breeds along free-flowing rivers and streams (particularly in rapids) and generally restricts its flight to an area within several kilometers of these breeding sites, both biting and disease transmission are most intense in these locations.

PATHOLOGY

Onchocerciasis primarily affects the skin, eyes, and lymph nodes. In contrast to the pathology in lymphatic filariasis, the damage in

onchocerciasis is elicited by microfilariae and not by adult parasites. In the skin, there are mild but chronic inflammatory changes that can result in loss of elastic fibers, atrophy, and fibrosis. The subcutaneous nodules (*onchocercomata*) consist primarily of fibrous tissues surrounding the adult worm, often with a peripheral ring of inflammatory cells surrounded by an endothelial layer (characterized as lymphatic in origin). In the eye, neovascularization and corneal scarring lead to corneal opacities and blindness. Inflammation in the anterior and posterior chambers frequently results in anterior uveitis, chorioretinitis, and optic atrophy. Although punctate opacities are due to an inflammatory reaction surrounding dead or dying microfilariae, the pathogenesis of most manifestations of onchocerciasis is still unclear.

CLINICAL FEATURES

Skin Pruritus and rash are the most common manifestations of onchocerciasis. The pruritus can be incapacitating; the rash is typically a papular eruption **(Fig. 240-3)** that is generalized rather than localized to a particular region of the body. Long-term infection results in exaggerated and premature wrinkling of the skin, loss of elastic fibers, and epidermal atrophy that can lead to loose, redundant skin and hypo- or hyperpigmentation. Localized eczematoid dermatitis can cause hyperkeratosis, scaling, and pigmentary changes. In an immunologically hyperreactive form of onchodermatitis (commonly termed *sowdah* or *localized onchodermatitis*), the affected skin darkens as a consequence of the profound inflammation that occurs as microfilariae in the skin are cleared.

Onchocercomata These subcutaneous nodules, which can be palpable and/or visible, contain the adult worm. They are most common over the coccyx and sacrum, the trochanter of the femur, the lateral anterior crest, and other bony prominences. Nodules vary in size and characteristically are firm and not tender. It has been estimated that, for every palpable nodule, there are four deeper nonpalpable ones.

Ocular Tissue Visual impairment is the most serious complication of onchocerciasis and usually affects only those persons with moderate or heavy infections. Lesions may develop in all parts of the eye. The most common early finding is conjunctivitis with photophobia. Punctate keratitis—acute inflammatory reactions surrounding dying microfilariae and manifested as "snowflake" opacities—is common among younger patients and resolves without apparent complications. Sclerosing keratitis occurs in 1–5% of infected persons and is the leading cause of onchocercal blindness. Anterior uveitis and iridocyclitis develop in ~5% of infected persons. Characteristic chorioretinal lesions develop as a result of atrophy and hyperpigmentation of the retinal pigment epithelium. Constriction of the visual fields and overt optic atrophy may occur.

FIGURE 240-3 Papular eruption as a consequence of onchocerciasis.

Lymph Nodes Mild to moderate lymphadenopathy is common, particularly in the inguinal and femoral areas, where the enlarged nodes may hang down in response to gravity ("hanging groin"), sometimes predisposing to inguinal and femoral hernias.

Other Manifestations Some heavily infected individuals develop cachexia with loss of adipose tissue and muscle mass. A form of dwarfism, Nakalanga dwarfism, has been attributed to pituitary involvement in this infection. An association between onchocerciasis and epilepsy (including an epidemic form termed nodding syndrome) has gained attention recently. Among adults who become blind, there is a three- to fourfold increase in mortality rate.

DIAGNOSIS

Definitive diagnosis depends on the detection of an adult worm in an excised nodule or, more commonly, of microfilariae in a skin snip. Skin snips are obtained with a corneal-scleral punch or by lifting of the skin with the tip of a needle and excision of a small (1- to 3-mm) piece with a sterile scalpel blade. Both methods collect a blood-free skin biopsy sample extending to just below the epidermis. The biopsy tissue can be incubated in tissue culture medium or in saline on a glass slide or flat-bottomed microtiter plate. After incubation for 2–4 h (or occasionally overnight in light infections), microfilariae emergent from the skin can be seen by low-power microscopy or can be detected by PCR.

Eosinophilia and elevated serum IgE levels are common, but, because these features are seen in many parasitic infections, are not diagnostic in themselves. Immunoassays to detect antibodies to *Onchocerca*-specific antigens are being used both in specialized laboratories and at the point of contact in rapid-diagnostic formats.

TREATMENT

Onchocerciasis

The main goals of therapy are to prevent the development of irreversible lesions and to alleviate symptoms. Chemotherapy is the mainstay of management. Ivermectin, a semisynthetic macrocyclic lactone active against microfilariae, is the first-line agent for the treatment of onchocerciasis. It is given orally in a single dose of 150 μg/kg, either yearly or semiannually. More frequent ivermectin administration (every 3 months) has been suggested to ameliorate pruritus and skin disease.

After treatment, most individuals have few or no reactions. Pruritus, cutaneous edema, and/or maculopapular rash occur in ~1–10% of treated individuals. In areas of Africa co-endemic for *O. volvulus* and *L. loa*, however, ivermectin is contraindicated (as it is for pregnant or breast-feeding women) because of severe posttreatment encephalopathy, especially in patients who are heavily microfilaremic for *L. loa* (>30,000 microfilariae/mL). Although ivermectin treatment results in a marked drop in microfilarial density, its effect can be short-lived (<3 months in some cases). Thus, it is occasionally necessary to give ivermectin more frequently for persistent symptoms. Another macrocyclic lactone, moxidectin, has a more prolonged microfilaricidal effect but is not yet commercially available.

A 6-week course of doxycycline is macrofilaristatic, rendering female adult worms sterile for long periods.

PREVENTION

Vector control has been beneficial in highly endemic areas in which breeding sites are vulnerable to insecticide spraying, but most areas endemic for onchocerciasis are not suited to this type of control. Community-based administration of ivermectin every 6–12 months is being used to interrupt transmission in endemic areas. This measure, in conjunction with vector control, has already helped eliminate the

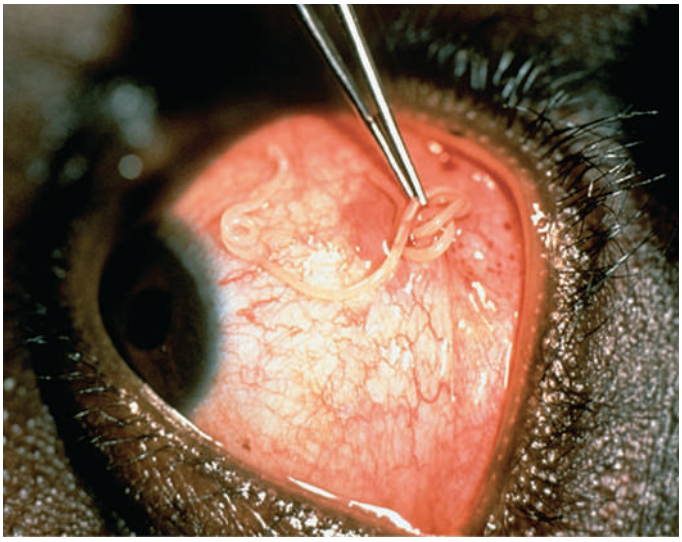

FIGURE 240-4 Adult *Loa loa* worm being surgically removed after its subconjunctival migration.

infection in most of Latin America and has reduced the prevalence of disease in many endemic foci in Africa. No drug has proved useful for prophylaxis of *O. volvulus* infection.

LOIASIS

ETIOLOGY AND EPIDEMIOLOGY

Loiasis is caused by *L. loa* (the African eye worm), which is present in the rainforests of West and Central Africa. Adult parasites (females, 50–70 mm long and 0.5 mm wide; males, 25–35 mm long and 0.25 mm wide) live in subcutaneous tissues. Microfilariae circulate in the blood with a diurnal periodicity that peaks between 10:00 A.M. and 2:00 P.M.

CLINICAL FEATURES

Manifestations of loiasis in natives of endemic areas may differ from those in temporary residents or visitors. Among the indigenous population, loiasis is often an asymptomatic infection with microfilaremia. Infection may be recognized only after subconjunctival migration of an adult worm **(Fig. 240-4)** or may be manifested by episodic *Calabar swellings*—evanescent localized areas of angioedema and erythema developing on the extremities and less frequently at other sites. Nephropathy, encephalopathy, and cardiomyopathy can occur but are infrequently diagnosed. Although historically considered relatively benign in endemic populations, recent studies show loiasis is associated with chronic morbidity and increased mortality in endemic populations. In patients who are not residents of endemic areas, allergic symptoms predominate, episodes of Calabar swelling tend to be more frequent, microfilaremia is less common, and eosinophilia and increased levels of antifilarial antibodies are characteristic.

PATHOLOGY

The pathogenesis of the manifestations of loiasis is poorly understood. Calabar swellings are thought to result from a hypersensitivity reaction to adult worm antigens.

DIAGNOSIS

Definitive diagnosis of loiasis requires the detection of microfilariae in the peripheral blood or the isolation of the adult worm from the eye (Fig. 240-4) or from a subcutaneous biopsy specimen collected from a site of swelling developing after treatment. PCR-based assays for the detection of *L. loa* DNA in blood are available in specialized laboratories and are highly sensitive and specific, as are some newer recombinant antigen–based serologic techniques. In practice, the diagnosis must often be based on a characteristic history and clinical presentation, blood eosinophilia, and elevated levels of antifilarial antibodies, particularly in travelers to an endemic region, who are often amicrofilaremic.

TREATMENT

Loiasis

DEC (8–10 mg/kg per day administered orally for 21 days) is effective against both the adult and the microfilarial forms of *L. loa*, but multiple courses are frequently necessary before loiasis resolves completely. In cases of heavy microfilaremia, allergic or other inflammatory reactions can take place during treatment, including central nervous system involvement with coma and encephalitis. Heavy infections can be treated initially with apheresis to remove the microfilariae and with glucocorticoids (40–60 mg of prednisone per day) followed by low doses of DEC (0.5 mg/kg per day). If antifilarial treatment has no adverse effects, the prednisone dose can be tapered rapidly and the dose of DEC gradually increased to 8–10 mg/kg per day.

Albendazole or ivermectin is effective in reducing microfilarial loads, although neither is approved for this purpose by the U.S. Food and Drug Administration. Moreover, ivermectin is contraindicated in patients with >30,000 microfilariae/mL because this drug has been associated with severe adverse events (including encephalopathy and death) in heavily infected patients with loiasis in West and Central Africa. DEC (300 mg weekly) is an effective prophylactic regimen for loiasis.

STREPTOCERCIASIS

Mansonella streptocerca, found mainly in the tropical forest belt of Africa from Ghana to the Democratic Republic of the Congo, is transmitted by biting midges. The major clinical manifestations involve the skin and include pruritus, papular rashes, and pigmentation changes. Many infected individuals have inguinal adenopathy, although most are asymptomatic. The diagnosis is made by detection of the characteristic microfilariae in skin snips. Ivermectin at a single dose of 150 μg/kg leads to sustained suppression of microfilariae in the skin and is probably the treatment of choice for streptocerciasis.

MANSONELLA PERSTANS INFECTION

M. perstans, distributed across the center of Africa and in northeastern South America, is transmitted by midges. Adult worms reside in serous cavities—pericardial, pleural, and peritoneal—as well as in the mesentery and the perirenal and retroperitoneal tissues. Microfilariae circulate in the blood without periodicity. The clinical and pathologic features of the infection are poorly defined. Most patients appear to be asymptomatic, but manifestations may include transient angioedema and pruritus of the arms, face, or other parts of the body (analogous to the Calabar swellings of loiasis); fever; headache; arthralgias; and right-upper-quadrant pain. Occasionally, pericarditis and hepatitis occur. The diagnosis is based on the demonstration of microfilariae in blood or serosal effusions. Perstans filariasis is often associated with peripheral-blood eosinophilia and antifilarial antibody elevations.

With the identification of a *Wolbachia* endosymbiont in *M. perstans*, doxycycline (200 mg twice a day) for 6 weeks has been established as the first effective treatment for this infection.

MANSONELLA OZZARDI INFECTION

The distribution of *M. ozzardi* is restricted to Central and South America and certain Caribbean islands. Adult worms are rarely recovered from humans. Microfilariae circulate in the blood without periodicity. Although this organism has often been considered nonpathogenic, headache, articular pain, fever, pulmonary symptoms, adenopathy, hepatomegaly, pruritus, and eosinophilia have been ascribed to *M. ozzardi* infection. The diagnosis is made by detection of microfilariae in peripheral blood. Ivermectin is effective in treating this infection.

ZOONOTIC FILARIAL INFECTIONS

Dirofilariae that affect primarily dogs, cats, and raccoons occasionally infect humans incidentally, as do *Brugia* and *Onchocerca* parasites that affect small mammals. Because humans are an abnormal host, the

parasites never develop fully. Pulmonary dirofilarial infection caused by the canine heartworm *Dirofilaria immitis* generally presents in humans as a solitary pulmonary nodule. Chest pain, hemoptysis, and cough are uncommon. Infections with *Dirofilaria repens* (from dogs) or *Dirofilaria tenuis* (from raccoons) can cause local subcutaneous nodules in humans. Zoonotic *Brugia* infection can produce isolated lymph node enlargement, whereas zoonotic *Onchocerca* species (particularly *O. lupi*) can cause subconjunctival masses. Eosinophilia levels and antifilarial antibody titers are not commonly elevated. Excisional biopsy is both diagnostic and curative. These infections usually do not respond to antifilarial chemotherapy.

DRACUNCULIASIS (GUINEA WORM INFECTION)

ETIOLOGY AND EPIDEMIOLOGY

The incidence of dracunculiasis, caused by *Dracunculus medinensis*, has declined dramatically because of global eradication efforts. However, between 2017 and 2020, there were increases in the number of human cases, followed by a decline in 2021 and 2022. At the end of 2022, there were a total of 13 human cases of Guinea worm disease across four African countries, with 6 cases in Chad, 5 cases in South Sudan, and 1 each in Ethiopia and Central African Republic. Low-level persistence of infection in animal reservoirs (dogs and cats) is a major challenge to ongoing eradication efforts.

Humans acquire *D. medinensis* when they ingest water containing infective larvae derived from *Cyclops*, a crustacean that is the intermediate host. Larvae penetrate the stomach or intestinal wall, mate, and mature. The adult male probably dies; the female worm develops over a year and migrates to subcutaneous tissues, usually in the lower extremity. As the thin female worm, ranging in length from 30 cm to 1 m, approaches the skin, a blister forms that, over days, breaks down and forms an ulcer. When the blister opens, large numbers of motile, rhabditiform larvae can be released into stagnant water; ingestion by *Cyclops* completes the life cycle.

CLINICAL FEATURES

Few or no clinical manifestations of dracunculiasis are evident until just before the blister forms, when there is an onset of fever and generalized allergic symptoms, including periorbital edema, wheezing, and urticaria. The emergence of the worm is associated with local pain and swelling. When the blister ruptures (usually as a result of immersion in water) and the adult worm releases larva-rich fluid, symptoms are relieved. The shallow ulcer surrounding the emerging adult worm heals over weeks to months. Such ulcers, however, can become secondarily infected, the result being cellulitis, local inflammation, abscess formation, or (uncommonly) tetanus. Occasionally, the adult worm does not emerge but becomes encapsulated and calcified.

DIAGNOSIS

The diagnosis is based on the findings developing with the emergence of the adult worm, as described above.

TREATMENT

Dracunculiasis

Gradual extraction of the worm by winding of a few centimeters on a stick each day remains the common and effective practice. Worms may be excised surgically. No drug is effective in treating dracunculiasis.

PREVENTION

Prevention, which remains the only real control measure, depends on the provision of safe drinking water.

Acknowledgment

The authors wish to acknowledge and thank Peter F. Weller, MD, author of prior editions of this chapter.

241 Schistosomiasis and Other Trematode Infections

Birgitte Jyding Vennervald, Anna-Sofie Stensgaard

Trematodes, or flatworms, are a group of helminths that belong to the phylum Platyhelminthes. The adult flatworms share some common characteristics, such as macroscopic size (from one to several centimeters); dorsoventrally flattened, bilaterally symmetric bodies; and two suckers—oral and ventral. Except for schistosomes, which have separate sexes, all human parasitic trematodes are hermaphroditic. Their life cycles involve a mammalian/human definitive host, in which sexual reproduction by adult worms takes place, and an intermediate host (snails), in which asexual multiplication occurs. Some species of trematodes have more than one intermediate host.

Humans are infected either by direct penetration of intact skin (schistosomiasis) or by ingestion of raw freshwater fish, crustaceans, or aquatic plants with metacercariae—the infective larval stage.

Significant trematode infections of humans may be divided according to the location of the adult worms: blood, liver (biliary tree), intestines, or lungs (Table 241-1). Adult worms do not multiply within the mammalian host but can live for up to 30 years. Infections are often chronic.

Although it is relatively rare to encounter patients with trematode infections in the United States, many millions of people are infected worldwide. Both schistosomiasis and food-borne trematode infections are poverty-related chronic diseases with high morbidity and a significant public health impact. Various factors may increase the spread of the infections globally. Increasing temperatures may render new areas suitable for the intermediate host snails, and an increase in travel and migration may increase the number of patients with trematode infections—for example, in the United States.

APPROACH TO THE PATIENT

Trematode Infection

In the evaluation of a patient in whom trematode infection is suspected, certain questions are highly relevant and can assist in establishing a diagnosis: Where have you been? If you have traveled, when

TABLE 241-1 Major Human Trematode Infections

TREMATODE	TRANSMISSION ROUTE	GEOGRAPHIC DISTRIBUTION
Blood Flukes		
Intestinal schistosomiasis		
Schistosoma mansoni	Skin penetration by cercariae released from snails (*Biomphalaria* spp.)	Africa, Brazil, Venezuela, Surinam, the Caribbean (low risk)
Shistosoma japonicum	Skin penetration by cercariae released from snails (*Oncomelania* spp.)	China, Indonesia, Philippines
Schistosoma guineensis and *Schistosoma intercalatum*	Skin penetration by cercariae released from snails (*Bulinus* spp.)	Rainforest areas of Central Africa
Schistosoma mekongi	Skin penetration by cercariae released from snails (*Neotricula aperta*)	Several districts of Cambodia and Lao People's Democratic Republic (PDR)
Urogenital schistosomiasis		
Schistosoma haematobium	Skin penetration by cercariae released from snails (*Bulinus* spp.)	Africa, Middle East, Corsica (France)
Liver Flukes		
Clonorchis sinensis	Ingestion of metacercariae in freshwater fish	Asia, including Republic of Korea, China, Taiwan, Vietnam
Opisthorchis viverrini	Ingestion of metacercariae in freshwater fish	Northeast Thailand, Lao PDR, Cambodia, Vietnam
Opisthorchis felineus	Ingestion of metacercariae in freshwater fish	Former Soviet Union, Kazakhstan, Ukraine, Turkey
Fasciola hepatica	Ingestion of metacercariae on aquatic plants or in water	Worldwide
Fasciola gigantica	Ingestion of metacercariae on aquatic plants or in water	Africa, Asia
Intestinal Flukes		
Fasciolopsis buski	Ingestion of metacercariae on aquatic plants	Bangladesh, China, India, Indonesia, Lao PDR, Malaysia, Taiwan, Thailand, Vietnam
Echinostoma spp.	Ingestion of freshwater fish, frogs, mussels, snails	China, India, Indonesia, Japan, Malaysia, Russia, Republic of Korea, Philippines, Thailand
Heterophyes heterophyes, several other species	Ingestion of metacercariae in freshwater or brackish-water fish	Egypt, Greece, Islamic Republic of Iran, Italy, Japan, Republic of Korea, Sudan, Tunisia, Turkey
Lung Flukes		
Paragonimus westermani	Ingestion of metacercariae in crayfish or crabs	Tropical and subtropical areas of eastern and southern Asia and sub-Saharan Africa
Paragonimus kellicotti	Ingestion of metacercariae in crayfish or crabs	North America

did you return? What activities have you been involved in (trekking, swimming, whitewater rafting)? What have you been eating (local dishes while traveling; raw, poorly cooked, or pickled freshwater fish or crustaceans)? Definitive diagnosis is based on detection of parasite eggs in stool, urine, sputum, and sometimes tissue samples or on serologic tests. The presence of eosinophilia and a history of travel to endemic areas should raise suspicion of trematode infection. The U.S. Centers for Disease Control and Prevention (CDC) can provide guidance with respect to diagnosis and treatment.

SCHISTOSOMIASIS

Human schistosomiasis is caused by six species of the parasitic genus *Schistosoma*: *S. mansoni, S. japonicum, S. mekongi*, *S. intercalatum*, and the recently described *S. guineensis* cause intestinal disease, and *S. haematobium* causes urogenital disease (Table 241-1). The infection may cause considerable intestinal, hepatic, and genitourinary morbidity. Avian schistosomes may penetrate human skin but die in subcutaneous tissue, producing only cutaneous manifestations.

ETIOLOGY

Schistosoma infection is contracted through contact with freshwater bodies harboring infected intermediate-host snails **(Fig. 241-1)**. Cercariae, the infective larval stage released from the snail, penetrate intact human skin within a few minutes after attaching to the skin. After penetration, the cercariae transform to schistosomula, which then enter a small vein or lymphatic vessel, circulate in the bloodstream through the lung capillaries, and are pumped via the heart to all parts of the body to reach the portal vein. There, the worms mature into adult males or females, pair, and migrate to their final location in the mesenteric or pelvic venous plexus.

The interval from cercarial penetration to sexual maturation and egg production, termed the *prepatent period*, lasts 5–7 weeks (up to 12 weeks for *S. haematobium*). The female worm then begins to produce eggs, which are excreted via feces or, for *S. haematobium*, urine. Approximately 50% of eggs are retained in tissue, where they are responsible for organ-specific morbidity (see "Pathogenesis," below). When excreted eggs reach water, they hatch and release a free-swimming larval stage (*miracidium*), which, after penetrating a host snail, undergoes several rounds of asexual multiplication. After ~4–6 weeks, infective cercariae are shed from the infected snails into the water. One snail, infected by one miracidium, can shed thousands of cercariae per day for several months; thus, the transmission potential of schistosomes is enormous. Environmental temperature is an important determinant of the development rate and the number of cercariae produced and released by the snails.

The schistosome egg **(Fig. 241-2)** is the only stage of the parasites' life cycle that can be detected in humans, either in excreta or in tissue biopsies. The eggs are large and can easily be distinguished morphologically from other helminth eggs. *S. haematobium* eggs are ~140 µm long, with a terminal spine; *S. mansoni* eggs are ~150 µm long, with a lateral spine; and *S. japonicum* eggs are smaller, rounder, and ~90 mm long, with a small lateral spine or knob.

Adult schistosomes are ~1–2 cm long. The male worm is flat, and the body forms a groove or gynecophoric canal in which the mature adult female is held like a sausage in a hotdog roll. Females are longer, thinner, and rounded. The females produce hundreds (African species) to thousands (Asian species) of eggs per day. Each ovum contains a ciliated miracidium larva, which secretes proteolytic enzymes that help the eggs to migrate into the lumen of the bladder (*S. haematobium*) or the intestine (other species). The lifespan of an adult schistosome averages 3–5 years but can be as long as 30 years. Schistosome worms feed on red blood cells; the debris is regurgitated in the host's blood, where it can be detected as circulating antigens (see "Diagnosis," below).

Adult schistosomes persist in the bloodstream for years and have evolved strategies of evading attack using immune effector mechanisms. This immune evasion is a result of several processes, such as binding of host proteins to the schistosome surface, which renders the parasite invisible to the host immune system.

The genome of schistosomes is relatively large (~300 Mb). Whole-genome sequences are available for *S. mansoni, S. japonicum*, and *S. haematobium*.

EPIDEMIOLOGY

Because of the complex life cycle of schistosomes, with snails as an intermediate host and humans as the final host, transmission is dependent on freshwater habitats that are suitable for the snails, are areas of human activity, and have climatic conditions favoring the survival of the snails and the development of the parasites inside the snail host. These requirements are reflected in the global distribution of

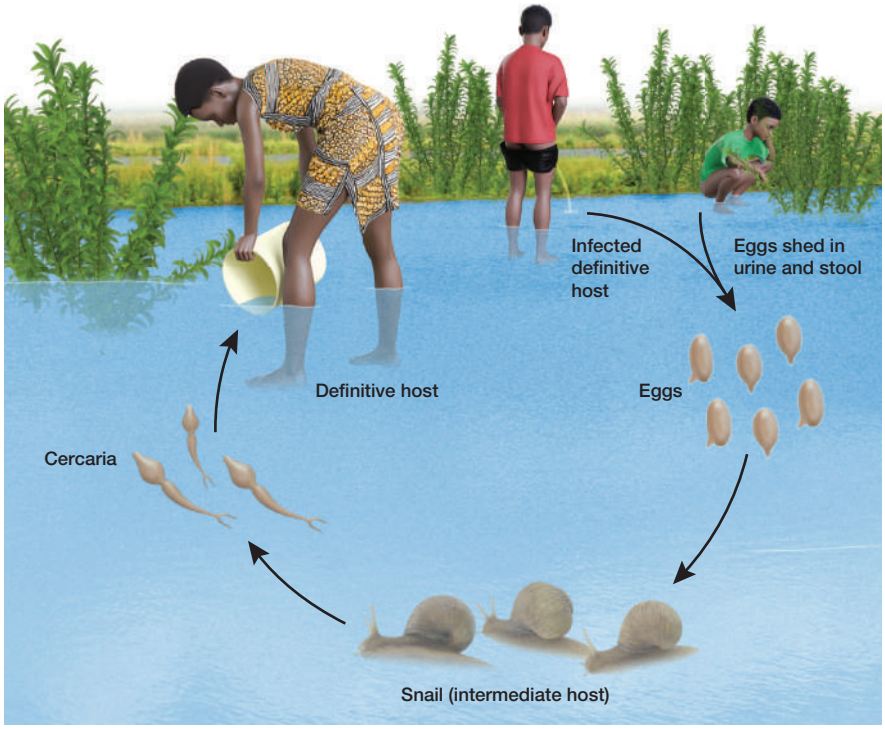

FIGURE 241-1 Life cycle of schistosomiasis.

schistosomiasis as well as in its microgeographic distribution within an endemic area. For *S. mansoni, S. haematobium*, *S. intercalatum*, and *S. guineensis*, humans are the most important definitive host. *S. japonicum* and *S. mekongi* are zoonotic parasites, with a wide range of definitive hosts such as pigs, water buffaloes, and various rodents.

It is estimated that at least 251.4 million people required preventive treatment in 2021, of whom more than 75.3 million people were reported to have been treated. Schistosomiasis transmission has been reported from 78 countries, of which 51 endemic countries have moderate to high transmission **(Fig. 241-3)**. More than 70% of infected people live in sub-Saharan Africa. Schistosomiasis is the most important of the neglected tropical diseases and is second only to malaria in public health impact. It is a poverty-related disease, and infection is prevalent in areas where adequate water supplies and sanitary facilities are lacking. In these areas, people come into contact with infested water through a variety of activities, including bathing, washing clothes, and collecting water for drinking or cooking. In some areas, adults have a high occupational risk of exposure; fishermen, canal cleaners, and workers in rice fields fall into this category. Among children, playing in water and swimming pose a risk. Large-scale irrigation and hydroelectric power operations can create suitable habitats for host snails and thus increase the risk of schistosomiasis transmission.

In general, children living in endemic areas initially acquire infection at ~3–4 years of age—i.e., when they are old enough to walk and come into contact with infested water. However, infection does occur in much younger children. As children grow older, the prevalence and intensity of infection increase, peaking around puberty. A characteristic feature of schistosomiasis infection in human populations is a convex age–prevalence curve, with low prevalence in very young children, higher prevalence in older children with a peak at 10–15 years of age, and declining prevalence in adults. The same pattern is observed between age and intensity of infection and is attributable to various factors. Generally, children have more frequent, prolonged, and extensive water contact than adults through activities like playing and swimming. Furthermore, several studies have indicated that acquired immunity to schistosomiasis develops slowly over several years, so that adults are reinfected to a much lesser extent than children. These factors, combined with progressive spontaneous death of adult worms from infections acquired during childhood, lead to lower levels of infection in the adult population.

It is important to note that ongoing climate change, resulting in rising water temperatures and altered precipitation patterns, affects the distribution, reproduction, survival, and dispersal of the intermediate host snails, as well as the rate of parasite development within the snail. Therefore, climate change could considerably alter the distribution and abundance of the intermediate host snail and its schistosome parasites, resulting in notable shifts in the global distribution, disease dynamics, and transmission of schistosomiasis in the future.

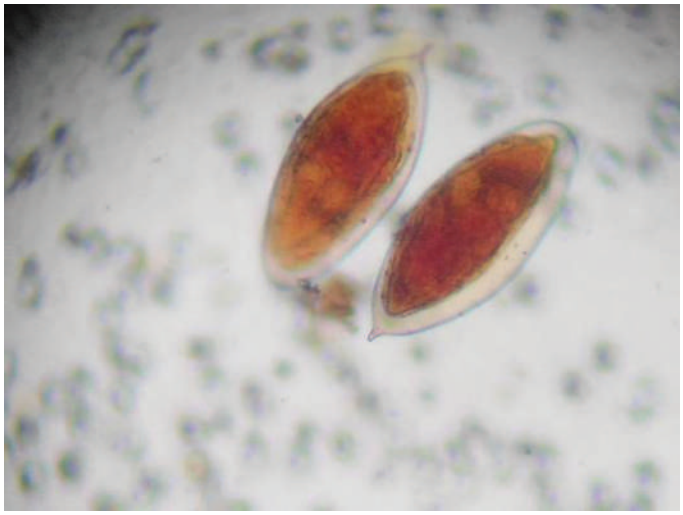

FIGURE 241-2 *Schistosoma haematobium* eggs.

PATHOGENESIS

Cercarial invasion may be associated with dermatitis arising from dermal and subdermal inflammatory reactions in response to dying cercariae that trigger innate immune responses. However, most manifestations of schistosomiasis—in the acute, established, and chronic phases of infection—are due to immunologic reactions to eggs retained in host tissues.

Around the time when oviposition commences, acute schistosomiasis (Katayama fever) may occur (see "Clinical Features," below). Antigen excess from eggs results in the formation of soluble immune complexes, which may be deposited in several tissues and initiate a serum sickness–like illness. All evidence suggests that schistosome eggs, and not adult worms, induce the organ-specific morbidity caused by schistosome infections. Approximately half of the eggs are not excreted via feces or urine but are trapped in intestinal or hepatic tissue (*S. mansoni*, *S. japonicum*, and *S. mekongi*) or in the bladder and urogenital system (*S. haematobium*). The eggs induce a granulomatous host immune response composed primarily of lymphocytes, eosinophils, and alternatively activated macrophages. The lymphocytes produce various T_H2 cytokines such as interleukins 4, 5, and 13. Later, in the chronic phase of infection, regulatory cytokines are responsible for immunomodulation or downregulation of host responses to schistosome eggs and play an important role in reducing the size of granulomas.

When *S. mansoni* or *S. japonicum* eggs are swept into the small portal branches of the liver via the portal vein, they lodge in the presinusoidal periportal tissues. The formation of granulomas around the eggs can cause significant enlargement of the spleen and liver. High-intensity infections in children are often accompanied by hepatosplenomegaly that generally decreases over time, partly because the

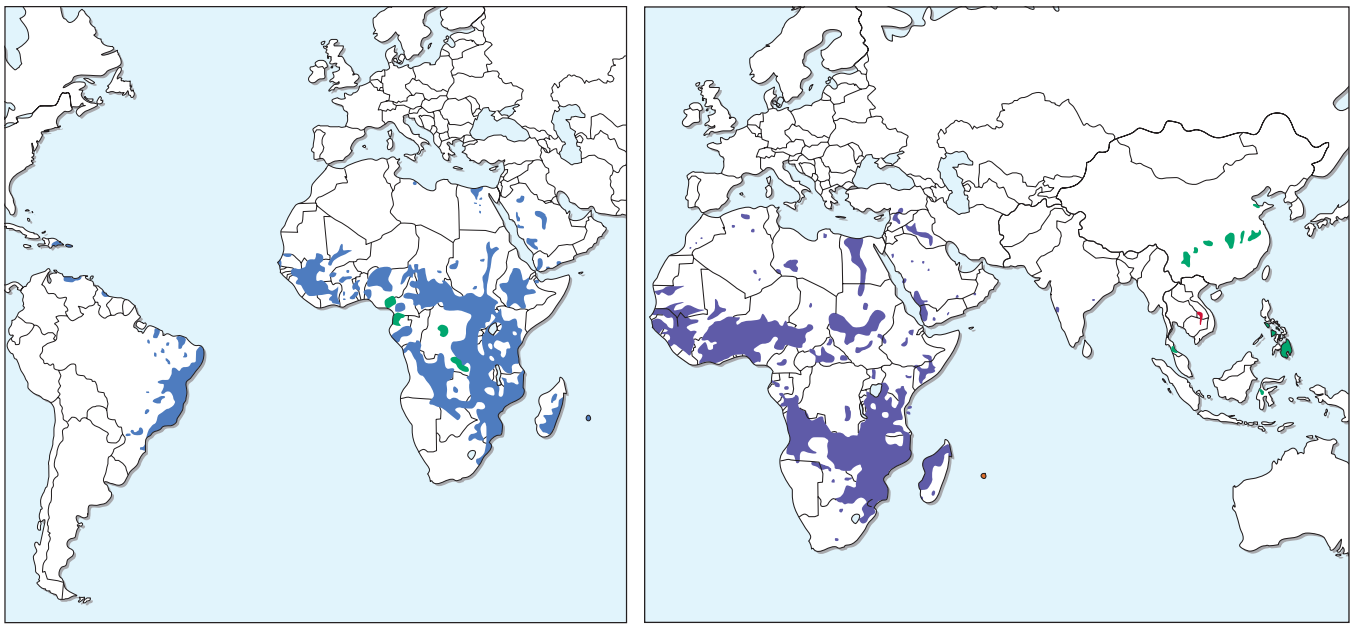

FIGURE 241-3 Global distribution of human schistosomiasis. ***A.*** *Schistosoma mansoni* infection (*dark blue*) is endemic in Africa, the Middle East, South America, and a few Caribbean countries. *S. intercalatum* infection (*green*) is endemic in sporadic foci in West and Central Africa. ***B.*** *Schistosoma haematobium* infection (*purple*) is endemic in Africa and the Middle East. The major endemic countries for *S. japonicum* infection (*green*) are China, the Philippines, and Indonesia. *Schistosoma mekongi* infection (*red*) is endemic in sporadic foci in Southeast Asia. *(Reprinted from CH King, AAF Mahmoud: Schistosomiasis and other trematode infections, in DL Kasper et al [eds], Harrison's Principles of Internal Medicine, 19th ed. New York, McGraw-Hill Education, 2015, pp 1423–1429.)*

number of eggs being deposited in the tissue gradually declines after the early teenage years as partial immunity to new infections develops and partly because of immunologic downregulation of the granulomatous response. However, in some infected individuals, egg-induced granulomatous responses lead to severe periportal fibrosis (*Symmers clay pipestem fibrosis*), with deposition of collagen around the portal vein, occlusion of the smaller portal branches, and severe, often irreversible, pathology. Occlusion of the portal branches may result in marked portal hypertension **(Fig. 241-4)**.

The signs and symptoms of *S. haematobium* infection relate to the worms' predilection for the veins of the urogenital plexus and result from deposition of eggs in the bladder, ureters, and genital organs. During established active infection, clusters of living eggs in the urogenital tissues can be found surrounded by intense inflammatory reactions and intense tissue eosinophilia. Movement of egg clusters into the lumen of the bladder is often followed by sloughing off of the epithelial surface, ulceration, and bleeding. Intense egg-induced tissue inflammation can result in bladder wall thickening and development of masses and pseudopolyps. Inflammation and granuloma formation around the ureteral ostia can lead to hydronephrosis.

FIGURE 241-4 Portal hypertension with ascites. *(Photo courtesy of Birgitte J. Vennervald.)*

Generally, late chronic-stage infections are characterized by accumulation of dead calcified eggs in tissue. Characteristic cervical lesions are found in *S. haematobium* infections, including active-stage lesions with intense tissue inflammation around live eggs and chronic-stage sandy patches with clusters of calcified eggs.

CLINICAL FEATURES

In general, disease manifestations of schistosomiasis occur in three stages—acute, active, and chronic—according to the duration and intensity of infection.

Cercarial Dermatitis ("Swimmer's Itch") Cercarial penetration of the skin may result in a maculopapular rash called cercarial dermatitis or "swimmer's itch." Cercarial dermatitis can develop in people who have not previously been exposed to schistosomiasis (e.g., travelers), whereas it is rare among people living in endemic areas. A particularly severe form of cercarial dermatitis is commonly seen after exposure to cercariae from avian schistosomes. These cercariae cannot complete their development in humans and die in the skin, causing an inflammatory allergic reaction. This form of cercarial dermatitis can occur in people who have been in contact with water from lakes (e.g., in Europe or the United States) where various species of water birds, such as ducks, geese, and swans, are found. The rash may last for 1–2 weeks. This condition normally requires no treatment, but systemic antihistamines, topical antihistamines, or glucocorticoids can be used to reduce symptoms.

Acute Schistosomiasis (Katayama Fever) Symptomatic acute schistosomiasis, also known as Katayama fever or Katayama syndrome, is usually seen in travelers who have contracted the infection for the first time. The onset occurs between 2 weeks and 3 months after exposure to the parasite. The symptoms may appear suddenly and include fever, myalgia, general malaise and fatigue, headache, nonproductive cough, and intestinal symptoms such as abdominal tenderness or pain. Various combinations of these symptoms are often accompanied by eosinophilia and transient pulmonary infiltrates. Many patients

recover spontaneously from acute schistosomiasis after 2–10 weeks, but the illness follows a more severe clinical course in some individuals, with weight loss, dyspnea, diarrhea, and hepatomegaly. Severe cerebral or spinal cord manifestations may occur, and even light infections may cause severe illness. The syndrome can, in rare cases, be fatal.

Differential diagnosis includes many other febrile infectious diseases with acute onset, including malaria, salmonellosis, and acute hepatitis. Fever and eosinophilia occur in trichinosis, tropical eosinophilia, invasive ankylostomiasis, strongyloidiasis, visceral larva migrans, and infections with *Opisthorchis* and *Clonorchis* species. Katayama fever is rare in people chronically exposed to infection in areas endemic for *S. mansoni* or *S. haematobium*.

Intestinal Schistosomiasis (*S. mansoni, S. japonicum*) In intestinal schistosomiasis, adult worms are located in the mesenteric veins, and disease manifestations are associated with parasite eggs passing through or becoming trapped in intestinal tissue. This event induces mucosal granulomatous inflammation with microulcerations, superficial bleeding, and sometimes pseudopolyposis. The symptoms tend to be more pronounced with a high intensity of infection and include intermittent abdominal pain, loss of appetite, and sometimes bloody diarrhea. The clinical manifestations of *S. intercalatum, S. guineensis*, and *S. mekongi* infection are generally milder.

Hepatosplenic Schistosomiasis Hepatosplenic schistosomiasis is caused by schistosome eggs trapped in liver tissue and occurs in *S. mansoni* and *S. japonicum* infections. There are two distinct clinical entities: early inflammatory hepatosplenomegaly and late hepatosplenic disease with periportal fibrosis.

Early inflammatory hepatosplenic schistosomiasis is the main entity seen in children and adolescents. The liver is enlarged, especially the left lobe, and is smooth and firm. The spleen is enlarged, often extending below the umbilicus, and is firm or hard. Generally, ultrasonography shows no hepatic fibrosis. This form of hepatosplenic schistosomiasis may be found in up to 80% of infected children. Its severity is closely associated with the intensity of infection and may also be associated with concomitant chronic exposure to malaria.

Late hepatosplenic schistosomiasis with periportal or Symmers fibrosis may develop in young and middle-aged adults with long-standing, high-level exposure to infection. Patients with periportal fibrosis may excrete very few or no eggs in feces. During the early stage, the liver is enlarged, especially the left lobe; it is smooth and firm or hard. The spleen is enlarged, often massively, and is firm or hard. The patient may report a left hypochondrial mass with discomfort and anorexia. Ultrasonography reveals typical periportal fibrosis and dilation of the portal vein. Other complications include delayed growth and puberty, especially in *S. japonicum* infections, and severe anemia. Severe hepatosplenic schistosomiasis may lead to portal hypertension, but hepatic function usually remains normal, even in cases with marked periportal fibrosis and portal hypertension.

Ascites, attributable both to portal hypertension and to hypoalbuminemia, may be seen, especially in *S. japonicum* infection. Patients with severe hepatosplenic disease and portal hypertension may develop esophageal varices detectable by endoscopy or ultrasound. These patients may experience repeated bouts of hematemesis, melena, or both. Hematemesis is the most severe complication of hepatosplenic schistosomiasis, and death may result from massive loss of blood.

Urogenital Schistosomiasis (*S. haematobium*) The signs and symptoms of *S. haematobium* infection relate to the worms' predilection for the veins of the urogenital tract. Two stages of infection are recognized. An active stage occurring mainly in children, adolescents, and younger adults is characterized by egg excretion in the urine, with proteinuria and macroscopic or microscopic hematuria and deposition of eggs in the urinary tract. A chronic stage in older individuals is characterized by sparse or no urinary egg excretion despite urogenital tract pathology.

A characteristic sign in the active stage is painless, terminal hematuria. Dysuria and suprapubic discomfort or pain are associated with active urogenital schistosomiasis and may persist throughout the course of active infection. Eggs deposited in the bladder mucosa may give rise to an intense inflammatory response of the bladder wall, which may cause ureteric obstruction and lead to hydroureter and hydronephrosis. These early inflammatory lesions, including obstructive uropathy, can be visualized by ultrasonography.

As the infection progresses, the inflammatory component decreases and fibrosis becomes more prominent. The symptoms at this stage are nocturia, urine retention, dribbling, and incontinence. Cystoscopy reveals "sandy patches" composed of large numbers of calcified eggs surrounded by fibrous tissue and an atrophic mucosal surface. The ureters are less commonly involved, but ureteral fibrosis can cause irreversible obstructive uropathy that can progress to uremia.

Egg deposition may cause granulomas and lesions in the genital organs, most commonly in the cervix and vagina in women and the seminal vessels in men. The results may include dyspareunia, abnormal vaginal discharge, contact bleeding, and lower back pain in women and perineal pain, painful ejaculation, and hematospermia in men. Genital symptoms like bloody discharge and genital itch are associated with *S. haematobium* infection in school-aged girls living in schistosomiasis-endemic areas. Symptoms such as hematospermia and perineal discomfort have been described in travelers, and eggs have been demonstrated in seminal fluid. An association between female genital schistosomiasis and HIV infection has been demonstrated, but the impact of genital schistosomiasis on HIV transmission needs further elucidation.

S. haematobium has been classified by the International Agency for Research on Cancer (IARC) as definitely carcinogenic to humans (i.e., a group 1 carcinogen). Chronic *S. haematobium* infection is associated with squamous cell carcinoma of the urinary bladder.

Other Manifestations Worms and eggs can sometimes be located in ectopic sites, causing site-specific manifestations and symptoms. Neuroschistosomiasis is one of the most severe clinical forms of schistosomiasis and is caused by the inflammatory response around eggs in the cerebral or spinal venous plexus. *S. mansoni* and *S. haematobium* worms can end up in the spinal venous plexus, where they may cause transverse myelitis—an acute complication sometimes seen in travelers returning home with schistosomiasis. *S. japonicum* is mainly associated with granulomatous lesions in the brain, causing epileptic seizures, encephalopathy with headache, visual impairment, motor deficit, and ataxia. Pulmonary schistosomiasis is caused by portacaval shunting of eggs into the lung capillaries, where they induce granulomas in the perialveolar area. The consequences may be fibrosis, pulmonary hypertension, and cor pulmonale.

DIAGNOSIS

Anamnestic information on recent travels to endemic areas and exposure to freshwater bodies through recreational or other activities is important in the diagnosis of schistosomiasis in travelers. Information about exact geographic locations can facilitate identification of the relevant species of *Schistosoma*. Eosinophilia is a common finding and is often associated with helminthic infections such as schistosomiasis.

Detection of schistosome eggs in stool or urine is indicative of active infection and is the standard diagnostic method. The diagnosis is often based on the detection of eggs in a fixed small amount of excreta—e.g., 50 mg of stool or filtration of 10 mL of urine. This method is widely used among populations in endemic areas and allows quantitation of the level of infection (eggs per gram of feces or per 10 mL of urine). However, levels of egg excretion in people from nonendemic areas may be very low, in which case a larger sample and concentration methods (e.g., formol-ether concentration) may be needed.

Eggs can also be detected in rectal biopsies (both *S. mansoni* and *S. haematobium*) and occasionally in Pap smears and semen samples (*S. haematobium*). Polymerase chain reaction (PCR)–based detection of parasite DNA in stool or urine is more sensitive than parasitologic methods and is increasingly used. *Schistosoma* DNA can be detected in cerebrospinal fluid samples for diagnosis of neuroschistosomiasis.

Serology, with detection of specific antibodies to schistosomes, is useful in travelers but less so in people from endemic areas where

transmission is ongoing. The serologic assays employed at the CDC are a Falcon assay screening test/enzyme-linked immunosorbent assay (FAST-ELISA) using *S. mansoni* adult microsomal antigen and a confirmatory species-specific immunoblot assay performed in light of the patient's travel history.

Schistosome proteoglycans—circulating anodic and cathodic antigens (CAAs and CCAs)—regurgitated into the bloodstream by the feeding worms can be detected in serum and urine by ELISA or monoclonal antibody–based lateral flow assays. The presence of CAA or CCA is an indication of active infection, and levels of these antigens correlate well with the intensity of infection. However, detection of CAAs and CCAs is not currently suitable for diagnosis in travelers, who are likely to have low levels of infection and very few worms, but promising results have been obtained using an ultrasensitive lateral flow assay. A commercially available point-of-care assay (Rapid Medical Diagnostics, Pretoria, South Africa) that detects CCA in urine is now widely used for screening of infected communities in relation to mass drug administration programs.

TREATMENT

Schistosomiasis

The drug of choice for treatment of schistosomiasis is praziquantel. It is administered orally, is available as 600-mg tablets, and is effective against all schistosome species infecting humans. The drug is safe and well tolerated. Standard regimens are shown in **Table 241-2**. In patients who are not cured by initial treatment, the same dose can be repeated at weekly intervals for 2 weeks. Since praziquantel does not affect the young migrating stages of the schistosomes, it may be necessary to repeat the dose 6–12 weeks later, especially if eosinophilia or symptoms persist despite treatment.

As a general principle, all patients with acute schistosomiasis should be treated with praziquantel. Glucocorticoids can be added in Katayama fever to suppress the hypersensitivity reaction. However, treatment for acute schistosomiasis or Katayama fever must be adjusted appropriately for each case, and in the most severe cases, management in an acute-care setting is necessary.

Praziquantel is effective in cerebral *S. japonicum* infections, resulting in rapid dissipation of cerebral edema and resolution of cerebral masses. However, glucocorticoids and anticonvulsants are sometimes needed in neuroschistosomiasis.

The effect of antischistosomal treatment on disease manifestations depends on the stage and severity of the lesions. Early hepatosplenomegaly, mild or moderate fibrosis, and urinary bladder lesions seen during active infection resolve after chemotherapy. However, for late-stage manifestations (e.g., severe fibrosis with portal hypertension), praziquantel treatment is only one component of management, since the main complications are due to obstructive pathology. Management of portal hypertension and prevention of bleeding from esophageal varices should follow clinical guidelines for treatment of these conditions.

TABLE 241-2 Treatment of Schistosomiasis and Food-Borne Trematode Infections

INFECTION	DRUG OF CHOICE	ADULT DOSE[a]
Schistosoma mansoni, S. haematobium, S. intercalatum, S. guineensis	Praziquantel[b]	40 mg/kg PO in 2 divided doses for 1 day
S. japonicum, S. mekongi	Praziquantel	60 mg/kg PO in 3 divided doses for 1 day
Clonorchis sinensis, Opisthorchis viverrini, Opisthorchis felineus	Praziquantel	25 mg/kg PO tid for 2 consecutive days
Fasciola hepatica, Fasciola gigantica	Triclabendazole[c]	2 doses of 10 mg/kg PO given 12 h apart
Fasciolopsis buski	Praziquantel	75 mg/kg PO in 3 divided doses for 1 day
Echinostoma spp., *Heterophyes heterophyes*, several other species	Praziquantel	25 mg/kg PO tid
Paragonimus westermani, Paragonimus kellicotti	Praziquantel Triclabendazole[c]	25 mg/kg PO tid for 2 consecutive days 10 mg/kg PO once (or twice, 12–24 h apart)

[a]The pediatric dose is the same as the adult dose in all instances. [b]The safety of praziquantel in children <4 years old has not been established, although many children in this age group have been treated with praziquantel during mass drug-administration programs. [c]In February 2019, the U.S. Food and Drug Administration (FDA) approved triclabendazole for treatment of fascioliasis in patients at least 6 years of age.

PREVENTION AND CONTROL

Schistosomiasis is contracted through direct contact with infested freshwater. Travelers should be made aware of the risk of infection if they come into contact with freshwater sources in schistosomiasis-endemic areas. For people living in rural areas where schistosomiasis is endemic, it may be very difficult, if not impossible, to avoid water contact—for example, during occupational activities such as fishing and working in rice fields. Schistosomiasis is a poverty-related disease, and access to safe water and good sanitary facilities may rarely be available. Because *S. japonicum* is a zoonotic parasite, preventive measures should target not only the human population but also animals such as water buffalo, which act as reservoirs for infection.

Praziquantel treatment of infected people, often during mass drug-administration programs, is a cornerstone of the management and control of schistosomiasis. Regular treatment will reduce the level of schistosomiasis morbidity in affected populations. However, treatment should be combined with other relevant strategies, such as control of the intermediate host snails, improved water-quality and sanitation facilities, and health education. Schistosomiasis control measures should be integrated into local health programs.

There have been intensive efforts to develop vaccines, but none is yet available. Three vaccine candidates have been tested in clinical phase 1 or 2 trials. Only one candidate, *S. haematobium* 28GST, has been tested in a clinical phase 3 trial in populations living in an endemic area. The vaccine candidate was immunogenic and well tolerated by infected children, but a sufficient efficacy was not reached.

FOOD-BORNE TREMATODE INFECTIONS

Food-borne trematode infections are a group of zoonotic diseases caused by hepatic, intestinal, and pulmonary parasitic flukes. These infections are contracted by ingestion of infective parasites in undercooked aquatic food or water plants. Infections can cause severe liver and lung disease, and together, this may result in 2 million life-years lost to disability and death worldwide every year.

LIVER FLUKES

The most important liver flukes causing human infections are the related species *Opisthorchis viverrini* and *Opisthorchis felineus*, which cause opisthorchiasis; *Clonorchis sinensis*, which causes clonorchiasis; and *Fasciola hepatica* and *Fasciola gigantica*, which cause fascioliasis (Table 241-1).

Opisthorchiasis and Clonorchiasis *O. viverrini* is found mainly in northeastern Thailand, Laos, and Cambodia; *O. felineus* mainly in Europe and Asia, including the former Soviet Union; and *C. sinensis* in Asia, including Korea, China, Taiwan, Vietnam, Japan, and Asian regions of Russia. Parasite eggs excreted from infected humans or animals are ingested by a host snail (the first intermediate host), where they undergo several developmental stages. Cercariae are then released from the snail and penetrate freshwater fish (the second intermediate host), encysting as metacercariae in the muscles or under the scales. Humans become infected by eating raw or undercooked fish from endemic countries. After ingestion, the metacercariae excyst in gastric juices and migrate via the duodenum, the ampulla of Vater, and the extrahepatic biliary system to the intrahepatic bile ducts.

TABLE 241-3 Clinical Features of Food-Borne Trematode Infections

INFECTION	SYMPTOMS OR SIGNS		COMPLICATIONS
	EARLY OR ACUTE STAGE	ESTABLISHED OR CHRONIC STAGE	
Liver Flukes			
Clonorchis sinensis, Opisthorchis viverrini, Opisthorchis felineus	Often asymptomatic; sometimes hepatitis-like symptoms and high fever (especially with *O. felineus*)	Biliary colic, cholestatic jaundice, recurrent cholangitis and cholelithiasis; hepatomegaly, gallbladder enlargement, periductal fibrosis. Light infections are often asymptomatic and remain so for years.	Pancreatitis, cholangiocarcinoma[a]
Fasciola hepatica, Fasciola gigantica	Acute onset (1–4 weeks after infection) with high fever, weight loss, sometimes urticaria and liver tenderness	Biliary colic, cholestatic jaundice, recurrent cholangitis and cholelithiasis; thickening, enlargement, and fibrosis of biliary ducts; sometimes repeated relapses of acute symptoms	Pancreatitis. In rare cases: ectopic infections in the central nervous system, orbital area, gastrointestinal tract, lungs, and other organs. Rarely, fascioliasis can be fatal.
Intestinal Flukes			
Fasciolopsis buski, Echinostoma spp., *Heterophyes heterophyes*, several other species	Often asymptomatic; sometimes nonspecific gastrointestinal symptoms	Heavy infection may lead to ulceration of intestinal mucosa and malabsorption. Mild infections are often asymptomatic.	Malnutrition, anemia; rarely, ectopic infection in the central nervous system
Lung Flukes			
Paragonimus westermani, Paragonimus kellicotti	Often asymptomatic; sometimes insidious onset with anorexia and weight loss	Bronchitis-, asthma-, and tuberculosis-like symptoms and signs such as chronic cough, dyspnea, bloody ("rusty") sputum	Pulmonary cyst formation; ectopic infection in the central nervous system, eyes, skin, heart, abdominal and reproductive organs

[a]Carcinogenesis has not yet been established for *O. felineus*.

The clinical manifestations of infection with *Opisthorchis* species and *C. sinensis* are similar. Pathologic changes are typically seen in the bile ducts, liver, and gallbladder (Table 241-3). Tissue damage and intense inflammation are caused by mechanical and chemical irritation and immune responses to worms or worm products, and chronic inflammation may result in the development of cholangiocarcinoma. Both *O. viverrini* and *C. sinensis* are classified by the IARC as definitely carcinogenic (class 1). Acute and light infections are mostly asymptomatic, but hepatitis-like signs and symptoms, with high fever and chills, have been reported, especially in *O. felineus* infections. In general, only heavily infected people have symptoms and severe complications (Table 241-3).

The diagnosis of these infections is based on microscopic identification of parasite eggs in stool specimens. The eggs of *Opisthorchis* are indistinguishable from those of *Clonorchis*.

Fascioliasis Fascioliasis occurs in many areas of the world and usually is caused by *Fasciola hepatica*, a common liver fluke of sheep and cattle. *F. hepatica* is found in more than 50 countries on all continents except Antarctica; *F. gigantica* is less widespread. The areas with the highest known rates of human *Fasciola* infection are in the Andean highlands of Bolivia and Peru. In other areas where fascioliasis is found, human cases are sporadic.

Unlike the other liver flukes, *Fasciola* species have no second intermediate host, as their infectious metacercariae adhere directly to aquatic plants. Humans usually acquire infection by ingesting aquatic plants, such as watercress, that contain viable metacercariae or by drinking water with free metacercariae.

After metacercariae have excysted in the duodenum, *Fasciola* species migrate through the intestinal wall into the body cavity, penetrate the liver capsule, and move through the liver into the bile ducts. This migration route is different from that of other liver flukes and gives rise to symptoms during the acute migratory phase; the parasites may cause tissue destruction, focal bleeding, and inflammation. Some migrating flukes may deviate from their usual route to cause ectopic infections. In the established latent stage of infection, the parasites may cause bile duct inflammation, resulting in thickening and expansion of the ducts, fibrosis, and ultimately biliary obstruction (Table 241-3). Although some infected people are asymptomatic in the latent phase, others may experience repeated relapses of acute manifestations.

The most widely used diagnostic approach is direct detection of *Fasciola* eggs by microscopic examination of stool or of duodenal or biliary aspirates. Eggs generally cannot be detected until 3–4 months after exposure, whereas antibodies to the parasite may become detectable 2–4 weeks after exposure. More than one stool specimen may be needed for diagnosis, especially in light infections.

INTESTINAL FLUKES

More than 70 species of intestinal flukes can cause human infection. These parasites are found in different geographic areas, with a relatively high prevalence in Southeast Asia. Humans are infected by ingestion of infective metacercariae attached to aquatic plants (*Fasciolopsis buski*) or encysted in freshwater fish. Flukes mature in the human intestines, and eggs are passed with feces. Mechanical irritation of the intestinal wall and inflammation may lead to nonspecific gastrointestinal symptoms such as diarrhea, constipation, and abdominal pain. Most individuals infected with intestinal flukes are asymptomatic, but heavy infections can be severe, with intestinal mucosal ulcerations and malabsorption (Table 241-3). The diagnosis is established by detection of eggs in stool samples. However, eggs from various intestinal trematodes are often morphologically similar, and it is very difficult to distinguish among species. A cautionary note: *Fasciola* eggs can be difficult to distinguish on the basis of morphologic criteria from the eggs of the intestinal fluke *F. buski*. The distinction has implications for therapy: infection with *F. buski* is treated with praziquantel, which is not effective against fascioliasis (Table 241-2).

LUNG FLUKES

Paragonimiasis is a parasitic lung infection caused by lung flukes of the genus *Paragonimus*. It is a food-borne parasitic zoonosis, with most cases reported from Asia and attributable to consumption of raw or undercooked freshwater crustaceans. *Paragonimus westermani* and related species (e.g., *Paragonimus africanus*) are endemic in West Africa, Central and South America, and Asia. The United States has one indigenous species of lung fluke, *Paragonimus kellicotti*.

Paragonimus species require two intermediate hosts: first, a freshwater snail; and second, a freshwater crustacean, such as a freshwater crab. Humans are infected by consuming raw or undercooked infected crustaceans containing *Paragonimus* metacercariae. *Paragonimus* infects other carnivores such as cats, dogs, foxes, rodents, and pigs in addition to humans. After ingestion, metacercariae quickly penetrate the duodenum and traverse the peritoneal cavity, diaphragm, and parietal pleura to mature into hermaphroditic worm pairs in the pleural spaces or lungs within 6–10 weeks. Adults cross-fertilize in cystic cavities

in the pleural spaces or lungs within another 4–16 weeks and release unembryonated eggs into bronchioles. The eggs are then coughed up in bloody ("rusty") sputum and either discharged in sputum or swallowed and later excreted in feces. Unembryonated eggs are passed from the mammalian host into freshwater ecosystems, where they infect intermediate host snails.

The symptoms and signs of paragonimiasis are fever, cough, hemoptysis, and peripheral eosinophilia. Some patients with paragonimiasis and low parasite burdens may remain relatively asymptomatic for prolonged periods or may have recurrent attacks of cough, sputum production, fever, and night sweats that mimic tuberculosis. Infective metacercariae may migrate to extrapulmonary sites such as the brain (cerebral paragonimiasis).

Pulmonary paragonimiasis is diagnosed by detection of parasite ova in sputum and/or feces. Serology can be helpful in egg-negative cases and in cerebral paragonimiasis. Anamnestic information about the consumption of raw or undercooked freshwater crabs by immigrants, expatriates, and returning travelers—and, in the United States, the consumption of raw or undercooked crayfish from freshwater river systems where *P. kellicotti* is endemic—is important in patients presenting with fever, cough, hemoptysis, pleural effusions, and peripheral eosinophilia.

TREATMENT

Food-Borne Trematode Infections

Praziquantel and triclabendazole are the two drugs of choice; Table 241-2 summarizes the dosages recommended for the various trematode infections. All confirmed cases of human paragonimiasis should be treated with praziquantel (Table 241-2) to avoid the complications of extrapulmonary disease. Surgical management may be needed for pulmonary or cerebral lesions.

CONTROL AND PREVENTION

Drugs are currently the main method of controlling the morbidity associated with food-borne trematode infections, but integrated programs (including improved sanitation; food inspections; and information, education, and communication campaigns) are important for sustainable disease control. Collaboration with other sectors (e.g., agricultural, environmental, and educational) is necessary to tackle highly complex situations in which human behavior, biological factors, and agricultural practices all play a role.

242 Cestode Infections

A. Clinton White, Jr., Miguel M. Cabada

Cestodes, or tapeworms, are members of the flatworm phylum (Platyhelminthes) and comprise the subphylum (Cestoda). The adult worms are segmented worms found in the gastrointestinal tract of the definitive host. The larval forms are typically cystic and found in the tissues of the intermediate host. Human cestode infections include both tapeworm and larval-form infections. For tapeworm infections, humans are the definitive hosts, with adult tapeworms living in the gastrointestinal tract (*Taenia saginata*, *Dibothriocephalus latus*, and *Dipylidium caninum*). Humans are an intermediate or dead-end host with larval-stage parasites living in the tissues for *Echinococcus* spp., *Spirometra* spp., and *Taenia multiceps*. Humans may be either the intermediate hosts or the definitive hosts for *Taenia solium* and are the hosts of both stages of *Rodentolepis nana* (formerly *Hymenolepis nana*).

The tapeworm forms are typically elongated and ribbon-shaped and attach to the intestinal mucosa by means of sucking cups or hooks located on the scolex. A short, narrow neck is found at the base of the scolex from which proglottids (segments) form. As proglottids mature, they are displaced from the neck by the formation of new, less mature segments. The elongating chain of attached proglottids, called the strobila, constitutes the bulk of the tapeworm. The length of the strobila varies between species. Some tapeworms consist of more than 1000 proglottids and may be several meters long. Mature proglottids are hermaphroditic and produce eggs, which are intermittently released.

Most human tapeworms require at least one intermediate host to complete the life cycle. After ingestion of the eggs or proglottids by an intermediate host, the eggs are activated to release the invasive larvae (oncospheres). The oncosphere penetrates the intestinal mucosa and migrates to tissues and develops into an encysted form known as a cysticercus (single scolex), a coenurus (multiple scolices), or a hydatid (cyst with daughter cysts, each containing multiple protoscolices). After ingestion of the cystic forms by the definitive host, the scolex evaginates and develops into a tapeworm.

TAENIASIS SAGINATA AND *TAENIASIS ASIATICA*

The beef tapeworm *T. saginata* is found in all countries where raw or undercooked beef is eaten. It is most prevalent in subSaharan African and Middle Eastern countries. *Taenia asiatica* is closely related to *T. saginata* and is found in Asia, with pigs as intermediate hosts. Since the clinical manifestations and morphology of the two species are very similar, they are discussed together.

Etiology and Pathogenesis Humans serve as the definitive host for the adult stage of *T. saginata* and *T. asiatica*. The scolex attaches to the small intestines and the strobila with 1000–2000 proglottids can reach 8 m in length. The scolex of *T. asiatica* has an unarmed (with no hooks) rostellum and four suckers, whereas *T. saginata* has no rostellum but attaches via four prominent suckers. Each gravid segment has 15–30 uterine branches (in contrast to 8–12 for *T. solium*). The eggs of the three human-infecting *Taenia* species are indistinguishable morphologically and are 30–40 μm in diameter, contain the oncosphere with six hooklets, and have a thick brown striated shell. Eggs can live for months to years on vegetation until they are ingested by cattle or other herbivores (*T. saginata*) or pigs (*T. asiatica*). After ingestion, the oncosphere egresses the egg, invades into the intestinal wall, and is distributed throughout the body via the bloodstream. The invasive larva transforms into the cysticercus (cystic forms) in muscle or viscera of the intermediate host. When raw or undercooked meat containing the larvae is ingested, the cysticercus evaginates and forms a tapeworm in the human intestines. The adult worm matures over several months to produce eggs. The proglottids or eggs are then shed intermittently with stool.

Clinical Manifestations Patients may be asymptomatic or may note passing proglottids in their feces. Patients may note the sensation

of something moving while the motile proglottids of *T. saginata* are passed. Patients occasionally note abdominal pain or discomfort, nausea, change in appetite, or weakness. Weight loss is unusual.

Diagnosis Diagnosis depends on detection of eggs or proglottids in the stool. Eggs may not be found by stool examination but are sometimes only present in the perianal area; thus, when suspected, the perianal region should be examined with use of a cellophane-tape swab (as in pinworm infection; **Chap. 239**). Antigen-detection assays are more sensitive than microscopic examination but are not commercially available. Distinguishing *T. saginata* or *T. asiatica* from *T. solium* requires examination of mature proglottids or the scolex or via molecular tests. Eosinophilia and elevated levels of serum IgE are usually absent.

TREATMENT

Taeniasis saginata and *Taeniasis asiatica*

A single dose of praziquantel (10 mg/kg) is highly effective. Niclosamide (adult dose, 2 g; 1 g for children weighing 11–34 kg) is also effective but is less available. Nitazoxanide can also be used.

Prevention Adequate cooking of beef and pork viscera or exposure to temperatures as low as 56°C for 5 min will destroy cysticerci. Refrigeration, salting for long periods, or freezing at –10°C for 9 days also kills the parasites in beef. General preventive measures include inspection of beef and pork viscera and proper disposal of human feces.

TAENIASIS SOLIUM AND CYSTICERCOSIS

T. solium, also known as the pork tapeworm, causes two forms of infection in humans: adult tapeworms in the intestine (taeniasis) or larval forms in the tissues (cysticercosis). Humans are the only hosts for the *T. solium* tapeworm; pigs are the usual intermediate hosts, although other animals may rarely harbor the cysticercus forms.

T. solium has a wide global distribution including all areas where pigs are raised with access to human feces. Cysticercosis is highly prevalent in Latin America, subSaharan Africa, China, India, and Southeast Asia. Cysticercosis also occurs in nonendemic nations due to the immigration of tapeworm carriers or cysticercosis-infected persons from endemic areas.

Etiology and Pathogenesis The tapeworms of *T. solium* reside primarily in the small intestines. The scolex attaches to the mucosa via sucking disks and the armed rostellum with two rows of hooklets. The mature tapeworm can reach a length of 3 m and have up to 1000 proglottids. The adult tapeworms are thought to live for just few years. Each mature proglottid may produce approximately 50,000 eggs. Proglottids are released from the terminal end of the tapeworm intermittently and excreted into the feces. The eggs are immediately infective for both humans and pigs. After ingestion of eggs by the intermediate host, the oncospheres are released, penetrate the intestinal wall, and are carried via the bloodstream to tissues. In the pig, larvae usually mature in striated muscle of the neck, tongue, and trunk. By 60–90 days, the invasive larvae transform into the encysted larval stage. In the pigs, cysticerci typically survive for months to years, until the pig is slaughtered. Humans develop intestinal tapeworm infections after ingestion of contaminated pork. Human cysticercosis follows ingestion of *T. solium* eggs. Transmission is associated with close contact with a tapeworm carrier. The eggs are sticky and may be found under the fingernails of tapeworm carriers. The tapeworm carrier can also infect themselves by ingestion of ova, likely via the fecal-oral route.

Clinical Manifestations Intestinal infections (taeniasis) with *T. solium* are often asymptomatic. Some patients note passage of proglottids in stool. The proglottids are typically off-white in color and 1–3 cm in length, 0.5–1 cm wide, and about 1 mm thick. The clinical manifestations of cysticercosis are variable. Cysticerci can be found anywhere in the body but are commonly detected in the central nervous system (CNS), skeletal muscle, subcutaneous tissue, or the eye. Involvement of the brain, spine, or cerebrospinal fluid (CSF) is termed neurocysticercosis. The clinical manifestations of human cysticercosis vary with the location of the cysticerci as well as with the extent of associated inflammatory responses or scarring. The most common clinical manifestations are neurologic symptoms. Headache is common with all CNS forms of disease. Seizures are the most frequent clinical manifestation and are associated with inflammation of the brain parenchyma surrounding the cysticercus. Seizures may be focal, focal with secondary generalization, or generalized. Another common clinical manifestation is with symptoms of hydrocephalus, which may result from CSF flow obstruction by cysticerci and/or accompanying inflammation or communicating hydrocephalus from arachnoiditis. The symptoms of increased intracranial pressure may include headache, nausea and vomiting, dizziness, and ataxia. Patients with hydrocephalus may present with altered mental status or papilledema with altered visual acuity. Some patients present with intermittent acute hydrocephalus (termed Bruns' syndrome) associated with change in position due to the cysticercus working as a ball valve. Cysticerci at the base of the brain or in the subarachnoid space may cause chronic meningitis or arachnoiditis, communicating hydrocephalus, mass lesions, hemorrhages, or strokes.

Diagnosis The diagnosis of tapeworm infection with *T. solium* is made by the demonstration of eggs or proglottids, as described for *T. saginata*. However, eggs and proglottids are only shed intermittently, limiting the sensitivity of direct testing. Antigen-capture enzyme-linked immunosorbent assay (ELISA), polymerase chain reaction (PCR), and serology for tapeworm stage-specific antigens are more sensitive but are only available as research techniques. The diagnosis of neurocysticercosis can be difficult since the symptoms are nonspecific and there is no readily available material for demonstration of the parasite. A group of international experts proposed revised diagnostic criteria **(Table 242-1)**. The diagnosis is only certain with definite demonstration of the parasite (absolute criteria). Definitive diagnosis is possible with histologic observation of the parasite in excised tissue, by funduscopic visualization of the parasite in the subretinal or vitreous spaces of the eye, or by neuroimaging demonstrating a cystic lesion containing a characteristic scolex **(Fig. 242-1)**. With high-resolution neuroimaging, the scolex can often be identified. In other cases, a clinical diagnosis is based on a combination of clinical presentation, radiographic studies, exposure or evidence demonstrating presence of the parasites by antigen-detection, quantitative PCR, or even next-generation sequencing in spinal fluid.

Neuroimaging is the primary major diagnostic method (Fig. 242-1). Demonstration of a cystic lesion with a mural nodule consistent with a scolex ("dot-in-hole") is diagnostic. Major findings include cystic lesions with or without enhancement (e.g., ring enhancement), one or more nodular calcifications (which may also have associated edema or enhancement), focal enhancing lesions, or cystic lesions in the subarachnoid space. Cysticerci in the brain parenchyma are usually 5–20 mm in diameter and round. Cystic lesions in the subarachnoid space or fissures may enlarge up to 6 cm in diameter and may be lobulated. The cyst wall for cysticerci in the subarachnoid space or ventricles is usually very thin, and the cyst fluid is often isodense with CSF. Thus, obstructive hydrocephalus or enhancement of the basilar meninges may be the only finding on computed tomography (CT) in extraparenchymal neurocysticercosis. However, since these findings are less specific, they are considered only minor criteria. Cysticerci in the ventricles or subarachnoid space are more readily identified by magnetic resonance imaging (MRI), especially fast imaging employing steady-state acquisition (FIESTA) or three-dimensional constructive interference in steady state (3D CISS). CT is more sensitive than MRI in identifying calcified lesions, whereas MRI is more sensitive than CT for identifying small cystic lesions, scolexes, and enhancement. Spontaneous resolution, resolution after albendazole therapy, or mobile cystic lesions within the ventricles are findings that can support the diagnosis of neurocysticercosis.

Exposure history significantly modifies the interpretation of neuroimaging studies. Detection of specific antibodies to or antigens of *T. solium* are major exposure criteria. Antibody tests using unfractionated

TABLE 242-1 Revised Diagnostic Criteria for Neurocysticercosis[a]

1. **Absolute criteria**
   - **a.** Histologic demonstration of the parasite from biopsy of a brain or spinal cord lesion
   - **b.** Visualization of subretinal cysticercus
   - **c.** Conclusive demonstration of a scolex with a cystic lesion on neuroimaging studies
2. **Neuroimaging criteria**
   - **a. Major neuroimaging criteria**
     - Cystic lesions without a discernible scolex, typical small enhancing lesions, multilobulated cystic lesions in the subarachnoid space, typical parenchymal brain calcifications
   - **b. Confirmative neuroimaging criteria**
     - Resolution of cystic lesions spontaneously or after cysticidal drug therapy
     - Migration of ventricular cysts documented on sequential neuroimaging studies
   - **c. Minor neuroimaging criteria**
     - Obstructive hydrocephalus or abnormal enhancement of basal leptomeninges
3. **Clinical/exposure criteria**
   - **a. Major clinical/exposure criteria**
     - Detection of specific anticysticercal antibodies (e.g., by enzyme-linked immunoelectrotransfer blot [EITB]) or cysticercal antigens by well-standardized immunodiagnostic tests
     - Cysticercosis outside the central nervous system
     - Evidence of a household contact with *T. solium* infection
   - **b. Minor clinical/exposure criteria**
     - Clinical manifestations suggestive of neurocysticercosis
     - Individuals coming from or living in an area where cysticercosis is endemic

[a]Diagnosis is confirmed by one absolute criterion, by two major criteria or one major and one confirmatory neuroimaging criteria plus any clinical/exposure criterion, or by one major neuroimaging criterion plus two clinical/exposure criteria (including at least one major clinical/exposure criterion), together with the exclusion of other pathologies producing similar neuroimaging findings. A probable diagnosis is supported by one major neuroimaging criterion plus any two clinical/exposure criteria or by one minor neuroimaging criterion plus at least one major clinical/exposure criterion.

antigens (e.g., ELISAs using crude parasite antigen) have high rates of false-positive and false-negative results and should be avoided. An immunoblot assay (enzyme-linked immunoelectrotransfer blot [EITB]) using lentil lectin–purified glycoproteins is >99% specific and sensitive in patients with multiple cysts. However, patients with single intracranial lesions or with calcifications may be seronegative. Serum samples are more sensitive than CSF using EITB. Each of the diagnostic antigens has been cloned, and assays using recombinant or synthetic antigens are in development. Assays using monoclonal antibodies to detect parasite antigen in the blood, CSF, or urine may also facilitate diagnosis and patient follow-up. Antigen-detection assays are currently available commercially in Europe but not in the United States. More recently, real-time PCR has been employed for diagnosis and follow-up of extraparenchymal disease.

Other major clinical/exposure criteria for neurocysticercosis include the presence of cysticerci outside the CNS (e.g., typical cigar-shaped calcifications in muscle) or exposure to a tapeworm carrier or a household member infected with *T. solium*. Minor clinical/exposure criteria include residence in an endemic village or clinical symptoms suggestive of neurocysticercosis (e.g., seizures or obstructive hydrocephalus).

Studies from India validated clinical criteria for diagnosis in selected cases. In patients from endemic areas who had single enhancing lesions presenting with seizures, a normal physical examination, and no evidence of systemic disease (e.g., no fever, adenopathy, or chest radiographic abnormalities), the presence on CT of round lesions 5–20 mm in diameter with no midline shift was almost always caused by neurocysticercosis. Definite or probable diagnosis can be made using the criteria and combinations of criteria listed in the footnote of Table 242-1. Patients often have CSF pleocytosis with a predominance of lymphocytes, neutrophils, or eosinophils. The protein level in CSF may be elevated; the glucose concentration is usually normal but can be markedly reduced.

TREATMENT

Taenia solium and Cysticercosis

Tapeworm infection by *T. solium* infection is treated with a single dose of praziquantel (10 mg/kg). However, praziquantel may occasionally trigger an inflammatory response in the CNS if concomitant cryptic cysticercosis is present. Niclosamide (2 g) is also effective but is not as widely available.

INITIAL MANAGEMENT OF NEUROCYSTICERCOSIS

Initial management of neurocysticercosis should focus on treatment of seizures or hydrocephalus. Seizures can be controlled with antiseizure medications. Seizure medications can usually be tapered after 6 months in patients with single enhancing lesions in whom imaging normalizes and in whom there are no breakthrough seizures. Subjects with multiple parenchymal lesions require more prolonged therapy. However, antiseizure medications can often be tapered off after 2 years if lesions resolve without development of calcifications and patients remain free of seizures. Patients with calcified lesions are at higher risk of recurrent seizures, especially if the lesions are associated with perilesional edema or enhancement.

MANAGING HYDROCEPHALUS

For patients with hydrocephalus, the reduction of intracranial pressure should be the priority of the initial therapy. Patients with cysticerci in the cerebral ventricles typically present with obstructive hydrocephalus, and the preferred approach is removal of the cysticercus via neurosurgery. Cysticerci in the lateral or third ventricles should be removed via neuroendoscopy. Antiparasitic drugs make the cysticerci more friable and should be avoided prior to surgery. The cysticerci in the fourth ventricle can be approached by microdissection using a posterior approach or, in some cases, via neuroendoscopy. When complete removal of the cysticercus is not possible, a diverting procedure, such as ventriculoperitoneal shunting, can be used to manage hydrocephalus. Historically, shunt failure was a major problem. The risk of shunt failure may be limited by administration of antiparasitic drugs and glucocorticoids.

ANTIPARASITIC DRUGS AND ANTI-INFLAMMATORY THERAPY

Antiparasitic drug treatment is never an emergency in neurocysticercosis and should wait until patients are stabilized with antiseizure and anti-inflammatory medications and exclusion of intraocular disease. Antiparasitic drugs should never be started in patients with elevated intracranial pressure. Antiparasitics do hasten resolution of neuroradiologic abnormalities in parenchymal neurocysticercosis. Clinical benefits consist mainly of decreasing the number of recurrent generalized seizures. In viable parenchymal cysticercosis, most authorities recommend antiparasitic drugs, especially albendazole (15 mg/kg per day for 8–28 days). A combination of albendazole and praziquantel (50 mg/kg per day) is more effective in patients with more than two cystic lesions. A longer course or combination therapy is needed in patients with multiple subarachnoid cysticerci. Both antiparasitic agents may exacerbate the inflammatory response around the dying parasite, thereby exacerbating seizures or hydrocephalus. Patients receiving these drugs should be carefully monitored. High-dose glucocorticoids should always be used during treatment (e.g., dexamethasone 0.1–0.4 mg/kg per day or prednisone 60 mg/d).

For patients with subarachnoid cysts or giant cysticerci, anti-inflammatory medications such as glucocorticoids are needed to reduce arachnoiditis and accompanying vasculitis. Most authorities recommend prolonged courses of antiparasitic drugs as well as shunting when hydrocephalus is present. Patients typically require prolonged anti-inflammatory treatment along with antiparasitics.

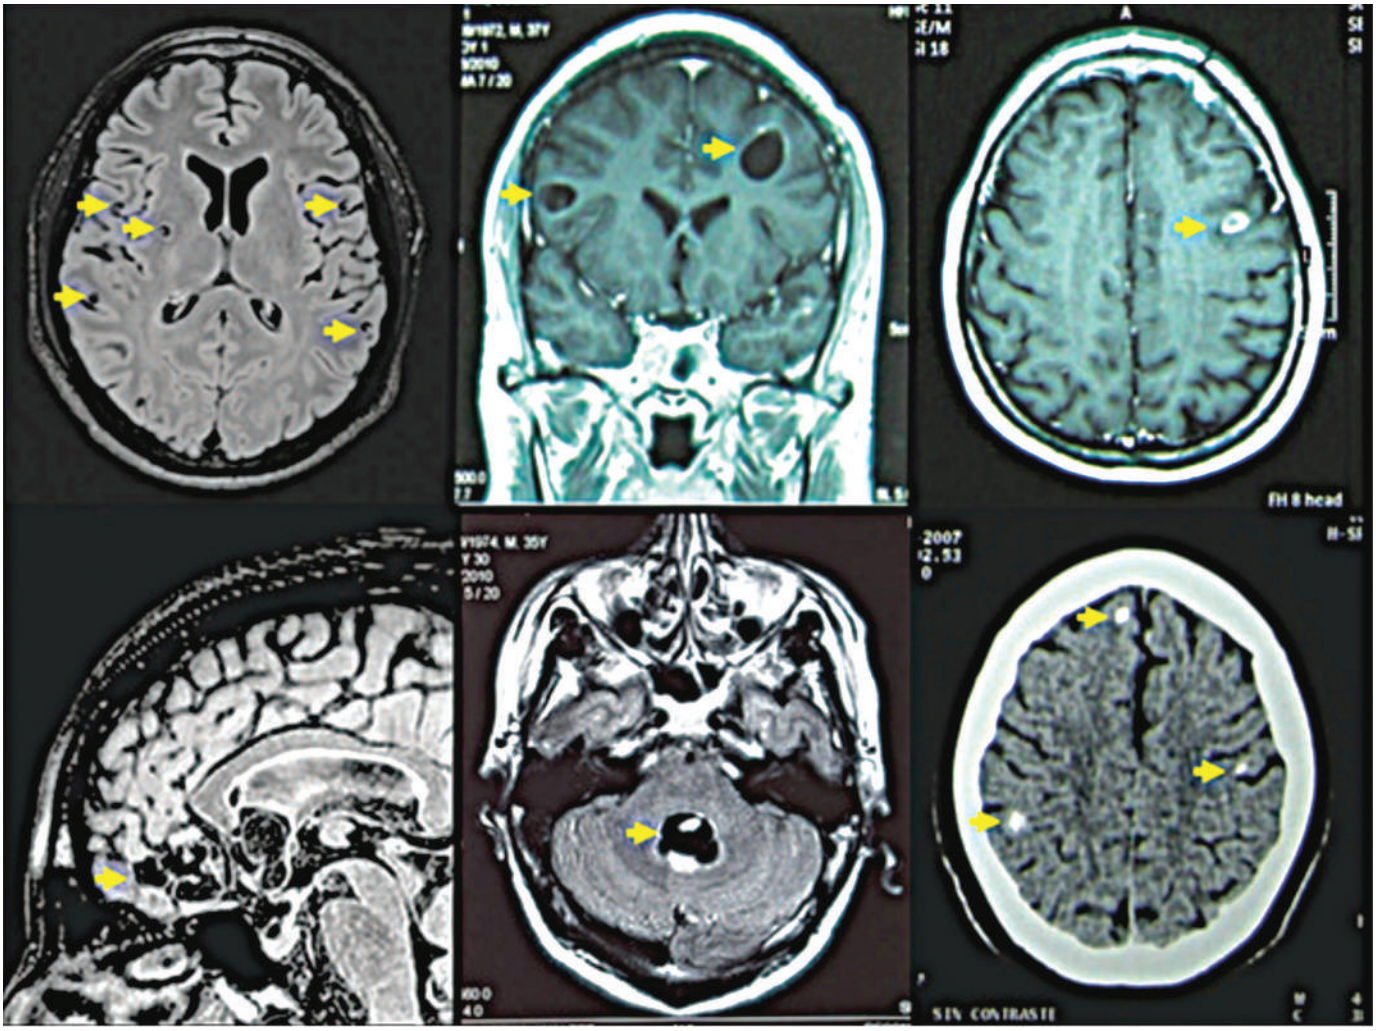

FIGURE 242-1 Neurocysticercosis is caused by *Taenia solium*. Neurologic infection can be classified based on the location and viability of the parasites. ***Upper left:*** Parenchymal viable cysts (FLAIR MRI sequence). ***Upper center:*** Parenchymal viable cysts (postcontrast T1 MRI sequence). ***Upper right:*** Single enhancing lesion (postcontrast T1 MRI sequence). ***Bottom left:*** Extensive basal subarachnoid neurocysticercosis in the anterior fossa (FLAIR MRI sequence). ***Bottom center:*** Viable cyst in the fourth ventricle (FLAIR MRI sequence). ***Bottom right:*** Intraparenchymal brain calcifications (noncontrasted CT scan). Lesions are marked with *arrowheads*. FLAIR, fluid-attenuated inversion recovery. *(Modified with permission from White AC Jr, Garcia HH. Updates on the management of neurocysticercosis. Curr Opin Infect Dis. 2018;31(5):377-382. Lippincott Williams & Wilkins.)*

Methotrexate and, in some cases, tumor necrosis factor inhibitors have been used as steroid-sparing agents in patients requiring prolonged therapy. In patients with diffuse cerebral edema and elevated intracranial pressure due to multiple inflamed parenchymal lesions, glucocorticoids are the mainstay of therapy, and antiparasitic drugs should be avoided. For ocular and spinal lesions, drug-induced inflammation may cause irreversible damage. Intraocular disease should be managed surgically. Recent data suggest that spinal disease is best managed using both medical and surgical therapy.

Prevention Prevention of *T. solium* tapeworm infection consists of precautions in handling pork, as described for *T. asiatica*, and thoroughly cooking or freezing pork to destroy the cysticerci. Pork inspections and condemnation of infected meat prevent transmission. The prevention of cysticercosis involves good personal hygiene including handwashing, effective disposal of feces, and treatment and prevention of human intestinal infections. Optimal eradication programs to eradicate *T. solium* in endemic areas include mass chemotherapy administered to human and porcine populations and vaccinations of pigs. A vaccine for porcine infection is licensed in India and a few other countries.

ECHINOCOCCOSIS

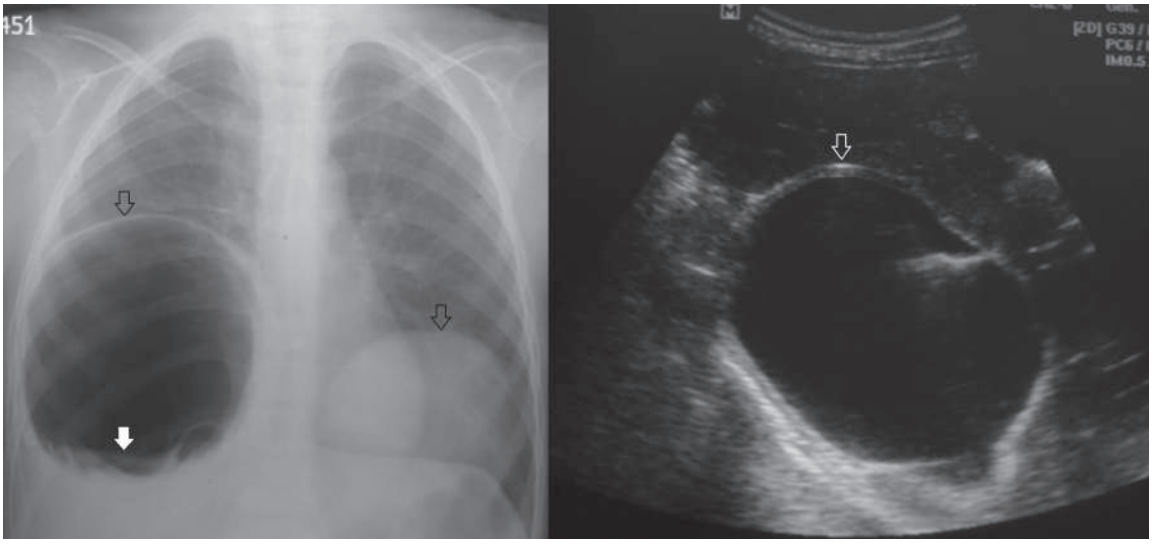
Echinococcosis (also known as hydatid disease) refers to infection by the larval stage of *Echinococcus* species (*E. granulosus* sensu lato, *E. multilocularis*, or *E. vogeli*). *E. granulosus* sensu lato parasites produce cystic hydatid disease or cystic echinococcosis, which is prevalent worldwide in most areas where livestock is raised in association with dogs. *E. granulosus* sensu lato is a complex of several distinct species with important genotypic and phenotypic differences. Human cystic echinococcosis is caused by *E. granulosus* sensu stricto (genotypes 1–3), *E. canadensis* (genotypes 6–8 and 10), and *E. ortleppi* (genotype 5). Some classify genotypes 6 and 7 as a separate species—*E. intermedius*. *E. granulosus* sensu lato parasites are found on all continents, with areas of high prevalence in western China, central Asia, the Middle East, the Mediterranean region, eastern Africa, and parts of South America. *E. multilocularis* causes multilocular or alveolar echinococcosis characterized by locally invasive lesions. Alveolar echinococcosis is prevalent in Alpine, sub-Arctic, and Arctic regions of the northern hemisphere, including western China, central Asia, central and northern Europe, and in isolated areas of North America with an expanding range of endemic areas. Neotropical echinococcosis (formerly termed polycystic hydatid disease) is caused by *E. vogeli* and *E. oligarthrus*, which are only found in limited foci in South America.

Echinococcal species require both intermediate and definitive hosts. The definitive hosts are usually canines (dogs, foxes, wolves) that harbor the small tapeworms in the intestine and shed eggs in stool. After the ingestion of eggs, oncospheres invade through the intestines into the circulatory system and form cysts in the intermediate hosts including sheep, cattle, goats, camels, pig, and horses for *E. granulosus* sensu lato and mice and other rodents for *E. multilocularis*. When a dog

(*E. granulosus*) or fox/wolf (*E. multilocularis*) ingests viscera containing cysts, the protoscolices in the cyst fluid develop into tapeworms in the intestine, completing the life cycle. Humans are a dead-end intermediate host and not part of the parasite's life cycle.

Etiology The adult tapeworms of *E. granulosus* sensu lato are small (5 mm long) and live for 5–20 months in the small intestine of dogs. Each tapeworm has only three proglottids: one immature, one mature, and one gravid. The latter are shed and release eggs that are morphologically similar to *Taenia* eggs. Heavy infections of dogs with many tapeworms are common in endemic areas. When humans ingest the eggs, the invasive oncospheres are released from eggs, penetrate the intestinal mucosa, enter the portal circulation, and are carried mostly to the liver and lungs. However, virtually any organ can be infected including kidneys, spleen, heart, bone, and brain. Larvae of *E. granulosus* sensu lato develop into fluid-filled unilocular hydatid cysts. The wall of the cystic lesion consists of an external membrane and an inner germinal layer, which are surrounded by the host's adventitial layer that may contain different patterns of inflammation and fibrosis. Daughter cysts and germinating cystic structures called brood capsules develop from the inner aspect of the germinal layer. New organisms, called protoscolices, develop in large numbers within the brood capsule. A protoscolex is an invaginated scolex with the capacity to form an adult tapeworm if ingested by a definitive host or form a new cystic lesion if released in the intermediate host's tissues. The cysts expand slowly over a period of years and may contain thousands of protoscolices.

E. multilocularis has a life cycle involving wild canines such as foxes or wolves, which are the main definitive hosts. Domestic dogs can also serve as definitive hosts of these tapeworms. Small rodents are the main intermediate hosts. Humans are dead-end intermediate hosts that develop alveolar echinococcosis. The larval stage of this parasite forms multilocular, small irregular cysts with proliferating and invasive capacity. The parasite larvae invade the host tissue by peripheral extension of processes from the germinal layer. These lesions do not contain brood capsules or protoscolices.



Clinical Manifestations The slowly enlarging echinococcal cysts generally remain asymptomatic for years until their expanding size elicits organ-specific symptoms. Spontaneous or traumatic rupture may lead to type I allergic reactions including anaphylaxis. The liver is involved in two-thirds of *E. granulosus* sensu lato infections and nearly all *E. multilocularis* infections. The lungs are involved in about 20% of *E. granulosus* sensu lato infections. The parasites are often discovered incidentally on a routine x-ray or ultrasound study prior to onset of symptoms.

Symptoms of hepatic cystic echinococcosis may include abdominal fullness or pain or a palpable mass in the right upper quadrant. Compression of a bile duct or leakage of cyst fluid into the biliary tree may present with symptoms mimicking cholelithiasis. Jaundice can result from biliary obstruction. Rupture of or leakage from a hydatid cyst may present more acutely with symptoms including fever, pruritus, urticaria, eosinophilia, or anaphylaxis. Cystic echinococcosis in the lungs may present with chronic cough, shortness of breath, chest pain, or hemoptysis. Rupture into the bronchial tree leads to sudden expectoration of the cyst fluid and membranes and rupture into the pleural cavity may produce pleuritic chest pain and hydatid empyema. Rupture of hydatid cysts, which can occur spontaneously, after trauma, or during surgery, may lead to release of protoscolices into the patient's tissues, each of which can form new cysts. Hydatid disease may also involve bone (invasion of the medullary cavity with bony erosion producing pathologic fractures), the CNS (space-occupying lesions), the heart (conduction defects, pericarditis), and the pelvis (pelvic mass).

E. multilocularis characteristically presents as a slow-growing hepatic mass, which typically presents decades after the initial infection. The lesions resemble tumors causing progressive destruction of the liver and extension into adjoining structures. Frequent symptoms include upper-quadrant and epigastric discomfort. Physical examination may reveal liver enlargement and obstructive jaundice. The lesions may infiltrate adjoining organs (e.g., diaphragm, kidneys, or lungs) or may metastasize to the spleen, lungs, or brain.

Diagnosis Imaging studies are the main diagnostic methods to detect and evaluate echinococcal cysts. Chest x-ray or CT can identify pulmonary cysts due to *E. granulosus* sensu lato, which appear as rounded masses of uniform density **(Fig. 242-2)**.

Ultrasound, CT, or MRI can be used to identify cystic echinococcosis lesions in solid organs of the abdomen, particularly in the liver. The ultrasound classification proposed by the World Health Organization Informal Working Group on Echinococcosis has diagnostic and management applications for liver cystic echinococcosis **(Figs.** 242-2 **and 242-3)**. MRI can also be used to classify lesions. MRI and CT may be more useful than ultrasound to evaluate the presence of cyst complications, such as communication with the biliary tree, that preclude some management options. Imaging of cystic echinococcosis shows well-defined cysts walls and, in some cases, internal trabeculation, dense cyst material, and/or calcifications (Fig. 242-3). In some cases, the protoscolices and brood capsules of *E. granulosus* complex may be visible within the cysts as fine particles termed hydatid sand. Identification of daughter cysts within the larger cyst is diagnostic of cystic echinococcosis disease. Eggshell or mural calcification on CT is also diagnostic of *E. granulosus* infection. In contrast, ultrasound or CT of alveolar hydatid cysts often reveals an indistinct solid mass. Some cases will display central necrosis or plaque-like calcifications.

A *B*

FIGURE 242-2. Imaging studies of cystic echinococcosis. ***A.*** Chest x-ray film of a patient with bilateral cysts. The hollow arrows show well-defined cyst walls with a complicated right chest cyst and an intact left chest cyst. ***B.*** Liver ultrasound of a patient with CE1 cysts. The hollow arrow shows a well-defined bilayer cyst wall.

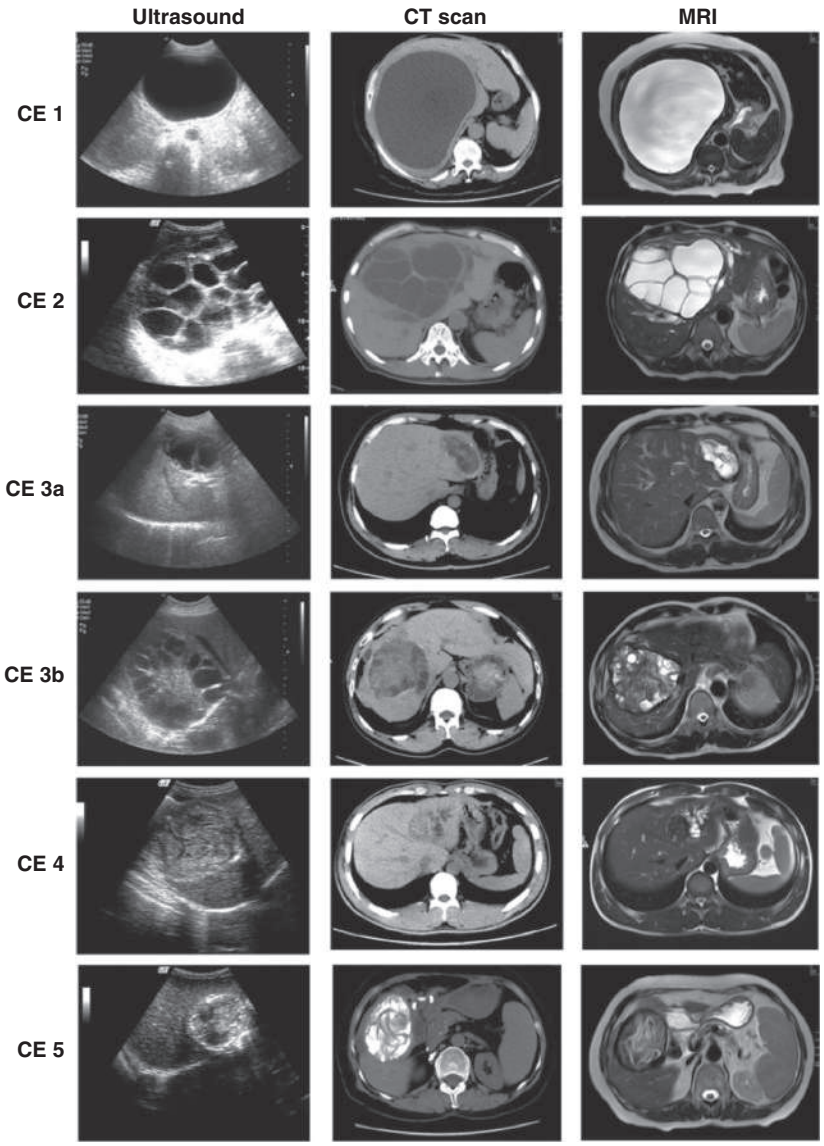


FIGURE 242-3 Management of cystic hydatid disease caused by *Echinococcus granulosus* should be based on viability of the parasite, which can be estimated from radiographic appearance. Staging is done by imaging studies including ultrasound, CT, or MRI and includes lesions classified as active, transitional, and inactive. *Active* cysts include types CL (with a cystic lesion and no visible cyst wall), CE1 (with a visible cyst wall and internal echoes [*snowflake sign*]), and CE2 (with a visible cyst wall and internal septation). *Transitional* cysts may have detached laminar membranes (CE3a) or may be partially collapsed (CE3b). *Inactive cysts* include types CE4 (a nonhomogeneous mass) and CE5 (a cyst with a thick calcified wall).

For cystic echinococcosis disease, a definitive diagnosis can also be made by the examination of aspirated fluids for protoscolices and/or hooklets. However, due to the potential risk of fluid leakage resulting in either dissemination of infection or, more rarely, anaphylactic reactions, aspiration should only be performed by experienced interventionists and following the precautions used for percutaneous treatment (see below). Serodiagnostic assays can be useful, but current serologic tests are insensitive and cannot be used to exclude the diagnosis of echinococcosis. ELISA and immunoblot assays for specific antibody are positive in ~90% of cases of hydatid liver disease. By contrast, the sensitivity is only ~50% for patients with cysts in the lungs.

TREATMENT

Echinococcosis

CYSTIC HYDATID DISEASE

Optimal treatment of cystic echinococcosis varies depending on the size, stage, location, and clinical manifestations of cysts. In the past, surgery was the main treatment method, but numerous studies have demonstrated that other treatment modalities may be just as effective and lead to less morbidity. Staging is recommended for cystic echinococcosis of the liver, which allows assessment of the cyst size and viability (Fig. 242-3). CL, CE1, and CE3a lesions <5 cm in diameter may respond well to chemotherapy with albendazole alone. Other small liver cysts (<5 cm) such as CE2 or CE3b are less responsive to medical treatment alone. Larger CE1 lesions and uncomplicated CE3a lesions in the liver can often be managed by PAIR (percutaneous aspiration, instillation of scolicidal agents, and reaspiration). Contraindications to PAIR include cysts communicating with the biliary tree, large cysts (>10 cm), or superficial cysts, which are more likely to rupture and spill protoscolices. Albendazole (15 mg/kg daily in two divided doses) should be initiated at least 2 days before the procedure and continued for at least 4 weeks afterward. Fine-needle ultrasound or CT-guided aspiration should enter the cyst through solid tissues to limit spillage of cyst fluid. Aspiration can confirm the diagnosis by microscopic demonstration of protoscolices or hooks. After aspiration, bilirubin should be measured in the cyst fluid using a dipstick, or contrast material should be injected to detect occult communications with the biliary

tract. If no bile is found and no communication is visualized, instillation of scolicidal agents (usually hypertonic saline) and reaspiration are performed. PAIR, when performed by a skilled practitioner, results in cure and relapse rates equivalent to surgery, with less perioperative morbidity and shorter hospitalization. In some centers, CE2 lesions have been treated by modified catheter drainage, including puncture of each daughter cyst within the primary cyst.

Patients with treatment failure can often be treated again successfully with PAIR or additional courses of medical therapy. Response to treatment is best assessed by serial imaging studies, with attention to cyst size and consistency. Cysts may not demonstrate complete radiologic resolution even though no viable protoscolices are present. Those cysts classified as CE4 or CE5 are considered nonviable and require periodic reevaluations to assess for reactivation.

Surgery remains the treatment of choice for complicated cystic echinococcosis (e.g., cysts communicating with the biliary tract), for most thoracic and intracranial cysts, and when PAIR is not possible. Liver cysts should be removed via a pericystectomy, in which the entire cyst and the surrounding fibrous tissue are removed to prevent spillage and recurrence. Recent reports demonstrate that, in experienced hands, cysts can often be safely removed by laparoscopic or robotic surgery. The risks posed by leakage of fluid during surgery or PAIR include anaphylaxis and dissemination of protoscolices. Spillage can be minimized by careful dissection and using surgical draping soaked in hypertonic saline. Infusion of scolicidal agents is no longer recommended because of problems with hypernatremia, intoxication, or sclerosing cholangitis. Albendazole should be administered adjunctively, beginning several days to weeks before resection of the liver cyst and continuing for several weeks afterwards. Albendazole at 10-15 mg/kg divided in two daily doses (400 mg BID in adults) is recommended for treatment in association with clinical and laboratory monitoring.

ALVEOLAR HYDATID DISEASE

Surgical resection is required to attempt cure of *E. multilocularis* infection. Complete removal of the parasite continues to offer the best chance for cure. Patients who have undergone presumed curative resection should be treated with albendazole for at least 2 years after presumptively curative surgery. Positron emission tomography can be used to follow disease activity. Unfortunately, most cases are only diagnosed at a stage in which complete resection is impossible; in these cases, albendazole treatment should be continued indefinitely, with careful monitoring. In some cases of larger lesions, complete removal of the liver followed by liver transplantation has been used. Unfortunately, the immunosuppression required to prevent rejection of the transplanted liver also promotes proliferation of *E. multilocularis* and reinfection of the transplanted liver. Thus, indefinite treatment with albendazole is required.

Prevention Cystic echinococcosis can be prevented by administering praziquantel to infected dogs, by preventing dogs from having access to viscera from infected animals, or by vaccinating sheep. Limiting the number of stray dogs that are more likely to evade prevention measures may help decrease transmission. In Europe, *E. multilocularis* infection is associated with human settlement encroaching into forested areas, gardening in those areas, and collecting activities in forested areas. Thus, gloves and hand hygiene should be used in these situations. Praziquantel-impregnated bait can be used to treat tapeworms in wild canines.

■ *RODENTOLEPIS NANA* (PREVIOUSLY *HYMENOLEPIS NANA*)

The dwarf tapeworm, previously known as *H. nana*, is the most common human cestode infection. Recent molecular data have led to the reclassification of this organism to a different genus and new name *Rodentolepis nana*. *R. nana* is endemic worldwide, including temperate and tropical regions. Transmission is mostly person-to-person by the fecal-oral route.

Etiology and Pathogenesis *R. nana* is the only human cestode that does not require an intermediate host. Both the larval and adult stages coexist in the intestine of infected persons. The adult tapeworm is only ~2 cm long and lives in the human proximal ileum. The tiny proglottids are rarely seen in the stool. They release spherical eggs, 30–44 μm in diameter, containing the invasive larvae termed oncosphere, which has six hooklets. The eggs are immediately infective after leaving the host and survive for ≤10 days in the environment. After the eggs are ingested, the oncosphere is released, penetrates the intestinal villi, and develops into the cysticercoid larval form within the epithelium. After a few days, these larvae reenter the intestinal lumen, attach to the mucosa, and mature into adult tapeworms over 10–12 days. The life span of adult *R. nana* worms is typically ~4–10 weeks. However, infection is perpetuated by cycles of reinfection and autoinfection in which some eggs hatch in the intestinal lumen and form the cysticercoid larva without leaving the host.

Clinical Manifestations *R. nana* infection is most often asymptomatic. However, infection may be associated with diarrhea, abdominal pain, and weight loss, particularly in children with the highest burden of infection.

Diagnosis Infection is diagnosed by finding the characteristic *R. nana* eggs in microscopy of the stool.

TREATMENT

Rodentolepis nana Infection

The treatment of choice for *R. nana* is praziquantel (25 mg/kg once), which is active against both the adult worms and the cysticercoids in the intestinal wall. Nitazoxanide (500 mg twice a day for 3 days) has been used as an alternative treatment.

Prevention Since *R. nana* is acquired by the fecal-oral route, improved sanitation and personal hygiene can be used to eliminate disease. Hand washing in the household and school is important. Mass chemotherapy and improved hygiene have been used to control epidemics.

■ *HYMENOLEPIASIS DIMINUTA*

Hymenolepis diminuta is a cestode of rodents that occasionally causes infection in small children. Infection is acquired by ingesting uncooked cereal and other foods contaminated by fleas and other insects that serve as intermediate hosts for *H. diminuta*. Infection is diagnosed by detection of eggs in the stool. The treatment of choice is praziquantel (25 mg/kg once).

■ DIPHYLLOBOTHRIASIS (*DIBOTHRIOCEPHALUS/ADENOCEPHALUS*)

The broad fish tapeworms comprised several species that were formerly classified under the genus *Diphyllobothrium*. Molecular and phylogenetic studies have now demonstrated several important differences between these parasites, which led to modification of the taxonomic classification of cestodes of the *Diphyllobothriidae* family infecting humans. *Dibothriocephalus latus* (formerly *Diphyllobothrium latum*), *Adenocephalus pacificus* (formerly *Diphyllobothrium pacificum*), and *Dibothriocephalus nihonkaiensis* (formerly *Diphyllobothrium nihonkaiensis*) are the most common species infecting humans. These parasites were initially identified in freshwater lakes, rivers, and deltas of the Northern Hemisphere and central Africa. However, they are also found in marine environments in the northern Pacific Ocean (*D. nihonkaisensis*) and the Pacific coast of South America (*A. pacificus*).

Etiology and Pathogenesis The adult tapeworm can reach a length of up to 25 m, making them the longest tapeworms of humans. The scolex attaches to the small intestinal mucosa by a modified sucker called *bothria*, which is located on the elongated scolex. The mature tapeworms have 3000–4000 proglottids, producing ~1 million eggs per day. *D. latus* eggs hatch in fresh water and release the free-swimming coracidium. The coracidia are ingested by small freshwater crustaceans

(*Cyclops* or *Diaptomus* species). Within the infected crustaceans, the procercoid larvae develop. When the infected crustaceans are ingested by fish, the procercoid larva migrate to the fish's flesh and transform into a sparganum or plerocercoid larva. Humans acquire the infection by ingesting infected raw or smoked fish. Within 3–5 weeks, the tapeworm matures into an adult in the human intestine. For *A. pacificus*, the definite hosts include seals, dogs, and humans, and the second intermediate hosts are marine fish.

Clinical Manifestations Most infections by these tapeworms are asymptomatic. Some patients note abdominal discomfort, diarrhea, vomiting, weakness, or weight loss. The proglottids may be passed in stool or found incidentally during endoscopy. Diphyllobothriidae can cause acute abdominal pain or intestinal obstruction in rare cases. *D. latus* tapeworms have avid receptors for vitamin B_{12} that can interfere with absorption and, in patients with other risk factors, produce vitamin B_{12} deficiency. In patients with B_{12} deficiency, pernicious anemia and neurologic sequelae may develop.

Diagnosis The diagnosis is made by the detection of the characteristic eggs in the stool. The eggs possess a single shell with an operculum at one end and a knob at the other, which may be confused with trematode eggs by the inexperienced technician. Mild to moderate eosinophilia may be detected. Examination of the tapeworms passed also provides a diagnosis, as proglottids have a characteristic uterus with a rosette-like shape.

TREATMENT

Diphyllobothriasis

Praziquantel (5–10 mg/kg once) is highly effective against all Diphyllobothriid species. Parenteral vitamin B_{12} may be given for B_{12} deficiency.

Prevention Heating fish to 54°C for 5 min or freezing at –18°C for 24 h kills the larval forms. Placing fish in brine with a high salt concentration for long periods can also kill the plerocercoid larvae.

DIPYLIDIASIS

Dipylidium caninum is a common tapeworm of dogs and cats. Dogs, cats, and occasionally humans become infected by swallowing fleas harboring the intermediate forms (cysticercoid larvae). Children are more often infected than adults. Infections are usually asymptomatic except for the passage of motile proglottids in stool and, less often, vague abdominal symptoms. The diagnosis is made by the detection of proglottids or the characteristic egg packets in the stool. Eggs within the packet resemble other *Taenia* eggs. The motile proglottids resemble flattened grains of rice and, in small children, may migrate out of the anus. Praziquantel is the treatment of choice. Prevention should mainly focus on antiparasitic and flea treatment of dogs and cats.

SPARGANOSIS

The plerocercoid larvae of Diphyllobothriid tapeworms of the genus *Spirometra* cause human sparganosis. Dogs, cats, and pigs are hosts of the adult tapeworm; crustaceans of the *Cyclops* species in fresh water are the first intermediate host; and snakes, frogs, or birds are the second intermediate hosts. Human infection commonly follows topical application of poultices with infected flesh from snakes, frogs, or birds used in traditional medicine. Infection can also be acquired by the ingestion of water containing infected *Cyclops* and raw or undercooked meat from infected snakes, birds, or some mammals. Infection commonly presents as a subcutaneous swelling that contains the parasite. Periorbital infections can present with swelling and intraocular infections may lead to blindness. Infections of the brain can present as a mass or slowly migrating lesions. Proliferative lesions may cause tissue infiltration and are poorly responsive to medical treatment. Surgical excision is used to treat localized sparganosis.

COENUROSIS

Coenurosis is a rare infection of humans by the larval stage (coenurus) of the dog tapeworms *Taenia multiceps* or *Taenia serialis*. The main clinical manifestations are space-occupying cystic lesions in various tissues. The commonly involved tissues include the CNS or subcutaneous tissue. Surgical excision is usually required for both definitive diagnosis and treatment. There are limited data on response to antiparasitic treatment.

Section 1 Introduction to Cardiovascular Disorders

243 Approach to the Patient with Possible Cardiovascular Disease

Joseph Loscalzo

THE MAGNITUDE OF THE PROBLEM

Cardiovascular diseases comprise the most prevalent serious disorders in industrialized nations and are a rapidly increasing problem in developing nations (Chap. 245). Age-adjusted death rates for coronary heart disease have declined by two-thirds in the past four decades in the United States, reflecting the identification and reduction of risk factors as well as improved treatments and interventions for the management of coronary artery disease, arrhythmias, and heart failure. Nonetheless, cardiovascular diseases remain the most common causes of death, responsible for nearly 700,000 deaths each year. Approximately one-third of these deaths are sudden. In addition, cardiovascular diseases are highly prevalent, diagnosed in nearly half of the adult population. The growing prevalence of obesity (Chap. 414), type 2 diabetes mellitus (Chap. 415), and metabolic syndrome (Chap. 420), which are important risk factors for atherosclerosis, now threatens to reverse the progress that has been made in the age-adjusted reduction in the mortality rate of coronary heart disease. Globally, the impact of cardiovascular diseases is steadily mounting, with an estimated 19 million deaths worldwide.

For many years, cardiovascular disease was considered to be more common in men than in women. In fact, cardiovascular disease is the leading cause of all deaths among women and men (Chap. 410). In addition, although the absolute number of deaths secondary to cardiovascular disease has declined over the past decades in men, this number has actually risen in women. Inflammation, obesity, type 2 diabetes mellitus, and the metabolic syndrome appear to play more prominent roles in the development of coronary atherosclerosis in women than in men. Coronary artery disease (CAD) is more frequently associated with dysfunction of the coronary microcirculation in women than in men. Exercise electrocardiography has a lower diagnostic accuracy in the prediction of epicardial obstruction in women than in men.

NATURAL HISTORY

Cardiovascular disorders often present acutely, as in a previously asymptomatic person who develops an acute myocardial infarction (Chap. 286), or a previously asymptomatic patient with hypertrophic cardiomyopathy (Chaps. 266–270) or with a prolonged QT interval (Chap. 259) whose first clinical manifestation is syncope or even sudden death. However, the alert physician may recognize the patient at risk for these complications long before they occur and often can take measures to prevent them. For example, a patient with acute myocardial infarction will often have had risk factors for atherosclerosis for many years. Had these risk factors been recognized, their elimination or reduction might have delayed or even prevented the infarction. Similarly, a patient with hypertrophic cardiomyopathy may have had a heart murmur for years and a family history of this disorder. These findings could have led to an echocardiographic examination, recognition of the condition, and appropriate therapy long before the occurrence of a serious acute manifestation.

Patients with valvular heart disease or idiopathic dilated cardiomyopathy, by contrast, may have a prolonged course of gradually increasing dyspnea and other manifestations of chronic heart failure that is punctuated by episodes of acute deterioration only late in the course of the disease. Understanding the natural history of various cardiac disorders is essential for applying appropriate diagnostic and therapeutic measures to each stage of the condition, as well as for providing the patient and family with the likely prognosis.

CARDIAC SYMPTOMS

The symptoms caused by heart disease result most commonly from myocardial ischemia, disturbance of the contraction and/or relaxation of the myocardium, obstruction to blood flow, or an abnormal cardiac rhythm or rate. Ischemia, which is caused by an imbalance between the heart's oxygen supply and demand, is manifest most frequently as chest discomfort (Chap. 15), whereas reduction of the pumping ability of the heart commonly leads to fatigue and elevated intravascular pressure upstream of the failing ventricle. The latter results in abnormal fluid accumulation, with peripheral edema (Chap. 43) or pulmonary congestion and dyspnea (Chap. 39). Obstruction to blood flow, as occurs in valvular stenosis, can cause symptoms resembling those of myocardial failure (Chap. 264). Cardiac arrhythmias often develop suddenly, and the resulting symptoms and signs—palpitations (Chap. 45), dyspnea, hypotension, and syncope (Chap. 23)—generally occur abruptly and may disappear as rapidly as they develop.

Although dyspnea, chest discomfort, edema, and syncope are cardinal manifestations of cardiac disease, they occur in other conditions, as well. Thus, dyspnea is observed in disorders as diverse as pulmonary disease, marked obesity, and anxiety (Chap. 39). Similarly, chest discomfort may result from a variety of noncardiac and cardiac causes other than myocardial ischemia (Chap. 15). Edema, an important finding in untreated or inadequately treated heart failure, also may occur with primary renal disease and in hepatic cirrhosis (Chap. 43). Syncope occurs not only with serious cardiac arrhythmias but in a number of neurologic conditions as well (Chap. 23). Whether heart disease is responsible for these symptoms frequently can be determined by carrying out a careful clinical examination (Chap. 246), supplemented by noninvasive testing using electrocardiography at rest and during exercise (Chap. 247), echocardiography, and cardiopulmonary imaging (Chap. 248).

Myocardial or coronary function that may be adequate at rest may be insufficient during exertion. Thus, dyspnea and/or chest discomfort that appear during activity are characteristic of patients with heart disease, whereas the opposite pattern, that is, the appearance of these symptoms at rest and their remission during exertion, is rarely observed in such patients. It is important, therefore, to question the patient carefully about the relation of symptoms to exertion.

Many patients with cardiovascular disease may be asymptomatic both at rest and during exertion but may present with an abnormal physical finding such as a heart murmur, elevated arterial pressure, or an abnormality of the electrocardiogram (ECG) or imaging test. It is important to assess the global risk of CAD in asymptomatic individuals, using a combination of clinical assessment and measurement of cholesterol and its fractions, as well as other biomarkers, such as C-reactive protein, in some patients. Since the first clinical manifestation of CAD may be catastrophic—sudden cardiac death, acute myocardial infarction, or stroke in previous asymptomatic persons—it is mandatory to identify those at high risk for such events and institute further testing and preventive measures.

DIAGNOSIS

As outlined by the New York Heart Association (NYHA), the elements of a complete cardiac diagnosis include the systematic consideration of the following:

1. *The underlying etiology*. Is the disease congenital, hypertensive, ischemic, or inflammatory in origin?
2. *The anatomic abnormalities*. Which chambers are involved? Are they hypertrophied, dilated, or both? Which valves are affected? Are they regurgitant and/or stenotic? Is there pericardial involvement? Has there been a myocardial infarction?

TABLE 243-1 New York Heart Association Functional Classification

Class I	**Class III**
No limitation of physical activity	Marked limitation of physical activity
No symptoms with ordinary exertion	Less than ordinary activity causes symptoms
Class II	Asymptomatic at rest
Slight limitation of physical activity	**Class IV**
Ordinary activity causes symptoms	Inability to carry out any physical activity without discomfort
	Symptoms at rest

3. *The physiologic disturbances*. Is an arrhythmia present? Is there evidence of congestive heart failure or myocardial ischemia?
4. *Functional disability*. How strenuous is the physical activity required to elicit symptoms? The classification provided by the NYHA has been found to be useful in describing functional disability **(Table 243-1)**.

One example may serve to illustrate the importance of establishing a complete diagnosis. In a patient who presents with exertional chest discomfort, the identification of myocardial ischemia as the etiology is of great clinical importance. However, the simple recognition of ischemia is insufficient to formulate a therapeutic strategy or prognosis until the underlying anatomic abnormalities responsible for the myocardial ischemia, for example, coronary atherosclerosis or aortic stenosis, are identified and a judgment is made about whether other physiologic disturbances that cause an imbalance between myocardial oxygen supply and demand, such as severe anemia, thyrotoxicosis, or supraventricular tachycardia, play contributory roles. Finally, the severity of the disability should govern the extent and tempo of the workup and strongly influence the therapeutic strategy that is selected.

The establishment of a correct and complete cardiac diagnosis usually commences with the history and physical examination **(Chap. 246)**. Indeed, the clinical examination remains the basis for the diagnosis of a wide variety of disorders. The clinical examination may then be supplemented by five types of laboratory tests: (1) ECG **(Chap. 247)**; (2) noninvasive imaging examinations (chest x-ray, echocardiogram, radionuclide imaging, computed tomographic imaging, positron emission tomography, and magnetic resonance imaging) **(Chap. 248)**; (3) blood tests to assess risk (e.g., lipid determinations, C-reactive protein) or cardiac function (e.g., brain natriuretic peptide [BNP] **[Chap. 264]**); (4) occasionally, specialized invasive examinations (i.e., cardiac catheterization and coronary arteriography **[Chap. 249]**); and (5) genetic tests to identify monogenic cardiac diseases (e.g., hypertrophic cardiomyopathy **[Chaps. 266–270]**, Marfan's syndrome **[Chap. 425]**, and abnormalities of cardiac ion channels that lead to prolongation of the QT interval and an increase in the risk of sudden death **[Chap. 253]**). These genetic tests are becoming more widely available.

FAMILY HISTORY

In eliciting the history of a patient with known or suspected cardiovascular disease, particular attention should be directed to the family history. Familial clustering is common in many forms of heart disease. Mendelian transmission of single-gene defects may occur, as in hypertrophic cardiomyopathy **(Chaps. 266–270)**, Marfan's syndrome **(Chap. 425)**, and sudden death associated with a prolonged QT syndrome **(Chap. 259)**. Premature coronary disease and essential hypertension, type 2 diabetes mellitus, and hyperlipidemia (the most important risk factors for CAD) are usually polygenic disorders. Although familial transmission may be less obvious than in the monogenic disorders, it is helpful in assessing risk and prognosis in polygenic disorders, as well. Familial clustering of cardiovascular diseases not only may occur on a genetic basis but also may be related to familial dietary or behavior patterns, such as excessive ingestion of salt or calories and cigarette smoking.

ASSESSMENT OF FUNCTIONAL IMPAIRMENT

When an attempt is made to determine the severity of functional impairment in a patient with heart disease, it is helpful to ascertain the level of activity and the rate at which it is performed before symptoms develop. Thus, it is not sufficient to state that the patient complains of dyspnea. The breathlessness that occurs after running up two long flights of stairs denotes far less functional impairment than do similar symptoms that occur after taking a few steps on level ground. In addition, the degree of customary physical activity at work and during recreation should be considered. The development of two-flight dyspnea in a well-conditioned marathon runner may be far more significant than the development of one-flight dyspnea in a previously sedentary person. The history should include a detailed consideration of the patient's therapeutic regimen. For example, the persistence or development of edema, breathlessness, and other manifestations of heart failure in a patient who is receiving optimal doses of diuretics and other therapies for heart failure **(Chap. 264)** is far graver than are similar manifestations in the absence of treatment. In an effort to determine the progression of symptoms, and thus the severity of the underlying illness, it may be useful to ascertain what, if any, specific tasks the patient could have carried out 6 months or 1 year earlier that they cannot perform at present.

ELECTROCARDIOGRAM

(See also Chap. 247) Although an ECG usually should be recorded in patients with known or suspected heart disease, with the exception of the identification of arrhythmias, conduction abnormalities, ventricular hypertrophy, and acute myocardial infarction, it generally does not establish a specific diagnosis. The range of normal electrocardiographic findings is wide, and the tracing can be affected significantly by many noncardiac factors, such as age, body habitus, and serum electrolyte concentrations. In general, electrocardiographic changes should be interpreted in the context of other abnormal cardiovascular findings.

ASSESSMENT OF THE PATIENT WITH A HEART MURMUR

(Fig. 243-1) The cause of a heart murmur can often be readily elucidated from a systematic evaluation of its major attributes: timing, duration, intensity, quality, frequency, configuration, location, and radiation when considered in the light of the history, general physical examination, and other features of the cardiac examination, as described in **Chap. 246**.

The majority of heart murmurs are midsystolic and soft (grades I–II/VI). When such a murmur occurs in an asymptomatic child or young adult *without* other evidence of heart disease on clinical examination, it is usually benign and echocardiography generally is not required.

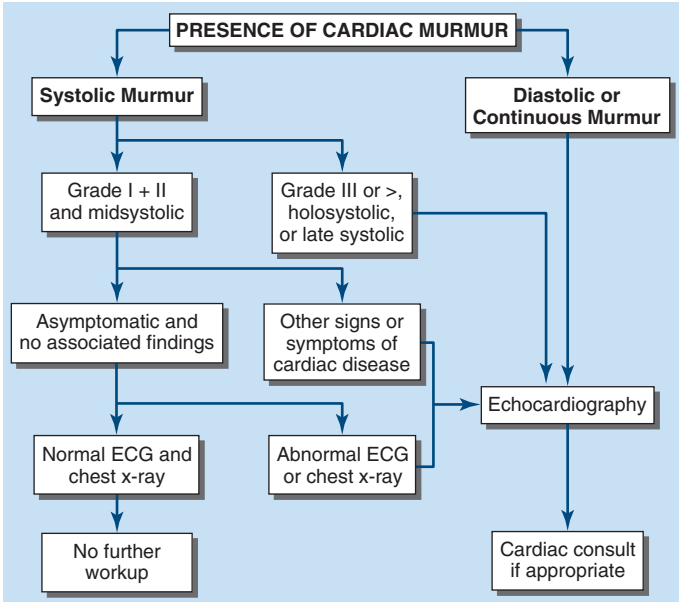

FIGURE 243-1 Approach to the evaluation of a heart murmur. ECG, electrocardiogram. *(Reproduced with permission from E Braunwald, L Goldman [eds]: Primary Cardiology, 2nd ed. Philadelphia, Saunders, 2003.)*

By contrast, two-dimensional and Doppler echocardiography **(Chap. 248)** are indicated in patients with loud systolic murmurs (grades ≥III/VI), especially those that are holosystolic or late systolic, and in most patients with diastolic or continuous murmurs.

PITFALLS IN CARDIOVASCULAR MEDICINE

Increasing subspecialization in internal medicine and the perfection of advanced diagnostic techniques in cardiology can lead to several undesirable consequences. Examples include the following:

1. Failure by the *noncardiologist* to recognize important cardiac manifestations of systemic illnesses. For example, the presence of mitral stenosis, patent foramen ovale, and/or transient atrial arrhythmia should be considered in a patient with stroke, or the presence of pulmonary hypertension and cor pulmonale should be considered in a patient with scleroderma or Raynaud's syndrome. A cardiovascular examination should be carried out to identify and estimate the severity of the cardiovascular involvement that accompanies many noncardiac disorders.
2. Failure by the *cardiologist* to recognize underlying systemic disorders in patients with heart disease. For example, hyperthyroidism should be considered in an elderly patient with atrial fibrillation and unexplained heart failure, and Lyme disease should be considered in a patient with unexplained (fluctuating) atrioventricular block. A cardiovascular abnormality may provide the clue critical to the recognition of some systemic disorders. For example, an unexplained pericardial effusion may provide an early clue to the diagnosis of tuberculosis or a neoplasm.
3. Overreliance on and overutilization of laboratory tests, particularly invasive techniques, for the evaluation of the cardiovascular system. Cardiac catheterization and coronary arteriography **(Chap. 249)** provide precise diagnostic information that may be crucial in developing a therapeutic plan in patients with known or suspected CAD. Although a great deal of attention has been directed to these examinations, it is important to recognize that they serve to *supplement*, not *supplant*, a careful examination carried out with clinical and noninvasive techniques. A coronary arteriogram should not be performed in lieu of a careful history in patients with chest pain suspected of having ischemic heart disease. Although coronary arteriography may establish whether the coronary arteries are obstructed and to what extent, the results of the procedure by themselves often do not provide a definitive answer to the question of whether a patient's symptom of chest discomfort is attributable to coronary atherosclerosis and whether or not revascularization is indicated.

Despite the value of invasive tests in certain circumstances, they entail some small risk to the patient, involve discomfort and substantial cost, and place a strain on medical facilities. Therefore, they should be carried out only if the results can be expected to modify the patient's management.

DISEASE PREVENTION AND MANAGEMENT

The prevention of heart disease, especially of CAD, is one of the most important tasks of primary health care givers as well as cardiologists. Prevention begins with risk assessment, followed by attention to lifestyle, such as achieving optimal weight, physical activity, and smoking cessation, and then aggressive treatment of all abnormal risk factors, such as hypertension, hyperlipidemia, and diabetes mellitus **(Chap. 415)**.

After a complete diagnosis has been established in patients with known heart disease, a number of management options are usually available. Several examples may be used to demonstrate some of the principles of cardiovascular therapeutics:

1. In the absence of evidence of heart disease, the patient should be clearly informed of this assessment and *not* be asked to return at intervals for repeated examinations. If there is no evidence of disease, such continued attention may lead to the patient's developing inappropriate concern about the possibility of heart disease.
2. If there is no evidence of cardiovascular disease but the patient has one or more risk factors for the development of ischemic heart disease **(Chap. 284)**, a plan for their reduction should be developed and the patient should be retested at intervals to assess compliance and efficacy in risk reduction.
3. Asymptomatic or mildly symptomatic patients with valvular heart disease that is anatomically severe should be evaluated periodically, every 6–12 months, by clinical and noninvasive examinations. Early signs of deterioration of ventricular function may signify the need for surgical treatment before the development of disabling symptoms, irreversible myocardial damage, and excessive surgical risk **(Chap. 272)**.
4. In patients with CAD **(Chap. 284)**, available practice guidelines should be considered in the decision on the form of treatment (medical, percutaneous coronary intervention, or surgical revascularization). Mechanical revascularization may be employed too frequently in the United States and too infrequently in Eastern Europe and developing nations. The mere presence of angina pectoris and/or the demonstration of critical coronary arterial narrowing at angiography should not reflexively evoke a decision to treat the patient by revascularization. Instead, these interventions should be limited to patients with CAD in whom revascularization has been shown to improve the natural history (e.g., acute coronary syndrome or multivessel CAD with left ventricular dysfunction).

244 Basic Biology of the Cardiovascular System

Joseph Loscalzo, John F. Keaney, Jr., Calum A. MacRae

DEVELOPMENTAL BIOLOGY OF THE CARDIOVASCULAR SYSTEM

The heart forms early during embryogenesis **(Fig. 244-1)**, circulating blood, nutrients, molecular signals, and oxygen to the other developing organs while continuing to grow and undergo complex morphogenetic changes. Early cardiac progenitors arise within crescent-shaped fields of lateral splanchnic mesoderm under the influence of multiple cues and migrate to the midline to form the linear heart tube: a single layer of endocardium and a single layer of spontaneously beating cardiomyocytes.

The simple linear heart tube undergoes chamber specification and asymmetric looping, coordinated with longitudinal and concentric growth of different regions of the heart tube, to produce the presumptive atria and ventricles. Cells continue to migrate into the heart at both ends from additional heart fields in pharyngeal mesoderm as looping and growth occur. These cells exhibit distinctive gene expression (e.g., Islet-1) and distinctive physiology (e.g., calcium handling), contributing to discrete areas of the adult heart, including the right atrium and the right ventricle. These different embryonic origins of cells within the right and left ventricles correlate with distinctive single-cell RNA sequencing profiles decades later and help explain why some forms of congenital and adult cardiac diseases affect different regions of the heart.

After looping and chamber formation, a series of morphogenetic events divide the left side from the right side of the heart, separate the

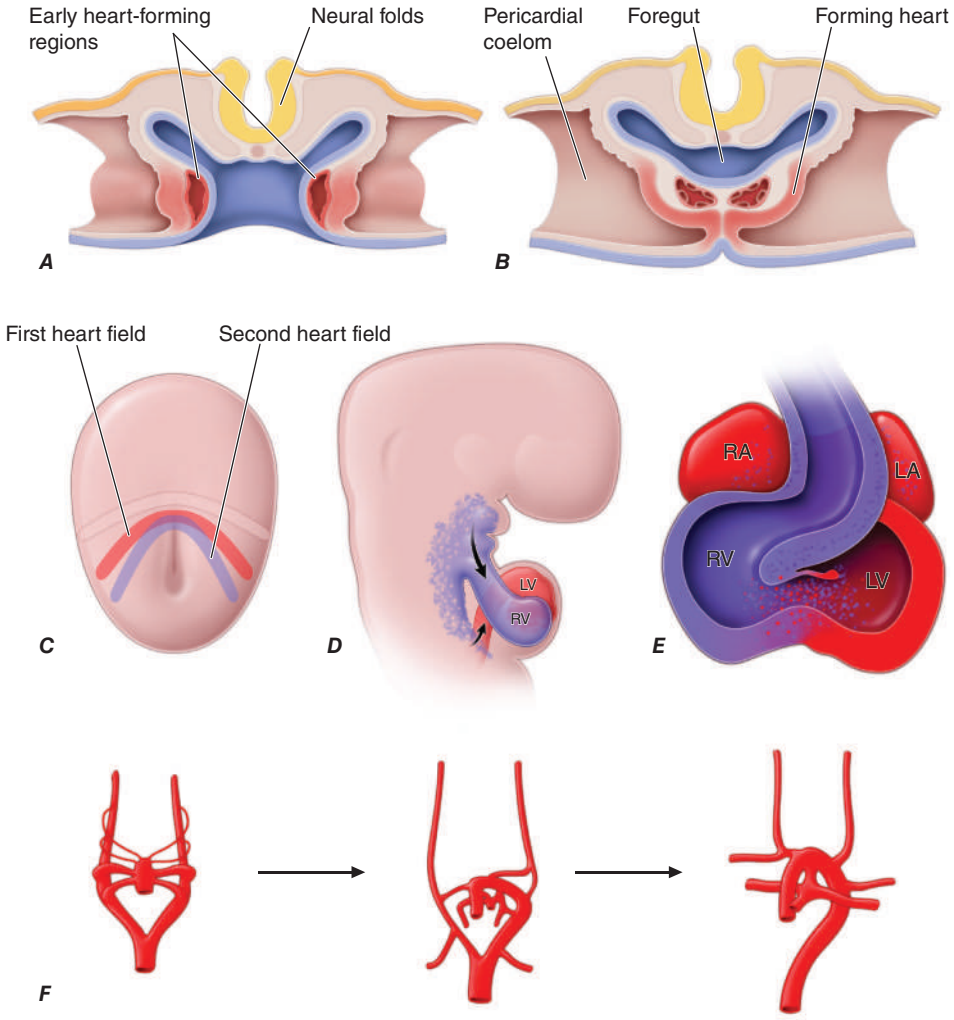

FIGURE 244-1 ***A.*** Schematic depiction of a transverse section through an early embryo depicts the bilateral regions where early heart tubes form. ***B.*** The bilateral heart tubes subsequently migrate to the midline and fuse to form the linear heart tube. ***C.*** At the early cardiac crescent stage of embryonic development, cardiac precursors include a primary heart field fated to form the linear heart tube and a second heart field fated to add myocardium to the inflow and outflow poles of the heart. ***D.*** Second heart field cells populate the pharyngeal region before subsequently migrating to the maturing heart. ***E.*** Large portions of the right ventricle and outflow tract and some cells within the atria derive from the second heart field. ***F.*** The aortic arch arteries form as symmetric sets of vessels that then remodel under the influence of the neural crest to form the asymmetric mature vasculature. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

atria from the ventricles, and fashion the aorta and pulmonary artery from the truncus arteriosus. Cardiac valves form between the atria and the ventricles and between the ventricles and the outflow vessels. Early in development, myocardial cells secrete an extracellular matrix rich in hyaluronic acid, or "cardiac jelly," which accumulates within the endocardial cushions, precursors of the valves. Signals from overlying myocardial cells trigger migration, invasion, and phenotypic changes in underlying endocardial cells, an epithelial-mesenchymal transformation, that then invade and populate the endocardial cushion matrix. Mesenchymal cells then proliferate and form the mature valve leaflets.

The great vessels form as a series of symmetric bilateral aortic arch arteries that remodel asymmetrically to define the mature central vasculature. Migrating neural crest cells from the dorsal neural tube orchestrate this process and are necessary for aortic arch remodeling and septation of the truncus arteriosus. Smooth-muscle cells within the tunica media of the aortic arch, the ductus arteriosus, and the carotid arteries all derive from neural crest. By contrast, smooth muscle within the descending aorta arises from lateral plate mesoderm, and smooth muscle of the proximal outflow tract arises from the second heart field. Neural crest cells are sensitive to both vitamin A and folic acid, and congenital heart diseases involving abnormal remodeling of the aortic arch arteries are observed with maternal deficiencies of these vitamins. Shared embryonic origins of different cardiovascular cell types lead to syndromic associations between various congenital heart diseases and a range of extracardiac abnormalities.

Coronary artery formation requires the addition of yet another cell population to the embryonic heart. Epicardial cells arise in the proepicardial organ, a derivative of the septum transversum, which also contributes to the fibrous portion of the diaphragm and to the liver. Proepicardial cells contribute smooth muscle to the coronary arteries and are required for proper coronary patterning. Other cell types within the heart (e.g., fibroblasts) also can arise from the proepicardium.

The cardiac conduction system, which generates and propagates electrical impulses, differentiates from cardiomyocyte precursors. The conduction system is composed of slow-conducting (proximal) components, such as the sinoatrial (SA) and atrioventricular (AV) nodes, as well as fast-conducting (distal) components, including the His bundle, bundle branches, and Purkinje fibers. Precursors within the sinus venosus give rise to the SA node, whereas those within the AV canal mature into heterogeneous cell types that compose the AV node. Decremental conduction through the AV node delays electrical impulses between atria and ventricles, enabling sequential antegrade contraction. The AV node also reduces the transmission of higher impulse rates to the vulnerable ventricle, whereas the distal conduction system rapidly propagates each impulse throughout the ventricles. The conduction system is composed of complex and heterogeneous cell populations with distinct gap junction proteins and ion channels that define the particular local electrical properties. Developmental defects in the conduction system can lead to clinical electrophysiologic disorders, such as congenital heart block or pre-excitation (Wolff-Parkinson-White syndrome) **(Chap. 256)**.

■ ORIGIN OF VASCULAR CELLS

Smooth-muscle cells are of varied origin. Some upper-body arterial smooth-muscle cells derive from the neural crest, whereas lower-body arteries develop smooth-muscle cells from neighboring mesodermal structures. Embryonic endothelial progenitor cells are derived from mesoderm. In adults, resident vascular or bone marrow–derived endothelial progenitors may aid repair of damaged or aging arteries. Bone marrow clonality, increasingly prevalent in aging, may impart significant clonality to endothelial cell populations. Vascular stem cells resident in the vessel wall may give rise to some smooth-muscle cells in injured or atheromatous arteries.

THE BLOOD VESSEL

■ VASCULAR ULTRASTRUCTURE

Blood vessels participate in disease biology as well as physiologic function in virtually every organ system. The smallest blood vessels—capillaries—consist of a monolayer of endothelial cells on a basement membrane adjacent to a discontinuous layer of smooth-muscle-like cells known as *pericytes* **(Fig. 244-2*A*)**. Arteries typically have

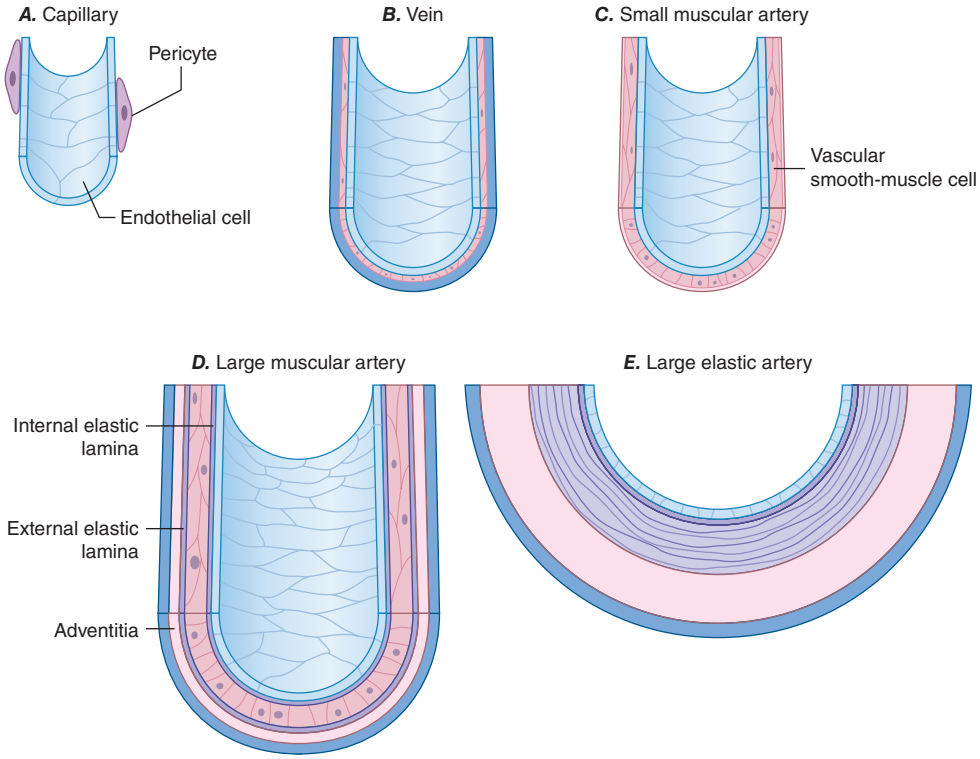

FIGURE 244-2 Schematics of the structures of various types of blood vessels. ***A.*** Capillaries consist of an endothelial tube in contact with a discontinuous population of pericytes. ***B.*** Veins typically have thin medias and thicker adventitias. ***C.*** A small muscular artery features a prominent tunica media. ***D.*** Larger muscular arteries have a prominent media with smooth-muscle cells embedded in a complex extracellular matrix. ***E.*** Larger elastic arteries have cylindrical layers of elastic tissue alternating with concentric rings of smooth-muscle cells as well as *vasa vasorum* to facilitate tissue blood supply.

a trilaminar structure (Fig. 244-2*B–E*). The *intima* consists of a monolayer of endothelial cells continuous with those of the capillaries. The middle layer, or *tunica media*, consists of a syncytium of smooth-muscle cells that in veins are much sparser than in arteries (Fig. 244-2*B*). The outer layer, or *adventitia*, consists of extracellular matrix with fibroblasts, mast cells, and nerve terminals. Larger arteries require nourishment of the tunica media that is accomplished via their own vasculature, the *vasa vasorum* (Fig. 244-2*E*).

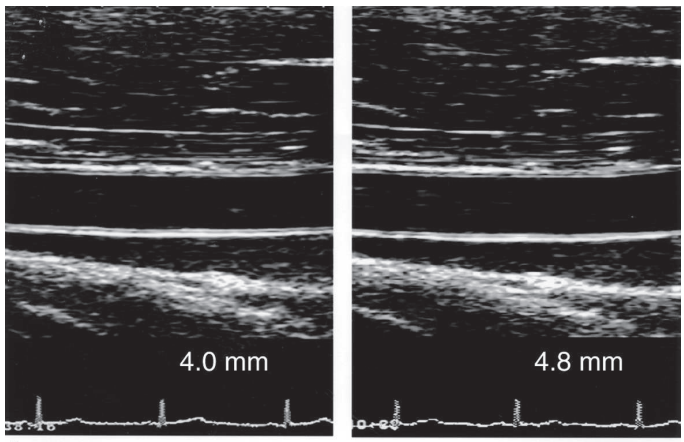
Arterioles are small muscular arteries (Fig. 244-2*C*) that regulate blood pressure and flow through arterial beds. Medium-size muscular arteries also contain prominent smooth-muscle layers (Fig. 244-2*D*) that participate in atherogenesis. Larger elastic arteries have a highly structured tunica media with concentric bands of smooth-muscle cells, interspersed with strata of elastin-rich extracellular matrix (Fig. 244-2*E*). Larger arteries form an internal elastic lamina between intima and media while an external elastic lamina partitions the media from surrounding adventitia.

VASCULAR CELL BIOLOGY

Endothelial Cell The endothelium forms the interface between tissues and the blood compartment, regulating the passage of molecules and cells. This function of endothelial cells as a selectively permeable barrier fails in vascular diseases, including atherosclerosis, hypertension, and renal disease, as well as in pulmonary edema, sepsis, and other situations exhibiting "capillary leak."

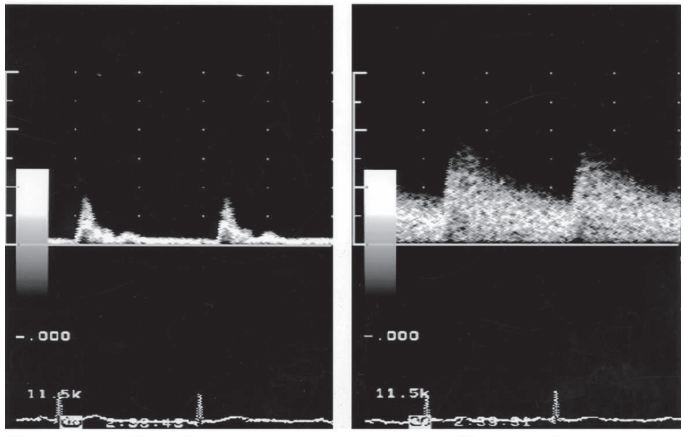
The endothelium also participates in the local regulation of vascular tone and blood flow. Endogenous endothelium-derived substances, such as prostacyclin, endothelium-derived hyperpolarizing factor, nitric oxide (NO), and hydrogen peroxide (H_2O_2), provide tonic stimulation of endothelial homeostatic properties under physiologic conditions in vivo (Table 244-1). Impaired production or excess catabolism of these substances can mediate dysfunctional properties of the endothelium. A major homeostatic influence on the endothelium is laminar blood flow, and the measurement of flow-mediated dilatation directly assesses endothelial vasodilator function in humans (Fig. 244-3).

Endothelial cells also produce potent vasoconstrictor substances such as endothelin. Excessive production of reactive oxygen species, such as superoxide anion (O_2^-), by endothelial or smooth-muscle cells under pathologic conditions (e.g., excessive exposure to angiotensin II) can promote local oxidative stress and inactivate NO.



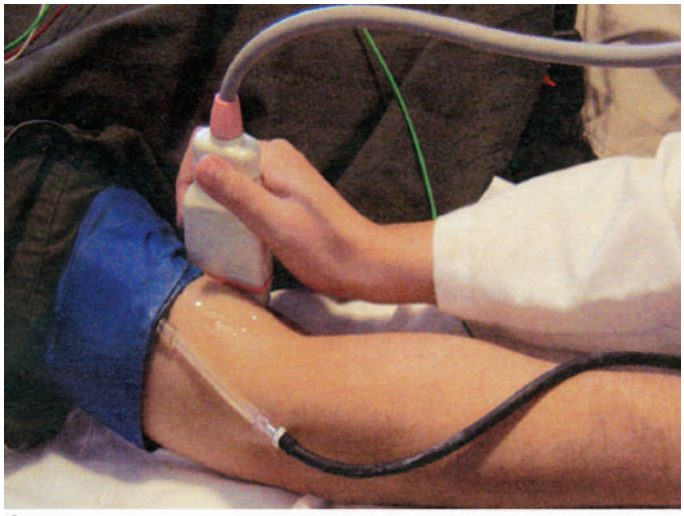
Endothelial cells also regulate cellular traffic through tissues. Normal endothelium exhibits limited interaction with circulating leukocytes, but bacterial products such as endotoxin or proinflammatory cytokines can induce endothelial cells to express an array of adhesion molecules that selectively bind various classes of leukocytes in different pathologic conditions. The adhesion molecules and chemokines generated during acute bacterial infection tend to recruit granulocytes, while in chronic inflammatory diseases such as tuberculosis or atherosclerosis, the adhesion molecules expressed favor monocyte recruitment. Endothelial cell injury participates in the pathophysiology of many immune-mediated diseases. For example, complement-mediated lysis of endothelial cells contributes to tissue injury. The foreign histocompatibility complex antigens on endothelial cells in solid-organ allografts can promote allograft arteriopathy, while immune-mediated endothelial injury also plays a role in thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome.

The endothelium also regulates the balance between thrombosis and hemostasis through a highly tuned set of regulatory pathways. For example, inflammatory cytokines, bacterial endotoxin, or angiotensin II can activate endothelial cells to produce substantial quantities of plasminogen activator inhibitor 1 (PAI-1), the major inhibitor of fibrinolysis. Inflammatory stimuli also induce endothelial expression of the potent procoagulant tissue factor, a contributor to disseminated intravascular coagulation in sepsis; similar effects are observed in hyperglycemia. Thus, in pathologic circumstances, endothelial dysfunction tends to promote local thrombus accumulation rather than combat it.



Endothelial cells regulate the growth of subjacent smooth-muscle cells by elaborating heparan sulfate glycosaminoglycans that inhibit smooth-muscle proliferation. In the setting of vascular injury, endothelium-derived growth factors and chemoattractants (e.g., platelet-derived growth factor) induce the migration and proliferation of vascular smooth-muscle cells. Dysregulation of these growth-stimulatory molecules may promote smooth-muscle accumulation in atherosclerotic lesions.

TABLE 244-1 Endothelial Functions in Health and Disease



HOMEOSTATIC PROPERTIES	DYSFUNCTIONAL PROPERTIES
Optimize balance between vasodilation and vasoconstriction	Impaired dilation, vasoconstriction
Antithrombotic, profibrinolytic	Prothrombotic, antifibrinolytic
Anti-inflammatory	Proinflammatory
Antiproliferative	Proproliferative
Antioxidant	Prooxidant
Selective permeability	Impaired barrier function

Vascular Smooth-Muscle Cell Contraction and relaxation of vascular smooth-muscle cells in muscular arteries determine blood pressure, regional flow, and the afterload experienced by the left ventricle (see below). Venous tone regulates venous tree capacitance and influences ventricular preload. Smooth-muscle cells in the adult vessel seldom replicate in the absence of arterial injury or inflammatory activation, but proliferation and migration of arterial smooth-muscle cells contribute to arterial stenoses in atherosclerosis, arteriolar remodeling in hypertension, and the hyperplastic response of arteries to injury. In the pulmonary circulation, smooth-muscle migration and proliferation underlie the vascular pathology that occurs in sustained high-flow states such as left-to-right shunts in congenital heart disease with resulting pulmonary hypertension.

Smooth-muscle cells secrete the bulk of vascular extracellular matrix. Excessive production of collagen and glycosaminoglycans contributes to the remodeling, altered biomechanics, and physiology of arteries affected by hypertension or atherosclerosis. In larger elastic arteries, such as the aorta, the ability to store the kinetic energy of systole promotes tissue perfusion during diastole. Arterial stiffness, associated with aging or disease, increases left ventricular afterload and portends a poor outcome.

Like endothelial cells, vascular smooth-muscle cells not only respond to paracrine stimuli from other cells but can themselves serve as a source of such stimuli. For example, proinflammatory stimuli induce smooth-muscle cells to elaborate cytokines and other mediators that drive thrombosis and fibrinolysis as well as proliferation.

Vascular Smooth-Muscle Cell Contraction The principal mechanism for vascular smooth-muscle cell contraction is increased cytoplasmic calcium concentration due to transmembrane influx and triggered release from intracellular calcium stores **(Fig. 244-4)**. In vascular smooth-muscle cells, voltage-dependent L-type calcium channels open with membrane depolarization. Local influx of calcium, termed *calcium sparks*, can trigger release from intracellular stores, which results in more contraction and increased vessel tone (see below). Opposing currents balance the effects of individual ionic fluxes promoting homeostasis, which is tightly regulated by neural and metabolic influences.

Vasoconstricting agonists also increase intracellular [Ca^{2+}] by various mechanisms including receptor-dependent phospholipase C activation producing hydrolysis of phosphatidylinositol 4,5-bisphosphate to generate diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). These membrane lipid derivatives, in turn, activate protein kinase C and increase intracellular [Ca^{2+}]. In addition, IP_3 binds specific sarcoplasmic reticulum (SR) receptors to increase calcium efflux from this storage pool into the cytoplasm.

Vascular smooth-muscle cell contraction depends on myosin light chain phosphorylation that reflects the balance between the activity of relevant kinases and phosphatases. Calcium activates myosin light chain kinase via calmodulin, augmenting myosin ATPase activity and enhancing contraction. Conversely, myosin light chain phosphatase reduces myosin ATPase activity and contractile force. Other kinase/phosphorylase combinations result in a complex regulatory network that refines vascular tone and links it to physiologic requirements.

Control of Vascular Smooth-Muscle Cell Tone The autonomic nervous system and endothelial cells modulate vascular smooth-muscle cells through similar convergent pathways. Autonomic neurons enter vessel media and modulate vascular smooth-muscle cell tone in response to baroreceptors and chemoreceptors within the aortic arch or carotid bodies and to thermoreceptors in the skin. Rapidly acting reflex arcs modulated by central inputs respond to multiple sensory inputs as well as emotional stimuli through three neuronal classes: *sympathetic*, whose principal neurotransmitters are epinephrine and norepinephrine; *parasympathetic*, whose principal neurotransmitter is acetylcholine; and *nonadrenergic/noncholinergic*, which include two subgroups—nitrergic, whose principal neurotransmitter is NO, and peptidergic, whose principal neurotransmitters are substance P, vasoactive intestinal peptide, calcitonin gene-related peptide, and the nonpeptide, adenosine triphosphate (ATP).

Each of these neurotransmitters acts through specific receptors on the vascular smooth-muscle cell to modulate intracellular Ca^{2+} and, consequently, contractile tone. Norepinephrine activates α-adrenergic receptors, and epinephrine activates both α and β receptors. In most blood vessels, norepinephrine activates postjunctional α_1 receptors in large arteries and α_2 receptors in small arteries and arterioles, leading to vasoconstriction. Most blood vessels express β_2-adrenergic receptors on their vascular smooth-muscle cells and respond to β agonists by cyclic AMP–dependent relaxation. Acetylcholine released from parasympathetic neurons may bind to muscarinic receptors on either vascular smooth-muscle cells, causing vasoconstriction, or on

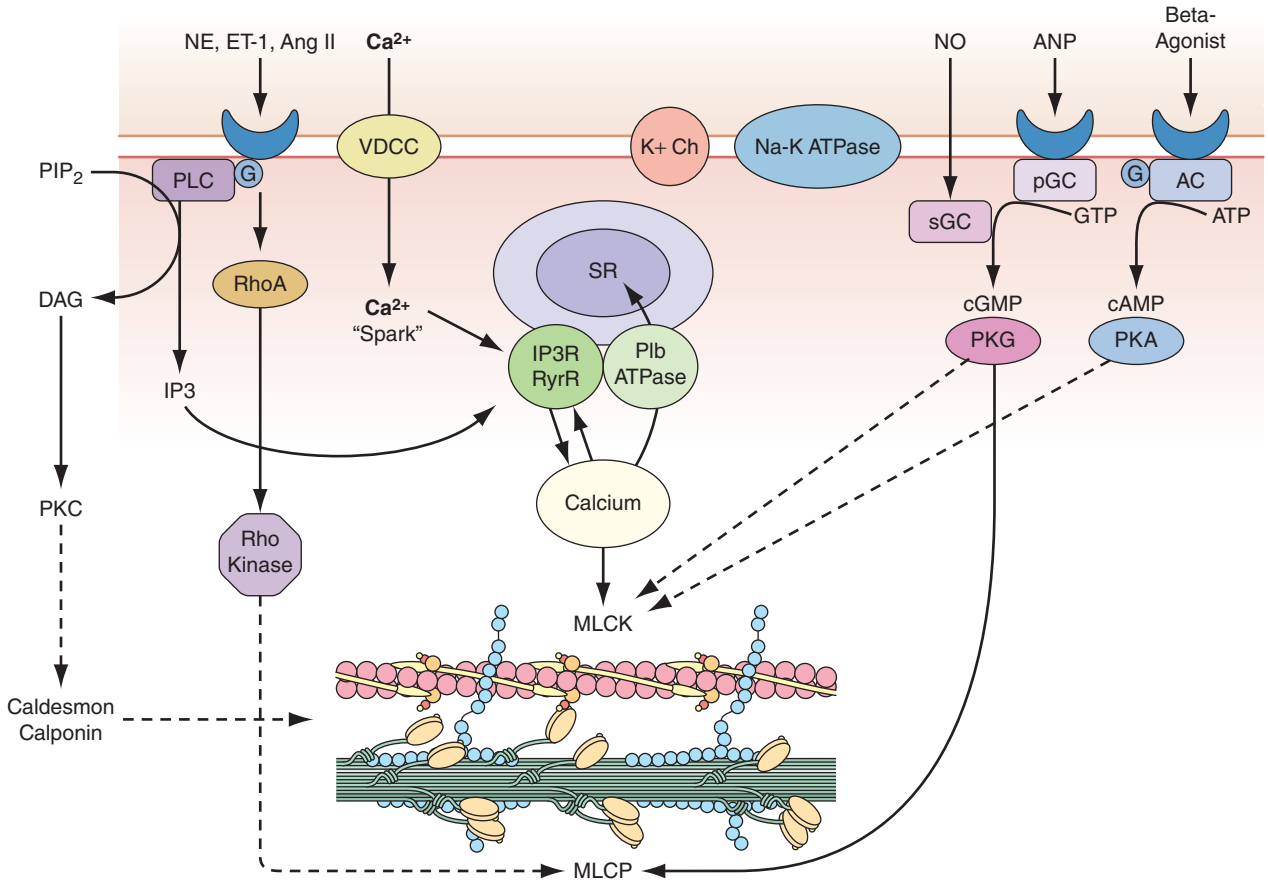

FIGURE 244-4 Regulation of vascular smooth-muscle cell calcium concentration and actomyosin ATPase-dependent contraction. Philadelphia, Saunders, Elsevier; 2006.)*

endothelial cells, causing NO-dependent vasorelaxation. Nitrergic neurons release NO, which relaxes vascular smooth-muscle cell via the cyclic GMP–dependent and –independent mechanisms outlined, and other peptidergic inputs that regulate vascular tone. **For the detailed molecular physiology of the autonomic nervous system, see Chap. 451.**

The release of endothelial effectors of vascular smooth-muscle cell tone integrates the smooth-muscle response to mechanical (e.g., shear stress, cyclic strain) and biochemical stimuli (purinergic agonists, muscarinic agonists, peptidergic agonists). In addition to these local paracrine modulators, a complex system of circulating modulators ranging from norepinephrine to the natriuretic peptides also modify vascular smooth-muscle cell tone.

ARTERIOGENESIS AND ANGIOGENESIS

Recruitment and growth of blood vessels (arteriogenesis) and new capillaries (angiogenesis) can occur in response to conditions such as chronic hypoxemia and tissue ischemia. Growth factors, including vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF), can activate a signaling cascade that stimulates endothelial proliferation and tube formation, defined as *angiogenesis*. Guidance molecules, including members of the semaphorin family of secreted peptides, direct blood vessel patterning by attracting or repelling nascent endothelial tubes. The recruitment and expansion of preexisting collateral vascular networks in response to a blocked artery, an example of arteriogenesis, can result from selective activation of both growth factors and, perhaps, local or circulating endothelial progenitor cells. True vascular regeneration, or the development of a new blood vessel that includes all three cell layers, normally does not occur in adult mammals, but recent scientific advances might help obviate such limitations.

CELLULAR BASIS OF CARDIAC CONTRACTION

CARDIAC ULTRASTRUCTURE

Most of the ventricular mass is composed of cardiomyocytes, normally 60–140 μm in length and 17–25 μm in diameter **(Fig. 244-5*A*)**. Each cell contains multiple myofibrils that run the length of the cell and are composed of series of repeating sarcomeres. The cytoplasm between the myofibrils contains other cell constituents, including a single centrally located nucleus, mitochondria, and the intracellular membrane system, the SR.

The *sarcomere*, the structural and functional unit of contraction, lies between adjacent Z lines, which on transmission electron microscopy are seen as dark repeating bands. The distance between Z lines varies with the degree of contraction or stretch of the muscle and ranges between 1.6 and 2.2 μm. At the center of the sarcomere is a dark band of constant length (1.5 μm), the A band, which is flanked by two lighter bands, the I bands, which are of variable length. The sarcomere of heart muscle, like that of skeletal muscle, consists of interdigitating thick and thin myofilaments. Thicker filaments, composed principally of the protein myosin, traverse the A band; they are about 10 nm (100 Å) in diameter, with tapered ends. Thinner filaments, composed primarily of actin, course from the Z lines through the I band into the A band; they are ~5 nm (50 Å) in diameter and 1.0 μm in length. Thus, thick and thin filaments overlap only within the (dark) A band, whereas the (light) I band contains only thin filaments. On electron-microscopic examination, bridges extend between the thick and thin filaments within the A band; these are myosin heads (see below) bound to actin filaments.

THE CONTRACTILE PROCESS

The sliding filament model for muscle contraction rests on the central observation that both the thick and the thin filaments are constant in

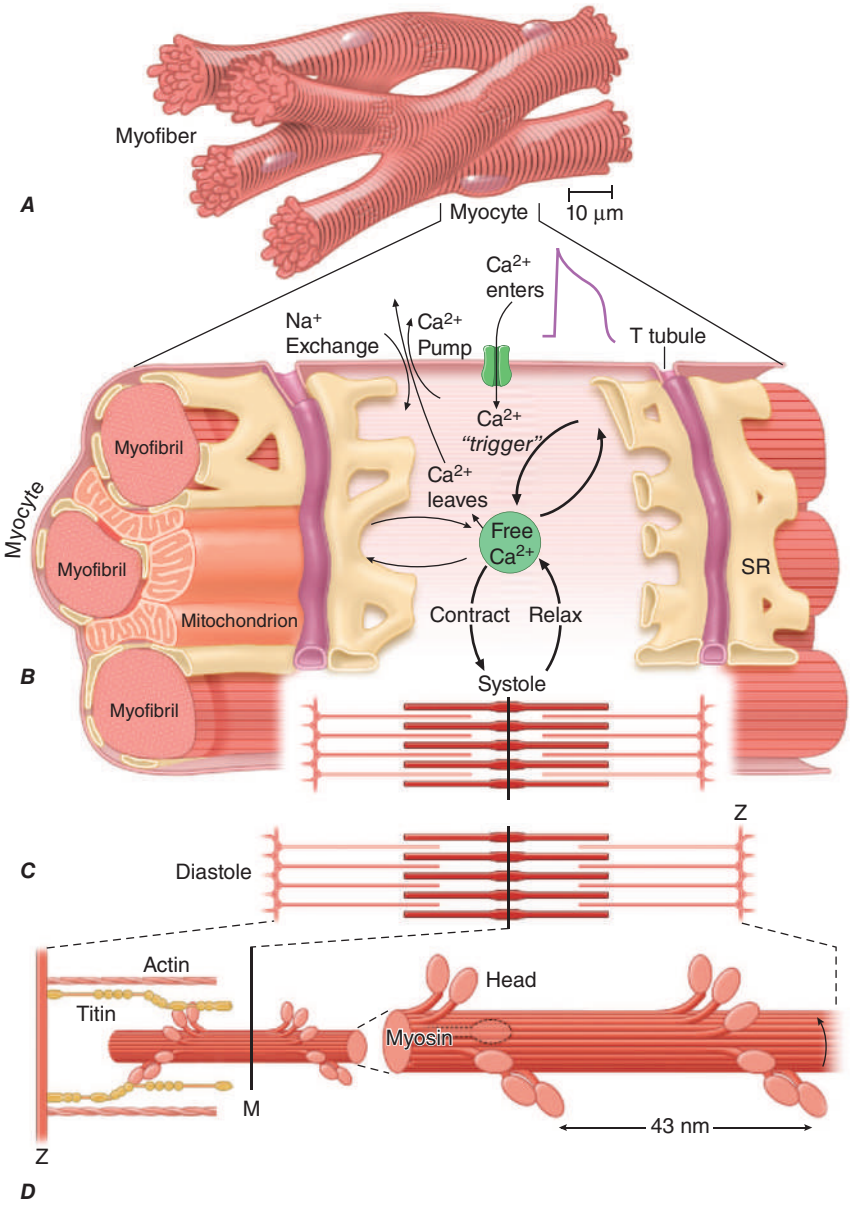

FIGURE 244-5 ***A*** shows the branching myocytes making up the cardiac myofibers. ***B*** illustrates the critical role played by the changing [Ca^{2+}] in the myocardial cytosol. Ca^{2+} ions are schematically shown as entering through the calcium channel that opens in response to the wave of depolarization that travels along the sarcolemma. These Ca^{2+} ions "trigger" the release of more calcium from the sarcoplasmic reticulum (SR) and thereby initiate a contraction-relaxation cycle. Eventually the small quantity of Ca^{2+} that has entered the cell leaves predominantly through an Na^+/Ca^{2+} exchanger, with a lesser role for the sarcolemmal Ca^{2+} pump. The varying actin-myosin overlap is shown for (***B***) systole, when [Ca^{2+}] is maximal, and (***C***) diastole, when [Ca^{2+}] is minimal. ***D.*** The myosin heads, attached to the thick filaments, interact with the thin actin filaments. *(Reproduced with permission from LH Opie: Heart Physiology: From Cell to Circulation, 4th ed. Philadelphia, Lippincott, Williams & Wilkins, 2004.)*

length during both contraction and relaxation. With activation, the actin filaments are propelled farther into the A band. In this process, the A band remains constant in length, whereas the I band shortens and the Z lines move toward one another.

The *myosin* molecule is a complex, asymmetric protein with a molecular mass of about 500,000 Da; it has a rod-like portion that is about 150 nm (1500 Å) in length with a globular portion (head) at its end. The globular portions of myosin form the bridges to actin and are the site of ATPase activity. In thick myofilaments, composed of ~300 longitudinally stacked myosin molecules, the rod-like segments of myosin assume an orderly, polarized orientation, with outwardly projecting globular heads interacting with actin to generate force and shorten **(Fig. 244-5*B*)**.

Actin has a molecular mass of about 47,000 Da. Thin filaments consist of a double helix of two chains of actin molecules wound about each other on a larger molecule, tropomyosin. A group of regulatory proteins—troponins C, I, and T—localize at regular intervals on this filament **(Fig. 244-6)**. In contrast to myosin, actin lacks intrinsic enzymatic activity but combines reversibly with myosin in the presence of ATP and Ca^{2+}. Calcium activates the myosin ATPase, which breaks down ATP to supply the energy for contraction (Fig. 244-6). The activity of myosin ATPase determines the rate of actomyosin cross-bridge formation and breakdown, and ultimately determines contraction velocity. In relaxed muscle, tropomyosin inhibits this interaction. *Titin* (Fig. 244-5*D*) an enormous, flexible, myofibrillar protein, connects myosin to the Z line; its elasticity contributes to the passive mechanical characteristics of the heart. Dystrophin, a cytoskeletal protein that binds to the dystroglycan complex at membrane adherens junctions, tethers the sarcomere to the cell membrane at these regions of tight coupling to adjacent myocytes. Mutations in multiple sarcomeric and cytoskeletal proteins cause different Mendelian disorders involving the heart and skeletal muscle and also sensitize individuals to toxic cardiomyopathies (e.g., due to alcohol or chemotherapy) and to those caused by other acquired stressors, such as inflammatory or peripartum cardiomyopathy.

During activation of the cardiac myocyte, Ca^{2+} binds the heterotrimer troponin C, resulting in regulatory conformational changes in tropomyosin and exposing actin cross-bridge interaction sites

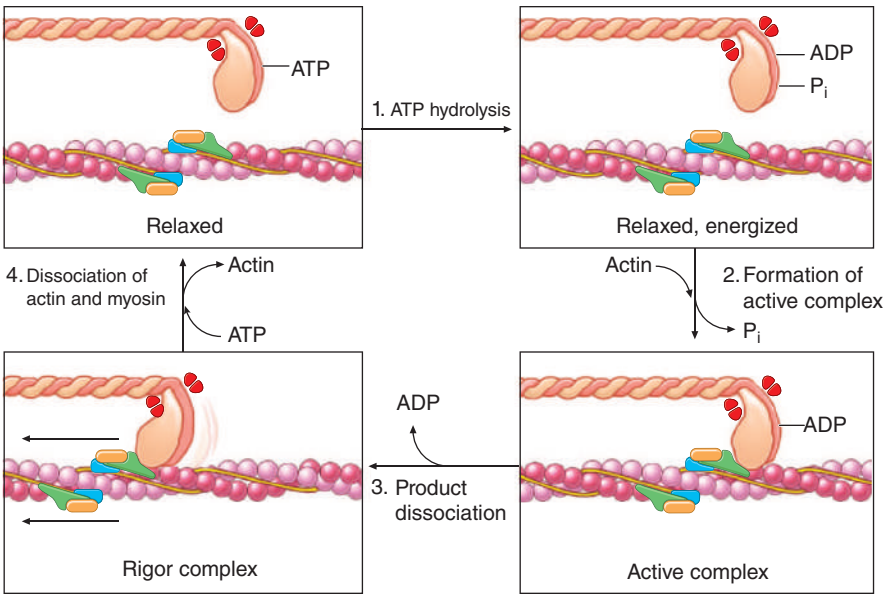

FIGURE 244-6 Four steps in cardiac muscle contraction and relaxation. In relaxed muscle (*upper left*), ATP bound to the myosin cross-bridge dissociates the thick and thin filaments. ***Step 1:*** Hydrolysis of myosin-bound ATP by the ATPase site on the myosin head transfers the chemical energy of the nucleotide to the activated cross-bridge (*upper right*). When cytosolic Ca^{2+} concentration is low, as in relaxed muscle, the reaction cannot proceed because tropomyosin and the troponin complex on the thin filament do not allow the active sites on actin to interact with the cross-bridges. Therefore, even though the cross-bridges are energized, they cannot interact with actin. ***Step 2:*** When Ca^{2+} binding to troponin C has exposed active sites on the thin filament, actin interacts with the myosin cross-bridges to form an active complex (*lower right*) in which the energy derived from ATP is retained in the actin-bound cross-bridge, whose orientation has not yet shifted. ***Step 3:*** The muscle contracts when ADP dissociates from the cross-bridge. This step leads to the formation of the low-energy rigor complex (*lower left*) in which the chemical energy derived from ATP hydrolysis has been expended to perform mechanical work (the "rowing" motion of the cross-bridge). ***Step 4:*** The muscle returns to its resting state, and the cycle ends when a new molecule of ATP binds to the rigor complex and dissociates the cross-bridge from the thin filament. This cycle continues until calcium is dissociated from troponin C in the thin filament, which causes the contractile proteins to return to the resting state with the cross-bridge in the energized state. ADP, adenosine diphosphate; ATP, adenosine triphosphate; ATPase, adenosine triphosphatase. *(Reproduced with permission from AM Katz: Heart failure: Cardiac function and dysfunction, in Atlas of Heart Diseases, 3rd ed, WS Colucci [ed]. Philadelphia, Current Medicine, 2002.)*

(Fig. 244-6). Repetitive interaction between myosin heads and actin filaments is termed *cross-bridge cycling* and results in sliding of the actin along the myosin filaments, with muscle shortening and/or the development of tension. The splitting of ATP then dissociates the myosin cross-bridge from actin. In the presence of ATP (Fig. 244-6), actin and myosin filaments bind and dissociate cyclically if sufficient Ca^{2+} is present; these processes cease when $[Ca^{2+}]$ falls below a critical level, and the troponin-tropomyosin complex once more inhibits actin-myosin interactions **(Fig. 244-7)**.

Cytoplasmic $[Ca^{2+}]$ is a principal determinant of the inotropic state of the heart. Most agents that stimulate myocardial contractility (positive inotropic stimuli), including digitalis glycosides and β-adrenergic agonists, increase cytoplasmic $[Ca^{2+}]$, triggering cross-bridge cycling. Increased adrenergic neuronal activity stimulates myocardial contractility through norepinephrine release, activation of β-adrenergic receptors, and, via G_s-stimulated guanine nucleotide-binding proteins, activation of the adenylyl cyclase, which leads to the formation of the intracellular second messenger cyclic AMP from ATP (Fig. 244-7). Cyclic AMP in turn activates protein kinase A (PKA), which phosphorylates sarcolemmal Ca^{2+} channels, thereby enhancing the influx of Ca^{2+} into the myocyte.

The SR **(Fig. 244-8)**, a complex network of anastomosing intracellular channels, invests the myofibrils. The transverse tubules, or T system, closely related to the SR, both structurally and functionally, arise as sarcolemmal invaginations that extend into the myofibrillar bundles along the Z lines, i.e., the ends of the sarcomeres.

CARDIAC ACTIVATION

In the inactive state, the cardiomyocyte membrane is electrically polarized; i.e., the interior has a negative charge relative to the outside of the cell, with a transmembrane potential of −80 to −100 mV **(Chap. 250)**. The sarcolemma, which in the resting state is largely impermeable to Na^+, and a Na^+- and K^+-pump energized by ATP extrudes Na^+ from the cell and maintains the resting potential. In this resting state, intracellular $[K^+]$ is relatively high and $[Na^+]$ is far lower; conversely, extracellular $[Na^+]$ is high and $[K^+]$ is low. At the same time, extracellular $[Ca^{2+}]$ greatly exceeds free intracellular $[Ca^{2+}]$.

The action potential has four phases **(see Fig. 250-1*B*)**. Depolarizing current spreads across the cell membrane, penetrating deeply into the cell via the T tubular system. During the action potential plateau (phase 2), there is a slow inward current through sarcolemmal L-type Ca^{2+} channels (Fig. 244-8). The absolute quantity of Ca^{2+} traversing sarcolemmal and T tubular membranes is modest and insufficient to fully activate contraction. However, this initial Ca^{2+} current, through *Ca^{2+}-induced Ca^{2+} release*, triggers substantial Ca^{2+} release from the SR, inducing contraction.

Ca^{2+} is released from the SR through a Ca^{2+} release channel, a cardiac isoform of the ryanodine receptor (RyR2). Several regulatory proteins inhibit RyR2 and thus SR Ca^{2+} release. Inherited disorders or exogenous factors affecting the efficiency or stability of SR Ca^{2+} handling can impair contraction, leading to heart failure or to ventricular arrhythmias.

The Ca^{2+} released from the SR diffuses to interact with myofibrillar troponin C (Fig. 244-7), repressing this protein's inhibition of contraction, and so activating myofilaments to shorten. During repolarization, the activity of the SR Ca^{2+}-ATPase ($SERCA_{2A}$) leads to Ca^{2+} uptake against a concentration gradient into the SR where it complexes with another specialized protein, *calsequestrin*. The uptake of Ca^{2+} is ATP (energy)-dependent and lowers cytoplasmic $[Ca^{2+}]$ to a level where actomyosin interaction is inhibited and myocardial relaxation occurs. There is also a sarcolemmal exchange of Ca^{2+} for Na^+ (Fig. 244-8), reducing cytoplasmic $[Ca^{2+}]$. Additional control of calcium compartmentalization results from cyclic AMP–dependent PKA phosphorylation of the SR protein *phospholamban*, permitting $SERCA_{2A\ activation}$, increasing SR Ca^{2+} uptake, and so accelerating relaxation rates, and loading the SR with Ca^{2+} for subsequent cycles of release and contraction.

Thus, the combination of the cell membrane, transverse tubules, and SR, transmitting the action potential, releasing and then re-accumulating Ca^{2+}, controls the cyclic contraction and relaxation of heart muscle.

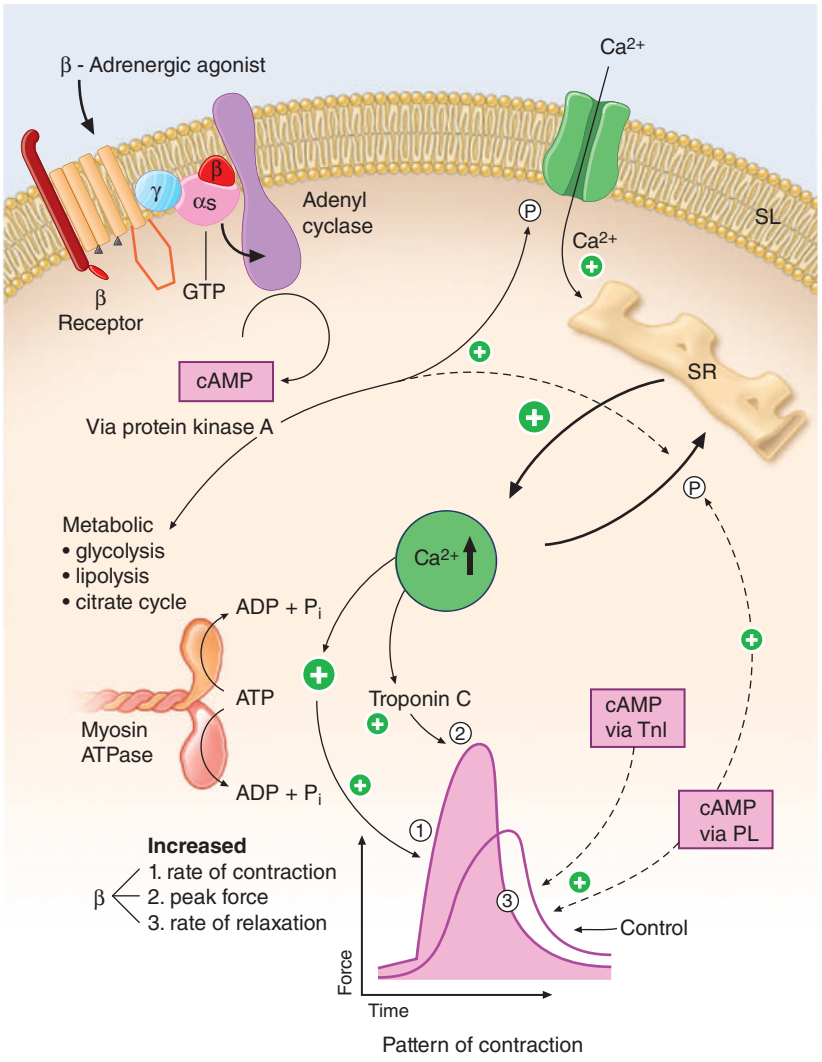

FIGURE 244-7 Signal systems involved in positive inotropic and lusitropic (enhanced relaxation) effects of α-adrenergic stimulation. When the β-adrenergic agonist interacts with the β receptor, a series of G protein–mediated changes leads to activation of adenylyl cyclase and the formation of cyclic adenosine monophosphate (cAMP). The latter acts via protein kinase A to stimulate metabolism (*left*) and phosphorylate the Ca^{2+} channel protein (*right*). The result is an enhanced opening probability of the Ca^{2+} channel, thereby increasing the inward movement of Ca^{2+} ions through the sarcolemma (SL) of the T tubule. These Ca^{2+} ions release more calcium from the sarcoplasmic reticulum (SR) to increase cytosolic Ca^{2+} and activate troponin C. Ca^{2+} ions also increase the rate of breakdown of adenosine triphosphate (ATP) to adenosine diphosphate (ADP) and inorganic phosphate (Pi). Enhanced myosin ATPase activity explains the increased rate of contraction, with increased activation of troponin C explaining increased peak force development. An increased rate of relaxation results from the ability of cAMP to activate as well the protein phospholamban, situated on the membrane of the SR, that controls the rate of uptake of calcium into the SR. The latter effect explains enhanced relaxation (lusitropic effect). P, phosphorylation; PL, phospholamban; TnI, troponin I. *(Reproduced with permission from LH Opie: Heart Physiology: From Cell to Circulation, 4th ed. Philadelphia, Lippincott, Williams & Wilkins, 2004.)*

Genetic or pharmacologic alterations of any component can disturb any of the functions of this finely tuned system.

CONTROL OF CARDIAC PERFORMANCE AND OUTPUT

The extent of shortening of heart muscle and, therefore, ventricular stroke volume in the intact heart depends on three major influences: (1) the length of the muscle at the onset of contraction, i.e., the preload; (2) the tension that the muscle must develop during contraction, i.e., the afterload; and (3) muscle contractility, i.e., the extent and velocity of shortening at any given preload and afterload. Table 244-2 lists the major determinants of preload, afterload, and contractility.

THE ROLE OF MUSCLE LENGTH (PRELOAD)

Preload determines sarcomere length at the onset of contraction. Contractile force is optimal at specific sarcomere lengths (~2.2 μm) where both myofilament Ca^{2+} sensitivity is maximal, and myofilament interactions and activation of contraction are most efficient. The relationship between initial muscle fiber length and the developed force is the basis of Starling's law of the heart, which states that, within limits, the ventricular contraction force depends on the end-diastolic length of the cardiac muscle; in vivo, end-diastolic length relates closely to the ventricular end-diastolic volume.

CARDIAC PERFORMANCE

Ventricular end-diastolic or "filling" pressure can serve as a surrogate for end-diastolic volume. In isolated heart and heart-lung preparations, stroke volume varies directly with the end-diastolic fiber length (preload) and inversely with the arterial resistance (afterload), and as the heart fails—i.e., as its contractility declines—it delivers a progressively smaller stroke volume from a normal or even elevated end-diastolic volume. The relation between ventricular end-diastolic pressure and the stroke work of the ventricle (the ventricular function curve) provides a working definition of cardiac contractility in the intact organism. An increase in contractility is accompanied by a shift of the ventricular function curve upward and to the left (greater stroke work at any level of ventricular end-diastolic pressure, or lower end-diastolic volume at any level of stroke work), whereas a shift downward and to the right characterizes reduction of contractility (Fig. 244-9).

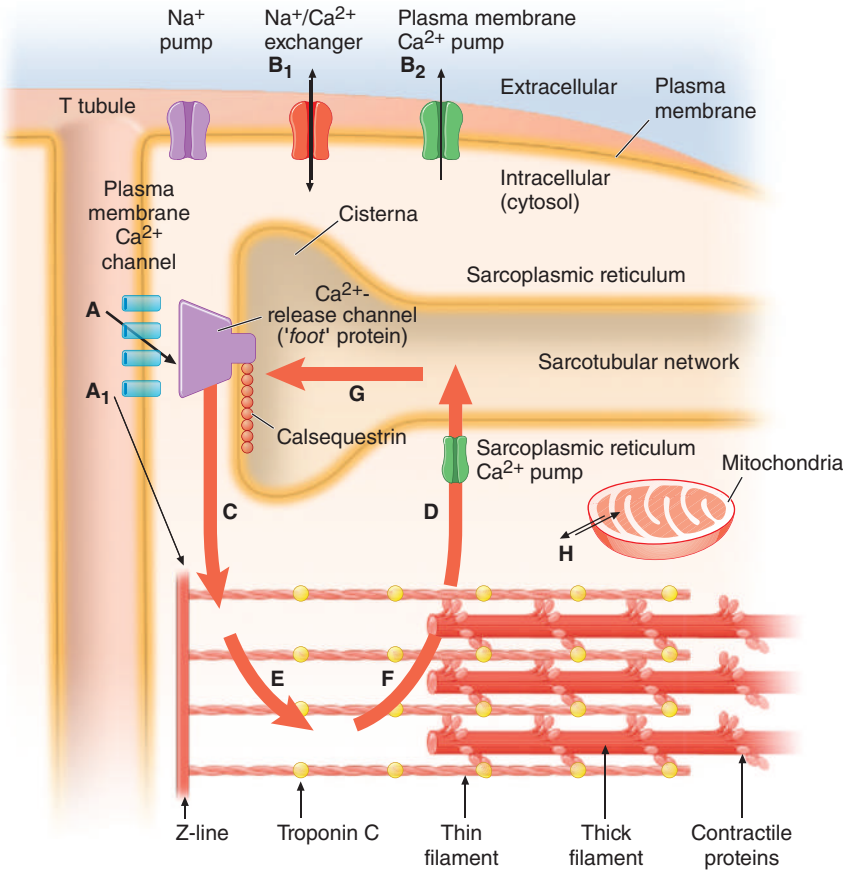

FIGURE 244-8 The Ca^{2+} fluxes and key structures involved in cardiac excitation-contraction coupling. The *arrows* denote the direction of Ca^{2+} fluxes. The *thickness* of each arrow indicates the magnitude of the calcium flux. Two Ca^{2+} cycles regulate excitation-contraction coupling and relaxation. The larger cycle is entirely intracellular and involves Ca^{2+} fluxes into and out of the sarcoplasmic reticulum, as well as Ca^{2+} binding to and release from troponin C. The smaller extracellular Ca^{2+} cycle occurs when this cation moves into and out of the cell. The action potential opens plasma membrane Ca^{2+} channels to allow passive entry of Ca^{2+} into the cell from the extracellular fluid (*arrow A*). Only a small portion of the Ca^{2+} that enters the cell directly activates the contractile proteins (*arrow* A_1). The extracellular cycle is completed when Ca^{2+} is actively transported back out to the extracellular fluid by way of two plasma membrane fluxes mediated by the sodium-calcium exchanger (*arrow* B_1) and the plasma membrane calcium pump (*arrow* B_2). In the intracellular Ca^{2+} cycle, passive Ca^{2+} release occurs through channels in the cisternae (*arrow C*) and initiates contraction; active Ca^{2+} uptake by the Ca^{2+} pump of the sarcotubular network (*arrow D*) relaxes the heart. Diffusion of Ca^{2+} within the sarcoplasmic reticulum (*arrow G*) returns this activator cation to the cisternae, where it is stored in a complex with calsequestrin and other calcium-binding proteins. Ca^{2+} released from the sarcoplasmic reticulum initiates systole when it binds to troponin *C* (*arrow E*). Lowering of cytosolic [Ca^{2+}] by the sarcoplasmic reticulum (SR) causes this ion to dissociate from troponin (*arrow F*) and relaxes the heart. Ca^{2+} also may move between mitochondria and cytoplasm (H). *(Reproduced with permission from AM Katz: Physiology of the Heart, 4th ed. Philadelphia, Lippincott, Williams & Wilkins, 2005.)*

VENTRICULAR AFTERLOAD

In the intact heart, as ex vivo, the extent and velocity of shortening of ventricular muscle fibers at any level of preload and of myocardial contractility relate inversely to the afterload, i.e., the instantaneous load opposing shortening. In the intact heart, the afterload may be defined as the tension developed in the ventricular wall during ejection. Afterload is determined by the aortic pressure as well as by the volume of the ventricular cavity and myocardial tissue characteristics including thickness. Laplace's law models the tension of the myocardial fiber as the product of intra-cavitary ventricular pressure and ventricular radius divided by wall thickness. Therefore, at any given aortic pressure, the afterload on a dilated left ventricle exceeds that on a normal-sized ventricle. Conversely, at the same aortic pressure and ventricular diastolic volume, the afterload on a hypertrophied ventricle is lower than that on a normal chamber. Aortic pressure in turn depends on the peripheral vascular resistance, the biomechanics of the arterial tree, and the volume of blood it contains at the onset of ejection.

Ventricular afterload finely regulates cardiovascular performance **(Fig. 244-10)**. As noted, elevations in both preload and contractility increase myocardial fiber shortening, whereas increases in afterload reduce it. The extent of myocardial fiber shortening and left ventricular size determine stroke volume. An increase in arterial pressure induced by vasoconstriction, for example, augments afterload, which opposes myocardial fiber shortening, reducing stroke volume.

When myocardial contractility is impaired and the ventricle dilates, afterload rises (Laplace's law) and limits cardiac output. Increased afterload also may result from neural and humoral stimuli that occur in response to a fall in cardiac output. This increased afterload may reduce cardiac output further, thereby increasing ventricular volume and initiating a vicious circle, especially in patients with ischemic heart disease and limited myocardial O_2 supply. Treatment with vasodilators has the opposite effect; when afterload falls, cardiac output rises **(Chaps. 266–270)**.

Under normal circumstances, the various influences acting on cardiac performance interact in a complex fashion to maintain cardiac output at a level responsive to the requirements of tissue metabolic demands (Fig. 244-10). Interference with a single mechanism may not influence the cardiac output due to homeostatic adjustments. For example, a moderate reduction of blood volume or the loss of the atrial contribution to ventricular contraction can be tolerated without a reduction in resting cardiac output. Under these circumstances, other factors, such as adrenergic neuronal impulses increasing cardiac contractility, heart rate, and venous tone, will serve as compensatory mechanisms and sustain cardiac output in a normal individual. Ultimately, understanding the complex interactions between so many different phasic variables requires rigorous models to predict relevant outcomes, and led to the early application of systems engineering principles in medicine.

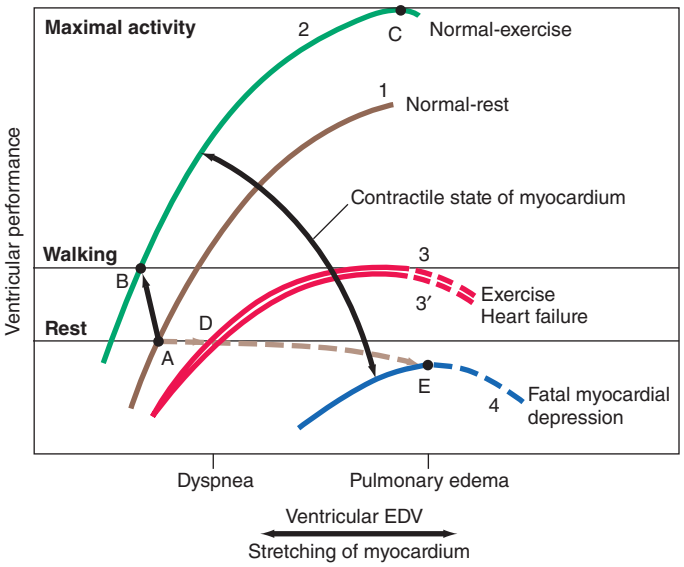

FIGURE 244-9 The interrelations among influences on ventricular end-diastolic volume (EDV) through stretching of the myocardium and the contractile state of the myocardium. Levels of ventricular EDV associated with filling pressures that result in dyspnea and pulmonary edema are shown on the abscissa. Levels of ventricular performance required when the subject is at rest, while walking, and during maximal activity are designated on the ordinate. The *broken lines* are the descending limbs of the ventricular-performance curves, which are rarely seen during life but show the level of ventricular performance if end-diastolic volume could be elevated to very high levels. For further explanation, see text. *(Reproduced with permission from WS Colucci, and E Braunwald: Pathophysiology of heart failure, in Braunwald's Heart Disease, 7th ed, Philadelphia: Elsevier, 2005.)*

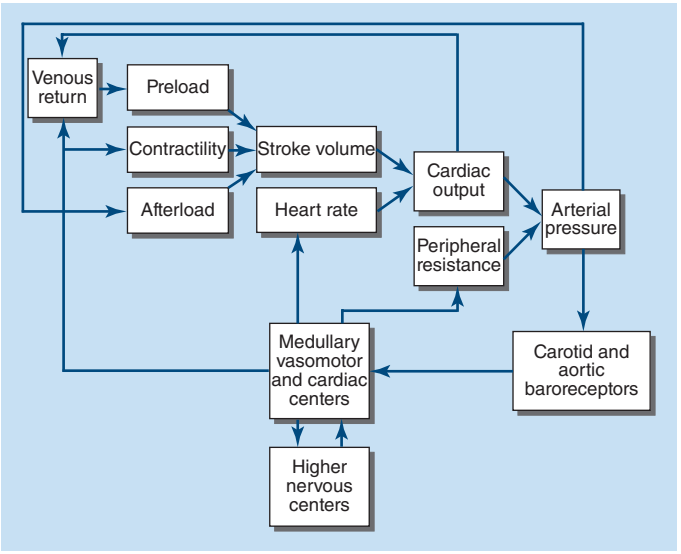

FIGURE 244-10 Interactions in the intact circulation of preload, contractility, and afterload in producing stroke volume. Stroke volume combined with heart rate determines cardiac output, which, when combined with peripheral vascular resistance, determines arterial pressure for tissue perfusion. The characteristics of the arterial system also contribute to afterload, an increase that reduces stroke volume. The interaction of these components with carotid and aortic arch baroreceptors provides a feedback mechanism to higher medullary and vasomotor cardiac centers and to higher levels in the central nervous system to effect a modulating influence on heart rate, peripheral vascular resistance, venous return, and contractility. *(Reproduced with permission from MR Starling: Physiology of myocardial contraction, in Atlas of Heart Failure: Cardiac Function and Dysfunction, 3rd ed, WS Colucci and E Braunwald [eds]. Philadelphia: Current Medicine; 2002.)*

EXERCISE

The integrated response to exercise illustrates typical interactions among the three determinants of stroke volume: preload, afterload, and contractility (Fig. 244-9). Hyperventilation, the pumping action of the exercising muscles, and venoconstriction during exercise all augment venous return and hence ventricular filling and preload (Table 244-2). Simultaneously, the increase in neuronal and humoral adrenergic stimulation of the myocardium and the tachycardia that occur during exercise combine to augment the myocardial contractility (Fig. 244-9, curves 1 and 2), together elevating stroke volume and stroke work, with little or no change in end-diastolic pressure and volume (Fig. 244-9, points A and B). Vasodilation occurs in the exercising muscles, thus limiting the increase in afterload that otherwise would occur as cardiac output rises to levels as high as five times greater than basal levels during maximal exercise. This vasodilation ultimately allows the achievement of elevated cardiac outputs during exercise at arterial pressures only moderately higher than the resting state.

ASSESSMENT OF CARDIAC FUNCTION

Several techniques can define impaired cardiac function in clinical practice. Cardiac output and stroke volume may decline in the presence of heart failure, but these variables are often within normal limits, especially at rest, even late in disease. A more sensitive index of cardiac function is the ejection fraction, i.e., the ratio of stroke volume to end-diastolic volume (normal value = 67 ± 8%), which is frequently depressed in systolic heart failure even when stroke volume is normal. Alternatively, abnormally elevated ventricular end-diastolic volume (normal value = 75 ± 20 mL/m^2) or end-systolic volume (normal value = 25 ± 7 mL/m^2) signifies left ventricular systolic impairment.

Noninvasive techniques, particularly echocardiography, radionuclide scintigraphy, and cardiac magnetic resonance imaging (MRI) **(Chap. 248)**, have great value in the clinical assessment of myocardial function. They provide measurements of end-diastolic and end-systolic volumes, ejection fraction, and systolic shortening rate, and they allow assessment of ventricular filling (see below) as well as regional contraction, relaxation, and tissue characterization. The latter measurements

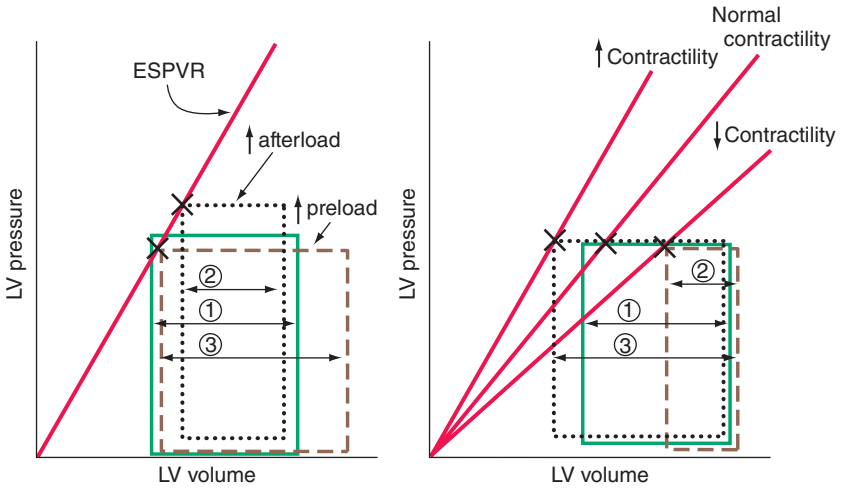

FIGURE 244-11 The responses of the left ventricle to increased afterload, increased preload, and increased and reduced contractility are shown in the pressure-volume plane. ***Left***. Effects of increases in preload and afterload on the pressure-volume loop. Because there has been no change in contractility, the end-systolic pressure-volume relationship (ESPVR) is unchanged. With an increase in afterload, stroke volume falls (1 → 2); with an increase in preload, stroke volume rises (1 → 3). ***Right***. With increased myocardial contractility and constant left ventricular end-diastolic volume, the ESPVR moves to the left of the normal line (lower end-systolic volume at any end-systolic pressure) and stroke volume rises (1 → 3). With reduced myocardial contractility, the ESPVR moves to the right; end-systolic volume is increased, and stroke volume falls (1 → 2).

have particular importance in ischemic heart disease, as myocardial infarction causes regional myocardial damage.

Strong dependence on ventricular loading conditions influences the precision of measurements of cardiac output, ejection fraction, and ventricular volumes as indices of cardiac function. Thus, a depressed ejection fraction and lowered cardiac output may occur in patients with normal ventricular function but reduced preload, as occurs in hypovolemia, or with increased afterload, as occurs in acutely elevated arterial pressure.

The end-systolic left ventricular pressure-volume relationship has particular value as an index of ventricular performance as it does not depend on preload and afterload **(Fig. 244-11)**. At any level of myocardial contractility, left ventricular end-systolic volume varies inversely with end-systolic pressure; as contractility declines, end-systolic volume (at any level of end-systolic pressure) rises. Invasive measurement of end-systolic left ventricular pressure-volume loops adds rigor to research studies of left ventricular function, but these techniques are less pragmatic than the more readily assessed indices obtained in routine clinical practice, such as ventricular volumes and ejection fraction. Integrated cardiopulmonary exercise testing with formal analysis of exhaled gases is now more broadly available and can estimate maximal oxygen delivery as an indirect metric of physiologic reserve. Longitudinal measurements of some aspects of cardiovascular physiology are increasingly feasible with implantable or wearable devices.

DIASTOLIC FUNCTION

Ventricular filling is influenced by several characteristics of the myocardium including: (1) the extent and speed of myocardial relaxation; and (2) the passive stiffness of the ventricular wall. The former is largely a function of the rate of uptake of Ca^{2+} by the SR that may be enhanced by adrenergic activation and reduced by ischemia due to limited ATP available for pumping Ca^{2+} into the SR (see above). For the latter, ventricular stiffness increases with hypertrophy, fibrosis, and conditions that infiltrate the ventricle, such as amyloid, or can result from an extrinsic constraint (e.g., pericardial constriction) **(Fig. 244-12)**.

Ventricular filling can be assessed by measuring flow velocity across the mitral valve using Doppler ultrasound. Normally, inflow velocity is more rapid in early diastole than during atrial systole. However, with mild to moderately impaired relaxation, the rate of early diastolic filling declines, as presystolic filling rates rise. With further stiffening, flow is "pseudo-normalized," as early ventricular filling becomes more rapid with rising left atrial pressure upstream of the left ventricle.

CARDIAC METABOLISM

The heart requires a continuous supply of energy (ATP) not only to drive mechanical contraction, but also to maintain ionic and biochemical homeostasis. The development of tension, the frequency of contraction, and myocardial contractility levels are the principal determinants of the heart's energy and oxygen requirements, representing ~15% of that of the entire organism.

The heart's ATP production requires the generation of acetyl coenzyme A that can be derived from (in descending order) free fatty acids (FFAs), glucose, lactate, amino acids, and ketone bodies. Myocardial FFAs derive from circulating FFAs, whereas the cardiomyocyte's glucose derives from plasma as well as from myocardial glycogen stores (via glycogenolysis). These two principal sources of acetyl coenzyme

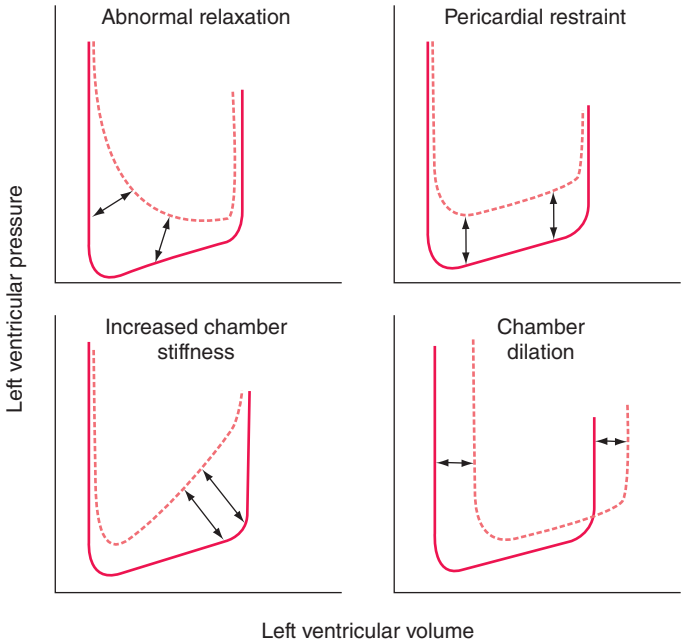

FIGURE 244-12 Mechanisms that cause diastolic dysfunction reflected in the pressure-volume relation. The bottom half of the pressure-volume loop is depicted. *Solid lines* represent normal subjects; *broken lines* represent patients with diastolic dysfunction. *(Reproduced with permission from JD Carroll et al: The differential effects of positive inotropic and vasodilator therapy on diastolic properties in patients with congestive cardiomyopathy. Circulation; 1986; 74: 815.)*

A are metabolized distinctly in cardiac muscle. Glucose is converted in the cytoplasm into pyruvate, which passes into mitochondria for conversion into acetyl-CoA that then undergoes oxidation. FFAs are converted to acyl-CoA in the cytoplasm and acetyl-CoA in the mitochondria. Acetyl-CoA enters the citric acid (Krebs) cycle to produce ATP by oxidative phosphorylation; ATP then enters the cytoplasm from the mitochondrial compartment. Intracellular adenosine diphosphate (ADP), resulting from ATP breakdown, enhances ATP production.

In the fasted, resting state, circulating FFAs furnish most of the heart's acetyl-CoA (~70%). In the fed state, with elevations of blood glucose and insulin, glucose oxidation increases and FFA oxidation subsides. Increased cardiac work, inotropic agents, hypoxia, and mild ischemia all enhance myocardial glucose uptake, production (glycogenolysis), and metabolism to pyruvate (glycolysis). Exercise raises circulating lactate levels and myocardial utilization of acetyl-CoA. By contrast, β-adrenergic stimulation raises the circulating levels and metabolism of FFAs in favor of glucose. Severe myocardial ischemia inhibits cytoplasmic pyruvate dehydrogenase, producing incomplete glucose metabolism to lactic acid (anaerobic glycolysis). Anaerobic glycolysis produces much less ATP per mole of glucose than does aerobic glucose metabolism. High concentrations of circulating FFAs, which can occur when adrenergic stimulation is superimposed on severe ischemia, reduce oxidative phosphorylation, and the myocardial content of ATP declines, impairing contraction. In addition, FFA breakdown products may exert toxic or arrhythmogenic effects on cardiac cell membranes.

Myocardial energy is stored as creatine phosphate (CP), which is in equilibrium with ATP, the immediate energy source. In states of reduced energy availability, the CP stores decline first. Cardiac hypertrophy, fibrosis, tachycardia, increased wall tension due to ventricular dilation, and increased intracytoplasmic [Ca^{2+}] all contribute to increased myocardial energy needs. When coupled with reduced coronary flow reserve, as occurs with obstruction of coronary arteries or abnormalities of the coronary microcirculation, an imbalance in myocardial ATP production relative to demand may occur, and the resulting ischemia can worsen or cause heart failure.

CARDIAC CELLULAR INTERVENTIONS: REGENERATION AND REPAIR

Adult mammalian myocardial cells are fully differentiated and have little or no regenerative potential; however, there is evidence that the immature mammalian heart has some limited regenerative potential that rapidly becomes constrained with increasing maturity and workload. Considerable current effort is being devoted to evaluating the utility of various approaches to facilitate the transient release of these constraints on regeneration to enhance cardiac repair after injury. Recent work has also shown that by engineering chimeric antigen receptors on T lymphocytes (CAR-T), it may be possible to reverse fibrosis in the heart. The success of such approaches would offer the exciting possibility of reconstructing an infarcted or failing ventricle.

245 Epidemiology of Cardiovascular Disease

J. Michael Gaziano, Thomas A. Gaziano

Cardiovascular disease (CVD) is now the most common cause of death worldwide. Before 1900, infectious diseases and malnutrition were the most common causes, and CVD was responsible for <10% of all deaths. In 2022, CVD accounted for over 19 million deaths worldwide (33%), with the same rate now occurring in both high-income countries and low- and middle-income countries.

THE EPIDEMIOLOGIC TRANSITION

The global rise in CVD is the result of an unprecedented transformation in the causes of morbidity and mortality during the twentieth century. Known as the epidemiologic transition, this shift is driven by industrialization, urbanization, and associated lifestyle and demographic changes and is taking place in every part of the world among all races, ethnic groups, and cultures. The transition is divided into four basic stages: pestilence and famine, receding pandemics, degenerative and man-made diseases, and delayed degenerative diseases. A fifth stage, characterized by an epidemic of inactivity and obesity, is emerging in many countries that have moderate economic development (Table 245-1).

The *age of pestilence and famine* is marked by malnutrition, infectious diseases, and high infant and child mortality that are offset by high fertility. Tuberculosis, dysentery, cholera, and influenza are often fatal, resulting in a mean life expectancy of about 30 years. CVD, which accounts for <10% of deaths, takes the form of rheumatic heart disease and cardiomyopathies due to infection and malnutrition. Despite advances in treatment of those with rheumatic heart disease, incidence and prevalence rates increased between 1990 and 2019.

Per capita income and life expectancy increase during the *age of receding pandemics* as the emergence of public health systems, cleaner water supplies, and improved nutrition combine to drive down deaths from infectious disease and malnutrition. Infant and childhood mortality also decline, but deaths due to CVD increase to between 10 and 35% of all deaths. Rheumatic valvular disease, hypertension, coronary heart disease (CHD), and stroke are the predominant forms of CVD. Almost 40% of the world's population is currently in this stage.

The *age of degenerative and man-made diseases* is distinguished by mortality from noncommunicable diseases—primarily CVD—surpassing mortality from malnutrition and infectious diseases. Caloric intake, particularly from animal fat, increases. CHD and stroke are prevalent, and between 35 and 65% of all deaths can be traced to CVD. Typically, the rate of CHD deaths exceeds that of stroke by a ratio of 2:1 to 3:1. During this period, average life expectancy surpasses the age of 50. Roughly 35% of the world's population falls into this category.

In the *age of delayed degenerative diseases*, CVD and cancer remain the major causes of morbidity and mortality, with CVD accounting for 40% of all deaths. However, age-adjusted CVD mortality declines, aided by preventive strategies (for example, smoking cessation programs and effective blood pressure control), acute hospital management, and technologic advances, such as the availability of bypass

TABLE 245-1 Five Stages of the Epidemiologic Transition

STAGE	DESCRIPTION	DEATHS RELATED TO CVD, %	PREDOMINANT CVD TYPE
Pestilence and famine	Predominance of malnutrition and infectious diseases as causes of death; high rates of infant and child mortality; low mean life expectancy	<10	Rheumatic heart disease, cardiomyopathies caused by infection and malnutrition
Receding pandemics	Improvements in nutrition and public health lead to decrease in rates of deaths related to malnutrition and infection; precipitous decline in infant and child mortality rates	10–35	Rheumatic valvular disease, hypertension, CHD, and stroke (predominantly hemorrhagic)
Degenerative and man-made diseases	Increased fat and caloric intake and decrease in physical activity lead to emergence of hypertension and atherosclerosis; with increase in life expectancy, mortality from chronic, noncommunicable diseases exceeds mortality from malnutrition and infectious disease	35–65	CHD and stroke (ischemic and hemorrhagic)
Delayed degenerative diseases	CVD and cancer are the major causes of morbidity and mortality; better treatment and prevention efforts help avoid deaths among those with disease and delay primary events; age-adjusted CVD morality declines; CVD affecting older and older individuals	40–50	CHD, stroke, and congestive heart failure
Inactivity and obesity	Overweight and obesity increase at alarming rate; diabetes and hypertension increase; decline in smoking rates levels off; a minority of the population meets physical activity recommendations	<40	CHD, stroke, and congestive heart failure, peripheral vascular disease

Abbreviations: CHD, coronary heart disease; CVD, cardiovascular disease.

Source: Data from AR Omran: The epidemiologic transition: A theory of the epidemiology of population change. Milbank Mem Fund Q 49:509, 1971; and SJ Olshansky, AB Ault: The fourth stage of the epidemiologic transition: The age of delayed degenerative diseases. Milbank Q 64:355, 1986.

surgery. CHD, stroke, and congestive heart failure are the primary forms of CVD. About 15% of the world's population is now in the age of delayed degenerative diseases or is exiting this age and moving into the fifth stage of the epidemiologic transition.

In the industrialized world, physical activity continues to decline while total caloric intake increases. The resulting epidemic of overweight and obesity may signal the start of the *age of inactivity and obesity*. Rates of type 2 diabetes mellitus, hypertension, and lipid abnormalities are on the rise, trends that are particularly evident in children. As these risk factor trends continue, age-adjusted CVD mortality rates that have fallen for decades during the fourth phase have started to increase in recent years during this fifth phase.

PATTERNS IN THE EPIDEMIOLOGIC TRANSITION

Unique regional features have modified aspects of the transition in various parts of the world. High-income countries experienced declines in CVD death rates by as much as 50–60% over the past 60 years, whereas CVD deaths increased by 15% over the past 20 years in the low- and middle-income range and the rate of change has been faster. However, given the large amount of available data, the United States serves as a useful reference point for comparisons. The age of pestilence and famine occurred before 1900, with a largely agrarian economy and population. Infectious diseases accounted for more deaths than any other cause. By the 1930s, the country proceeded through the age of receding pandemics. The establishment of public health infrastructures resulted in dramatic declines in infectious disease mortality rates. Lifestyle changes due to rapid urbanization resulted in a simultaneous increase in CVD mortality rates, reaching ~390 per 100,000. Between 1930 and 1965, the country entered the age of degenerative and man-made diseases. Infectious disease mortality rates fell to fewer than 50 per 100,000 per year, whereas CVD mortality rates reached peak levels with increasing urbanization and lifestyle changes in diet, physical activity, and tobacco consumption. The age of delayed degenerative diseases took place between 1965 and 2000. New therapeutic approaches, preventive measures, and exposure to public health campaigns promoting lifestyle modifications led to substantial declines in age-adjusted mortality rates and a steadily rising age at which a first CVD event occurs.

Currently, the United States is entering what appears to be a fifth phase. The decline in the age-adjusted CVD death rate of 3% per year through the 1970s and 1980s has tapered off in the 1990s to 2% through 2010. There was then limited reduction in the 2010–2019 period, and in 2020 and 2021, there was an increase in CVD mortality rates that had not been seen since the early 1960s. Competing trends appear to be at play. On the one hand, an increase in the prevalence of diabetes and obesity, a slowing in the rate of decline in smoking, and a leveling off in the rate of detection and worsening treatment for hypertension are in the negative column. On the other hand, cholesterol levels continue to decline in the face of increased statin use.

Many high-income countries (HICs)—which together account for 15% of the population—have proceeded through four stages of the epidemiologic transition in roughly the same pattern as the United States. CHD is the dominant form of CVD in these countries, with rates that tend to be two- to fivefold higher than stroke rates. However, variations exist. Whereas North America, Australia, and central northwestern European HICs experienced significant increases then rapid declines in CVD rates, southern and central European countries experienced a more gradual rise and fall in rates. More specifically, central European countries (i.e., Austria, Belgium, and Germany) declined at slower rates compared to their northern counterparts (i.e., Finland, Sweden, Denmark, and Norway). Countries such as Portugal, Spain, and Japan never reached the high mortality rates that the United States and other countries did, with CHD mortality rates at 200 per 100,000, or less. The countries of Western Europe also exhibit a clear north/south gradient in absolute rates of CVD, with rates highest in northern countries (i.e., Finland, Ireland, and Scotland) and lowest in Mediterranean countries (i.e., France, Spain, and Italy). Japan is unique among the HICs, most likely due to the unique dietary patterns of its population. Although stroke rates increased dramatically, CHD rates did not rise as sharply in Japan. However, Japanese dietary habits are undergoing substantial changes, reflected in an increase in cholesterol levels.

Patterns in low- and middle-income countries (LMICs; gross national income per capita $11,666) depend, in part, on cultural differences, secular trends, and responses at the country level, with regard to both public health and treatment infrastructure. Although communicable diseases continue to be a major cause of death, CVD has emerged as a significant health concern in LMICs. With 85% of the world's population, LMICs are driving the rates of change in the global burden of CVD **(Fig. 245-1)**. In most LMICs, an urban/rural gradient has emerged for CHD, stroke, and hypertension, with higher rates in urban centers.

However, although CVD rates are rapidly rising globally, vast differences exist among the regions and countries, and even within the countries themselves **(Fig. 245-2)**. The East Asia and Pacific regions appear to be fully in the third phases of the epidemiologic transition. CVD is a major cause of death in China, but like Japan, stroke causes more deaths than CHD in a ratio of about three to one. Vietnam and Cambodia, on the other hand, are just emerging from the pestilence and famine transition. The Middle East and North Africa regions also appear to be well into the third phase of the epidemiologic transition, with increasing life expectancy and CVD death rates just below those of HICs. In general, Latin America appears to be in the third phase of

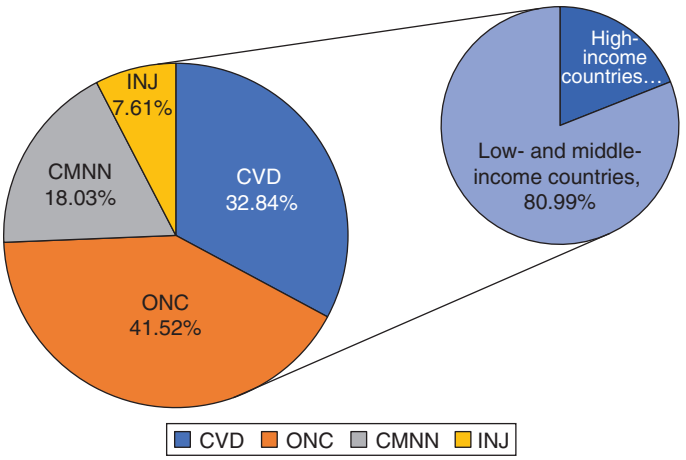

FIGURE 245-1 Global deaths by cause, 2019. CMNN, communicable, maternal, neonatal, and nutritional disorders; CVD, cardiovascular diseases; INJ, injuries; ONC, other noncommunicable diseases. *(Based on data from Global Burden of Disease Study 2017. Global Burden of Disease Study 2017 [GBD 2017] Results. Seattle, United States: Institute for Health Metrics and Evaluation [IHME], 2020.)*

the transition, although there is vast regional heterogeneity with some areas in the second phase of the transition and more in the fourth. The Eastern Europe and Central Asia regions, however, are firmly in the peak of the third phase, with the highest death rates due to CVD (~55%) in the world. Importantly, deaths due to CHD are not limited to the elderly in this region and have a significant effect on working-age populations. South Asia—and more specifically, India, which accounts for the greatest proportion of the region's population—is experiencing an alarming increase in heart disease. The transition appears to be in the Western style, with CHD as the dominant form of CVD. However, rheumatic heart disease continues to be a major cause of morbidity and mortality. As in South Asia, rheumatic heart disease is also an important cause of CVD morbidity and mortality in sub-Saharan Africa, which largely remains in the first phase of the epidemiologic transition.

Many factors contribute to this heterogeneity among LMICs. First, the regions are in various stages of the epidemiologic transition. Second, vast differences in lifestyle and behavioral risk factors exist. Third, racial and ethnic differences may lead to altered susceptibilities to various forms of CVD. In addition, it should be noted that for most countries in these regions, accurate country-wide data on cause-specific mortality are not complete.

GLOBAL TRENDS IN CARDIOVASCULAR DISEASE

Over the past 5 years, there have been changes in the trends of CVD that are reflective of both trends in demographics and management of disease, but also of the way deaths and diseases have been measured and estimated. In 2017, the Global Burden of Disease (GBD) Study updated its estimates with several important changes based on newly available data, refinement in the causes of death, and the introduction of new modeling techniques. The major changes include the addition of an independent estimation of population and fertility, the addition of over 127 country-years of vital registration and verbal autopsy data, revisions of some deaths from "misclassified" to dementia, Parkinson's disease and atrial fibrillation, and the addition of new diseases such as nonrheumatic calcific aortic and degenerative mitral valve disease. CVD accounts for 32% of deaths worldwide, a number expected to increase. In 2019, CHD accounted for 16.2% of all deaths globally and the largest portion (10%) of global years of life lost (YLLs) and disability-adjusted life-years (DALYs) (7.2%). Stroke moved from the third to the second largest cause of death (11.6% of all deaths) and remained the third largest contributor to global YLLs (7.5%) and DALYs (5.7%). Together, CHD and stroke accounted for more than a quarter of all deaths worldwide. The burden of stroke is of growing concern among LMICs. The impact of stroke on DALYs and mortality rates is more than three times greater in LMICs as compared to HICs.

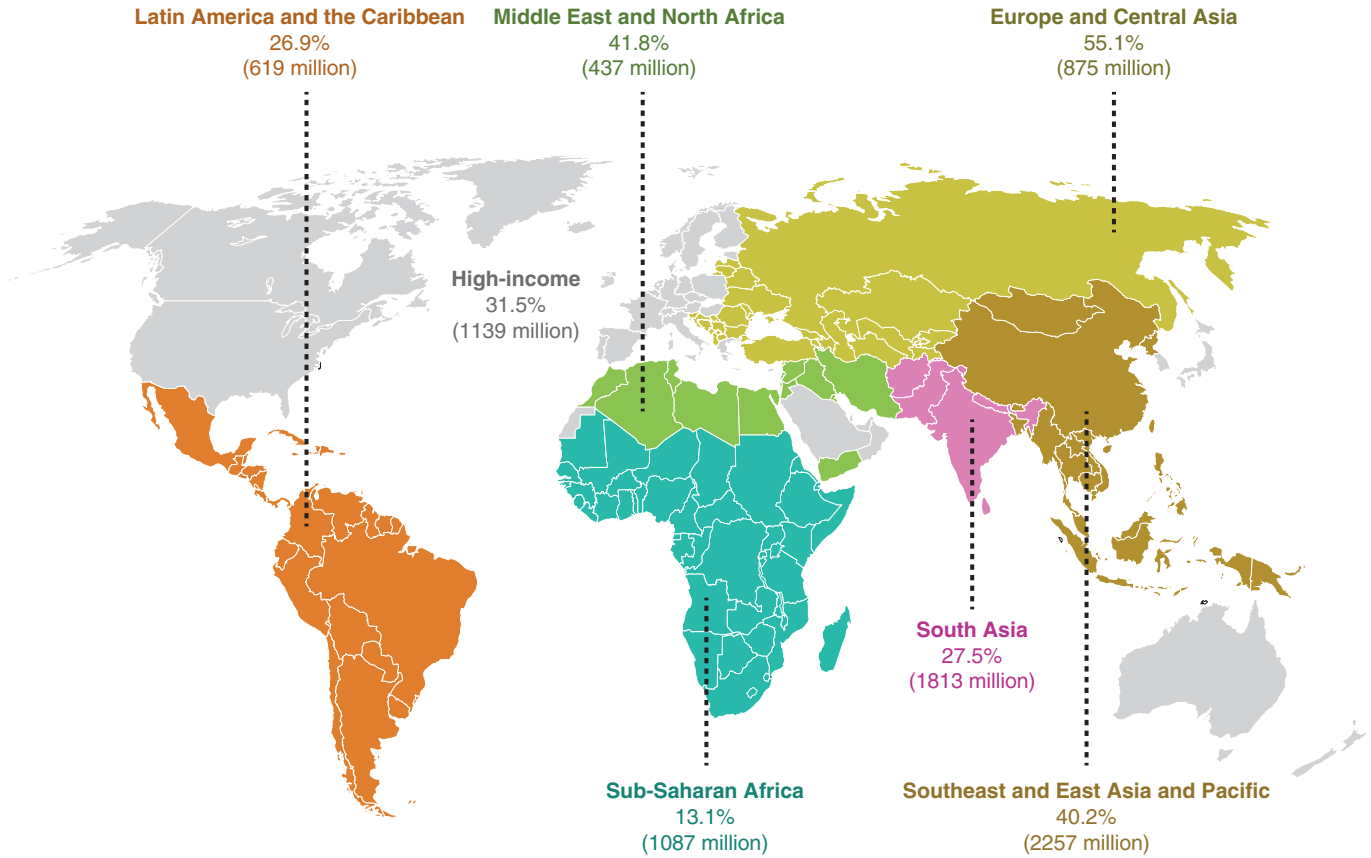

FIGURE 245-2 Cardiovascular disease deaths as a percentage of total deaths and total population in seven economic regions of the world defined by the World Bank. *(Based on data from Global Burden of Disease Study 2017. Global Burden of Disease Study 2019 [GBD 2019] Results. Seattle, United States: Institute for Health Metrics and Evaluation [IHME], 2023.)*

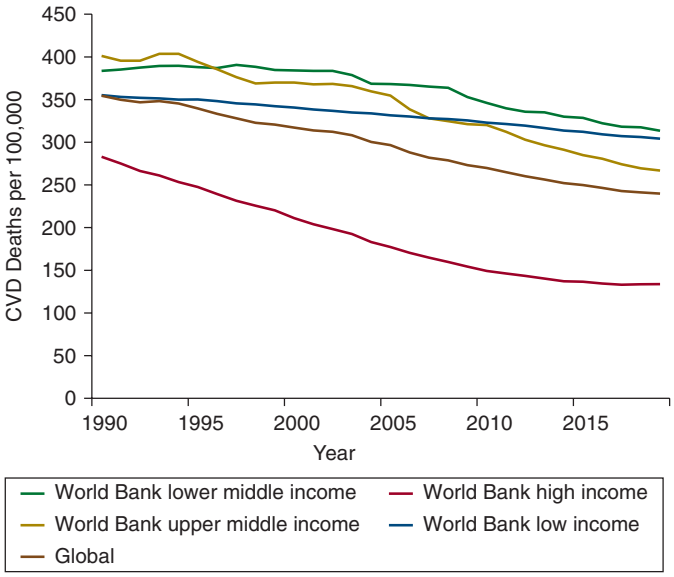

FIGURE 245-3 Age-standardized cardiovascular diseases (CVD) death rate per 100,000 from 1990 to 2019, by World Bank income. *(Based on data from Global Burden of Disease Study 2019. Global Burden of Disease Study 2019 [GBD 2019] Results. Seattle, United States: Institute for Health Metrics and Evaluation [IHME], 2023.)*

With 85% of the world's population, LMICs largely drive global CVD rates and trends. More than 15 million CVD deaths occurred in LMICs in 2019, compared to 3.5 million in HICs. Globally, there is evidence of significant delays in age of occurrence and/or improvements in case fatality rates; between 1990 and 2019, the number of CVD deaths increased by 54%, but age-adjusted death rates decreased by 32.4% in the same period. Age-standardized death rates, however, have declined faster in HICs than in middle-income and lower-income regions **(Fig. 245-3)**. Population growth has been greater in LMICs compared to HICs. As a result of slower rates of population growth in HICs, overall CVD deaths remained steady. However, in the LMICs, the population aging and growth outstripped gains in age-adjusted mortality reductions such that overall CVD deaths continued to climb over the past 25 years **(Fig. 245-4)**.

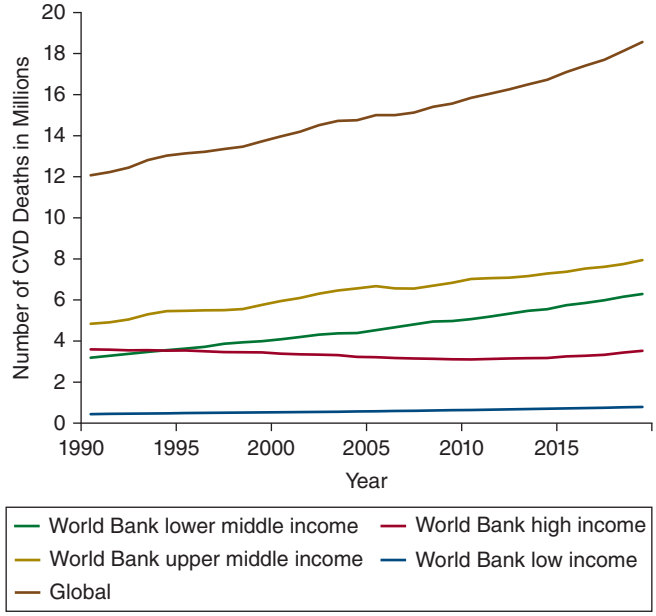

FIGURE 245-4 Number of cardiovascular diseases (CVD) deaths from 1990 to 2019, by World Bank income. *(Based on data from Global Burden of Disease Study 2019. Global Burden of Disease Study 2017 [GBD 2019] Results. Seattle, United States: Institute for Health Metrics and Evaluation [IHME], 2023.)*

Although HIC population growth will be fueled by immigration from LMICs, the populations of HICs will shrink as a proportion of the world's population. The modest decline in CVD death rates that began in the HICs in the latter third of the twentieth century will continue, but the rate of decline appears to be slowing. However, these countries are expected to see an increase in the prevalence of CVD, as well as the absolute number of deaths as the population ages.

Significant portions of the population living in LMICs have entered the third phase of the epidemiologic transition, and some are entering the fourth stage. Changing demographics play a significant role in future predictions for CVD throughout the world. For example, the population in Eastern Europe declined by 3% between 2010 and 2023, whereas it grew by 30% in South Asia. CVD rates will also have an economic impact. Even assuming no increase in CVD risk factors, most countries, but especially India and South Africa, will see a large number of people between 35 and 64 die of CVD over the next 30 years, as well as an increasing level of morbidity among middle-aged people related to heart disease and stroke.

RISK FACTORS

Global variation in CVD rates is related to temporal and regional variations in known risk factors and behaviors. Ecologic analyses of major CVD risk factors and mortality demonstrate high correlations between expected and observed mortality rates for the three main risk factors—smoking, serum cholesterol, and hypertension—and suggest that many regional variations are based on differences in conventional risk factors.

Behavioral Risk Factors

• TOBACCO Over 1.3 billion people use tobacco worldwide. Tobacco use currently causes about 8.7 million deaths annually (15.4% of all deaths), 3.2 million of which are CVD related. The population of the HIC group smokes (21.6%) at almost double the rate of the low-income countries (11.2%), whereas the middle-income country group's smoking rate (19.5%) approximates the global average (22.3%). From 2007 to 2017, smoking rates decreased across low-, middle-, and high-income country groups, with relative reductions of 19%, 12%, and 20%, respectively. By 2030, the global average smoking rate is expected to decline from 19% to 16% (women, 4%; men, 28%); however, the number of tobacco users is expected to rise owing to population growth. Secondhand smoke is another well-established cause of CVD, responsible for 598,000 CVD deaths of nonsmokers in 2019. Although smoking bans have both immediate and long-term benefits, implementation varies greatly between countries.

DIET Total caloric intake per capita increases as countries develop. With regard to CVD, a key element of dietary change is an increase in intake of saturated animal fats and hydrogenated vegetable fats, which contain atherogenic *trans* fatty acids, along with a decrease in intake of plant-based foods and an increase in simple carbohydrates. Fat contributes <20% of calories in rural China and India, <30% in Japan, and over 35% in the United States. Caloric contributions from fat appear to be increasing in the United States but falling in the other HICs.

PHYSICAL INACTIVITY The increased mechanization that accompanies the economic transition leads to a shift from physically demanding, agriculture-based work to largely sedentary industry- and office-based work. Physical inactivity is responsible for 1.3 million global deaths in 2019. The global prevalence of physical inactivity has remained steady between 2001 and 2016 (28.5% to 27.5%). Mortality rates attributable to inactivity are highest in North Africa and the Middle East and in Central and Eastern Europe and lowest in sub-Saharan Africa.

METABOLIC RISK FACTORS

Examination of trends in metabolic risk factors provides insight into changes in the CVD burden globally. Here we describe four metabolic risk factors—lipid levels, hypertension, obesity, and diabetes mellitus—using data from the Global Burden of Disease, Injuries, and Risk Factors Study (GBD 2019). The GBD project identified and compiled mortality and morbidity data from 195 countries from 1980 to 2017.

Lipid Levels Worldwide, high low-density lipoprotein cholesterol levels are estimated to play a role in 41% of ischemic heart disease deaths and 9% of stroke deaths, amounting to 4 million deaths in 2019. Although mean population plasma cholesterol levels tend to rise as countries move through the epidemiologic transition, mean serum total cholesterol levels have decreased globally between 1980 and 2008 by 0.08 mmol/L per decade in men and 0.07 mmol/L per decade in women. Large declines occurred in Australasia, North America, and Western Europe (0.19–0.21 mmol/L). Countries in the East Asia and Pacific region experienced increases of >0.08 mmol/L in both men and women. More recent research including Mendelian studies suggests that lipoprotein(a) may act as an individual predictor of CVD risk beyond traditional total or low-density lipoprotein cholesterol through increased cellular lipid accumulation, endothelial dysfunction, and impacts on coagulation. It appears to be elevated in ~20% of the global population, although fewer data are available from LMICs. Nonrandomized data suggest higher rates among those of African descent with twice the levels of Caucasians, with East Asians and South Asians having intermediate levels. There are limited clinical trial data on clinical agents that target lipoprotein(a), although PCSK9 inhibitors lower it or other specific targets, so this remains an area of intense research.

Hypertension Elevated blood pressure is an early indicator of the epidemiologic transition. Observational studies show increased risk of CVD beginning with systolic blood pressures (SBPs) >110–115 mmHg. Between 1990 and 2015, the global prevalence of SBP ≥110–115 mmHg increased from 73,119 to 81,373 per 100,000, whereas the prevalence of SBP ≥140 mmHg rose from 17,307 to 20,526 per 100,000. In 2015, of the estimated 3.47 billion adults with SBP ≥110–115 mmHg, 874 million (25%) had SBP ≥140 mmHg. While SBP ≥140 mmHg accounts for only 25% of those with elevated blood pressure, it accounted for 73% (7.8 million) of deaths due to SBP of ≥110–115 mmHg in 2015. Worldwide, 53% of stroke deaths (3.44 million) and 53% of CHD deaths (4.86 million) are attributable to high blood pressure, accounting for 10.8 million deaths in 2019. From 1990 to 2015, the number of deaths related to SBP ≥140 mmHg increased in all LMIC groups but fell in HICs. Between 1980 and 2008, the age-standardized prevalence of uncontrolled hypertension decreased even as the number of people with uncontrolled hypertension increased due to population growth and aging. However, concerning trends of declining hypertension control rates were seen in the United States since 2016 with many middle-income countries now outperforming high-income nations. Rising mean population blood pressure also occurs as populations industrialize and move from rural to urban settings. For example, the prevalence of hypertension in urban India is 33.8%, but varies between 14.5 and 31.7% in rural regions. One major concern in LMICs is the high rate of undetected, and therefore untreated, hypertension. This may explain, at least in part, the higher stroke rates in these countries in relation to CHD rates during the early stages of the transition. The high rates of hypertension throughout Asia, especially undiagnosed hypertension, likely contribute to the high prevalence of hemorrhagic stroke in the region.

Obesity In 2025, an estimated 892 million adults will be obese. Global obesity prevalence is projected to be 16.1% among adults and is increasing throughout the world, particularly in developing countries where the trajectories are steeper than those experienced by the developed countries. High body mass index (BMI) contributed to 5.0 million deaths worldwide (7.1% deaths from any cause); CVD was the leading cause of these deaths (1.95 million) and also of associated DALYs (160 million) followed by diabetes (0.6 million deaths, 30.4 million DALYs). Women are more affected by obesity than men; from 1975 to 2014, global mean age-standardized BMI increased from 22.1 to 24.4 kg/m^2 in females and from 21.7 to 24.2 kg/m^2 in males, whereas the prevalence of obesity increased from 6.4% to 14.9% in females and 3.2% to 10.8% in males. The proportion of the world's adult women who are either overweight or obese rose from 29.8% to 38.0% between 1980 and 2013, while an increase from 28.8% to 36.9% was observed for men. Country and regional differences are observed. The highest prevalence of male obesity is in the United States, Southern and Central Latin America, Australasia, and Central and Western Europe. For females, the highest prevalence of obesity is in Southern and North Africa, the Middle East, Central and Southern Latin America, and the United States. The lowest prevalence for both males and females was observed in South and Southeast Asia and in East, Central, and West Africa.

Diabetes Mellitus As a consequence of, or in addition to, increasing BMI and decreasing levels of physical activity, worldwide rates of diabetes—predominantly type 2 diabetes—are on the rise. According to the most recent data from the GBD project, the prevalence of diabetes increased 129.7% for males and 120.9% for females between 1990 and 2017. An estimated 476 million people worldwide have diabetes, and the International Diabetes Foundation predicts this number will reach 693 million by 2045. Nearly 50% of people with diabetes are undiagnosed, and 80% live in LMICs. The Middle East and North Africa have the highest regional age-standardized prevalence (8.7% of the population) and incidence rates (400 per 100,000) of diabetes, whereas East Asia and the Pacific have the lowest (5.8%; 249 per 100,000). Future growth will also largely occur in the Middle East and Africa, along with other LMICs in South Asia and sub-Saharan Africa.

COVID-19 The impact of COVID-19 on CVD was significant. First, patients with acute conditions were hesitant to present to hospitals for fear of infection, resulting in delayed presentation for those with acute coronary syndrome (ACS) or stroke and missing critical early care. Additionally, even those who presented with ACS had worse outcomes sometimes related to testing delays. Furthermore, the presence of obesity and/or diabetes mellitus worsened outcomes. Finally, control rates of hypertension and dyslipidemia may have been exacerbated due to difficulty of access to providers.

GENETIC RISK FACTORS

A great deal of effort has recently been invested in understanding how genes affect cardiovascular health in populations. These efforts have focused on germline genetic variants that are related to specific CVDs as well as those that are associated with cardiovascular risk factors. In both cases, every year, the number of associated variants has increased meaningfully to the point that it appears that hundreds or even thousands of variants are associated with these conditions, each explaining a small amount of the population variability in disease and risk factors. Collections of variants have been combined in polygenomic risk scores, but these too explain only a small amount of the variability of the disease in the population. Much more data will emerge in the coming years about these associations, the mechanisms that explain these associations, the relationships of variants that are specific to certain tissues such as the heart or the brain, and the interactions between genetic and lifestyle factors in causing disease. Currently, most of the data are among those with European ancestry; however, large-scale efforts are underway to understand the relationships between genes and diseases and their risk factors around the world. The early data suggest nontrivial differences among various world populations. Beyond germline risk, there appears to be increased cardiovascular risk associated with age-related expansion of hematopoietic clones with somatic mutations, including loss-of-function alleles of certain genes. Individuals with these mutations without other hematologic abnormalities are defined as having clonal hematopoiesis of indeterminate potential (CHIP). Recent studies suggest those with CHIP have up to a twofold increased risk of developing CHD.

SUMMARY

Although CVD rates are declining in the HICs, they are increasing in many other regions of the world. The consequences of this preventable epidemic will be substantial on many levels, including individual mortality and morbidity, family suffering, and staggering economic costs.

Three complementary strategies can be used to lessen the impact. First, the overall burden of CVD risk factors can be lowered through population-wide public health measures, such as national campaigns against cigarette smoking, unhealthy diets, and physical inactivity. Second, it is important to identify higher risk subgroups of the population

who stand to benefit the most from specific, low-cost prevention interventions, including screening for and treatment of hypertension and elevated cholesterol. Simple, low-cost interventions, such as the "polypill"—a regimen of aspirin, a statin, and an antihypertensive agent—now show trial data with reductions in events for both primary and secondary prevention and have been added to the WHO Essential Medicines list. Third, resources should be allocated to acute, as well as secondary, prevention interventions. For countries with limited resources, a critical first step in developing a comprehensive plan is better assessment of cause-specific mortality and morbidity, as well as the prevalence, of the major preventable risk factors.

In the meantime, the HICs must continue to bear the burden of research and development aimed at prevention and treatment, being mindful of the economic limitations of many countries. The concept of the epidemiologic transition provides insight into how to alter the course of the CVD epidemic. The efficient transfer of low-cost preventive and therapeutic strategies could alter the natural course of this epidemic and thereby reduce the excess global burden of preventable CVD.

Section 2 Diagnosis of Cardiovascular Disorders

246 Physical Examination of the Cardiovascular System

Patrick T. O'Gara, Joseph Loscalzo

The approach to a patient with known or suspected cardiovascular disease begins with the time-honored traditions of a directed history and a targeted physical examination. The scope of these activities depends on the clinical context, ranging from an elective ambulatory follow-up visit to a more urgent bedside encounter. There has been a gradual decline in physical examination skills over the past few decades at every level, from student to faculty specialist, a development of great concern to both clinicians and medical educators. Classic cardiac findings are recognized by only a minority of internal medicine and family practice residents. Despite popular perceptions, clinical performance does not improve predictably with experience; instead, the acquisition of new examination skills may become more difficult for a busy individual practitioner. Less time is now devoted to mentored cardiovascular examinations during the training of students and residents. One widely recognized outcome of these trends is the progressive utilization of noninvasive imaging studies to establish the presence and severity of cardiovascular disease even when the examination findings imply a low pretest probability of significant pathology. Proponents of the use of hand-held ultrasound devices to identify and characterize structural cardiac disease have called for its incorporation into educational curricula. Techniques to improve competency in bedside examination skills include repetition, patient-centered teaching conferences, visual display feedback of auscultatory events using Doppler echocardiographic imaging, and simulation-based training. The use of digital stethoscopes may enhance learning and is foundational to the application of computer- or artificial intelligence–assisted evaluation of auscultatory events.

The findings from the history and physical examination can help establish the presence, severity, and prognosis of several cardiovascular diseases. For example, observations regarding heart rate and blood pressure, signs of pulmonary congestion, and the presence of mitral regurgitation (MR) contribute importantly to bedside risk assessment in patients with acute coronary syndromes and can inform clinical decision-making before the results of cardiac biomarker testing are known. The prognosis of patients with heart failure can be predicted on the basis of the jugular venous pressure (JVP) and the presence or absence of a third heart sound (S_3). Accurate characterization of cardiac murmurs provides important insight into the natural history of many valvular and congenital heart lesions. Finally, the important role played by the physical examination in enhancing the clinician-patient relationship cannot be overstated.

THE GENERAL PHYSICAL EXAMINATION

The examination begins with an assessment of the general appearance of the patient, with notation of age, posture, demeanor, and overall health status. Is the patient in pain or resting quietly, dyspneic or diaphoretic? Does the patient choose to avoid certain body positions to reduce or eliminate pain, as might be the case with suspected acute pericarditis? Are there clues indicating that dyspnea may have a pulmonary cause, such as a barrel chest deformity with an increased anterior-posterior diameter, tachypnea, and pursed-lip breathing? Skin pallor, cyanosis, and jaundice can be appreciated readily and provide additional clues. The appearance of a chronically ill-appearing emaciated patient may suggest the presence of long-standing heart failure or another systemic disorder, such as a malignancy. Various genetic syndromes, often with cardiovascular involvement, can also be recognized easily, such as trisomy 21, Marfan syndrome, and Holt-Oram syndrome. Height and weight should be measured routinely, and both body mass index and body surface area should be calculated. Knowledge of the waist circumference and the waist-to-hip ratio can be used to predict long-term cardiovascular risk. Mental status, level of alertness, and mood should be assessed continuously during the interview and examination.

Skin Central cyanosis occurs with significant right-to-left shunting at the level of the heart or lungs, allowing deoxygenated blood to reach the systemic circulation. Peripheral cyanosis or acrocyanosis, in contrast, is usually related to reduced extremity blood flow due to small vessel constriction, as seen in patients with severe heart failure, shock, or peripheral vascular disease; it can be aggravated by the use of β-adrenergic blockers with unopposed α-mediated vasoconstriction. Differential cyanosis refers to isolated cyanosis affecting the lower but not the upper extremities in a patient with a large patent ductus arteriosus (PDA) and secondary pulmonary hypertension with right-to-left to shunting at the great vessel level. Telangiectasias on the lips, tongue, and mucous membranes, as part of the Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia), resemble spider nevi and can be a source of right-to-left shunting when also present in the lung. Malar telangiectasias also are seen in patients with advanced mitral stenosis (MS) or scleroderma. An unusually tan or bronze discoloration of the skin may suggest hemochromatosis as the cause of the associated systolic heart failure. Jaundice, which may be visible first in the sclerae, has a broad differential diagnosis but, in the appropriate setting, can be consistent with advanced right heart failure and congestive hepatomegaly. Various hereditary lipid disorders sometimes are associated with

subcutaneous xanthomas, particularly along the tendon sheaths or over the extensor surfaces of the extremities. Severe hypertriglyceridemia can be associated with eruptive xanthomatosis and lipemia retinalis. Palmar crease xanthomas are specific for type III hyperlipoproteinemia. Pseudoxanthoma elasticum, a disease associated with premature atherosclerosis, is manifested by a leathery, cobblestoned appearance of the skin in the axilla and neck creases and by angioid streaks on funduscopic examination. Extensive lentigenes have been described in a variety of development delay–cardiovascular syndromes, including Carney's syndrome, which includes multiple atrial myxomas. Cutaneous manifestations of sarcoidosis such as lupus pernio and erythema nodosum may suggest this disease as a cause of an associated dilated cardiomyopathy, especially with heart block, intraventricular conduction delay, or ventricular tachycardia.

Head and Neck Dentition and oral hygiene should be assessed in every patient both as a source of potential infection and as an index of general health. A high-arched palate is a feature of Marfan syndrome and other connective tissue disease syndromes. Bifid uvula has been described in patients with Loeys-Dietz syndrome, and orange tonsils are characteristic of Tangier disease. The ocular manifestations of hyperthyroidism have been well described. Many patients with congenital heart disease have associated hypertelorism, low-set ears, or micrognathia. Blue sclerae are a feature of osteogenesis imperfecta. An arcus senilis pattern lacks specificity as an index of coronary heart disease risk. The funduscopic examination is an often-underused method by which to assess the microvasculature, especially among patients with established atherosclerosis, hypertension, or diabetes mellitus. A mydriatic agent may be necessary for optimal visualization. A funduscopic examination should be performed routinely in the assessment of patients with suspected endocarditis and those with a history of acute visual change. Branch retinal artery occlusion or visualization of a Hollenhorst plaque can narrow the differential diagnosis rapidly in the appropriate setting. Relapsing polychondritis may manifest as an inflamed pinna or, in its later stages, as a saddle-nose deformity because of destruction of nasal cartilage; granulomatosis with polyangiitis can also lead to a saddle-nose deformity.

Chest Midline sternotomy, right anterior thoracotomy, left posterolateral thoracotomy, or infraclavicular scars should not be overlooked and may provide the first clue regarding an underlying cardiovascular disorder in patients unable to provide a relevant history. A prominent venous collateral pattern may suggest subclavian or vena caval obstruction. If the head and neck appear dusky and slightly cyanotic and the venous pressure is grossly elevated without visible pulsations, a diagnosis of superior vena cava syndrome should be entertained. Thoracic cage abnormalities have been well described among patients with connective tissue disease syndromes. They include pectus carinatum ("pigeon chest") and pectus excavatum ("funnel chest"). Obstructive lung disease is suggested by a barrel chest deformity, especially with tachypnea, pursed-lip breathing, and use of accessory muscles. The characteristically severe kyphosis and compensatory lumbar, pelvic, and knee flexion of ankylosing spondylitis should prompt careful auscultation for a murmur of aortic regurgitation (AR). Straight back syndrome refers to the loss of the normal kyphosis of the thoracic spine and has been described in patients with mitral valve prolapse (MVP) and its variants. In some patients with cyanotic congenital heart disease, the chest wall appears to be asymmetric, with anterior displacement of the left hemithorax. The respiratory rate and pattern should be noted during spontaneous breathing and sleep, with additional attention to depth, audible wheezing, and stridor. Lung examination can reveal adventitious sounds indicative of pulmonary edema, pneumonia, or pleuritis.

Abdomen In some patients with advanced obstructive lung disease, the point of maximal cardiac impulse may be in the epigastrium. The liver is frequently enlarged and tender in patients with chronic heart failure. Systolic pulsations over the liver signify severe tricuspid regurgitation (TR). Splenomegaly may be a feature of infective endocarditis, particularly when symptoms have persisted for weeks or months. Ascites is a nonspecific finding but may be present with advanced chronic right heart failure, constrictive pericarditis, hepatic cirrhosis, or an intraperitoneal malignancy. The finding of an elevated JVP implies a cardiovascular etiology. In nonobese patients, the aorta typically is palpated between the epigastrium and the umbilicus. The sensitivity of palpation for the detection of an abdominal aortic aneurysm (pulsatile and expansile mass) decreases as a function of body size. Because palpation alone is not sufficiently accurate to establish this diagnosis, a screening ultrasound examination is advised when appropriate. The presence of an arterial bruit over the abdomen suggests high-grade atherosclerotic disease, although precise localization is difficult.

Extremities The temperature and color of the extremities, the presence of clubbing, arachnodactyly, and pertinent nail findings can be surmised quickly during the examination. Clubbing implies the presence of central right-to-left shunting, although it has also been described in patients with endocarditis. Its appearance can range from cyanosis and softening of the root of the nail bed, to the classic loss of the normal angle between the base of the nail and the skin, to the skeletal and periosteal bony changes of hypertrophic osteoarthropathy, which is seen rarely in patients with advanced lung or liver disease. Patients with the Holt-Oram syndrome have an unopposable, "fingerized" thumb, whereas patients with Marfan syndrome may have arachnodactyly and a positive "wrist" (overlapping of the thumb and fifth finger around the wrist) or "thumb" (protrusion of the thumb beyond the ulnar aspect of the hand when the fingers are clenched over the thumb in a fist) sign. The Janeway lesions of endocarditis are nontender, slightly raised hemorrhagic lesions on the palms and soles, whereas Osler's nodes are tender, raised nodules on the pads of the fingers or toes. Splinter hemorrhages are classically identified as linear petechiae in the midposition of the nail bed and should be distinguished from the more common traumatic petechiae, which are seen closer to the distal edge.

Lower extremity or presacral edema in the setting of an elevated JVP defines volume overload and may be a feature of chronic heart failure or constrictive pericarditis. Lower extremity edema in the absence of jugular venous hypertension may be due to profound hypoalbuminemia as seen in nephrotic syndrome or liver failure. Other causes include lymphatic or venous obstruction or, more commonly, venous insufficiency, as would be further suggested by the appearance of varicosities, venous ulcers (typically medial in location), and brownish cutaneous discoloration from hemosiderin deposition (eburnation). Pitting edema can also be seen in patients who use dihydropyridine calcium channel blockers. A Homans' sign (posterior calf pain on active dorsiflexion of the foot against resistance) is neither specific nor sensitive for deep venous thrombosis. Muscular atrophy or the absence of hair along an extremity is consistent with severe arterial insufficiency or a primary neuromuscular disorder.

CARDIOVASCULAR EXAMINATION

Jugular Venous Pressure and Waveform The JVP is the single most important bedside measurement from which to estimate the volume status. The internal jugular vein is preferred because the external jugular vein is valved and not directly in line with the superior vena cava and right atrium. Nevertheless, the external jugular vein has been used to discriminate between high and low central venous pressure (CVP). Precise estimation of the central venous or right atrial pressure from bedside assessment of the jugular venous waveform can be difficult. Venous pressure traditionally has been measured as the vertical distance between the top of the jugular venous pulsation and the sternal inflection point (angle of Louis). A distance >4.5 cm at 30° elevation is considered abnormal. However, the actual distance between the mid-right atrium and the angle of Louis varies considerably as a function of both body size and the patient angle at which the assessment is made (30°, 45°, or 60°). The use of the sternal angle as a reference point leads to systematic underestimation of CVP, and this method should be used less for semiquantification than to distinguish a normal from an elevated CVP. The use of the clavicle may provide an easier reference

for standardization. Venous pulsations above this level in the sitting position are clearly abnormal, as the distance between the clavicle and the right atrium is at least 10 cm. The patient should always be placed in the sitting position, with the legs dangling below the bedside, when an elevated pressure is suspected in the semisupine position. It should also be noted that bedside estimates of CVP are made in centimeters of water, and must be converted to millimeters of mercury to provide correlation with accepted hemodynamic norms (1.36 cmH_2O = 1.0 mmHg).

The venous waveform sometimes can be difficult to distinguish from the carotid pulse, especially during casual inspection. Nevertheless, the venous waveform has several characteristic features, and its individual components can be appreciated in most patients **(Fig. 246-1)**. The arterial pulsation is not easily obliterated with palpation; the venous waveform in patients with sinus rhythm is usually biphasic, while the carotid pulse is monophasic; and the jugular venous pulsation should change with changes in posture or inspiration (unless the venous pressure is quite elevated).

The venous waveform is divided into several distinct peaks. The *a* wave reflects right atrial presystolic contraction and occurs just after the electrocardiographic P wave, preceding the first heart sound (S_1). A prominent *a* wave is seen in patients with reduced right ventricular compliance; a cannon *a* wave occurs with atrioventricular (AV) dissociation and right atrial contraction against a closed tricuspid valve. In a patient with a wide complex tachycardia, the appreciation of cannon *a* waves in the jugular venous waveform identifies the rhythm as ventricular in origin. The *a* wave is not present with atrial fibrillation. The *x* descent defines the fall in right atrial pressure after tricuspid valve opening, and occurs after inscription of the *a* wave. The *c* wave, which occurs as the closed tricuspid valve is pushed into the right atrium during early ventricular systole, interrupts this *x* descent and is followed by a further descent. The *v* wave represents atrial filling (atrial diastole) and occurs during ventricular systole. The height of the *v* wave is determined by right atrial compliance as well as the volume of blood returning to the right atrium either antegrade from the cavae or retrograde through an incompetent tricuspid valve. In patients with TR, the *v* wave is accentuated and the subsequent fall in pressure (*y* descent) is rapid. With progressive degrees of TR, the *v* wave merges with the *c* wave, and the right atrial and jugular vein waveforms become "ventricularized." The *y* descent, which follows the peak of the *v* wave, can become prolonged or blunted with obstruction to right ventricular inflow, as may occur with tricuspid stenosis or pericardial tamponade. Normally, the venous pressure should fall by at least 3 mmHg with inspiration. Kussmaul's sign is defined by either a rise or a lack of fall of the JVP with inspiration and is classically associated with constrictive pericarditis, although it has been reported in patients with restrictive cardiomyopathy, massive pulmonary embolism, right ventricular infarction, and advanced left ventricular (LV) systolic heart failure. It is also a common, isolated finding in patients after cardiac surgery without other hemodynamic abnormalities.

Venous hypertension sometimes can be elicited by passive leg elevation or performance of the abdominojugular reflux maneuver. When these signs are positive, a volume-overloaded state with limited compliance of an overly distended or constricted venous system is present. Abdominojugular reflux is produced with firm and consistent pressure over the upper portion of the abdomen, preferably over the right upper quadrant, for >15 s. A positive response is defined by a sustained rise of >3 cm in the JVP during the application of firm abdominal pressure. The response should be assessed after 10 s of continuous pressure to allow for respiratory artifacts and tensing of the abdominal muscles to subside. Patients must be coached to refrain from breath holding or a Valsalva-like maneuver during the procedure. Performance of the abdominojugular reflux maneuver is useful in predicting a pulmonary artery wedge pressure >15 mmHg in patients with heart failure.

Although the JVP estimates right ventricular filling pressure, it has a predictable relationship with the pulmonary artery wedge pressure. In a large study of patients with advanced heart failure, the presence of a right atrial pressure >10 mmHg (as predicted on bedside examination) had a positive value of 88% for the prediction of a pulmonary artery wedge pressure of >22 mmHg. In addition, an elevated JVP has prognostic significance in patients with both symptomatic heart failure and asymptomatic LV systolic dysfunction. The presence of an elevated JVP is associated with a higher risk of subsequent hospitalization for heart failure, death from heart failure, or both.

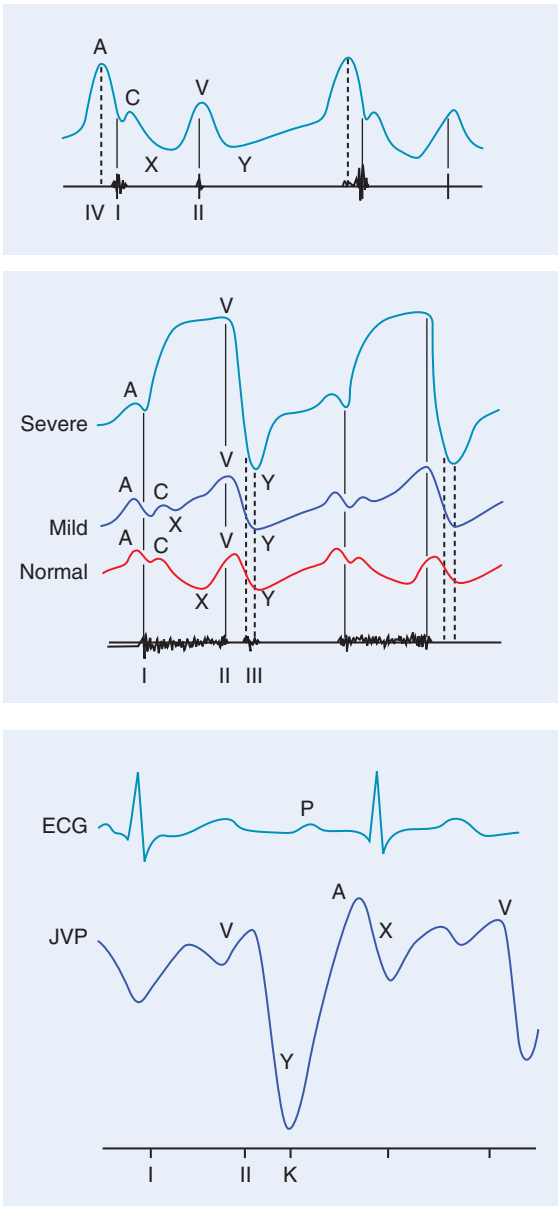

FIGURE 246-1 ***A.*** Jugular venous pulse wave tracing (*top*) with heart sounds (*bottom*) in a patient with reduced right ventricular compliance. The A wave represents right atrial presystolic contraction and occurs just after the electrocardiographic P wave and just before the first heart sound (I). In this example, the A wave is accentuated and larger than normal due to decreased right ventricular compliance, as also suggested by the right-sided S_4 (IV). The C wave may reflect the carotid pulsation in the neck and/or an early systolic increase in right atrial pressure as the right ventricle pushes the closed tricuspid valve into the right atrium. The *x* descent follows the A wave just as atrial pressure continues to fall. The V wave represents atrial filling during ventricular systole and peaks at the second heart sound (II). The *y* descent corresponds to the fall in right atrial pressure after tricuspid valve opening. ***B.*** Jugular venous wave forms in mild (*middle*) and severe (*top*) tricuspid regurgitation, compared with normal (*bottom*), with phonocardiographic representation of the corresponding heart sounds below. With increasing degrees of tricuspid regurgitation, the waveform becomes "ventricularized." ***C.*** Electrocardiogram (ECG) (*top*), jugular venous waveform (JVP) (*middle*), and heart sounds (*bottom*) in pericardial constriction. Note the prominent and rapid *y* descent, corresponding in timing to the pericardial knock (K). *(Reproduced with permission from J Abrams: Synopsis of Cardiac Physical Diagnosis, 2nd ed. Boston, Butterworth Heinemann, 2001.)*

Assessment of Blood Pressure Measurement of blood pressure usually is delegated to a medical assistant but should be repeated by the examining clinician. Accurate measurement depends on body position, arm size, time of measurement, place of measurement, type of device, device size, technique, and examiner. In general, physician-recorded blood pressures are higher than both nurse-recorded pressures and self-recorded pressures at home. Blood pressure is best measured in the seated position with the arm at the level of the heart and the feet on the floor with the back supported, using an appropriately sized cuff, after 5–10 min of relaxation. When it is measured in the supine position, the arm should be raised to bring it to the level of the mid-right atrium. The length and width of the blood pressure cuff bladder should be 80 and 40% of the arm's circumference, respectively. A common source of error in practice is to use an inappropriately small cuff, resulting in marked overestimation of true blood pressure, or an inappropriately large cuff, resulting in underestimation of true blood pressure. The cuff should be inflated to 30 mmHg above the expected systolic pressure and the pressure released at a rate of 2–3 mmHg/s. Systolic and diastolic pressures are defined by the first and fifth Korotkoff sounds, respectively. Very low (even 0 mmHg) diastolic blood pressures may be recorded in patients with chronic, severe AR or a large arteriovenous fistula because of enhanced diastolic "run-off." In these instances, both the phase IV and phase V Korotkoff sounds should be recorded. Blood pressure is best assessed at the brachial artery level, though it can be measured at the radial, popliteal, or pedal artery level. In general, systolic pressure increases and diastolic pressure decreases when measured in more distal arteries. Blood pressure should be measured in both arms, and the difference should be <10 mmHg. A blood pressure differential that exceeds this threshold may be associated with atherosclerotic or inflammatory subclavian artery disease, supravalvular aortic stenosis, aortic coarctation, or aortic dissection. Systolic leg pressures are usually as much as 20 mmHg higher than systolic arm pressures. Greater leg–arm pressure differences are seen in patients with chronic severe AR as well as patients with extensive and calcified lower extremity peripheral arterial disease. The ankle-brachial index (systolic pressure in the dorsalis pedis and/or posterior tibial artery divided by the higher of the two brachial artery pressures) is a powerful predictor of long-term cardiovascular mortality.

The blood pressure measured in an office or hospital setting may not accurately reflect the pressure in other venues. "White coat hypertension" (elevated clinic blood pressure and normal out of clinic blood pressure) is defined by at least three separate clinic-based measurements >130/80 mmHg and at least two non-clinic-based measurements <130/80 mmHg in the absence of any evidence of target organ damage. Individuals with white coat hypertension may not benefit from drug therapy, although they may be more likely to develop sustained hypertension over time. Masked hypertension (normal or low clinic blood pressure but elevated out of clinic blood pressure) should be suspected when normal or even low blood pressures are recorded in the office in patients with advanced atherosclerotic disease, especially when evidence of target organ damage is present or bruits are audible. Higher systolic blood pressures measured with a 24-h ambulatory blood pressure device are associated with a higher risk of cardiovascular disease and all-cause death independent of blood pressures measured in the outpatient setting.

Orthostatic hypotension is defined by a fall in systolic pressure >20 mmHg or in diastolic pressure >10 mmHg within 3 minutes of assumption of the upright posture from a supine position. There may also be a lack of a compensatory tachycardia, an abnormal response that suggests autonomic insufficiency, as may be seen in patients with diabetes mellitus or Parkinson's disease. Orthostatic hypotension is a common cause of postural lightheadedness/syncope and should be assessed routinely in patients for whom this diagnosis might pertain. It can be exacerbated by advanced age, dehydration, certain medications, food, deconditioning, and ambient temperature/humidity.

Arterial Pulse The carotid artery pulse occurs just after the ascending aortic pulse. The aortic pulse is best appreciated in the epigastrium, just above the level of the umbilicus. Peripheral arterial pulses that should be assessed routinely include the subclavian, brachial, radial, ulnar, femoral, popliteal, dorsalis pedis, and posterior tibial. In patients in whom the diagnosis of either temporal arteritis or polymyalgia rheumatica is suspected, the temporal arteries also should be examined. Although one of the two pedal pulses may not be palpable in up to 10% of normal subjects, the pair should be symmetric. The integrity of the arcuate system of the hand is assessed by Allen's test, which is performed routinely before instrumentation of the radial artery. The pulses should be examined for their symmetry, volume, timing, contour, amplitude, and duration. If necessary, simultaneous auscultation of the heart can help identify a delay in the arrival of an arterial pulse. Simultaneous palpation of the radial and femoral pulses may reveal a femoral delay in a patient with upper extremity hypertension and suspected aortic coarctation. The carotid upstrokes should never be examined simultaneously or before listening for a bruit. Light pressure should always be used to avoid precipitation of carotid hypersensitivity syndrome and syncope in a susceptible elderly individual. The arterial pulse usually becomes more rapid and spiking as a function of its distance from the heart, a phenomenon that reflects the muscular status of the more peripheral arteries and the summation of the incident and reflected waves. In general, the character and contour of the arterial pulse depend on the stroke volume, ejection velocity, vascular compliance, and systemic vascular resistance. The pulse examination can be misleading in patients with reduced cardiac output and in those with stiffened arteries from aging, chronic hypertension, or peripheral arterial disease.

The character of the pulse is best appreciated at the carotid level (Fig. 246-2). A weak and delayed pulse (*pulsus parvus et tardus*) defines severe aortic stenosis (AS). Some patients with AS may also have a slow, notched, or interrupted upstroke (anacrotic pulse) with a thrill

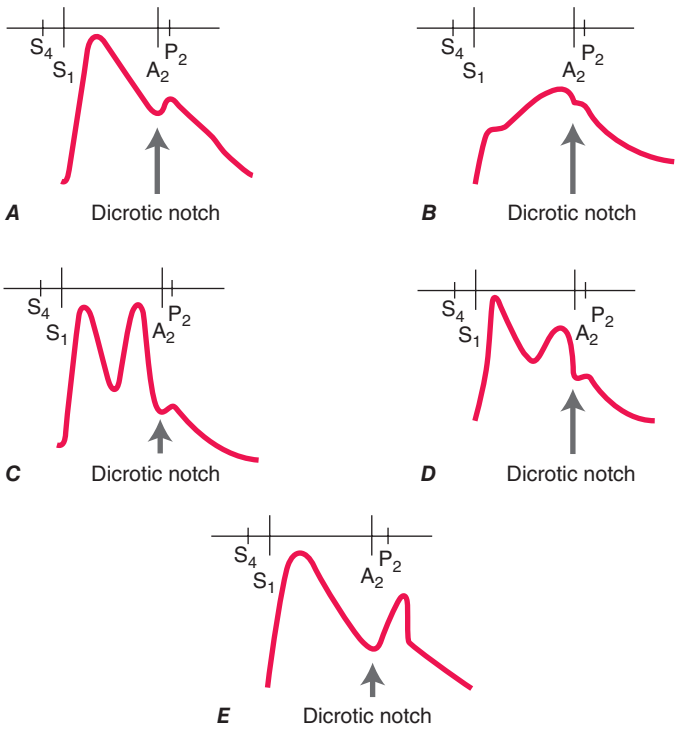

FIGURE 246-2 Schematic diagrams of the configurational changes in carotid pulse and their differential diagnoses. Heart sounds are also illustrated. ***A.*** Normal. S_4, fourth heart sound; S_1, first heart sound; A_2, aortic component of second heart sound; P_2, pulmonic component of second heart sound. ***B.*** Aortic stenosis. Anacrotic pulse with slow upstroke (tardus) to a reduced peak (parvus). ***C.*** Bisferiens pulse with two peaks in systole. This pulse is rarely appreciated in patients with severe aortic regurgitation. ***D.*** Bisferiens pulse in hypertrophic obstructive cardiomyopathy. There is a rapid upstroke to the first peak (percussion wave) and a slower rise to the second peak (tidal wave). ***E.*** Dicrotic pulse with peaks in systole and diastole. This waveform may be seen in patients with sepsis or during intraaortic balloon counterpulsation with inflation just after the dicrotic notch. *(Reproduced with permission from K Chatterjee, W Parmley [eds]: Cardiology: An Illustrated Text/Reference. Philadelphia, Gower Medical Publishers, 1991.)*

or shudder. With chronic severe AR, by contrast, the carotid upstroke has a sharp rise and rapid fall-off (Corrigan's or water-hammer pulse). Some patients with advanced AR may have a bifid or bisferiens pulse, in which two systolic peaks can be appreciated. A bifid pulse is also described in patients with hypertrophic obstructive cardiomyopathy (HOCM), with inscription of percussion and tidal waves. A bifid pulse is easily appreciated in patients on intraaortic balloon counterpulsation (IABP), in whom the second pulse is diastolic in timing.

Pulsus paradoxus refers to a fall in systolic pressure >10 mmHg with inspiration that is seen in patients with pericardial tamponade but also is described in those with massive pulmonary embolism, hemorrhagic shock, severe obstructive lung disease, and tension pneumothorax. Pulsus paradoxus is measured by noting the difference between the systolic pressure at which the Korotkoff sounds are first heard (during expiration) and the systolic pressure at which the Korotkoff sounds are heard with each heartbeat, independent of the respiratory phase. Between these two pressures, the Korotkoff sounds are heard only intermittently and during expiration. The cuff pressure must be decreased slowly to appreciate the finding. It can be difficult to measure pulsus paradoxus in patients with tachycardia, atrial fibrillation, or tachypnea. A pulsus paradoxus may be palpable at the brachial artery or femoral artery level when the pressure difference exceeds 15 mmHg. This inspiratory fall in systolic pressure is an exaggerated consequence of interventricular dependence.

Pulsus alternans, in contrast, is defined by beat-to-beat variability of pulse amplitude. It is present only when every other phase I Korotkoff sound is audible as the cuff pressure is lowered slowly, typically in a patient with a regular heart rhythm and independent of the respiratory cycle. Pulsus alternans is seen in patients with severe LV systolic dysfunction and is thought to be due to cyclic changes in intracellular calcium and action potential duration. When pulsus alternans is associated with electrocardiographic T-wave alternans, the risk for an arrhythmic event appears to be increased.

Ascending aortic aneurysms can rarely be appreciated as a pulsatile mass in the right parasternal area. Appreciation of a prominent abdominal aortic pulse should prompt noninvasive imaging with ultrasound or computed tomography for better characterization. Femoral and/or popliteal artery aneurysms should be sought in patients with abdominal aortic aneurysm disease.

The level of a claudication-producing arterial obstruction can often be identified on physical examination **(Fig. 246-3)**. For example, in a patient with calf claudication, a decrease in pulse amplitude between the common femoral and popliteal arteries will localize the obstruction to the level of the superficial femoral artery, although inflow obstruction above the level of the common femoral artery may coexist. Auscultation for carotid, subclavian, abdominal aortic, and femoral artery bruits should be routine. However, the correlation between the presence of a bruit and the degree of vascular obstruction is poor. A cervical bruit is a weak indicator of the degree of carotid artery stenosis; the absence of a bruit does not exclude the presence of significant luminal obstruction. If a bruit extends into diastole or if a thrill is present, the obstruction is usually severe. Another cause of an arterial bruit is an arteriovenous fistula with enhanced flow.

The likelihood of significant lower extremity peripheral arterial disease increases with typical symptoms of claudication, cool skin, abnormalities on pulse examination, or the presence of a vascular bruit. Abnormal pulse oximetry (a >2% difference between finger and toe oxygen saturation) can be used to detect lower extremity peripheral

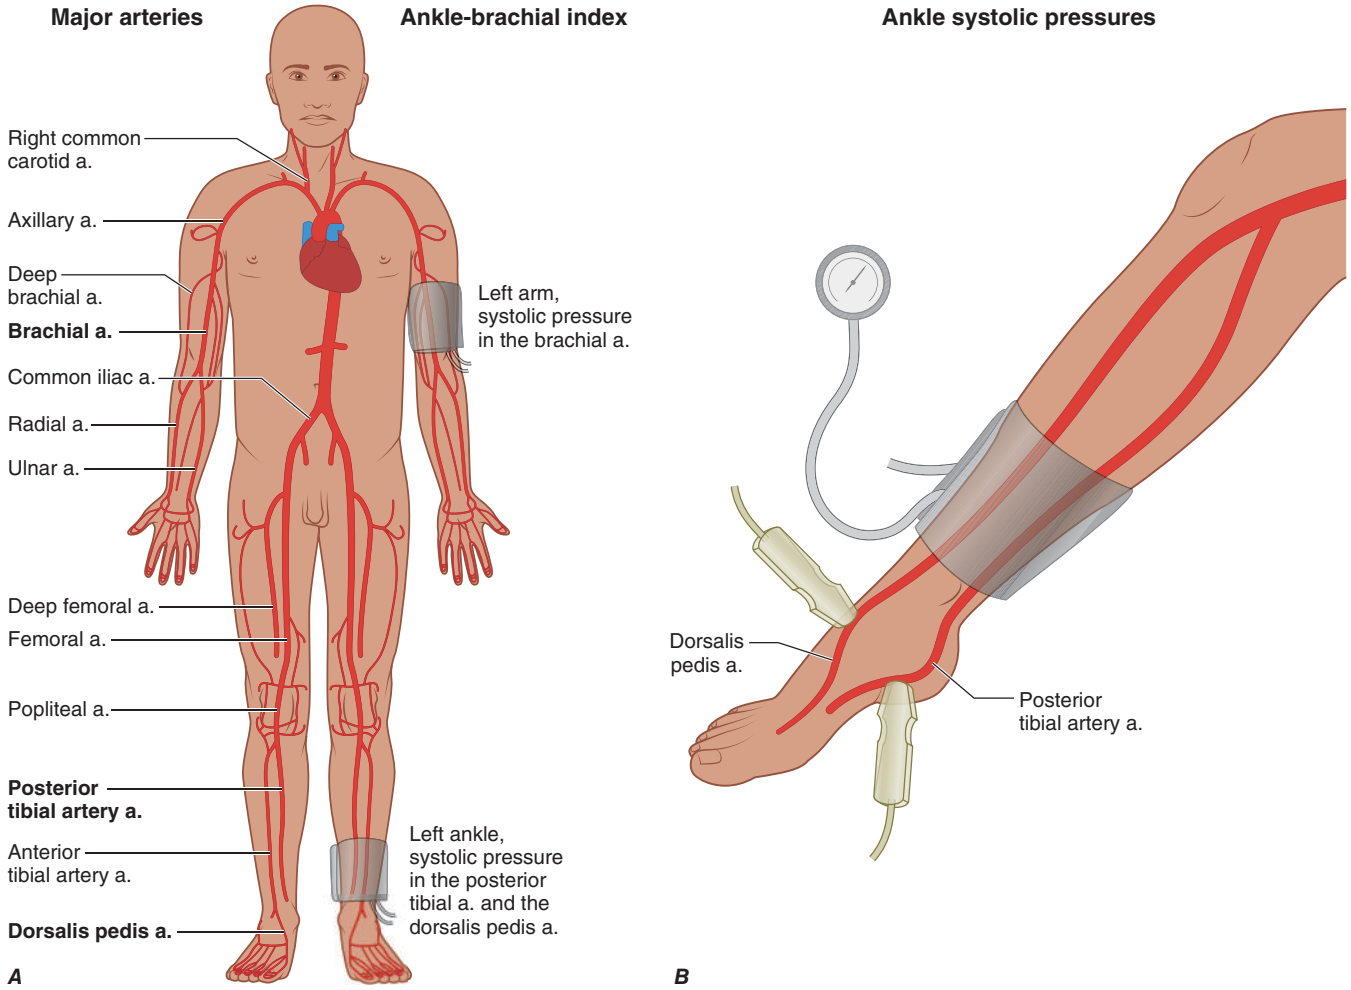

FIGURE 246-3 ***A.*** Anatomy of the major arteries of the leg. ***B.*** Measurement of the ankle systolic pressure. The ankle-brachial index (ABI) is calculated by dividing the lower of the two ankle pressures (i.e., the dorsalis pedis or posterior tibia) by the higher of the two arm pressures (i.e., left or right arm). Left and right ABIs should be recorded. *(Adapted from NA Khan et al: Does the clinical examination predict lower extremity peripheral arterial disease? JAMA 295:536, 2006.)*

arterial disease and is comparable in its performance characteristics to the ankle-brachial index.

Inspection and Palpation of the Heart The LV apex beat may be visible in the midclavicular line at the fifth intercostal space in thin-chested adults. Visible pulsations anywhere other than this expected location are abnormal. The left anterior chest wall may heave in patients with an enlarged or hyperdynamic left or right ventricle. As noted previously, a visible right upper parasternal pulsation may be suggestive of ascending aortic aneurysm disease. In thin, tall patients and patients with advanced obstructive lung disease and flattened diaphragms, the cardiac impulse may be visible in the epigastrium and should be distinguished from a pulsatile liver edge.

Palpation of the heart begins with the patient in the supine position at 30° and can be enhanced by placing the patient in the left lateral decubitus position. The normal LV impulse is <2 cm in diameter and moves quickly away from the fingers; it is better appreciated at end expiration, with the heart closer to the anterior chest wall. Characteristics such as size, amplitude, and rate of force development should be noted.

Enlargement of the LV cavity is manifested by a leftward and downward displacement of an enlarged apex beat. A sustained apex beat is a sign of pressure overload, such as that which may be present in patients with AS or chronic hypertension. A palpable presystolic impulse corresponds to the fourth heart sound (S_4) and is indicative of reduced LV compliance and the forceful contribution of atrial contraction to ventricular filling. A palpable third sound (S_3), which is indicative of a rapid early filling wave in patients with heart failure, may be present even when the gallop itself is not audible. A large LV aneurysm may sometimes be palpable as an ectopic impulse, discrete from the apex beat and often dyskinetic. HOCM may very rarely cause a triple cadence beat at the apex with contributions from a palpable S_4 and the two components of the bisferiens systolic pulse.

Right ventricular pressure or volume overload may create a sternal lift. Signs of either TR (*cv* waves in the jugular venous pulse) and/or pulmonary arterial hypertension (a loud single or palpable P_2) would be confirmatory. The right ventricle can enlarge to the extent that left-sided events are obscured. A zone of retraction between the right ventricular and LV impulses sometimes can be appreciated in patients with right ventricle pressure or volume overload when they are placed in the left lateral decubitus position. Systolic and diastolic thrills signify turbulent and high-velocity blood flow. Their locations help identify the origin of heart murmurs.

CARDIAC AUSCULTATION

Heart Sounds Ventricular systole is defined by the interval between the first (S_1) and second (S_2) heart sounds **(Fig. 246-4)**. The first heart sound (S_1) includes mitral and tricuspid valve closure. Normal splitting can be appreciated in young patients and those with right bundle branch block, in whom tricuspid valve closure is relatively delayed. The intensity of S_1 is determined by the distance over which the anterior leaflet of the mitral valve must travel to return to its annular plane, leaflet mobility, LV contractility, and the PR interval. S_1 is classically loud in the early phases of rheumatic MS and in patients with hyperkinetic circulatory states or short PR intervals. S_1 becomes softer in the later stages of MS when the leaflets are rigid and calcified, after exposure to β-adrenergic receptor blockers, with long PR intervals, and with LV contractile dysfunction. The intensity of heart sounds, however, can be reduced by any process that increases the distance between the stethoscope and the responsible cardiac event, including mechanical ventilation, obstructive lung disease, obesity, pneumothorax, and a pericardial effusion.

Aortic and pulmonic valve closure constitutes the second heart sound (S_2). With normal or physiologic splitting, the A_2–P_2 interval increases with inspiration and narrows during expiration. This physiologic interval will widen with right bundle branch block because of the further delay in pulmonic valve closure and in patients with severe MR because of the premature closure of the aortic valve. An unusually narrowly split or even a singular S_2 is a feature of pulmonary arterial hypertension. Fixed splitting of S_2, in which the A_2–P_2 interval is wide and does not change during the respiratory cycle, occurs in patients with a secundum atrial septal defect (ASD). Reversed or paradoxical splitting refers to a pathologic delay in aortic valve closure, such as that which occurs in patients with left bundle branch block, right ventricular pacing, severe AS, HOCM, and acute myocardial ischemia. With reversed or paradoxical splitting, the individual components of S_2 are audible at end expiration, and their interval narrows with inspiration, the opposite of what would be expected under normal physiologic conditions. P_2 is considered loud when its intensity exceeds that of A_2 at the base, when it can be palpated in the area of the proximal main pulmonary artery (second left interspace), or when both components of S_2 can be appreciated at the lower left sternal border or apex. The intensity of A_2 and P_2 decreases with AS and pulmonic stenosis (PS), respectively. In these conditions, a single S_2 may result.

Systolic Sounds An ejection sound is a high-pitched early systolic sound that corresponds in timing to the upstroke of the carotid pulse. It usually is associated with congenital bicuspid aortic or pulmonic valve disease; however, ejection sounds are also sometimes audible in patients with isolated aortic or pulmonary root dilation and normal semilunar valves. The ejection sound that accompanies bicuspid aortic valve disease becomes softer and then inaudible as the valve calcifies and becomes more rigid. The ejection sound that accompanies PS moves closer to the first heart sound as the severity of the stenosis increases. In addition, the pulmonic ejection sound is the only right-sided acoustic event that *decreases* in intensity with inspiration. Ejection sounds are often heard more easily at the lower left sternal border than they are at the base. Nonejection sounds (clicks), which occur after the onset of the carotid upstroke, are related to MVP and may be single or multiple. The nonejection click may introduce a murmur. This click-murmur complex will move away from the first heart sound with maneuvers that increase ventricular preload, such as squatting. On standing, the click and murmur move closer to S_1.

Diastolic Sounds The high-pitched opening snap (OS) of MS occurs after a very short interval after the second heart sound. The A_2–OS interval is inversely proportional to the height of the left atrial–left ventricular diastolic pressure gradient. The intensity of both S_1 and the OS of MS decreases with progressive calcification and rigidity of the anterior mitral leaflets. The pericardial knock (PK) is also high-pitched and occurs slightly later than the OS, corresponding in timing to the abrupt cessation of ventricular expansion after tricuspid valve opening and to an exaggerated *y* descent seen in the jugular venous waveform in patients with constrictive pericarditis. A tumor plop is a lower-pitched sound that rarely can be heard in patients with atrial myxoma. It may be appreciated only in certain positions and arises from the diastolic prolapse of the tumor across the mitral valve.

The third heart sound (S_3) occurs during the rapid filling phase of ventricular diastole. It can be a normal finding in children, adolescents, and young adults; however, in older patients, it signifies heart failure. A left-sided S_3 is a low-pitched sound best heard over the LV apex. A right-sided S_3 is usually better heard over the lower left sternal border and becomes louder with inspiration. A left-sided S_3 in patients with chronic heart failure is predictive of cardiovascular morbidity and mortality. Interestingly, an S_3 is equally prevalent among heart failure patients with preserved and reduced LV ejection fraction.

The fourth heart sound (S_4) occurs during the atrial filling phase of ventricular diastole and indicates LV presystolic expansion. An S_4 is more common among patients who derive significant benefit from the atrial contribution to ventricular filling, such as those with chronic LV hypertrophy or active myocardial ischemia. An S_4 is not present with atrial fibrillation.

Cardiac Murmurs Heart murmurs result from audible vibrations that are caused by increased turbulence and are defined by their timing within the cardiac cycle. Not all murmurs are indicative of structural heart disease, and the accurate identification of a benign or functional systolic murmur often can obviate the need for additional testing in healthy subjects, especially children and adolescents. The duration, frequency, configuration, and intensity of a heart murmur are dictated by the magnitude, variability, and duration of the responsible pressure difference between two cardiac chambers, the two ventricles, or the ventricles and their respective great arteries. The intensity of a heart murmur is graded on a scale of 1 to 6; a thrill is present with murmurs of grade 4 or greater intensity. Other attributes of the murmur that aid in its accurate identification include its location, radiation, and response to bedside maneuvers. Although clinicians can detect and correctly identify heart murmurs with only fair reliability, a careful and complete bedside examination usually can identify individuals with valvular heart disease for whom transthoracic echocardiography and clinical follow-up are indicated and exclude subjects for whom no further evaluation is necessary.

Systolic murmurs can be early, mid, late, or holosystolic in timing **(Fig. 246-5)**. Acute severe MR results in a decrescendo early systolic murmur, the characteristics of which are related to the progressive attenuation of the LV to left atrial pressure gradient during systole because of the steep and rapid rise in left atrial pressure in this context. Severe MR associated with posterior leaflet prolapse or flail radiates anteriorly and to the base, where it can be confused with the murmur of AS. MR that is due to anterior leaflet involvement radiates posteriorly and to the axilla. With acute TR in patients with normal pulmonary artery pressures, an early systolic murmur that may increase in intensity with inspiration may be heard at the left lower sternal border, with regurgitant *cv* waves visible in the jugular venous pulse.

A midsystolic murmur begins after S_1 and ends before S_2; it is typically crescendo-decrescendo in configuration. AS is the most common cause of a midsystolic murmur in an adult. It is often difficult to estimate the severity of the valve lesion on the basis of the physical examination findings, especially in older hypertensive patients with stiffened carotid arteries or patients with low cardiac output in whom the intensity of the systolic heart murmur is misleadingly soft. Examination findings consistent with severe AS would include *parvus et tardus* carotid upstrokes, a late-peaking grade 3 or greater midsystolic murmur, a soft A_2, a sustained LV apical impulse, and an S_4. It is sometimes difficult to distinguish aortic sclerosis from more advanced degrees of valve stenosis. The former is defined by focal thickening and calcification of the aortic valve leaflets that is not severe enough to result in obstruction. These valve changes are associated with a Doppler jet velocity across the aortic valve of 2.5 m/s or less. Patients with aortic sclerosis can have grade 2 or 3 midsystolic murmurs identical in their acoustic characteristics to the murmurs heard in patients with more advanced degrees of AS. Other causes of a midsystolic heart murmur include pulmonic valve stenosis (with or without an ejection sound), HOCM, increased pulmonary blood flow in patients with a large ASD and left-to-right shunting, and several states associated with accelerated blood flow in the absence of structural heart disease, such as fever, thyrotoxicosis, pregnancy, anemia, and normal childhood/adolescence.

The murmur of HOCM has features of both obstruction to LV outflow and MR, as would be expected from knowledge of the pathophysiology of this condition. The systolic murmur of HOCM usually can be distinguished from other causes on the basis of its response to bedside maneuvers, including Valsalva, passive leg raising, and standing/squatting. In general, maneuvers that decrease LV preload (or increase LV contractility) will cause the murmur to intensify, whereas maneuvers that increase LV preload or afterload will cause a decrease in the intensity of the murmur. Accordingly, the systolic murmur of HOCM becomes louder during the strain phase of the Valsalva maneuver and after standing quickly from a squatting position. The murmur becomes softer with passive leg raising and when squatting. The murmur of AS is typically loudest in the second right interspace with radiation into the carotids, whereas the murmur of HOCM is best heard between the lower left sternal border and the apex. The murmur of PS is best heard in the second left interspace. The midsystolic murmur associated with enhanced pulmonic blood flow in the setting of a large ASD is usually loudest at the mid-left sternal border.

A late systolic murmur, heard best at the apex, indicates MVP. As previously noted, the murmur may or may not be introduced by one or more nonejection clicks. Differential radiation of the murmur, as previously described, may help identify the specific leaflet involved by the myxomatous process. The click-murmur complex behaves in a manner directionally similar to that demonstrated by the murmur of HOCM during the Valsalva and stand/squat maneuvers **(Fig. 246-6)**. The murmur of MVP can be identified by the accompanying nonejection click.

Holosystolic murmurs are plateau in configuration and reflect a continuous and wide pressure gradient between the left ventricle and left atrium with chronic MR, the left ventricle and right ventricle with a ventricular septal defect (VSD), and the right ventricle and right atrium with TR. In contrast to acute MR, in chronic MR, the left atrium is enlarged and its compliance is normal or increased to the extent that there is little if any further increase in left atrial pressure from any increase in regurgitant volume. The murmur of MR is best heard over the cardiac apex. The intensity of the murmur increases with maneuvers that increase LV afterload, such as sustained hand grip. The murmur of a VSD (without significant pulmonary hypertension) is holosystolic and loudest at the mid-left sternal border, where a thrill is usually present. The murmur of TR is loudest at the lower left sternal border, increases in intensity with inspiration (Carvallo's sign), and is accompanied by visible *cv* waves in the jugular venous wave form and, on occasion, by pulsatile hepatomegaly.

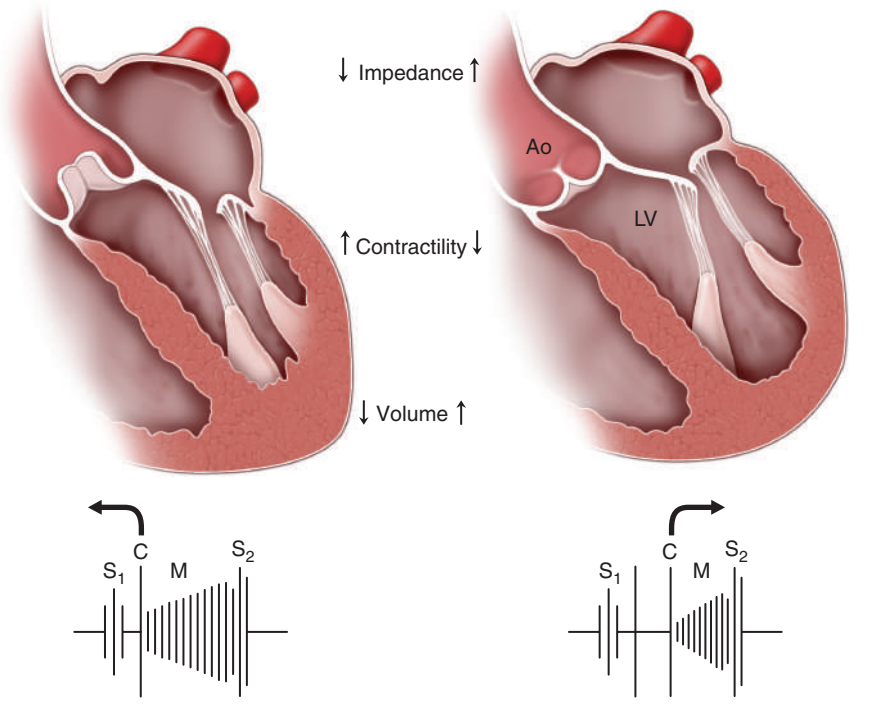

FIGURE 246-6 Behavior of the click (C) and murmur (M) of mitral valve prolapse with changes in loading (volume, impedance) and contractility. S_1, first heart sound; S_2, second heart sound. With standing (left side of figure), volume and impedance decrease, as a result of which the click and murmur move closer to S_1. With squatting (right), the click and murmur move away from S_1 due to the increases in left ventricular volume and impedance (afterload). Ao, aorta; LV, left ventricle. *(Adapted from RA O'Rourke, MH Crawford: Curr Prob Cardiol 1:9, 1976.)*

Diastolic Murmurs In contrast to some systolic murmurs, diastolic heart murmurs always signify structural heart disease (Fig. 246-5). The murmur associated with acute, severe AR is relatively soft and of short duration because of the rapid rise in LV diastolic pressure and the progressive diminution of the aortic-LV diastolic pressure gradient. In contrast, the murmur of chronic severe AR is classically heard as a decrescendo, blowing diastolic murmur along the left sternal border in patients with primary valve pathology and sometimes along the right sternal border in patients with primary aortic root pathology. When the jet of AR is directed posteriorly along the anterior leaflet of the mitral valve, the intensity of the murmur may be attenuated, and severity of the valve lesion underestimated. Detection of subtle AR murmurs can be enhanced by auscultation and end-expiration with the patient leaning forward. With chronic, severe AR, the pulse pressure is wide and the arterial pulses are bounding in character. Signs of significant diastolic run-off are often absent in the acute phase. The murmur of pulmonic regurgitation is also heard along the left sternal border. It is most commonly due to pulmonary hypertension and enlargement of the annulus of the pulmonic valve. S_2 is single and loud and may be palpable. There is a right ventricular/parasternal lift that is indicative of chronic right ventricular pressure overload. A less impressive murmur of PR is present after repair of tetralogy of Fallot or pulmonic valve atresia. In this postoperative setting, the murmur is softer and lower-pitched, and the severity of the accompanying pulmonic regurgitation can be underestimated significantly.

MS is the classic cause of a mid- to late-diastolic murmur, which is best heard over the apex in the left lateral decubitus position, is low-pitched or rumbling, and is introduced by an OS in the early stages of the rheumatic disease process. Presystolic accentuation refers to an increase in the intensity of the murmur just before the first heart sound and occurs in patients with sinus rhythm. It is absent in patients with atrial fibrillation. The auscultatory findings in patients with rheumatic tricuspid stenosis typically are obscured by left-sided events, although they are similar in nature to those described in patients with MS. "Functional" mitral or tricuspid stenosis refers to the generation of mid-diastolic murmurs that are created by increased and accelerated transvalvular diastolic flow, even in the absence of valvular obstruction, in the setting of severe MR, severe TR, or a large ASD with left-to-right shunting. The Austin Flint murmur of chronic severe AR is a low-pitched mid- to late apical diastolic murmur that sometimes can be confused with MS. The Austin Flint murmur typically decreases in intensity after exposure to vasodilators, whereas the murmur of MS may be accompanied by an OS and also may increase in intensity after vasodilators because of the associated increase in cardiac output. Unusual causes of a mid-diastolic murmur include atrial myxoma, complete heart block, and acute rheumatic mitral valvulitis.

Continuous Murmur A continuous murmur is predicated on a pressure gradient that persists between two cardiac chambers or blood vessels across systole and diastole. The murmurs typically begin in systole, envelop the second heart sound (S_2), and continue through some portion of diastole. They can often be difficult to distinguish from individual systolic and diastolic murmurs in patients with mixed valvular heart disease. The classic example of a continuous murmur is that associated with a PDA, which usually is heard in the second or third interspace at a slight distance from the sternal border. Other causes of a continuous murmur include a ruptured sinus of Valsalva aneurysm with creation of an aortic–right atrial or right ventricular fistula, a coronary or great vessel arteriovenous fistula, and an arteriovenous fistula constructed to provide dialysis access. There are two types of benign continuous murmurs. The cervical venous hum is heard in children or adolescents in the supraclavicular fossa. It can be obliterated with firm pressure applied to the diaphragm of the stethoscope, especially when the subject turns their head toward the examiner. The mammary soufflé of pregnancy relates to enhanced arterial blood flow through engorged breasts. The diastolic component of the murmur can be obliterated with firm pressure over the stethoscope.

TABLE 246-1 Effects of Physiologic Interventions on the Intensity of Heart Murmurs and Sounds

Respiration
Right-sided murmurs and sounds generally increase with inspiration, except for the PES. Left-sided murmurs and sounds are usually louder during expiration.
Valsalva Maneuver
Most murmurs decrease in length and intensity. Two exceptions are the systolic murmur of HOCM, which usually becomes much louder, and that of MVP, which becomes longer and often louder. After release of the Valsalva maneuver, right-sided murmurs tend to return to control intensity earlier than do left-sided murmurs.
After VPB or AF
Murmurs originating at normal or stenotic semilunar valves increase in the cardiac cycle after a VPB or in the cycle after a long cycle length in AF. By contrast, systolic murmurs due to AV valve regurgitation do not change or become shorter (MVP).
Positional Changes
With *standing*, most murmurs diminish, with two exceptions being the murmur of HOCM, which becomes louder, and that of MVP, which lengthens and often is intensified. With *squatting*, most murmurs become louder, but those of HOCM and MVP usually soften and may disappear. Passive leg raising usually produces the same results.
Exercise
Murmurs due to blood flow across normal or obstructed valves (e.g., PS, MS) become louder with both isotonic and submaximal isometric (hand grip) exercise. Murmurs of MR, VSD, and AR also increase with hand grip exercise. However, the murmur of HOCM often decreases with nearly maximum hand grip exercise. Left-sided S_4 and S_3 sounds are often accentuated by exercise, particularly when due to ischemic heart disease.

Abbreviations: AF, atrial fibrillation; AR, aortic regurgitation; HOCM, hypertrophic obstructive cardiomyopathy; MR, mitral regurgitation; MS, mitral stenosis; MVP, mitral valve prolapse; PES, pulmonic ejection sound; PR, pulmonic regurgitation; PS, pulmonic stenosis; TR, tricuspid regurgitation; TS, tricuspid stenosis; VPB, ventricular premature beat; VSD, ventricular septal defect.

Dynamic Auscultation Diagnostic accuracy can be enhanced by the performance of simple bedside maneuvers to identify heart murmurs and characterize their significance **(Table 246-1)**. Except for the pulmonic ejection sound, right-sided events increase in intensity with inspiration and decrease with expiration; left-sided events behave oppositely (100% sensitivity, 88% specificity). As previously noted, the intensity of the murmurs associated with MR, VSD, and AR will increase in response to maneuvers that increase LV afterload, such as hand grip and vasopressors. The intensity of these murmurs will decrease after exposure to vasodilating agents. Squatting is associated with an abrupt increase in LV preload and afterload, whereas rapid standing results in a sudden decrease in preload. In patients with MVP, the click and murmur move away from the first heart sound with squatting because of the delay in onset of leaflet prolapse at higher ventricular volumes. With rapid standing, however, the click and murmur move closer to the first heart sound as prolapse occurs earlier in systole at a smaller chamber dimension. The murmur of HOCM behaves similarly, becoming softer and shorter with squatting (95% sensitivity, 85% specificity) and longer and louder on rapid standing (95% sensitivity, 84% specificity). A change in the intensity of a systolic murmur in the first beat after a premature beat or in the beat after a long cycle length in patients with atrial fibrillation suggests valvular AS rather than MR, particularly in an older patient in whom the murmur of the AS may be well transmitted to the apex (Gallavardin effect). Of note, however, the systolic murmur of HOCM also increases in intensity in the beat after a premature beat. This increase in intensity of any LV outflow murmur in the beat after a premature beat relates to the combined effects of enhanced LV filling (from the longer diastolic period) and postextrasystolic potentiation of LV contractile function. In either instance, forward flow will accelerate, causing an increase in the gradient across the LV outflow tract (dynamic or fixed) and a louder systolic murmur. In contrast, the intensity of the murmur of MR does not change in a postpremature beat, because there is relatively little change in the nearly constant LV to left atrial pressure gradient or further alteration in mitral valve flow. Bedside exercise can sometimes be performed to increase cardiac output and, secondarily, the intensity of both systolic and diastolic heart murmurs. Most left-sided heart murmurs decrease in intensity and duration during the strain phase of the Valsalva maneuver. The murmurs associated with MVP and HOCM are the two notable exceptions. The Valsalva maneuver also can be used to assess the integrity of the heart and vasculature in the setting of advanced heart failure.

Prosthetic Heart Valves The first clue that prosthetic valve dysfunction may contribute to recurrent symptoms is frequently a change in the quality of the heart sounds or the appearance of a new murmur. The heart sounds with a bioprosthetic valve resemble those generated by native valves. A mitral bioprosthesis usually may be associated with a grade 1 to 2 midsystolic murmur along the left sternal border (created by turbulence across the valve struts as they project into the LV outflow tract) as well as by a soft mid-diastolic murmur that occurs with normal LV filling. This diastolic murmur often can be heard only in the left lateral decubitus position and after exercise. A high-pitched or holosystolic apical murmur is indicative of pathologic MR due to a paravalvular leak and/or intra-annular bioprosthetic regurgitation from leaflet degeneration, for which diagnostic noninvasive imaging is indicated. Clinical deterioration can occur rapidly after the first expression of mitral bioprosthetic valve failure. A tissue valve in the aortic position is always associated with a grade 1 to 3 midsystolic murmur at the base or just below the suprasternal notch. A diastolic murmur of AR is abnormal in any circumstance. Mechanical valve dysfunction may first be suggested by a decrease in the intensity of either the opening or the closing sound. A high-pitched apical systolic murmur in patients with a mechanical mitral prosthesis and a diastolic decrescendo murmur in patients with a mechanical aortic prosthesis indicate paravalvular regurgitation. Patients with prosthetic valve thrombosis may present clinically with signs of shock, muffled heart sounds, and soft murmurs in both systole and diastole.

Pericardial Disease A pericardial friction rub is nearly 100% specific for the diagnosis of acute pericarditis, although the sensitivity of this finding is not nearly as high, because the rub may come and go over the course of an acute illness or be very difficult to elicit. The rub is heard as a leathery or scratchy three-component or two-component sound, although it may be monophasic. Classically, the three components are ventricular systole, rapid early diastolic filling, and late presystolic filling after atrial contraction in patients in sinus rhythm. It is necessary to listen to the heart in several positions. Additional clues to the presence of acute pericarditis may be present from the history and 12-lead electrocardiogram. The rub typically disappears as the volume of any pericardial effusion increases. Pericardial tamponade can be diagnosed with a sensitivity of 98%, a specificity of 83%, and a positive likelihood ratio of 5.9 (95% confidence interval 2.4–14) by a pulsus paradoxus that exceeds 12 mmHg in a patient with a large pericardial effusion.

The findings on physical examination are integrated with the symptoms previously elicited with a careful history to construct an appropriate differential diagnosis and proceed with indicated imaging and laboratory assessment. The physical examination is an irreplaceable component of clinician-patient interaction. Educational efforts to enhance competence may result in improved diagnostic efficiency. The adjunctive use of point-of-care ultrasound and artificial intelligence tools is expected to increase.

247 Electrocardiography

Ary L. Goldberger

An *electrocardiogram* (ECG or EKG) is a graphical representation of electrical activity generated by the heart. The signals, detected by means of metallic electrodes attached to the extremities and chest wall, are amplified and recorded by the *electrocardiograph* device. ECG leads are configured to display the instantaneous *differences* in electrical potentials between specific sets of electrodes. The utility of the ECG derives from its immediate availability as a noninvasive, inexpensive, and highly versatile test. In addition to its use in detecting arrhythmias, conduction disturbances, and myocardial ischemia/infarction, the ECG may reveal findings related to life-threatening metabolic disturbances, drug toxicities, and increased susceptibility to sudden cardiac arrest **(see also Chaps. 317 and 420)**. The importance of electrocardiologic abnormalities in the diagnosis, prognosis, and management of muscular dystrophies and other hereditary neuromuscular diseases is discussed separately **(see Chap. 360)**.

ELECTROPHYSIOLOGIC BACKGROUND

Depolarization of the heart is the initiating event for cardiac contraction. The electrical currents that spread through the heart are produced by three components: cardiac pacemaker cells, specialized conduction tissue, and the heart muscle itself. The ECG records only the depolarization (stimulation) and repolarization (recovery) electrical activity generated by the "working" atrial and ventricular myocardium **(see also Chaps. 251 and 253)**.

The stimulus initiating the normal heartbeat originates in the *sinoatrial* (SA) *node* **(Fig. 247-1)**, which possesses spontaneous automaticity. Spread of the depolarization wave through the right and left atria induces contraction of these chambers. Next, the impulse stimulates specialized conduction tissues in the atrioventricular (AV) nodal and His-bundle areas; together, these two regions constitute the AV junction. The bundle of His bifurcates into two main divisions, the right and left bundle branches, which rapidly transmit depolarization wavefronts in a synchronous way to the right and left ventricular myocardium via the Purkinje fibers. The main left bundle fans out into left anterior and left posterior fascicular subdivisions. The depolarization wavefronts then spread through the ventricular wall, from endocardium to epicardium, triggering coordinated ventricular contraction. Since the cardiac depolarization and repolarization wavefronts have direction and magnitude, they can be represented by vectors.

BASIC ECG WAVEFORMS AND INTERVALS

The ECG waveforms are labeled alphabetically, beginning with the P wave, which represents atrial depolarization **(Fig. 247-2)**. The QRS complex represents ventricular depolarization; the ST-T-U complex (ST segment, T wave, and U wave) represents ventricular repolarization. The J point is the junction between the end of the QRS complex and the beginning of the ST segment. Atrial repolarization waveforms ($ST\text{-}T_a$) are usually too low in amplitude to be detected, but they may become apparent in acute pericarditis, atrial infarction, and AV heart block syndromes.

The QRS-T waveforms of the surface ECG correspond to sequential phases of simultaneously obtained ventricular *action potentials*, the intracellular recordings from single myocardial fibers **(Chap. 251)**. The rapid upstroke (phase 0) of the action potential corresponds to the onset of QRS. The plateau (phase 2) corresponds to the isoelectric ST segment, and active repolarization (phase 3) corresponds to the inscription of the T wave. Factors that decrease the slope of phase 0 by impairing the influx of Na^+ (e.g., hyperkalemia and drugs such as flecainide) tend to increase QRS duration. Factors that prolong phase 2 or 3 (e.g., amiodarone, hypocalcemia) increase the QT interval. In contrast, factors (e.g., hypercalcemia, digoxin) associated with shortening of ventricular repolarization duration abbreviate the QT. The hereditary short QT syndrome and its relationship to sudden cardiac arrest are discussed in **Chap. 262**.

The ECG is usually recorded on graph paper divided into a grid of 1-mm^2 boxes. When the recording (sweep) speed is 25 mm/s, the smallest (1 mm) horizontal divisions correspond to 40 ms (0.04 s), with heavier lines at intervals of 200 ms (0.20 s). Vertically, the ECG graph measures the amplitude of a specific wave or deflection (1 mV = 10 mm with standard calibration; the voltage criteria for hypertrophy mentioned below are given in millimeters). There are four major sets of ECG intervals: RR, PR, QRS, and QT/QT_c (Fig. 247-2). The instantaneous heart rate (beats per minute) can be computed from the interbeat (RR) interval by dividing the number of large (0.20 s) time units

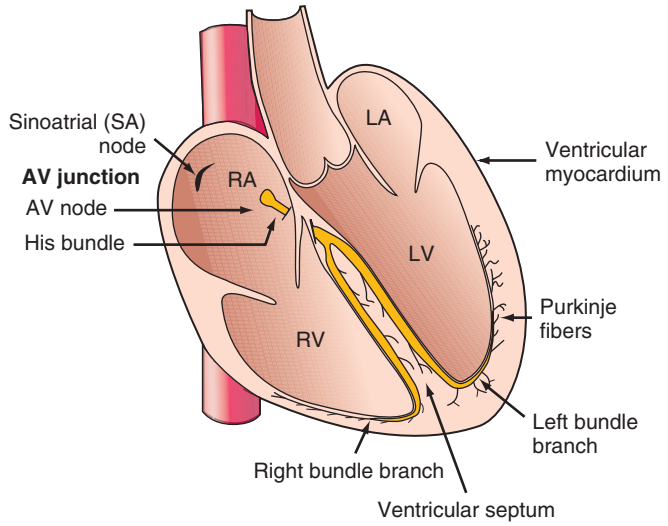

FIGURE 247-1 Schematic of the cardiac conduction system. AV, atrioventricular; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

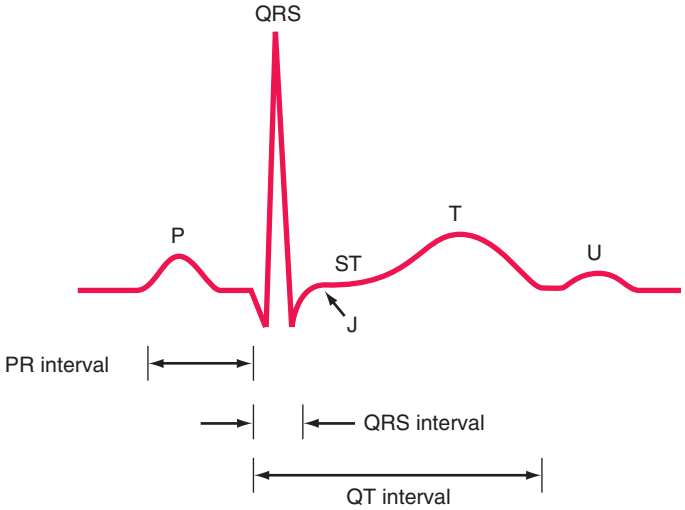

FIGURE 247-2 Basic ECG waveforms and intervals. Not shown is the RR interval, the time between consecutive QRS complexes.

between consecutive R waves into 300 or the number of small (40 ms) segments into 1500. The PR interval measures the time (normally 120–200 ms) between atrial and ventricular depolarization, which includes the physiologic delay imposed by stimulation of cells in the AV junction area. The QRS interval (normally 100–110 ms or less) reflects the duration of ventricular depolarization. The QT interval subtends both ventricular depolarization and (primarily) repolarization times and varies inversely with the heart rate. A variety of formulas has been proposed for computing a rate-corrected QT interval, termed QT_c, but without formal consensus. The classic "square root" formula ($QT_c = QT/\sqrt{RR}$, computed in second units) has been criticized for systematic errors at both lower and higher heart rates. One alternative is the Framingham formula (given here for units of milliseconds): $QT_c = QT + 0.154\,(1000 - RR)$. The following upper normal limits (based visually on the longest QT) have been proposed: QT_c of 460 ms in women and 450 ms in men. Lower limits are less well defined. Visual or electronic QT/QT_c measurements should be assessed in light of inherent limitations in their precise determination from standard ECGs waveforms.

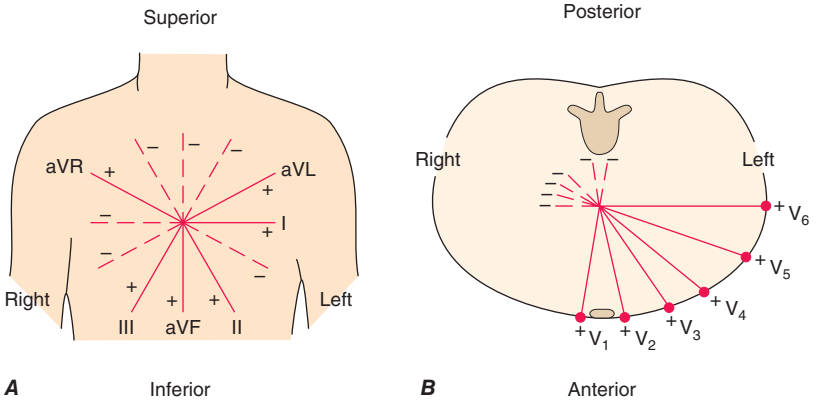

FIGURE 247-3 The six frontal plane (*A*) and six horizontal plane (*B*) leads provide a three-dimensional representation of cardiac electrical activity.

ECG LEADS

The 12 conventional ECG leads are divided into two groups: six limb (extremity) leads and six chest (precordial) leads. The limb leads record potentials transmitted onto the *frontal plane* (Fig. 247-3*A*); the chest leads record potentials transmitted onto the *horizontal plane* (Fig. 247-3*B*).

The orientation and polarity of the frontal plane leads are represented on a hexaxial diagram (Fig. 247-4). The six chest leads are obtained by exploring electrodes as shown in Fig. 247-5.

Each lead is analogous to a different video camera angle "looking" at the same events—atrial and ventricular depolarization and repolarization—from different spatial orientations. The 12-lead ECG can be supplemented with additional leads in special circumstances. For example, right precordial leads V_3R to V_6R are useful in detecting evidence of acute right ventricular ischemia/infarction. Bedside monitors and ambulatory ECGs (e.g., Holter monitors, event recorders, patch electrode and other medical wearable devices) usually employ only one or two modified leads. The standard ECG leads are configured such that a positive (upright) deflection is recorded in a lead if a wave of depolarization spreads toward the positive pole of that lead, and a negative deflection is recorded if the wave spreads toward the negative pole. If the *mean* orientation of the depolarization vector is at right angles to a particular lead axis, a biphasic (equally positive and negative) deflection will be inscribed.

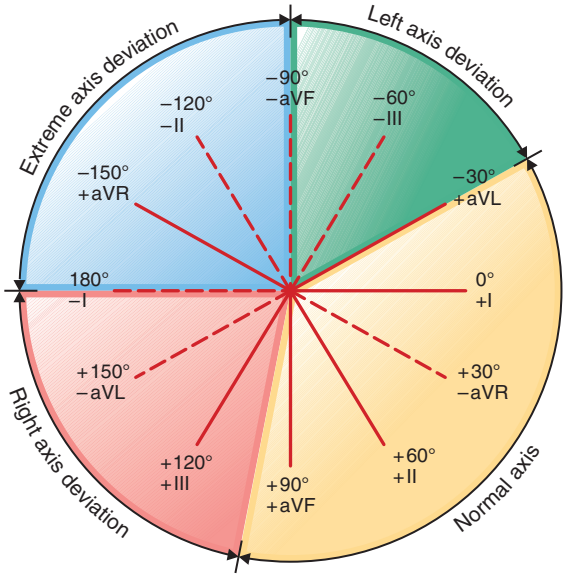

FIGURE 247-4 The frontal plane (limb or extremity) leads are represented on a hexaxial diagram. Each ECG lead has a specific spatial orientation and polarity. The positive pole of each lead axis (*solid line*) and the negative pole (*hatched line*) are designated by their angular position relative to the positive pole of lead I (0°). The mean electrical axis of the QRS complex is measured with respect to this display.

GENESIS OF THE NORMAL ECG

P WAVE

The normal atrial depolarization vector is oriented downward and toward the subject's left, reflecting the spread of depolarization from the sinus node to the right and then the left atrial myocardium. Since this vector points toward the positive pole of lead II and toward the negative pole of lead aVR, the sinus-generated P wave will be positive in lead II and negative in aVR. By contrast, activation of the atria from an ectopic pacemaker in the lower part of either atrium or in the AV junction region may produce retrograde P waves (negative in II, positive in aVR). The normal P wave in lead V_1 may be biphasic with a positive component reflecting right atrial depolarization, followed by a small (<1 mm^2) negative component reflecting left atrial depolarization.

QRS COMPLEX

Normal ventricular depolarization proceeds as a rapid, continuous spread of activation wave fronts. This complex process can be divided

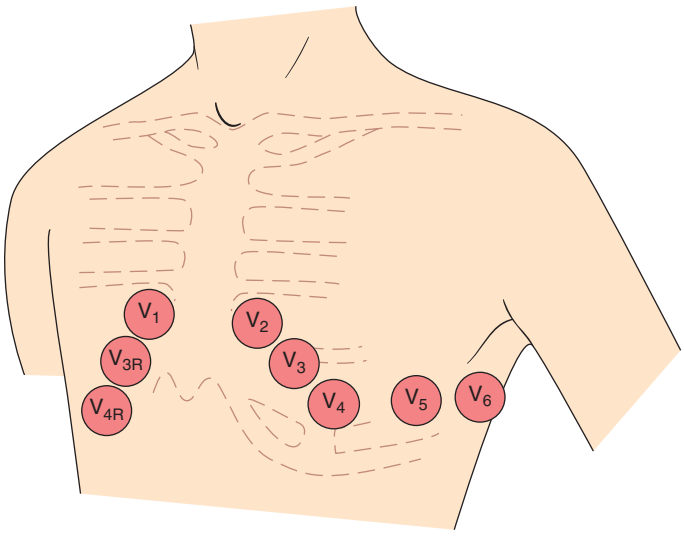

FIGURE 247-5 The horizontal plane (chest or precordial) leads are obtained with electrodes in the locations shown. Additional posterior leads are sometimes placed on the same horizontal plane as V_4 to facilitate detection of acute posterolateral infarction (V_7, midaxillary line; V_8, posterior axillary line; and V_9, posterior scapular line). Right chest leads (V_3R–V_6R) may enhance detection of right ventricular involvement in the context of inferior infarction.

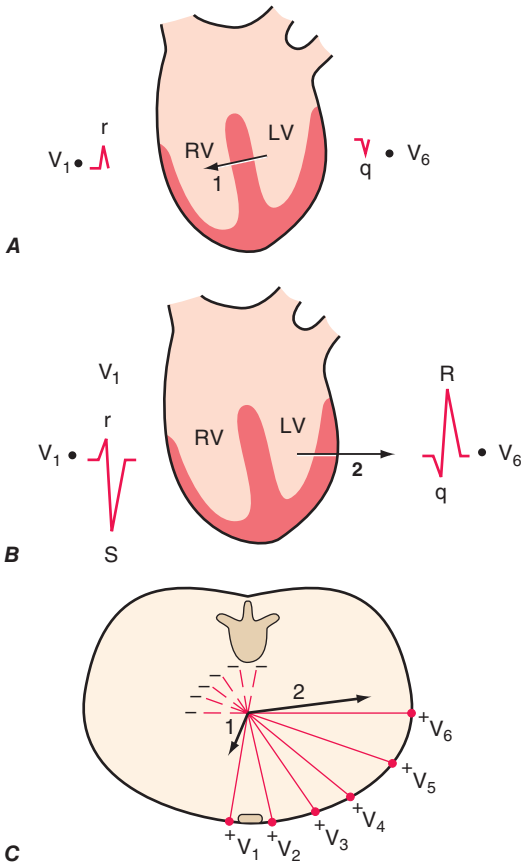

FIGURE 247-6 Ventricular depolarization can be divided into two major phases, each represented by a vector. ***A.*** The first phase (*arrow 1*) denotes depolarization of the ventricular septum, beginning on the left side and spreading to the right. This process is represented by a small "septal" r wave in lead V_1 and a small septal q wave in lead V_6. ***B.*** Simultaneous depolarization of the left and right ventricles (LV and RV) constitutes the second phase. Vector 2 is oriented to the left and posteriorly, reflecting the electrical predominance of the LV. ***C.*** Vectors (*arrows*) representing these two phases are shown in reference to the horizontal plane leads. *(Reproduced with permission from AL Goldberger et al: Goldberger's Clinical Electrocardiography: A Simplified Approach, 10th ed. Philadelphia, Elsevier, 2024.)*

into two major sequential phases, and each can be represented by a mean vector **(Fig. 247-6)**. The first and shortest phase is depolarization of the interventricular septum, proceeding from the left to the right and anteriorly (vector 1). The second and major phase results from the simultaneous depolarization of the right and left ventricles (vector 2). This phase is normally dominated by the more massive left ventricle, so that vector 2 points leftward and posteriorly. Therefore, a right precordial lead (V_1) will record this biphasic depolarization process with a small positive deflection (septal r wave) followed by a larger negative deflection (S wave). A left precordial lead, for example, V_6, will record the same sequence with a small negative deflection (septal q wave) followed by a relatively tall positive deflection (R wave). Intermediate leads show a relative increase in R-wave amplitude (normal R-wave progression) and a decrease in S-wave amplitude progressing across the chest from right to left. The lead where the R and S waves are of about equal amplitude is referred to as the *transition zone* (usually V_3 or V_4) **(Fig. 247-7)**.

The QRS pattern in the extremity leads may vary considerably from one normal subject to another depending on the *electrical axis* of the QRS, which describes the mean orientation of the QRS vector with reference to the six frontal plane leads. Normally, the QRS axis ranges from −30° to +100° (Fig. 247-4). An axis more negative than −30° is referred to as *left axis deviation*, and an axis more positive than +90 to +100° is referred to as *right axis deviation*. Left axis deviation may occur as a normal variant but is more commonly associated with left ventricular hypertrophy, a block in the anterior fascicle of the left bundle system (left anterior fascicular block or hemiblock), or inferior myocardial infarction. Right axis deviation also may occur as a normal variant (particularly in children and young adults), as a spurious finding due to reversal of the left and right arm electrodes, or in conditions such as right ventricular overload (acute or chronic), lateral infarction, dextrocardia, left pneumothorax, and left posterior fascicular block.

T WAVE AND U WAVE

Normally, the mean T-wave vector is oriented roughly concordant with the mean QRS vector (within about 45° in the frontal plane). Since depolarization and repolarization are electrically opposite processes, this normal QRS–T-wave vector concordance indicates that repolarization normally must proceed in the reverse direction from depolarization (i.e., from ventricular epicardium to endocardium). The normal U wave is a small, rounded deflection (≤1 mm) that follows the T wave and usually has the same polarity as the T wave. An abnormal increase in U-wave amplitude is most commonly due to hypokalemia or drugs (e.g., dofetilide, amiodarone, sotalol, quinidine). Very prominent U waves, as part of prolonged ventricular repolarization syndromes, are a marker of increased susceptibility to *torsades de pointes* **(Chap. 253)**.

MAJOR ECG ABNORMALITIES

CARDIAC ENLARGEMENT AND HYPERTROPHY

Right atrial overload (acute or chronic) may lead to an increase in P-wave amplitude (≥2.5 mm) **(Fig. 247-8)**, previously referred to as "P-pulmonale." Left atrial overload typically produces a biphasic P wave in V_1 with a broad negative component or a broad (≥120 ms), often with a notched P wave in one or more limb leads (Fig. 247-8). This pattern, historically referred to as "P-mitrale," may occur with *interatrial conduction delays* in the absence of actual atrial enlargement, leading to the more general designation of *left atrial abnormality*.

Right ventricular hypertrophy due to a sustained, severe pressure load (e.g., with pulmonic valve stenosis or certain pulmonary artery hypertension syndromes) is characterized by a relatively tall R wave in lead V_1 (R ≥ S wave), usually with right axis deviation **(Fig. 247-9)**; alternatively, there may be a qR pattern in V_1 or V_3R. ST depression and T-wave inversion in the right to mid-precordial leads are also

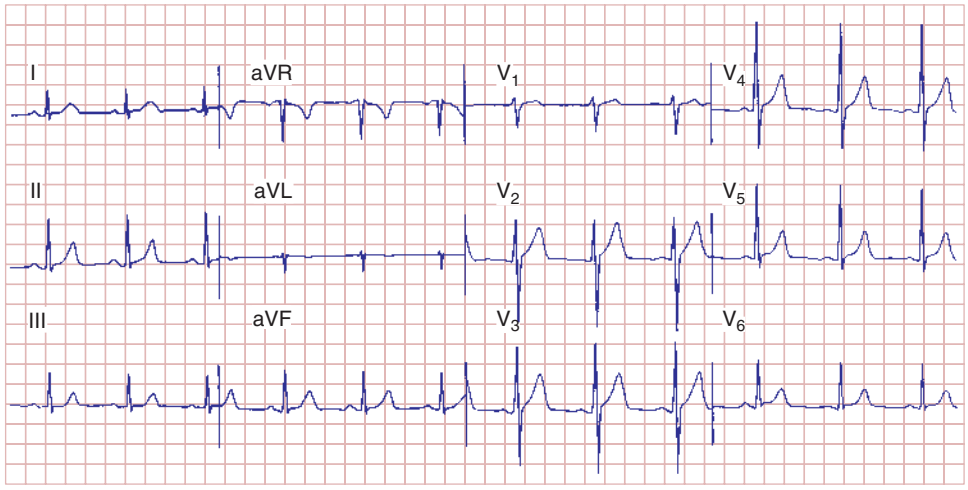

FIGURE 247-7 Normal electrocardiogram from a healthy male subject. Sinus rhythm is present with a heart rate of 75 beats per minute. PR interval is 160 ms; QRS interval (duration) is 80 ms; QT interval is 360 s; QT_c (Framingham formula) is about 390 ms; the mean QRS axis is about +70°. The precordial leads show normal R-wave progression with the transition zone (R wave ≈ S wave) in lead V_3.

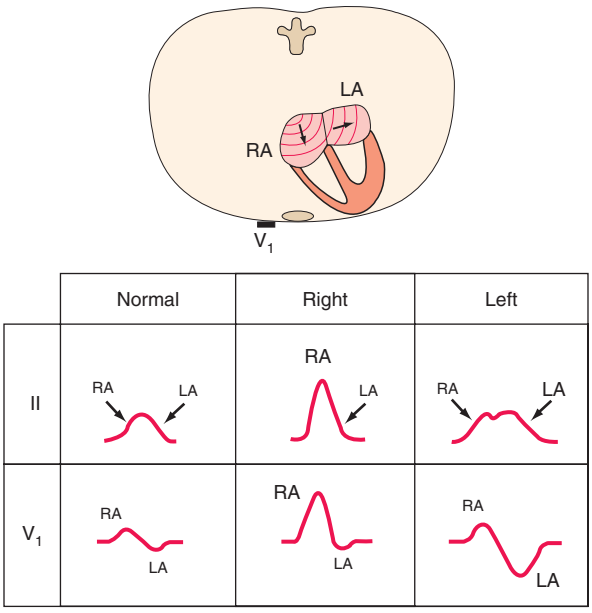

FIGURE 247-8 Right atrial (RA) overload may cause tall, peaked P waves in the limb or precordial leads. Left atrial (LA) abnormality may cause broad, often notched P waves in the limb leads and a biphasic P wave in lead V_1 with a prominent negative component representing delayed depolarization of the LA. *(Reproduced with permission from MK Park, WG Guntheroth: How to Read Pediatric ECGs, 4th ed. St. Louis, Mosby/Elsevier, 2006.)*

often present. This pattern, formerly called right ventricular "strain," is attributable to repolarization abnormalities in acutely or chronically overloaded muscle. Prominent S waves may occur in the left lateral precordial leads. Right ventricular hypertrophy due to ostium secundum atrial septal defects, with the accompanying right ventricular volume overload, is commonly associated with an incomplete or complete right bundle branch block pattern in concert with a rightward QRS axis.

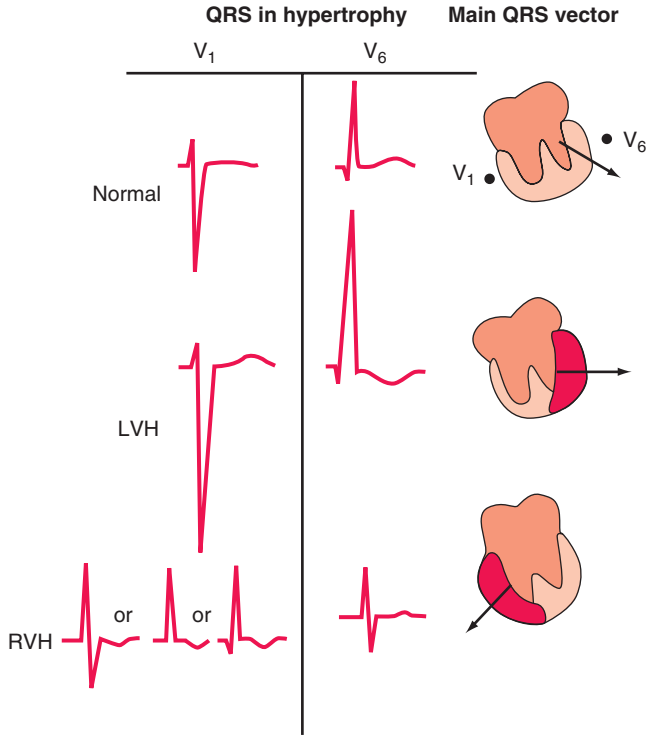

FIGURE 247-9 Left ventricular hypertrophy (LVH) increases the amplitude of electrical forces directed to the left and posteriorly. In addition, repolarization abnormalities may cause ST-segment depression and T-wave inversion in leads with a prominent R wave. Right ventricular hypertrophy (RVH) may shift the QRS vector to the right; this effect usually is associated with an R, RS, or qR complex in lead V_1. T-wave inversions may be present in right precordial leads.

Acute cor pulmonale due to pulmonary thromboembolism (Chap. 290) or acute respiratory distress syndromes (e.g., COVID-19) may be associated with a normal ECG or a variety of abnormalities. Sinus tachycardia is the most common arrhythmia, although other tachyarrhythmias, such as atrial fibrillation or flutter, may occur. The QRS axis may shift to the right, sometimes in concert with the so-called $S_1Q_3T_3$ pattern (prominence of the S wave in lead I and the Q wave in lead III, with T-wave inversion in lead III). Acute right ventricular dilation also may be associated with slow R-wave progression and ST-T abnormalities in V_1 to V_4 simulating acute anterior infarction. A right ventricular conduction disturbance may appear.

Chronic cor pulmonale due to obstructive lung disease (Chap. 307) usually does not produce the classic ECG patterns of right ventricular hypertrophy noted above. Instead of tall right precordial R waves, emphysema is more typically associated with diminished r waves in right to mid-precordial leads (slow R-wave progression) due in part to downward displacement of the diaphragm and the heart. Low-voltage complexes are commonly present, owing to hyperaeration.

Multiple voltage criteria for *left ventricular hypertrophy* (Fig. 247-9) have been proposed based on the presence of tall left precordial R waves and deep right precordial S waves (e.g., SV_1 + [RV_5 or RV_6] >35 mm). Repolarization abnormalities (ST depression with T-wave inversions, formerly called the left ventricular "strain" pattern) may appear in leads with prominent R waves. However, prominent precordial voltages occur as a common normal variant, especially in athletic or young individuals. Left ventricular hypertrophy may increase limb lead voltage with or without increased precordial voltage (e.g., RaVL + SV_3 >20 mm in women and >28 mm in men). The presence of left atrial abnormality increases the likelihood of underlying left ventricular hypertrophy in cases with borderline voltage criteria. Left ventricular hypertrophy often progresses to incomplete or complete left bundle branch block. The sensitivities of conventional voltage criteria for left ventricular hypertrophy are low in middle age to older adults and may be decreased further in obese persons and smokers, as well as with right bundle branch block. ECG evidence for left ventricular hypertrophy is a major noninvasive marker of increased risk of cardiovascular morbidity and mortality rates, including sudden cardiac death. However, because of false-positive and false-negative diagnoses, the ECG is of limited utility in diagnosing atrial or ventricular enlargement. More definitive anatomic and functional information is provided by echocardiographic and cardiac magnetic resonance imaging studies (Chaps. 248 and A9).

BUNDLE BRANCH BLOCKS AND RELATED PATTERNS

Intrinsic impairment of conduction in either the right or the left bundle system (intraventricular conduction disturbances) leads to prolongation of the QRS interval. With complete bundle branch blocks, the widest QRS interval is ≥120 ms in duration; with incomplete blocks, the QRS interval is between about 110 and 120 ms. The QRS vector usually is oriented in the direction of the myocardial region where depolarization is delayed (Fig. 247-10). Thus, with right bundle branch block, the terminal QRS vector is oriented to the right and anteriorly (rSR′ in V_1 and qRS in V_6, typically). Left bundle branch block alters both early and later phases of ventricular depolarization. The major QRS vector is directed to the left and posteriorly. In addition, the normal early left-to-right pattern of septal activation is disrupted such that septal depolarization proceeds from right to left as well. As a result, left bundle branch block generates wide, predominantly negative (QS) complexes in lead V_1 and entirely positive (R) complexes in V_6. Waveform patterns identical to those of left bundle branch block, preceded by a sharp (sometimes very low amplitude) spike, are seen in most cases of electronic right ventricular pacing due to the relative delay in left ventricular activation.

Bundle branch block may occur in a variety of conditions. In subjects without structural heart disease, right bundle branch block is seen more commonly than left bundle branch block. Right bundle branch block also occurs with heart disease, both congenital (e.g., atrial septal defect) and acquired (e.g., valvular, ischemic). Left bundle branch block is often a marker of one of four underlying conditions associated with increased risk of cardiovascular morbidity and mortality rates: coronary

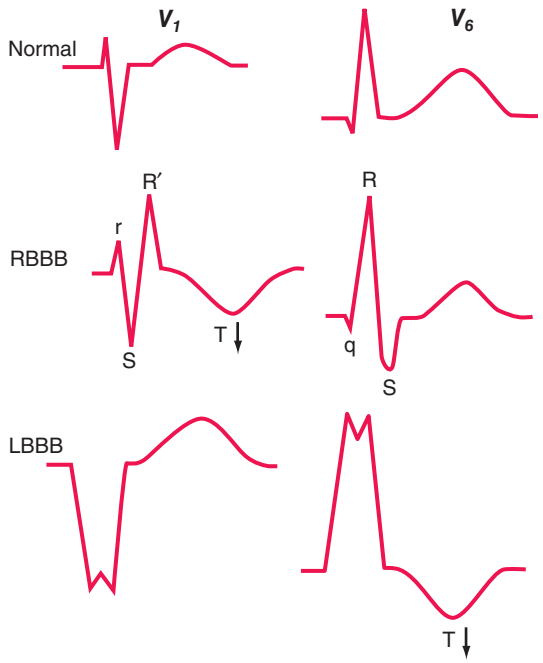

FIGURE 247-10 Comparison of typical QRS-T patterns in right bundle branch block (RBBB) and left bundle branch block (LBBB) with the normal pattern in leads V_1 and V_6. Note the secondary T-wave inversions (*arrows*) in leads with an rSR′ complex with RBBB and in leads with a wide R wave with LBBB.

heart disease (frequently with impaired left ventricular function), hypertensive heart disease, aortic valve disease (including after transcatheter aortic valve replacement), and cardiomyopathy. Bundle branch blocks may be chronic or intermittent. A bundle branch block may be rate-related, most commonly observed when the heart rate exceeds some critical value.

Bundle branch blocks and depolarization abnormalities secondary to artificial pacemakers not only affect ventricular depolarization (QRS) but also are characteristically associated with *secondary repolarization* (ST-T) abnormalities. With bundle branch blocks, the T wave is typically opposite in polarity to the last deflection of the QRS (Fig. 247-10). This discordance of the QRS–T-wave vectors is caused by the altered sequence of repolarization that occurs as a consequence of altered depolarization. In contrast, *primary repolarization* abnormalities are independent of QRS changes and are related instead to actual alterations in the electrical properties of the myocardial fibers themselves (e.g., in the resting membrane potential or action potential duration), not just to changes in the sequence of repolarization. Ischemia, electrolyte imbalance, and drugs such as digoxin all cause such primary ST–T-wave changes. Primary and secondary T-wave changes may coexist. For example, T-wave inversions in the right precordial leads with left bundle branch block or in the left precordial leads with right bundle branch block may be important markers of underlying ischemia or other abnormalities. A distinctive abnormality simulating right bundle branch block with ST-segment elevations in the right chest leads is seen with the Brugada pattern **(Chap. 262)**.

Partial blocks in the left bundle system (left anterior or posterior fascicular blocks; formerly called hemiblocks) generally do not prolong the QRS duration substantially. Instead, they are associated with shifts in the frontal plane QRS axis (leftward or rightward, respectively). Left anterior fascicular block (QRS axis more negative than −45°) is probably the most common cause of marked left axis deviation in adults. In contrast, left posterior fascicular block (QRS axis more rightward than +110–120°) is extremely rare as an isolated finding and requires exclusion of other factors causing right axis deviation. Intraventricular conduction delays also can be caused by factors extrinsic (toxic) to the conduction system that slow ventricular conduction, particularly hyperkalemia or drugs (e.g., class 1 antiarrhythmic agents, tricyclic antidepressants, phenothiazines). Prolongation of QRS duration does not necessarily indicate a conduction delay but may be due to *preexcitation* of the ventricles via a bypass tract, as in Wolff-Parkinson-White (WPW) patterns **(Chap. 256)** and related variants.

MYOCARDIAL ISCHEMIA AND INFARCTION

(See also Chap. 286) The ECG is central to the diagnosis of acute and chronic ischemic heart disease. Ischemia exerts complex time-dependent effects on the electrical properties of myocardial cells. Severe, acute ischemia lowers the resting membrane potential and shortens the duration of the action potential. Such changes cause a voltage gradient between normal and ischemic zones. As a consequence, current flows between those regions. These *currents of injury* are represented on the surface ECG by deviation of the ST segment **(Fig. 247-11)**. When the acute ischemia is *transmural*, the ST vector usually is shifted in the direction of the outer (epicardial) layers, producing ST elevations and sometimes, in the earliest stages of ischemia, tall, positive so-called hyperacute T waves over the ischemic zone. With ischemia confined primarily to the *subendocardium*, the ST vector typically shifts toward the subendocardium and ventricular cavity, so that overlying (e.g., anterior precordial) leads show ST-segment depression (with ST elevation in lead aVR). Multiple factors affect the amplitude of acute ischemic ST deviations. Profound ST elevation or depression in multiple leads usually indicates very severe ischemia. The division of acute myocardial infarction due to obstructive coronary artery disease into ST-segment elevation and non-ST elevation types is useful since the consistent efficacy of emergency (minutes to hours) reperfusion therapy is limited to the former group. Indications for acute reperfusion therapy in non-ST elevation myocardial infarction are a focus of ongoing investigation **(Chap. 285)**. Takotsubo syndrome, as well as other causes of myocardial infarction without atherosclerotic coronary disease, can simulate the patterns of acute or evolving ST-segment elevation or non-ST-segment elevation infarction **(Chap. 285)**.

The ECG leads are usually more helpful in localizing regions of ST elevation than non-ST elevation ischemia. For example, acute transmural anterior (including apical and lateral) wall ischemia is reflected by ST elevations or increased T-wave positivity in one or more of the precordial leads (V_1–V_6) and leads I and aVL. Inferior wall ischemia produces changes in leads II, III, and aVF. "Posterior" wall ischemia (almost always associated with lateral or inferior involvement) may be indirectly recognized by *reciprocal* ST depressions in leads V_1 to V_3 (thus constituting an ST elevation "equivalent" acute coronary syndrome). Acute right ventricular ischemia usually produces ST elevations in right-sided chest leads (Fig. 247-5). When ischemic ST elevations occur as the earliest sign of acute infarction, they typically are followed within a period ranging from hours to days by evolving T-wave inversions and often by Q waves occurring in the same lead distribution. Reversible transmural

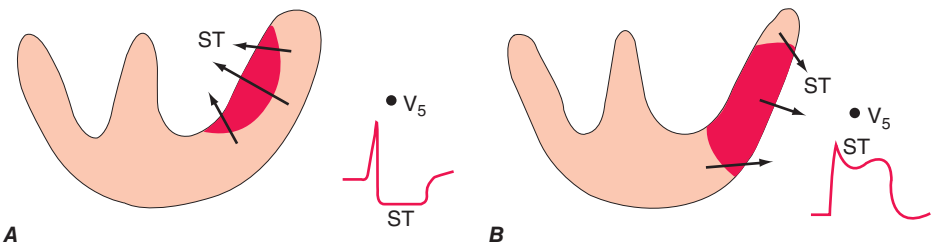

FIGURE 247-11 Acute ischemia causes a current of injury. *A.* With predominant subendocardial ischemia, the resultant ST vector will be directed toward the inner layer of the affected ventricle and the ventricular cavity. Overlying leads therefore will record ST depression. ***B.*** With ischemia involving the outer ventricular layer (transmural or epicardial injury), the ST vector will be directed outward. Overlying leads will record ST elevation.

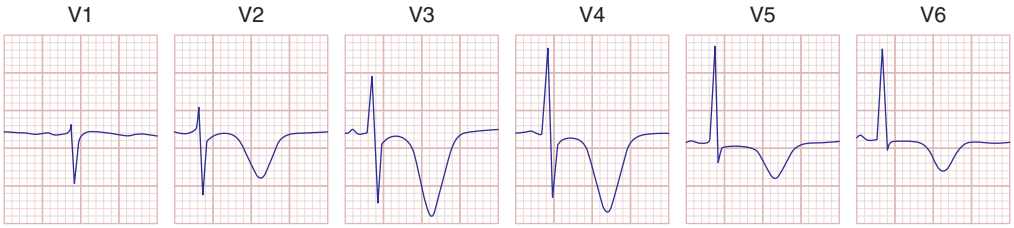

FIGURE 247-12 Severe anterior wall ischemia (with or without infarction) may cause prominent T-wave inversions in the precordial leads and in leads I and aVL. This pattern (sometimes referred to as the Wellens T wave sign) is usually associated with a high-grade stenosis of the left anterior descending coronary artery.

ischemia, for example, due to coronary vasospasm (Prinzmetal's angina) may cause transient ST-segment elevations without development of Q waves. Depending on the severity and duration of ischemia, ischemic ST elevations may resolve completely in minutes or be followed by T-wave inversions that persist for hours or even days. Patients with ischemic chest pain who present with deep T-wave inversions in multiple precordial leads (e.g., V_1–V_4, and sometimes I and aVL) with or without cardiac enzyme elevations typically have severe obstruction in the left anterior descending coronary artery **(Fig. 247-12)**.

With infarction, depolarization (QRS) changes often accompany repolarization (ST-T) abnormalities. Necrosis of sufficient myocardial tissue may lead to decreased R-wave amplitude or abnormal Q waves (even in the absence of transmural ischemia) in the anterior or inferior leads **(Fig. 247-13)**. Abnormal Q waves were once considered markers of transmural myocardial infarction, whereas subendocardial infarcts were thought not to produce Q waves. However, transmural infarcts may occur without Q waves, and subendocardial (nontransmural) infarcts may be associated with Q waves. Therefore, evolving or chronic infarcts are more appropriately classified as "Q-wave" or "non-Q-wave" **(Chap. A7)**. Loss of depolarization forces due to posterior or lateral infarction may cause reciprocal increases in R-wave amplitude in leads V_1 and V_2 without diagnostic Q waves in any of the conventional leads. (Additional leads V_7–V_9 may show acute changes.) In the weeks and months after infarction, these ECG changes may persist or begin to resolve. Complete normalization of the ECG after Q-wave infarction is uncommon but may occur, particularly with smaller infarcts. In contrast, ST-segment elevations that persist for several weeks or more after a Q-wave infarct usually correlate with a severe underlying wall motion disorder, although not necessarily a frank ventricular aneurysm.

The ECG has important limitations in both sensitivity and specificity in the diagnosis of acute and chronic ischemic heart disease. Although a single normal ECG does not exclude ischemia or even acute infarction, a normal ECG *throughout* the course of an acute infarct is distinctly uncommon. Prolonged chest pain without diagnostic ECG changes therefore should always prompt a careful search for other noncoronary causes of chest pain **(Chap. 15)**. Furthermore, the diagnostic changes of acute or evolving ischemia are often masked by the presence of left bundle branch block, electronic ventricular pacemaker patterns, and WPW preexcitation. However, clinicians may also overdiagnose ischemia or infarction based on the presence of ST-segment elevations or depressions; T-wave inversions; tall, positive T waves; or Q waves *not* related to ischemic heart disease (*pseudoinfarct* patterns). For example, ST-segment elevations simulating acute ischemia/infarction may occur with acute pericarditis or myocarditis, including COVID-19 infections, as a normal variant (including the typical "early repolarization" pattern), or in a variety of other conditions **(Table 247-1)**. Similarly, tall T waves do not invariably represent hyperacute ischemic changes but may also be caused by normal variants, hyperkalemia, or cerebrovascular injury, among other causes.

ST-segment elevations and tall, positive T waves are common findings in leads V_1 and V_2 in left bundle branch block or left ventricular hypertrophy in the absence of ischemia. The differential diagnosis of Q waves includes physiologic or positional variants, ventricular hypertrophy, acute or chronic noncoronary myocardial injury, hypertrophic cardiomyopathy, and ventricular conduction disorders. Ventricular hypertrophy, hypokalemia, drugs such as digoxin, and a variety of other factors may cause ST-segment depression mimicking subendocardial ischemia. Prominent T-wave inversion may occur with

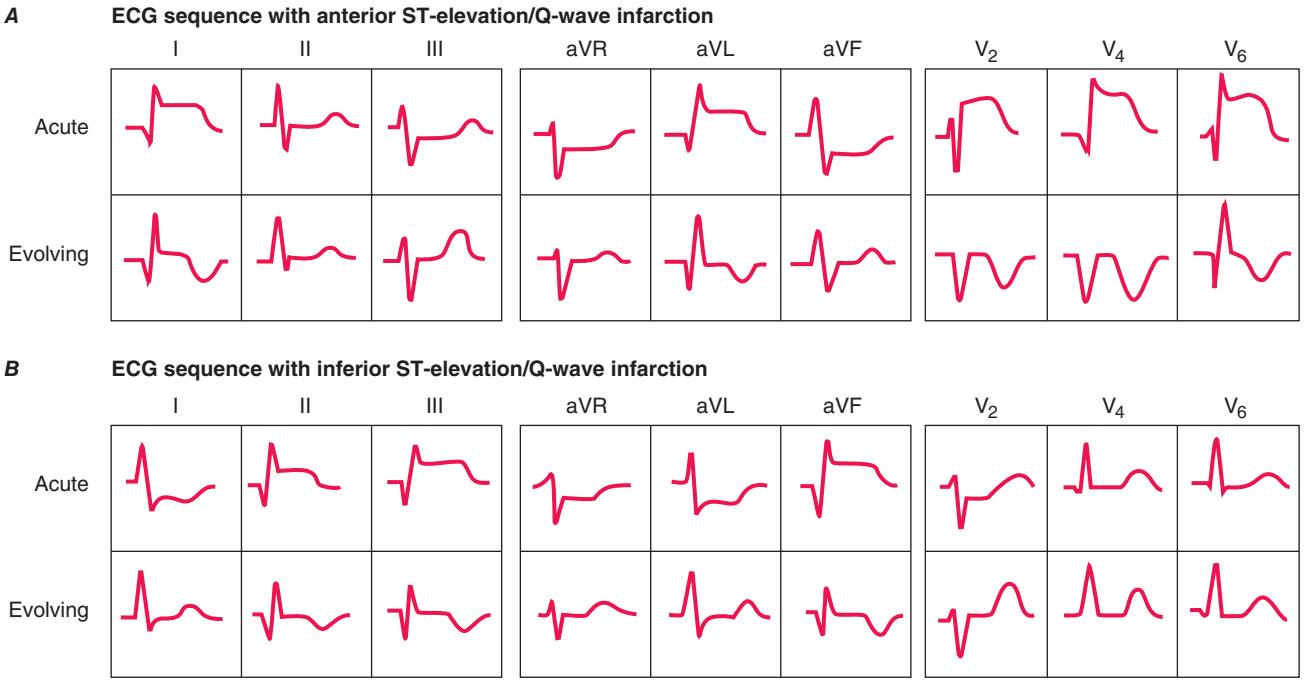

FIGURE 247-13 Sequence of depolarization and repolarization changes with acute and evolving anterior (*A*) and (*B*) inferior ST-elevation/Q-wave infarctions. With anterior infarcts, ST elevation in leads I and aVL and the precordial leads may be accompanied by reciprocal ST depressions in leads II, III, and aVF. Conversely, acute inferior (or posterolateral) infarcts may be associated with reciprocal ST depressions in leads V_1 to V_3. *(Reproduced with permission from AL Goldberger et al: Goldberger's Clinical Electrocardiography: A Simplified Approach, 10th ed. Philadelphia, Elsevier, 2024.)*

TABLE 247-1 Differential Diagnosis of ST-Segment Elevations

Myocardial ischemia/infarction
Noninfarction transmural ischemia (e.g., Prinzmetal's syndrome)
Acute myocardial infarction
Due to atherosclerotic coronary occlusion
Due to nonatherosclerotic causes (e.g., takotsubo syndrome, coronary dissection)
Post-myocardial infarction (left ventricular motion abnormality/aneurysm)
Acute pericarditis
Normal variants (including benign "early repolarization" patterns)
Left ventricular hypertrophy/left bundle branch block[a]
Other (rarer)
Acute pulmonary embolism[a]
Brugada patterns (right bundle branch block–like morphology with ST elevations in right precordial leads)
Class 1C antiarrhythmic drugs[a]
DC cardioversion (transient)
Hypercalcemia[a]
Hyperkalemia[a]
Hypothermia (J [Osborn] waves)
Nonischemic myocardial injury
Myocarditis syndromes (infectious and noninfectious)
Tumor invading left ventricle
Trauma to ventricles

[a]Usually localized to V_1–V_2 or V_3.

ventricular hypertrophy, cardiomyopathies, myocarditis, and "stress cardiomyopathies" associated with takotsubo syndrome and cerebrovascular injury (particularly intracranial bleeds), among others causes. Diagnostic confusion may also occur when nonischemic T-wave inversions ("cardiac memory" effect) appear in normally conducted beats in patients with intermittent wide QRS complexes, most commonly due to ventricular pacing or to left bundle branch block.

METABOLIC FACTORS AND DRUG EFFECTS

A variety of metabolic abnormalities and pharmacologic agents alter the ECG and, in particular, cause changes in repolarization (ST-T-U) and sometimes QRS prolongation. Certain life-threatening electrolyte disturbances may be diagnosed initially and monitored from the ECG. *Hyperkalemia* produces a sequence of changes **(Fig. 247-14)**, usually beginning with narrowing and peaking (tenting) of the T waves. Further elevation of extracellular K^+ leads to AV conduction disturbances, diminution in P-wave amplitude, and widening of the QRS interval. Severe hyperkalemia eventually causes cardiac arrest with a slow sinusoidal type of mechanism ("sine-wave" pattern) followed by asystole. *Hypokalemia* **(Fig. 247-15)** prolongs ventricular repolarization, often with prominent U waves. Prolongation of the QT interval is also seen with drugs that increase the duration of the ventricular action potential: class 1A antiarrhythmic agents and related drugs (e.g., quinidine, procainamide, tricyclic antidepressants, phenothiazines) and class III agents (e.g., amiodarone [Fig. 247-15], dofetilide, sotalol, ibutilide). Systemic *hypothermia* (Fig. 247-15) also prolongs repolarization, usually with a distinctive convex elevation of the J point (Osborn wave) and bradycardia. Marked QT prolongation, sometimes with deep, wide T-wave inversions, may occur with intracranial bleeds, particularly subarachnoid hemorrhage ("CVA T-wave" pattern) (Fig. 247-15). *Hypocalcemia* typically prolongs the QT interval (ST portion), whereas *hypercalcemia* shortens it **(Fig. 247-16)**. Digitalis glycosides also shorten the QT interval, often with a characteristic "scooping" of the ST–T-wave complex (*digitalis effect*).

NONSPECIFIC ST-T CHANGES AND LOW QRS VOLTAGE

Many other factors are associated with ECG changes, particularly alterations in ventricular repolarization. T-wave flattening, minimal T-wave inversions, or slight ST-segment depression ("nonspecific ST–T-wave changes") may occur with a variety of electrolyte and acid-base disturbances, infectious or inflammatory processes, central nervous system disorders, endocrine abnormalities, many drugs, ischemia, hypoxia, and virtually any type of cardiopulmonary abnormality, in addition to physiologic changes (e.g., with posture or after meals). Low QRS voltage is arbitrarily defined as peak-to-trough QRS amplitudes of ≤5 mm in the six limb leads and/or ≤10 mm in the chest leads. Multiple factors may be responsible. Among the most serious include pericardial **(Fig. 247-17)** or pleural effusions, chronic obstructive pulmonary disease, cardiac amyloid, and anasarca.

ELECTRICAL ALTERNANS SYNDROMES

Electrical alternans—a beat-to-beat alternation in one or more components of the ECG signal—is a common type of nonlinear cardiovascular response to a variety of hemodynamic and electrophysiologic perturbations. Total electrical alternans (P-QRS-T) with sinus tachycardia is a relatively specific sign of pericardial effusion, usually with cardiac tamponade (Fig. 247-17). In contrast, pure repolarization

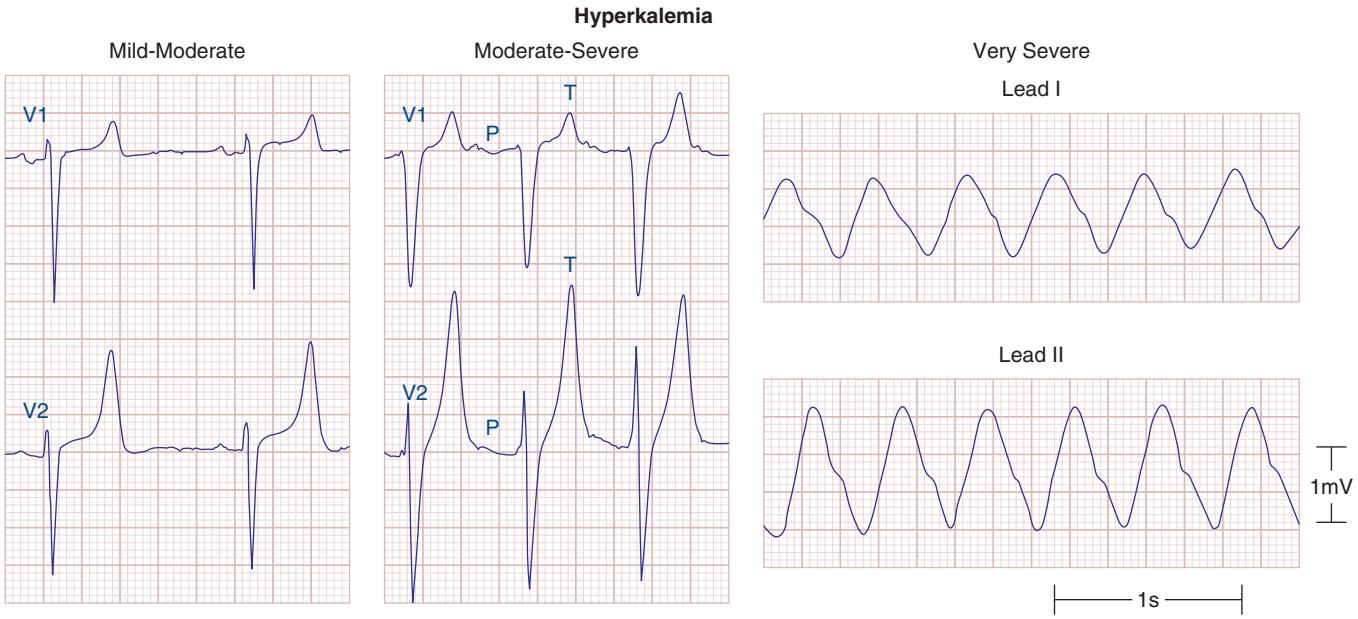

FIGURE 247-14 The earliest ECG change with hyperkalemia is usually peaking ("tenting") of the T waves. With further increases in the serum potassium concentration, the QRS complexes widen, the P waves decrease in amplitude and may disappear, and finally a sine-wave pattern leads to asystole unless emergency therapy is given. *(Reproduced with permission from AL Goldberger et al: Goldberger's Clinical Electrocardiography: A Simplified Approach, 10th ed. Philadelphia, Elsevier, 2024.)*

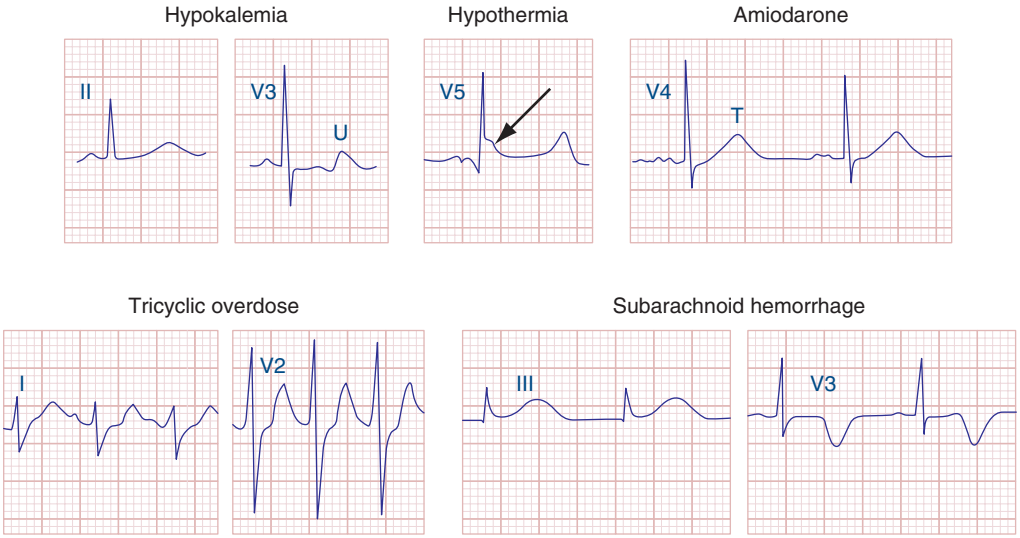

FIGURE 247-15 A variety of metabolic derangements, drug effects, and other factors may prolong ventricular repolarization with QT prolongation or prominent U waves. Prominent repolarization prolongation, particularly if due to hypokalemia, inherited "channelopathies," or certain pharmacologic agents, indicates increased susceptibility to *torsades des pointes* ventricular tachycardia **(Chap. 261)**. Marked systemic hypothermia is associated with a distinctive convex "hump" at the J point (Osborn wave, *arrow*) attributed to altered transmural ventricular action potential characteristics. Note QRS and QT prolongation along with sinus tachycardia in the case of tricyclic antidepressant overdose.

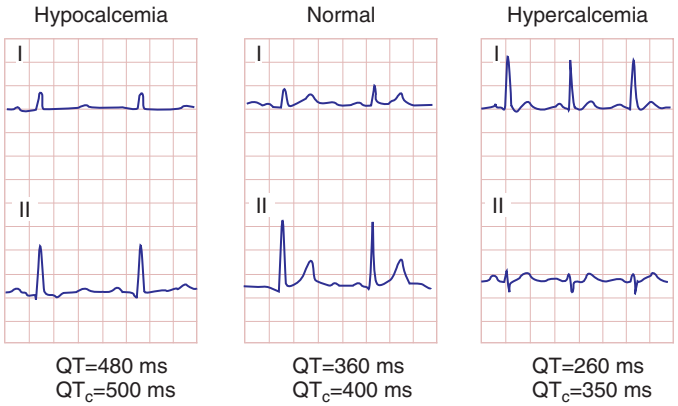

FIGURE 247-16 Prolongation of the Q-T interval (ST-segment portion) is typical of hypocalcemia. Hypercalcemia may cause abbreviation of the ST segment with relative or absolute shortening of the QT interval.

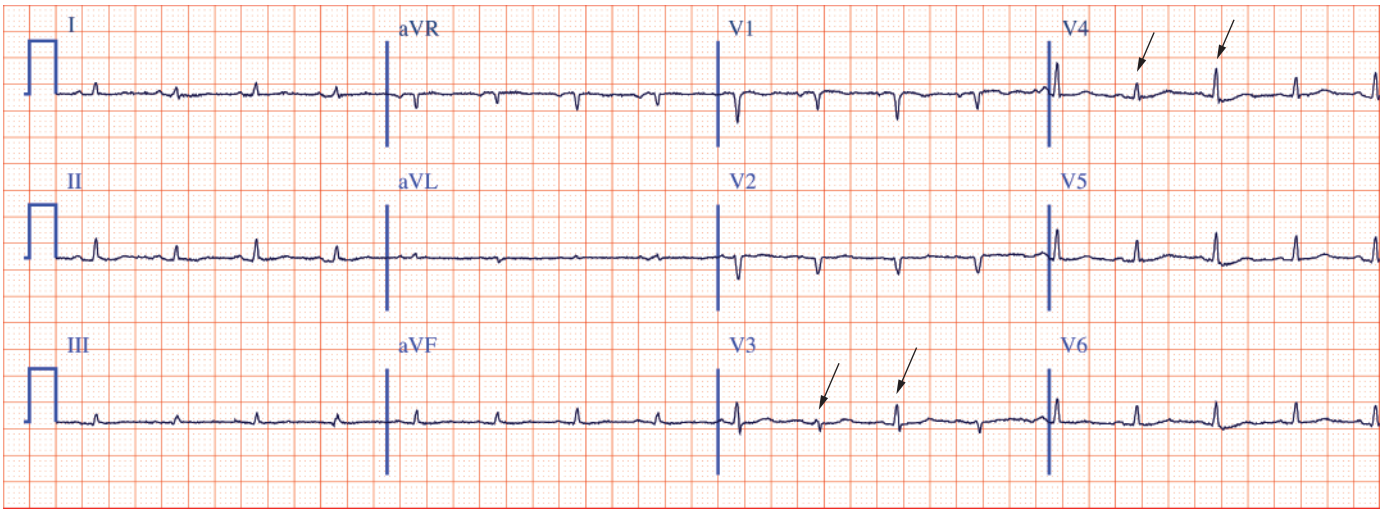

FIGURE 247-17 Classic triad of findings for pericardial effusion with cardiac tamponade: (1) sinus tachycardia; (2) low QRS voltages and (3) electrical alternans (best seen in leads V_3 and V_4 in this case; *arrows*). This triad is highly suggestive of pericardial effusion, usually with tamponade physiology, but is of limited sensitivity. *(Adapted from LA Nathanson et al: ECG Wave-Maven. ecg.bidmc.harvard.edu.)*

(ST-T or U wave) alternans is a sign of electrical instability and may precede life-threatening ventricular tachyarrhythmias.

CLINICAL INTERPRETATION OF THE ECG

Accurate analysis of ECGs requires thoroughness and care. The patient's age, biologic sex, and clinical status should always be considered. Many mistakes in ECG interpretation are errors of omission. Therefore, a systematic approach is essential. The following 14 parameters should be analyzed carefully in every ECG: (1) standardization (calibration) and technical features (including lead placement and artifacts); (2) rhythm; (3) heart rate; (4) PR interval/AV conduction; (5) QRS interval; (6) QT/QT_c intervals; (7) mean QRS electrical axis; (8) P waves; (9) QRS voltages; (10) precordial R-wave progression; (11) abnormal Q waves; (12) ST segments; (13) T waves; and (14) U waves. Comparison with any previous ECGs is invaluable.

COMPUTERIZED ELECTROCARDIOGRAPHY

Computerized systems are widely used for storage and immediate retrieval of vast numbers of ECG records. Fully automated computerized ECG analyses still have major limitations and, therefore, should not be accepted without careful clinician review.

248 Noninvasive Cardiac Imaging: Echocardiography, Nuclear Cardiology, and Magnetic Resonance/Computed Tomography Imaging

Marcelo F. DiCarli, Raymond Y. Kwong, Scott D. Solomon

The ability to image the heart and blood vessels noninvasively has been one of the greatest advances in cardiovascular medicine since the development of the electrocardiogram (ECG). Cardiac imaging complements history taking and physical examination, blood and laboratory testing, and exercise testing in the diagnosis and management of most diseases of the cardiovascular system. Modern cardiovascular imaging consists of echocardiography (cardiac ultrasound), nuclear scintigraphy including positron emission tomography (PET) imaging, magnetic resonance imaging (MRI), and computed tomography (CT). These studies, often used in conjunction with exercise or pharmacologic stress testing, can be used independently or can provide complementary information for patient diagnosis or prognosis. In this chapter, we review the principles of each of these modalities and the utility and relative benefits of each for the most common cardiovascular diseases.

PRINCIPLES OF MULTIMODALITY CARDIAC IMAGING

ECHOCARDIOGRAPHY

Echocardiography uses high-frequency sound waves (ultrasound) to penetrate the body, reflect from relevant structures, and generate an image. The basic physical principles of echocardiography are identical to other types of ultrasound imaging, although the hardware and software are optimized for evaluation of cardiac structure and function. Early echocardiography machines displayed "M-mode" echocardiograms in which a single ultrasound beam was displayed over time on a moving sheet of paper **(Fig. 248-1, *left panel*)**. Modern echocardiographic machinery uses phased array transducers that contain up to 512 elements and emit ultrasound in sequence. The reflected ultrasound is then sensed by the receiving elements, and images are generated by microprocessors that use information about the timing and magnitude of the reflected ultrasound to generate an image **(Fig. 248-1, *right panel*)**. This sequence happens repeatedly in "real time" to generate moving images with frame rates that are typically >30 frames per second but can exceed 100 frames per second. The gray scale of the image features indicates the intensity of the reflected ultrasound; fluid or blood appears black, and highly reflective structures, such as calcifications on cardiac valves or the pericardium, appear white. Tissues such as myocardium appear grayer, and tissues such as muscle display a unique speckle pattern.

The spatial resolution of ultrasound is dependent on the frequency of the ultrasound (inverse of wavelength). The higher the frequency of the ultrasound beam, the greater the spatial resolution and ability to discern small structures, but at the cost of penetration, which is decreased at higher frequencies. Thus, higher frequencies are used in pediatric imaging or transesophageal echocardiography where the transducer is typically much closer to the structures being interrogated.

Three-dimensional ultrasound transducers use a waffle-like matrix array transducer and receive a pyramidal data sector. Three-dimensional echocardiography is being increasingly used for assessment of congenital heart disease and valves, particularly with transesophageal echocardiography, although current image quality lags behind two-dimensional (2D) ultrasound **(Fig. 248-2)**.

In addition to the generation of 2D images that provide information about cardiac structure and function, echocardiography can be used to interrogate blood flow within the heart and blood vessels by using the Doppler principle to ascertain the velocity of blood flow. When ultrasound emitted from a transducer reflects off red blood cells that are moving toward the transducer, the reflected ultrasound will return at a slightly higher frequency than emitted; the opposite is true when flow moves away from the transducer. That frequency difference, termed the Doppler shift, is directly related to the velocity of the flow of the red blood cells. The velocity of blood flow between two chambers will be directly related to the pressure gradient between those chambers. A modified form of the Bernoulli equation,

$$p = 4v^2$$

where p = the pressure gradient and v = the velocity of blood flow in meters per second, can be used to calculate this pressure gradient in most clinical circumstances. This principle can be used to determine the pressure gradient between chambers and across valves and has become central to the quantitative assessment of valvular heart disease.

There are three types of Doppler ultrasound that are typically used in standard echocardiographic examinations: spectral Doppler, which consists of both pulsed wave Doppler and continuous wave Doppler, and color flow Doppler. Both types of spectral Doppler will display a waveform representing the velocity of blood flow, with time on the horizontal axis and velocity on the vertical axis. Pulsed wave Doppler

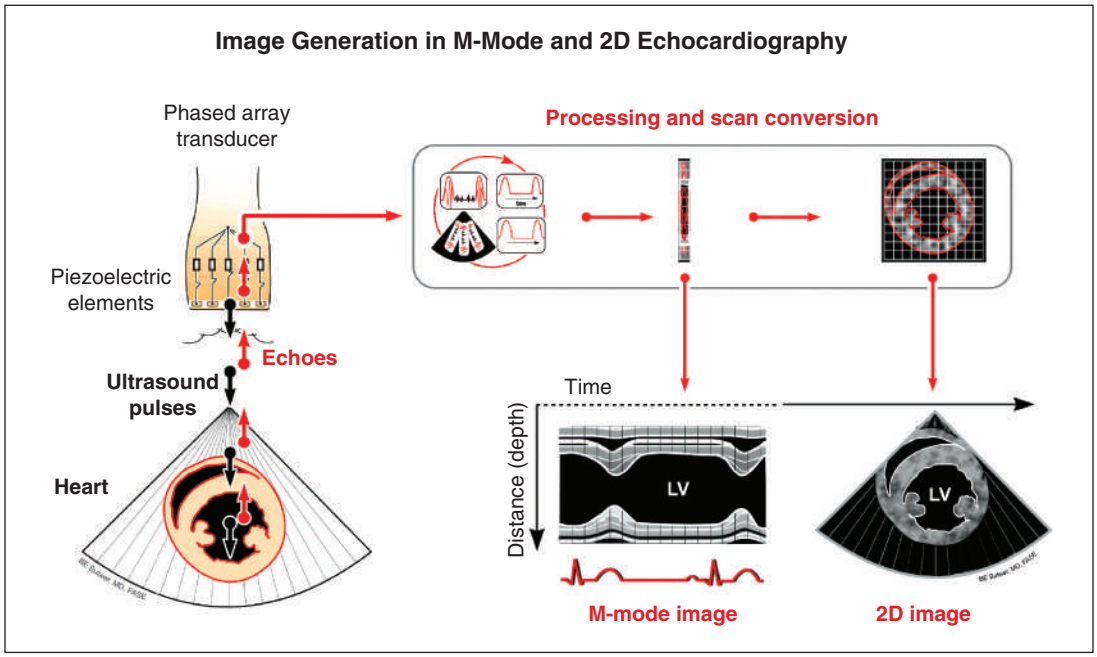

FIGURE 248-1 Principle of image generation in two-dimensional (2D) echocardiography. An electronically steerable phased-array transducer emits ultrasound from piezoelectric elements, and returning echoes are used to generate a 2D image (*right*) using a scan converter. Early echocardiography machines used a single ultrasound beam to generate an "M-mode" echocardiogram (see text), although modern equipment generates M-mode echocardiograms digitally from the 2D data. LV, left ventricle.

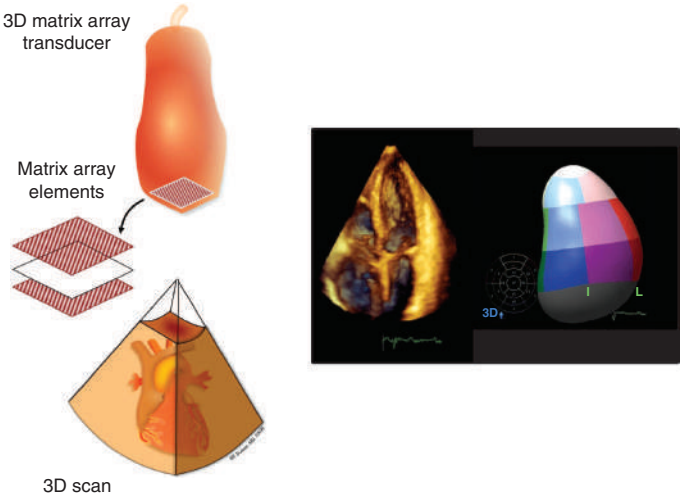

FIGURE 248-2 Three-dimensional (3D) probe and 3D image.

is used to interrogate relatively low velocity flow and has the ability to determine blood flow velocity at a particular location within the heart. Continuous wave Doppler is used to assess high velocity flow but can only identify the highest velocity in a particular direction and cannot interrogate the velocity at a specific depth location. Both techniques can only accurately assess velocities that are in the direction of the ultrasound scan lines, and velocities that are at an angle to the direction of the ultrasound beam will be underestimated. Color flow Doppler is a form of pulsed wave Doppler in which the velocity of blood flow is color encoded according to a scale and superimposed on a 2D gray-scale image in real time, giving the appearance of real-time flow within the heart. The Doppler principle can also be used to assess the velocity of myocardial motion, which is a sensitive way to assess myocardial function (Fig. 248-3). A standard full transthoracic echocardiographic examination consists of a series of 2D views made up of different imaging planes from various scanning locations and spectral and color flow Doppler assessment.

Transesophageal Echocardiography Transesophageal echocardiography is a form of echocardiography in which the transducer

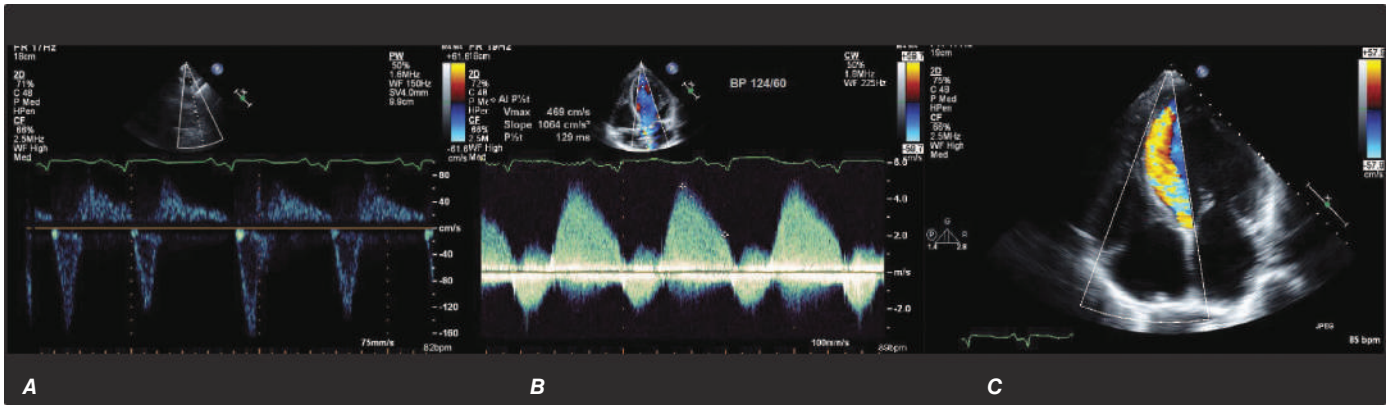

FIGURE 248-3 Three types of Doppler ultrasound. ***A and B.*** Pulsed and continuous wave Doppler waveforms with time on horizontal axis and velocity of blood flow on vertical axis. ***C.*** Color flow Doppler, where velocities are encoded by colors according to scale on right side of screen and superimposed on a two-dimensional grayscale image.

FIGURE 248-4 Two examples of handheld ultrasound equipment: V-Scan (General Electric, *left*) and Sonosite (*right*).

is located on the tip of an endoscope that can be inserted into the esophagus. This procedure allows closer, less obstructed views of cardiac structures, without having to penetrate through chest wall, muscle, and ribs. Because less penetration is needed, a higher frequency probe can be used, and image quality and spatial resolution are generally higher than with standard transthoracic imaging, particularly for structures that are more posterior. Transesophageal echocardiography has become the test of choice for assessment of small lesions in the heart such as valvular vegetations, especially in the setting of a prosthetic valve disease, and intracardiac thrombi, including assessment of the left atrial appendage, which is difficult to visualize with standard transthoracic imaging, and for assessment of congenital abnormalities. Transesophageal echocardiography requires both topical and systemic anesthesia, generally conscious sedation, and carries additional risks such as potential damage to the esophagus, including the rare possibility of perforation, aspiration, and anesthesia-related complications. Patients generally need to give consent for transesophageal echocardiography and be monitored during and after the procedure. Transesophageal echocardiography can be carried out in intubated patients and is routinely used for intraoperative monitoring during cardiac surgery.

Stress Echocardiography Stress echocardiography is routinely used to assess cardiac function during exercise and can be used to identify myocardial ischemia or to assess valvular function under exercise conditions. Stress echocardiography is typically performed in conjunction with treadmill or bicycle exercise testing but can also be performed using pharmacologic stress most typically with an intravenous infusion of dobutamine (see section on stress imaging below).

Point-of-Care/Handheld Echocardiography Whereas typical echocardiographic equipment is large, bulky, and expensive, small handheld or point-of-care ultrasound (POCUS) equipment developed over the last decade now offers diagnostic quality imaging in a package small enough to be carried on rounds **(Fig. 248-4)**. These relatively inexpensive point-of-care devices are gaining full diagnostic capabilities and currently represent an excellent screening tool if used by an experienced operator. As these units become even smaller and less expensive, they are being increasingly used not just by cardiologists, but also by emergency medicine physicians, intensivists, anesthesiologists, and internists.

Nevertheless, echocardiography is a nontomographic modality. The image obtained is dependent on the skill of the operator who, holding a transducer, identifies standard views from which measurements can be made. Images that are obtained off-axis can result in incorrect measurements such as chamber volumes or ejection fraction. As point-of-care echocardiography becomes more commonplace, practitioners will need sufficient training to obtain and interpret images. Artificial intelligence has been incorporated into several devices to help guide the user to obtain optimal images and to help with interpretation (see below). Myocardial strain or deformation imaging has emerged as an alternative way to assess cardiac contractile performance. Global and/or regional myocardial strain can be assessed by either Doppler or, more commonly, 2D echocardiography. Global longitudinal strain is assessed from the apical view and calculated as the endocardial perimeter length in end-diastole minus the endocardial perimeter length in end-systole and divided by the endocardial perimeter length in end-diastole. It is a more robust measure of contractile function than volumetric-based ejection fraction and has been shown to be predictive of outcome in a variety of cardiac diseases, including heart failure and following myocardial infarction.

RADIONUCLIDE IMAGING

Radionuclide imaging techniques are commonly used for the evaluation of patients with known or suspected coronary artery disease (CAD), including for initial diagnosis and risk stratification as well as the assessment of myocardial viability. In addition, radionuclide imaging is commonly used in the evaluation of patients with suspected cardiac amyloidosis, myocardial and vascular inflammation, and infective endocarditis. These techniques use small amounts of radiopharmaceuticals **(Table 248-1)**, which are injected intravenously and trapped in the heart and/or vascular cells. Radioactivity within the heart and vasculature decays by emitting gamma rays. The interaction between these gamma rays and the detectors in specialized scanners (single-photon emission computed tomography [SPECT] and PET) creates a scintillation event or light output, which can be captured by digital recording equipment to form an image of the heart and vasculature. Like CT and MRI, radionuclide images also generate tomographic (three-dimensional) views of the heart and vasculature.

Radiopharmaceuticals Used in Clinical Imaging Table 248-1 summarizes the most commonly used radiopharmaceuticals in clinical SPECT and PET imaging.

Protocols for Stress Myocardial Perfusion Imaging Both exercise and pharmacologic stress can be used for myocardial

TABLE 248-1 Radiopharmaceuticals for Clinical Nuclear Cardiology

RADIOPHARMACEUTICAL	IMAGING TECHNIQUE	PHYSICAL HALF-LIFE	APPLICATION
Technetium-99m sestamibi	SPECT	6 h	Myocardial perfusion imaging
Technetium-99m tetrofosmin	SPECT	6 h	Myocardial perfusion imaging
Thalium-201	SPECT	72 h	Myocardial perfusion imaging
Iodine-123 metaiodobenzylguanidine *(MIBG)*	SPECT	13 h	Cardiac sympathetic innervation
Rubidium-82	PET	76 s	Myocardial perfusion imaging
^{13}N-ammonia	PET	10 min	Myocardial perfusion imaging
^{18}F-fluorodeoxyglucose	PET	110 min	Myocardial viability, infection and inflammation imaging
Technetium-99m pyrophosphate (PYP), technetium-99m hydroxymethylene diphosphonate (HMDP), technetium-99m 3,3-diphosphono-1,2-propanodicarboxylic acid (DPD)	SPECT	6 h	Cardiac amyloidosis

Abbreviations: PET, positron emission tomography; SPECT, single-photon emission computed tomography.

perfusion imaging. Exercise stress is generally preferred because it is physiologic and provides additional clinically important information (i.e., clinical and hemodynamic responses, ST-segment changes, exercise duration, and functional status). However, submaximal effort will lower the sensitivity of the test and should be avoided, especially if the test is requested for initial diagnosis of CAD. In patients who are unable to exercise or who exercise submaximally, pharmacologic stress offers an adequate alternative to exercise stress testing. Pharmacologic stress can be accomplished either with coronary vasodilators, such as adenosine, dipyridamole, or regadenoson, or β_1-receptor agonists, such as dobutamine. For patients unable to exercise, vasodilators are the most commonly used stress agents in combination with myocardial perfusion imaging. Dobutamine is a potent β_1-receptor agonist that increases myocardial oxygen demand by augmenting contractility, heart rate, and blood pressure such as exercise. It is generally used as an alternative to vasodilator stress in patients with chronic pulmonary disease, in whom vasodilators may be contraindicated. Dobutamine is also commonly used as a pharmacologic alternative to stress testing in stress echocardiography.

Myocardial Perfusion and Viability Imaging Protocols

Imaging protocols are tailored to the individual patient based on the clinical question, patient's risk, ability to exercise, body mass index, and other factors.

For SPECT imaging, technetium-99m (^{99m}Tc)-labeled tracers are the most used imaging agents because they are associated with the best image quality and the lowest radiation dose to the patient **(Fig. 248-5)**. Selection of the protocol (stress-only, single-day, or 2-day) depends on the patient and clinical question. After intravenous injection, myocardial uptake of ^{99m}Tc-labeled tracers is rapid (1–2 min). After uptake, these tracers become trapped intracellularly in mitochondria and show minimal change over time. This is why ^{99m}Tc tracers can be helpful in patients with chest pain of unclear etiology occurring at rest because patients can be injected while having chest pain and imaged sometime later after symptoms subside. Indeed, a normal myocardial perfusion study following a rest injection in a patient with active chest pain effectively excludes myocardial ischemia as the cause of chest pain (high negative predictive value). While used commonly in the past for perfusion imaging, thallium-201 protocols are now rarely used because they are associated with a higher radiation dose to the patient.

PET myocardial perfusion imaging is an alternative to SPECT and is associated with improved diagnostic accuracy and lower radiation dose to patients (Table 248-1). The ultra-short half-life of some PET radiopharmaceuticals in clinical use (e.g., rubidium-82) is the primary reason why imaging is generally combined with pharmacologic stress, as opposed to exercise. However, exercise is possible for relatively longer-lived radiotracers (e.g., ^{13}N-ammonia). PET imaging protocols are typically faster than SPECT, but more expensive. In comparison to SPECT, PET has improved spatial and contrast resolution and provides absolute measures of myocardial perfusion (in mL/min per gram of tissue), thereby providing the patients' regional and global coronary flow reserve. The latter helps improve diagnostic accuracy and risk stratification, especially in obese patients, women, and higher risk individuals (e.g., diabetes mellitus) **(Fig. 248-6)**. Contemporary PET and SPECT scanners are combined with a CT scanner (so-called *hybrid PET/CT* and *SPECT/CT*). CT is used primarily to guide patient positioning in the field of view and for correcting inhomogeneities in radiotracer distribution due to attenuation by soft tissues (so-called *attenuation correction*). However, it can also be used to obtain diagnostic data including coronary artery calcium (CAC) score and/or CT coronary angiography (discussed below).

For the evaluation of myocardial viability in patients with ischemic cardiomyopathy, myocardial perfusion imaging (with SPECT or PET) is usually combined with metabolic imaging (i.e., fluorodeoxyglucose [FDG] PET). In hospital settings lacking access to PET scanning, thallium-201 SPECT imaging is an excellent alternative. FDG-PET is also used in the evaluation of myocardial and vascular inflammation and in patients with suspected infective endocarditis.

Bone scintigraphy with SPECT is currently used for the evaluation of patients with suspected cardiac amyloidosis. As discussed below under applications in new-onset heart failure, bone-seeking ^{99m}Tc radiotracers (Table 248-1) are currently used to diagnose transthyretin cardiac amyloidosis with high accuracy.

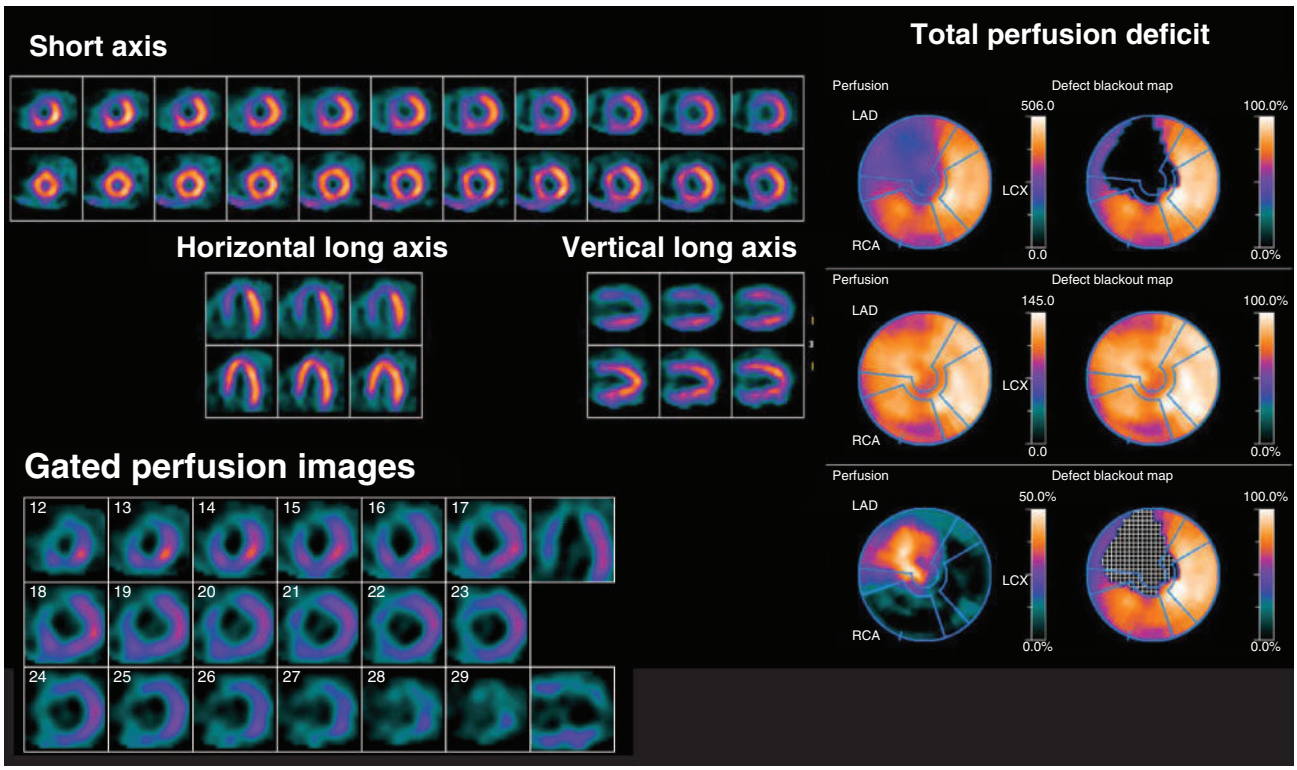

FIGURE 248-5 Tomographic stress (top of each pair) and rest myocardial perfusion images with technetium-99m sestamibi single-photon emission computed tomography imaging demonstrating a large perfusion defect throughout the anterior and anteroseptal walls. The *right panel* demonstrates the quantitative extent of the perfusion abnormality at stress (*top bull's-eye*) and at rest (*middle bull's-eye*), and the extent of defect reversibility (*lower bull's-eye*). The *lower left panel* demonstrates electrocardiogram-gated myocardial perfusion images from which one can determine the presence of regional wall motion abnormalities and calculate left ventricular volumes and ejection fraction.

CARDIAC COMPUTED TOMOGRAPHY

CT acquires images by passing a thin x-ray beam through the body at many angles to generate cross-sectional images. The x-ray transmission measurements are collected by a detector array and digitized into pixels that form an image. The grayscale information in individual pixels is determined by the attenuation of the x-ray beam along its path by tissues of different densities, referenced to the value for water in units known as Hounsfield units. In the resulting CT images, bone appears bright white, air is black, and blood and muscle show varying shades of gray. However, due to the limited contrast between cardiac chambers and vascular structures, iodinated contrast agents are necessary for most cardiovascular indications. Cardiac CT produces tomographic images of the heart and surrounding structures. With modern CT scanners, a three-dimensional dataset of the heart can be acquired in 5–15 s with submillimeter spatial resolution.

CT Calcium Scoring CT calcium scoring is the simplest application of cardiac CT and does not require administration of iodinated contrast. The presence of coronary artery calcification has been associated with increased burden of atherosclerosis and cardiovascular mortality. Coronary calcium is then quantified (e.g., Agatston score) and categorized as minimal (0–10), mild (10–100), moderate (100–400), or severe (>400) **(Fig. 248-7)**. CAC scores are then normalized by age and gender and reported as percentile scores. Population-based studies in asymptomatic cohorts have reported high cardiac prognostic value of CT calcium score. With appropriate techniques, the radiation dose associated with CAC scanning is very low (~1–2 mSv).

CT Coronary Angiography Coronary CT angiography (CTA) is a clinically important alternative to stress testing in selected patients with suspected CAD. Imaging of the coronary arteries by CT is challenging because of their small luminal size and because of cardiac and respiratory motion. Respiratory motion can be reduced by breath-holding, and cardiac motion is best reduced by slowing the patient's heart rate, ideally to under 60 beats/min, using intravenous or oral beta blockade or other rate-lowering drugs. When performing a coronary CTA, image quality is further enhanced using sublingual nitroglycerin to enlarge the coronary lumen just prior to contrast injection. Imaging the whole-heart volume is synchronized to the administration of weight-based and appropriately timed intravenous iodinated contrast. Image acquisition is linked to the timing of the cardiac cycle through ECG triggering. The resulting images are then postprocessed using a three-dimensional workstation, which facilitates interpretation of the coronary anatomy and estimation of the severity of atherosclerosis (Fig. 248-7). A modified version of the enhanced protocol outlined for coronary CTA is used for the evaluation of patients with structural heart disease, especially for preprocedural planning of those undergoing transcatheter valve replacement.

CARDIAC MAGNETIC RESONANCE

Cardiac magnetic resonance (CMR) imaging is based on imaging of protons in hydrogen, which is an advantage, given the abundance of water in the human body. When the body is placed inside an MRI scanner, protons in different tissues, such as in simple fluid or complex macromolecules such as fat or protein, interact with the magnetic field

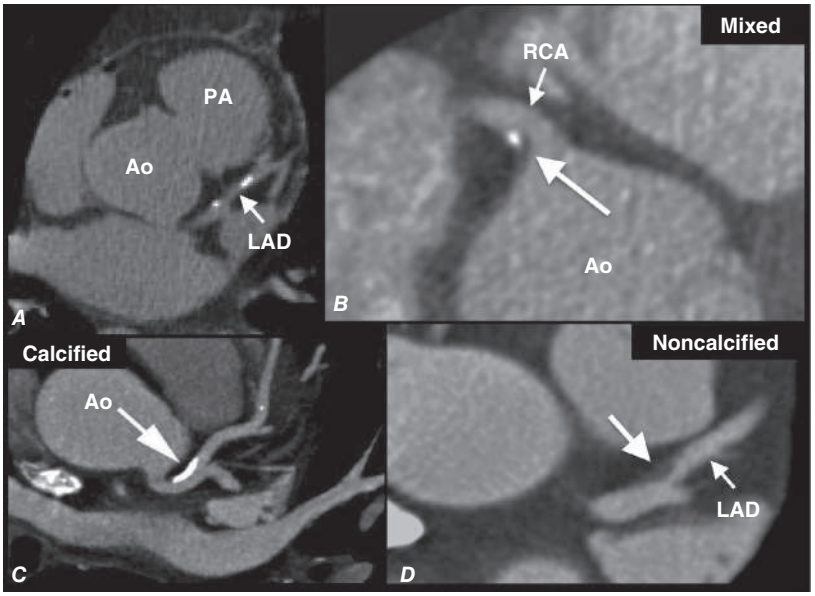

FIGURE 248-7 Examples of non-contrast- and contrast-enhanced coronary imaging with computed tomography (CT). ***A.*** Calcified coronary plaques in the distal left main and proximal left anterior descending coronary artery (LAD) in a noncontrast cardiac CT scan. Calcium deposits are dense and present as bright white structures on CT, even without contrast enhancement. ***B, C, and D.*** Different types of atherosclerotic plaques on contrast-enhanced CT scans. Importantly, noncalcified plaques are evident only on contrast-enhanced CT scans. AO, aorta; PA, pulmonary artery; RCA, right coronary artery.

at their unique frequencies. A set of orthogonal gradient coils in the scanner is designed to locate protons spatially so that radiofrequency (RF) energy pulses can be delivered to select imaging planes of interest. Once the RF pulses stop, the energy absorbed will be released, collected by the phased-array receiver coils placed on the patient's body surface, digitally recorded in a data matrix known as the K-space, then reconstructed into a magnetic resonance image. The large arrays of software methods of delivering RF pulses are known as pulse sequences, which aim to extract different types of cardiac structural or physiologic information. In CMR, T1-weighted pulse sequences are most common, and they assess cardiac structure and function, blood flow, and myocardial perfusion with pharmacologic stress. T2-weighted and T2*-weighted pulse sequences, on the other hand, evaluate myocardial edema and myocardial iron infiltration, respectively. In recent years, T1 and T2 mapping have become routinely used in experienced centers in quantifying myocardial tissue characteristics, with T1 mapping most commonly used to scale the spectrum of myocardial inflammation or fibrosis and T2 mapping for myocardial edema. Using a combination of these methods above, a CMR can accurately assess cardiac structures and function, myocardial infarction and viability, ischemia, and infiltration. Currently, the most common indications for a CMR include assessing the etiology of cardiomyopathy, myocardial ischemia from chest pain syndromes, myocardial viability for benefits of revascularization, pericardial diseases, and myocardial substrates of arrhythmias. Vector ECG-gating and repetitive patient breath-holding are used by convention to suppress cardiac and respiratory motions, respectively. However, with technical advent, rapid data collection algorithms and diaphragmatic position gating have eliminated the need for ECG gating and breath-holding in challenging situations. A list of common pulse sequences used in CMR is shown in Table 248-2.

ASSESSMENT OF CARDIAC STRUCTURE AND FUNCTION

Echocardiography, CMR, and cardiac CT are all capable of assessing cardiac structure and function, although echocardiography is generally considered the primary imaging method for these assessments. Radionuclide imaging can also be used to assess left ventricular regional and global systolic function. Echocardiography is most often used to assess the size of all four chambers and thickness of ventricular walls, which are affected by both cardiac and systemic diseases.

The structure of the left ventricle is generally assessed by determining its volume and mass. Left ventricular volumes can be easily estimated from 2D echocardiography by using methods incorporating geometric assumptions. The accuracy of these echocardiographic methods is reduced when foreshortening of the imaging plane leads to underestimation of volumes. Moreover, these methods require accurate delineation of the endocardial border. In this regard, high-resolution tomographic techniques such as CMR or cardiac CT are more accurate for volumetric assessment. Three-dimensional (3D) echocardiography does not require any geometric assumptions about the left ventricle for quantification of volumes and ejection fraction. However, 3D echocardiographic imaging requires substantial expertise and currently is not widely used in practice.

Left ventricular dilatation is common to several cardiac diseases. For example, regional dysfunction secondary to myocardial infarction can ultimately lead to progressive ventricular dilatation or remodeling. Although dilatation often begins in the region affected by the

TABLE 248-2 Clinical Cardiac Magnetic Resonance Pulse Sequences and Their Application

PULSE SEQUENCE	KEY IMAGING INTERESTS
Cardiac Morphology	
Still frame imaging (black or bright blood)	Cardiac structures
Cardiac Function	
Cine imaging	Left ventricular volume and function

Cine imaging	Regional wall motion
Myocardial Tissue Characterization	
Late gadolinium enhancement	Myocardial infarction and infiltrative disease
T2-weighted imaging	Myocardial edema
Iron content imaging	Myocardial iron infiltration
Magnetic Resonance Angiography	
Aorta, peripheral and coronary arteries	Luminal stenosis and vessel wall remodeling

infarction, subsequent compensatory dilatation can occur in remote myocardial regions as well. The presence of regional wall motion abnormalities associated with ventricular thinning (reflecting scar) in a coronary distribution is strongly suggestive of an ischemic etiology. Regional wall motion can be accurately assessed by echocardiography, CMR, and cardiac CT. Direct assessment of infarcted myocardium is possible with both CMR (evident as areas of late gadolinium enhancement [LGE]) and radionuclide imaging (as assessed by regional perfusion or metabolic defects at rest). CMR can be particularly useful in determining etiology of cardiomegaly and ventricular dysfunction, with LGE in coronary distributions being nearly pathognomonic for infarction **(Video 248-1)**.

More global ventricular dilatation is seen in cardiomyopathy and dilatation due to valvular heart disease. Idiopathic, nonischemic cardiomyopathies will typically result in global ventricular dilatation and dysfunction, with thinning of the walls. Patients with substantial ventricular dyssynchrony due to conduction abnormalities will have a typical pattern of contraction (e.g., delay of contraction of the lateral wall with left bundle branch block). As discussed later in this chapter, regurgitant lesions of either the mitral or aortic valves can lead to substantial ventricular dilatation, and assessment of ventricular size is integral in the evaluation and timing of surgical correction. Because changes in ventricular size are used clinically to determine which patients should undergo valve surgery, accurate assessment of changes in ventricular size is essential. Although serial echocardiography can provide these data, serial assessment by CMR may be more accurate when appreciation of subtle changes over time is important.

Left ventricular wall thickness and mass are also important measures of cardiac and systemic disease. The left ventricle will hypertrophy under any condition in which its afterload is increased, including conditions that obstruct outflow, such as aortic stenosis, hypertrophic cardiomyopathy, and subaortic membranes; in postcardiac aortic obstruction seen in coarctation; or in systemic conditions characterized by increased afterload, such as hypertension. The pattern of ventricular hypertrophy can change depending on the etiology. Aortic stenosis and hypertension are typically characterized by concentric hypertrophy, in which the ventricular walls thicken "concentrically" and cavity size is usually small. In volume overload conditions such as mitral or aortic regurgitation, there may be minimal increase in ventricular wall thickness, but substantial ventricular dilatation leads to marked increases in left ventricular mass.

Ventricular wall thickness can be measured, and ventricular mass can be calculated by either echocardiography or CMR. Although radionuclide imaging and cardiac CT can also provide measures of left ventricular mass, they are not generally used for this purpose. Although measurement of wall thickness with echocardiography is relatively straightforward and accurate, determining left ventricular mass by echocardiography requires using one of several formulas that consider both wall thickness and ventricular cavity dimensions. Assessment of left ventricular mass volumetrically by CMR has the advantage of not requiring geometric assumptions and is thus more accurate than echocardiography.

ASSESSMENT OF LEFT VENTRICULAR SYSTOLIC FUNCTION

Assessment of ejection fraction, or the percentage of blood ejected with each beat, has been the primary method to assess systolic function and is generally calculated by subtracting end-systolic volume from end-diastolic volume and dividing by end-diastolic volume. All cardiac imaging modalities can provide direct measurements of left ventricular ejection fraction (LVEF). As discussed above, tomographic techniques (e.g., CMR, CT, and radionuclide imaging) are generally more accurate and reproducible than echocardiography because there are no geometric assumptions and these techniques are not dependent on operator skill, although echocardiography remains the most utilized method. A LVEF of 55% or greater is generally considered normal, and an LVEF of 50–55% is considered in the low-normal range, although these can vary widely, and normal ejection fraction tends to be higher in women than in men.

Newer methods to assess systolic function, such as myocardial strain or deformation imaging using speckle-tracking methods on echocardiography, myocardial tagging, and more recently, feature tracking on CMR, can provide a more sensitive approach to the detection of systolic dysfunction, in part because these measures are geometric assumption-independent. Additional assessments based on these novel methods include assessment of myocardial twist and torsion. Regional strain patterns can differ in various diseases. For example, in subtypes of cardiac amyloidosis, it is common to see a reduction in myocardial strain at the base of the heart with relative sparing of the apex. Strain imaging is being increasingly utilized in conditions such as valvular heart disease and early detection of cardiotoxicity following chemotherapy and/or radiation therapy. In addition to the estimation or calculation of ejection fraction, stroke volume can be assessed by any of the imaging methods by subtracting the end-systolic volume from the end-diastolic volume or by quantifying forward flows using echocardiographic Doppler methods or phase-contrast CMR imaging. They offer an estimated measure of cardiac output other than LVEF.

ASSESSMENT OF LEFT VENTRICULAR DIASTOLIC FUNCTION

Echocardiography remains the primary method for clinical assessment of diastolic function, in part because echocardiography has the highest temporal resolution of all the imaging techniques. Recent advances in Doppler tissue imaging allow for accurate assessment of the velocity of myocardial wall motion by assessing the excursion of the mitral annulus in diastole. Mitral annular relaxation velocity, or E′, is inversely related to the time constant of relaxation, tau, and has been shown to have prognostic significance in patients with heart failure. Dividing the standard mitral inflow maximal velocity, E, by the mitral annular relaxation velocity yields E/E′, which has been shown to correlate with left ventricular filling pressures. The utility of standard E and A wave ratios for assessment of diastolic function has been questioned. Mitral deceleration time can be a useful measure if very short (<150 ms), suggesting restrictive physiology and severe diastolic dysfunction. Left atrial volume is considered an integrator of diastolic function, and minimal volume may be more reflective of left ventricular filling pressures than maximal volume. Several grading methods for diastolic function have been proposed that take into account a number of diastolic parameters, including Doppler tissue-based relaxation velocities, pulmonary venous Doppler, and left atrial size **(Fig. 248-8)**. Diastolic function worsens with aging, and most diastolic parameters need to be adjusted for age.

ASSESSMENT OF RIGHT VENTRICULAR FUNCTION

Right ventricular size and function have been shown to be prognostically important in a variety of conditions, and can be assessed by echocardiography, CMR, CT, or radionuclide imaging methods. CMR is considered the most accurate noninvasive technique to evaluate the structure and ejection fraction of the right ventricle **(Video 248-2)**. Assessment of the right ventricle by echocardiography has generally been qualitative, owing in part to the unusual geometry of the right ventricle. However, several quantitative methods are available for assessment of right ventricular function, including fractional area change (FAC = [diastolic area – systolic area]/diastolic area), which has been shown to correlate with outcomes in heart failure and after myocardial infarction. Excursion of the tricuspid annulus (tricuspid annular plane systolic excursion [TAPSE]) is another method to assess right ventricular function, although it is mostly used in research settings.

Abnormalities of right ventricular size and function are generally secondary to either diseases that affect the right ventricle intrinsically or diseases in which the right ventricle responds to abnormalities elsewhere in the heart or pulmonary vasculature. Intrinsic diseases that affect the right ventricle include congenital abnormalities, including hypoplastic right ventricle and arrhythmogenic right ventricular dysplasia, and acquired conditions, such as right ventricular infarction

and infiltrative diseases. Right ventricular dilatation can occur due to both chronic and acute processes. Long-standing pulmonary hypertension or pulmonary outflow tract obstruction leads to right ventricular hypertrophy and ultimately dilatation. An acute process that can cause profound right ventricular dilatation and dysfunction is acute pulmonary embolism. In the setting of acute occlusion of a pulmonary artery or branch, an acute rise in pulmonary vascular resistance causes a previously normal right ventricle to dilate and fail due to the increased afterload. In acute pulmonary embolism, right ventricular dilatation and dysfunction are signs of substantial hemodynamic compromise and are associated with a marked increased risk of death. In addition to right ventricular dilatation, acute pulmonary embolism is often associated with a specific pattern of regional right ventricular dysfunction, commonly referred to as the McConnell sign, characterized by preservation of right ventricular wall motion in the basal and apical regions and dyskinesis in the region of the mid right ventricular free wall. This abnormality is highly specific for acute pulmonary embolism and is likely secondary to acute increases in right ventricular load.

Any disease that causes increased pulmonary vascular resistance can lead to right ventricular dilatation and dysfunction. For example, long-standing chronic obstructive pulmonary disease increases pulmonary vascular resistance and results in cor pulmonale. Acute pneumonia can cause findings that are similar to acute pulmonary embolism, and right ventricular dysfunction has been a hallmark of severe COVID-19 disease due to either macro- or microthrombosis in the pulmonary vasculature. In patients with right ventricular dilatation without obvious pulmonary disease, intracardiac shunts should be considered. The increased flow through the pulmonary vasculature resulting from an atrial septal or ventricular septal defect can, over time, result in elevation in pulmonary vascular resistance with subsequent dilatation and hypertrophy of the right ventricle. Right ventricular dilatation and dysfunction can be seen in left-sided heart disease, and patients who develop right ventricular dilatation and dysfunction due to predominantly left-sided disease have worse outcomes.

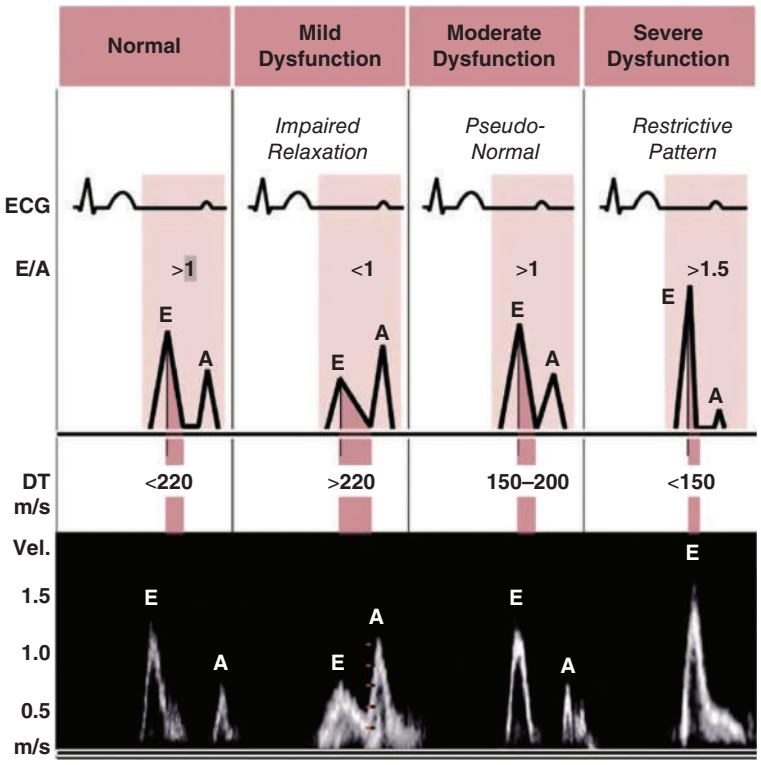

FIGURE 248-8 Mitral inflow Doppler waveforms in diastolic dysfunction. Left ventricle diastolic filling patterns (normal, impaired relaxation, pseudonormal, and restrictive filling). See text for details. ECG, electrocardiogram; LV, left ventricle; PW, pulsed wave. *(Modified from CY Ho, BE Bulwer: Echocardiographic assessment of diastolic function, in Essential Echocardiography. A Practical Handbook with DVD. CY Ho, BE Bulwer (eds). Totowa, NJ: Humana Press; 2007, p 124.)*

In addition to assessment of left and right ventricular structure and function, assessment of the other cardiac chambers also provides important clues to intracardiac and systemic diseases. Enlargement of the left atrium is common in patients with hypertension and is also suggestive of increased left ventricular filling pressures; indeed, left atrial size is often termed the "hemoglobin A_{1c}" of diastolic function, because left atrial enlargement reflects long-standing increase in left-sided filling pressures. Right atrial dilatation and dilatation of the inferior vena cava are common in conditions in which central venous pressure is elevated.

PATIENT SAFETY CONSIDERATIONS

RADIATION EXPOSURE

Both cardiac CT and radionuclide imaging expose patients to ionizing radiation. Several recent publications have raised concern regarding the potential harmful effects of ionizing radiation associated with cardiac imaging. The *effective dose* is a measure used to estimate the biologic effects of radiation and is expressed in millisieverts (mSv). However, measuring the radiation effective dose associated with diagnostic imaging is complex and imprecise and often results in varying estimates, even among experts. The effective dose from a typical myocardial perfusion SPECT scan ranges between ~4 and 11 mSv, depending on the protocol and type of scanner used. The effective dose from a typical myocardial perfusion PET scan is lower, ~2.0–4 mSv. Radiation exposure associated with cardiac CT is variable and, as with radionuclide imaging, also depends on the imaging protocol and scanner used. Although historic radiation doses with cardiac CT have been quite high, the introduction of newer technologies (e.g., x-ray tube modulation, prospective ECG gating) has resulted in a significant dose reduction. The current average radiation dose for a coronary CTA ranges from 3 to 15 mSv and, in selected cases, can be as low as 1 mSv. Imaging laboratories follow the ALARA (as low as reasonably achievable) principle when balancing the clinical need and imaging approach. By comparison, the average dose for invasive coronary angiography is ~7 mSv, whereas exposure to radiation from natural sources in the United States amounts to ~3 mSv annually.

The risk of a fatal malignancy from medical imaging–related radiation is difficult to estimate precisely but is likely small and difficult to discern from the background risk of natural malignancies. The small but potential radiation risks from imaging mandate an assessment of the risk-versus-benefit ratio in the individual patient. In this context, one must also consider the risks of missing important diagnostic information by not performing a test (which could potentially influence near-term management and outcomes) for a theoretical concern of a small long-term risk of malignancy. Before ordering any test, especially one associated with ionizing radiation, we must ensure the appropriateness of the study and that the potential benefits outweigh the risks. The likelihood that the study being considered will affect the patient's clinical management should be addressed before testing is performed. It is also important that "routine" follow-up scans in asymptomatic individuals be avoided.

CONTRAST AGENTS

Contrast agents are commonly used in cardiac CT, CMR, and echocardiography. Although their use significantly enhances the diagnostic information of each of these tests, there are also potential risks from the administration of contrast agents that should be considered.

The risk of adverse reactions from iodinated contrast agents used in cardiac CT is well established. The precise pathogenesis of contrast reactions following intravascular administration of iodinated contrast

media is not known. The overall incidence of contrast reactions is 0.4–3% with nonionic formulations and higher for ionic formulations. Most contrast adverse reactions are mild and self-limiting. The risk of contrast-induced nephropathy (CIN) in patients with relatively normal renal function (estimated glomerular filtration rate [eGFR] >60 mL/min) is low. In most patients, CIN is self-limited, and renal function usually returns to baseline within 7–10 days, without progressing to chronic renal failure. However, this risk increases in patients with GFR <60 mL/min, especially older diabetic subjects. In such patients, appropriate screening and pre- and postscan hydration are necessary.

The use of gadolinium-based contrast agents (GBCAs) improves CMR imaging by enhancing myocardial tissue contrast or delineating cardiac or vascular structures. All GBCAs are chelated to render the compounds nontoxic and facilitate renal excretion. Mild reactions from GBCAs, such as skin itchiness or redness, occur in ~1% of patients, but severe or anaphylactic reactions are very rare at approximately one in 200,000 patients. Older generation (group I) linear-structured GBCAs have been associated with a rare but serious condition known as nephrogenic systemic fibrosis (NSF), which is an interstitial inflammatory reaction manifested as fibrosis of tissues or internal organs and even death. Risk factors to developing NSF include high-dose use of group I GBCA in presence of severe renal dysfunction (eGFR <30 mL/min per 1.73 m^2), need for hemodialysis, an eGFR <15 mL/min per 1.73 m^2, acute renal deterioration, and concurrent proinflammatory/systemic illnesses. Newer generation (group II) macrocyclic-structured GBCAs have an excellent safety profile across all patients with chronic kidney dysfunction and indeed are now the standard GBCA of choice in most MRI centers. The American College of Radiology considers using group II agents as safe in patients with severe renal dysfunction or on dialysis. For patients with a clinical indication for MRI, checking the serum eGFR level is no longer recommended before the use of group II GBCA. With the widespread use of group II GBCA, routine pretest screening, and weight-based dosing, a near-zero incidence of NSF has been reported in the past decade.

Contrast agents can also be used in echocardiography. Injected agitated saline is used routinely to assess cardiac shunts, because these "bubbles" are too large to traverse the pulmonary circulation. After saline injection, the presence of bubbles in the left side of the heart is indicative of shunt, although the location can sometimes be difficult to determine. The current U.S. Food and Drug Administration (FDA)-approved use of echocardiographic contrast agents is for opacification of left-sided chambers and to improve delineation of left ventricular endocardial border in patients with suboptimal echocardiograms. These agents are either albumin- or lipid-based microspheres filled with inert gases, typically perfluorocarbons. They are considered extremely safe, although they have, in extremely rare instances, been associated with allergic reactions and neurologic events.

SAFETY CONSIDERATIONS OF CMR IN PATIENTS WITH PACEMAKERS AND DEFIBRILLATORS

There are now numerous FDA-approved MRI-conditional internal cardiac defibrillators and pacemakers that are safe to undergo an MRI study up to 3T, under well-defined scanning conditions in experienced centers. For non–FDA-approved cardiac devices (legacy devices), collective evidence has also indicated that MRI studies can be safely performed at 1.5T under normal operational settings, in absence of fractured, epicardial, or abandoned leads, and when an experienced staff is available to interrogate the cardiac device before and after MRI study. The Centers for Medicare and Medicaid Services have approved and expanded coverage of MRI studies in patients with an implanted legacy device since April 2018.

PATIENT-CENTERED APPLICATIONS OF CARDIAC IMAGING

CORONARY ARTERY DISEASE

The basis for the diagnostic application of imaging tests in patients with known or suspected CAD should be viewed considering the pretest probability of disease as well as the specific characteristics of imaging tests (i.e., sensitivity and specificity). In symptomatic patients, the prevalence or pretest probability of CAD differs based on the type of symptom (typical angina, atypical angina, noncardiac chest pain), as well as on age, gender, and coronary risk factors. In an individual patient, the results of the initial test inform the posttest likelihood of CAD. In patients undergoing sequential testing (e.g., ECG treadmill testing followed by stress imaging), the posttest probability of disease after the first test becomes the pretest likelihood of disease for the second test. Regardless of the sequence, the expectation is that a test will provide sufficient information to confirm or exclude the diagnosis of CAD and that such information will allow accurate risk stratification to be able to guide management decisions.

Table 248-3 summarizes the relative diagnostic accuracies of cardiac imaging modalities for the diagnosis of CAD.

It is important to highlight that most studies included in meta-analyses of the diagnostic accuracy of cardiac imaging modalities for the diagnosis of CAD were retrospective, small, single-center studies, comprising predominantly male patients with a high prevalence of CAD (>50–60%). Multicenter studies assessing the performance of individual modalities or comparing different modalities have consistently resulted in more modest diagnostic accuracies, tracking more closely with how these tests perform in clinical practice.

Stress Echocardiography The hallmark of myocardial ischemia during stress echocardiography is the development of new regional wall motion abnormalities and reduced systolic wall thickening (Video 248-3). Stress echocardiography can be performed in conjunction with exercise or dobutamine stress. Stress echocardiography is best at identifying inducible wall motion abnormalities in previously normally contracting segments. In a patient with wall motion abnormalities at rest, the specificity of stress echocardiography is reduced, and worsening regional function of a previously abnormal segment might reflect worsening contractile function in the setting of increased wall stress rather than new evidence of inducible ischemia.

The advantages of stress echocardiography over other stress imaging techniques include its relatively good diagnostic accuracy, widespread

TABLE 248-3 Comparative Diagnostic Accuracy of Cardiac Imaging Approaches to Coronary Artery Disease

IMAGING MODALITY	PUBLISHED DATA	SENSITIVITY	SPECIFICITY
Exercise echocardiography	15 studies (n = 1849 patients)	84%	82%
Dobutamine echocardiography	28 studies (n = 2246 patients)	80%	84%
SPECT MPI	113 studies (n = 11,212 patients)	88%	76%
Myocardial perfusion PET	9 studies (n = 650 patients)	93%	81%
CMR perfusion	37 studies (n = 2841 patients)	91%	81%
CMR wall motion	14 studies (n = 754 patients)	83%	86%
Coronary CTA	18 studies (n = 1286 patients)	99%	89%

Note: In these studies, the diagnosis of coronary artery disease was based on the presence of a >50% or >70% stenosis on invasive coronary angiography.

Abbreviations: CMR, cardiac magnetic resonance; CTA, computed tomography angiography; MPI, myocardial perfusion imaging; PET, positron emission tomography; SPECT, single-photon emission computed tomography.

availability, no use of ionizing radiation, and relatively low cost. Limitations of stress echocardiography include (1) the technical challenges associated with image acquisition at peak exercise because of exertional hyperpnea and cardiac excursion, (2) the fact that rapid recovery of wall motion abnormalities can be seen with mild ischemia (especially with one-vessel disease, which limits sensitivity), (3) difficulty detecting residual ischemia within an infarcted territory because of resting wall motion abnormality, (4) high operator dependence for acquisition of echocardiographic data and analysis of images, and (5) the fact that good-quality complete images viewing all myocardial segments occurs in only 85% of patients. Newer techniques including second harmonic imaging and the use of intravenous contrast agents improve image quality, but their effect on diagnostic accuracy has not been well documented.

As with nuclear perfusion imaging, stress echocardiography is often used for risk stratification in patients with suspected or known CAD. A negative stress echocardiogram is associated with an excellent prognosis, allowing identification of patients at low risk. Conversely, the risk of adverse events increases with the extent and severity of wall motion abnormalities on stress echocardiography.

Stress Radionuclide Imaging SPECT myocardial perfusion imaging is the most common form of stress imaging tests for CAD evaluation. The presence of a reversible myocardial perfusion defect is indicative of ischemia **(Fig. 248-9, *left panel*)**, whereas a fixed perfusion defect generally reflects prior myocardial infarction **(Fig. 248-9, *right panel*)**. As discussed above, PET has advantages compared to SPECT, but it is not widely available and is more expensive and, thus, considered an emerging technology in clinical practice.

Nuclear perfusion imaging is another robust approach to diagnose obstructive CAD, quantify the magnitude of inducible myocardial ischemia, assess the extent of tissue viability, and guide therapeutic management (i.e., selection of patients for revascularization). One of the most valuable clinical applications of radionuclide perfusion imaging is for risk stratification. It is well established that patients with a normal SPECT or PET study exhibit a low rate of major adverse cardiac events of <1% annually. Importantly, the risks of death and myocardial infarction increase linearly with increasing magnitude of perfusion abnormalities, reflecting the extent and severity of CAD.

Despite the widespread use and clinical acceptance of radionuclide imaging in CAD evaluation, a recognized limitation of this approach is that it often uncovers only coronary territories supplied by the most severe stenoses. Consequently, it is relatively insensitive to accurately delineate the extent of obstructive angiographic CAD, especially in the setting of multivessel disease. The use of quantitative myocardial blood flow and coronary flow reserve with PET can help mitigate this limitation. In patients with so-called "balanced" ischemia or diffuse CAD, measurements of coronary flow reserve uncover areas of myocardium at risk that would generally be missed by performing only relative assessments of myocardial perfusion **(Fig. 248-10)**. Conversely, a normal coronary flow reserve is associated with a very high negative predictive value for excluding high-risk angiographic CAD. These measurements of coronary flow reserve also contribute to risk stratification across the spectrum of ischemic changes, including patients with visually normal myocardial perfusion.

HYBRID CT AND NUCLEAR PERFUSION IMAGING Because many of the newer generation nuclear medicine scanners integrate CT and a gamma camera in the same acquisition gantry, it is now possible to acquire and quantify myocardial scar and ischemia and CAC scoring from a single dual-modality study (SPECT/CT or PET/CT) **(Fig. 248-11)**. The rationale for this integrated approach is predicated on the fact that the perfusion imaging approach is designed to uncover only obstructive atherosclerosis. Conversely, CAC scoring provides a quantitative measure of the anatomic extent of atherosclerosis. This provides an opportunity to improve the conventional models for risk assessment using nuclear imaging alone, especially in patients without known CAD.

Cardiac CT Voluminous plaques are more prone to calcification, and stenotic lesions frequently contain large amounts of calcium. Indeed, there is evidence that high CAC scores are generally predictive of a higher likelihood of obstructive CAD, and the available data support the concept of a threshold phenomenon governing this relationship (i.e., Agatston score >400). However, given the fact that CAC scores are not specific markers of obstructive CAD, one should be cautious in using this information as the basis for referral of patients to coronary angiography, especially in symptomatic patients with low-risk stress tests. Conversely, CAC scores <400, especially in symptomatic patients with intermediate-high likelihood of CAD, as in those with typical angina, may be less effective in excluding CAD, especially in young symptomatic men and women who may have primarily noncalcified atherosclerosis **(Fig. 248-12)**.

As discussed above, the improved temporal and spatial resolution of modern multidetector CT scanners offers a unique noninvasive approach to delineate the extent and severity of coronary

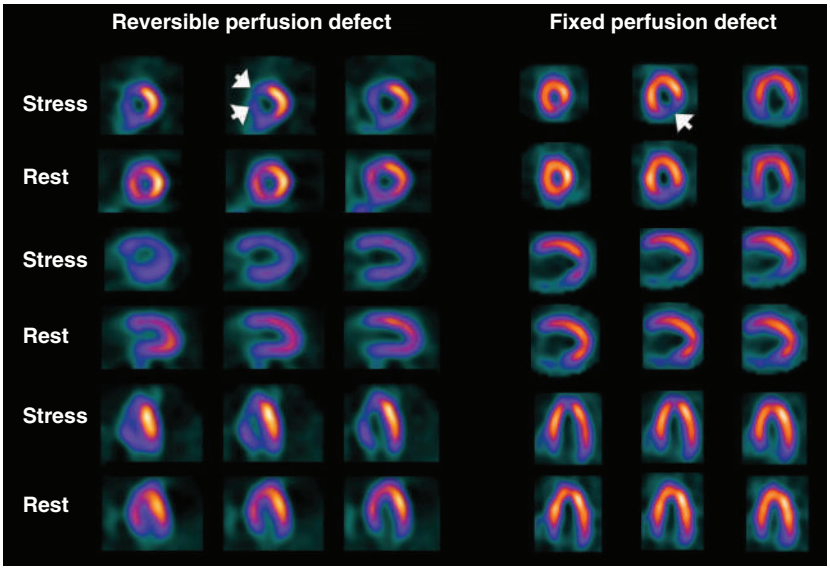

FIGURE 248-9 Selected technetium-99m sestamibi myocardial perfusion single-photon emission computed tomography images of two different patients demonstrating a reversible perfusion defect involving the anterior and septal left ventricular wall, reflecting ischemia in the left anterior descending coronary territory (*arrows in left panel*), and a fixed perfusion defect involving the inferior and inferolateral walls consistent with myocardial scar in the right coronary territory (*arrow in right panel*).

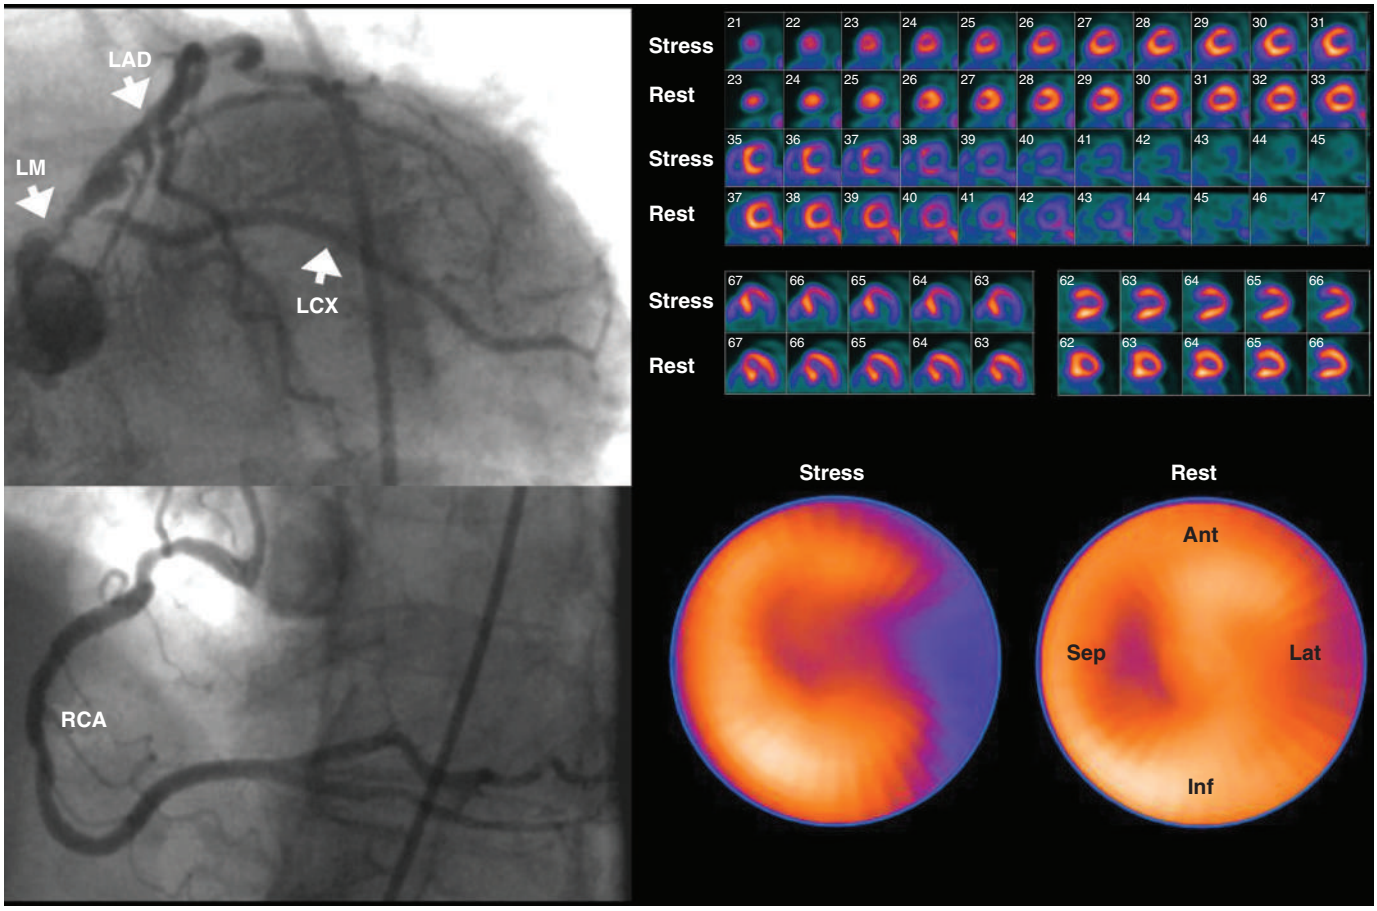

FIGURE 248-10 Coronary angiographic (*left panel*) and rubidium-82 myocardial perfusion positron emission tomography images (*right panel*) in an 85-year-old female with diabetes presenting with chest pain. The coronary angiogram demonstrates significant stenoses of the left main and circumflex coronary arteries. However, the perfusion images demonstrate only a reversible lateral wall defect. Quantification of stress and rest myocardial blood flow demonstrated a significant, global reduction on coronary flow reserve (estimated at 1.2, normal value >2.0), reflecting extensive myocardium risk that was underestimated by the semiquantitative estimates of myocardial perfusion. LAD, left anterior descending artery; LCX, left circumflex artery; LM, left main artery; RCA, right coronary artery.

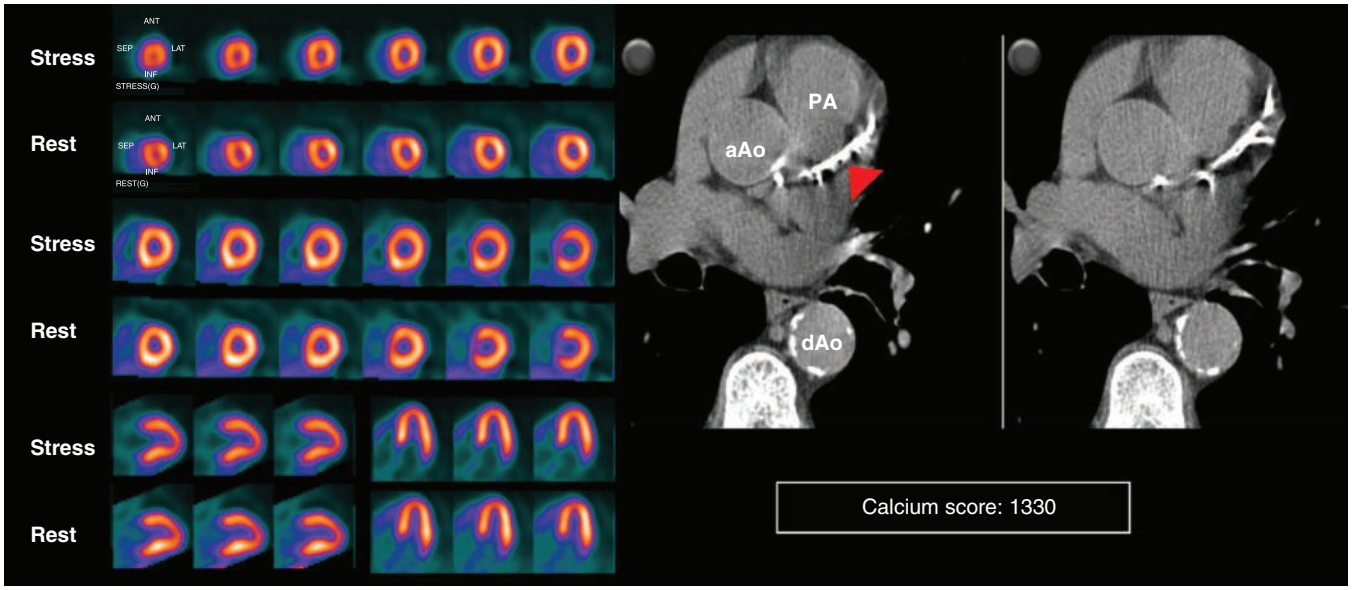

FIGURE 248-11 Stress and rest rubidium-82 myocardial perfusion positron emission tomography (PET) images (*left*) and noncontrast gated computed tomography (CT) images (*right*) delineating the extent and severity of coronary artery calcifications obtained with integrated PET/CT imaging. The images demonstrate extensive atherosclerosis (Agatston coronary calcium score = 1330) without flow-limiting disease based on the normal perfusion study. aAo, ascending aorta; dAo, descending aorta; PA, pulmonary artery.

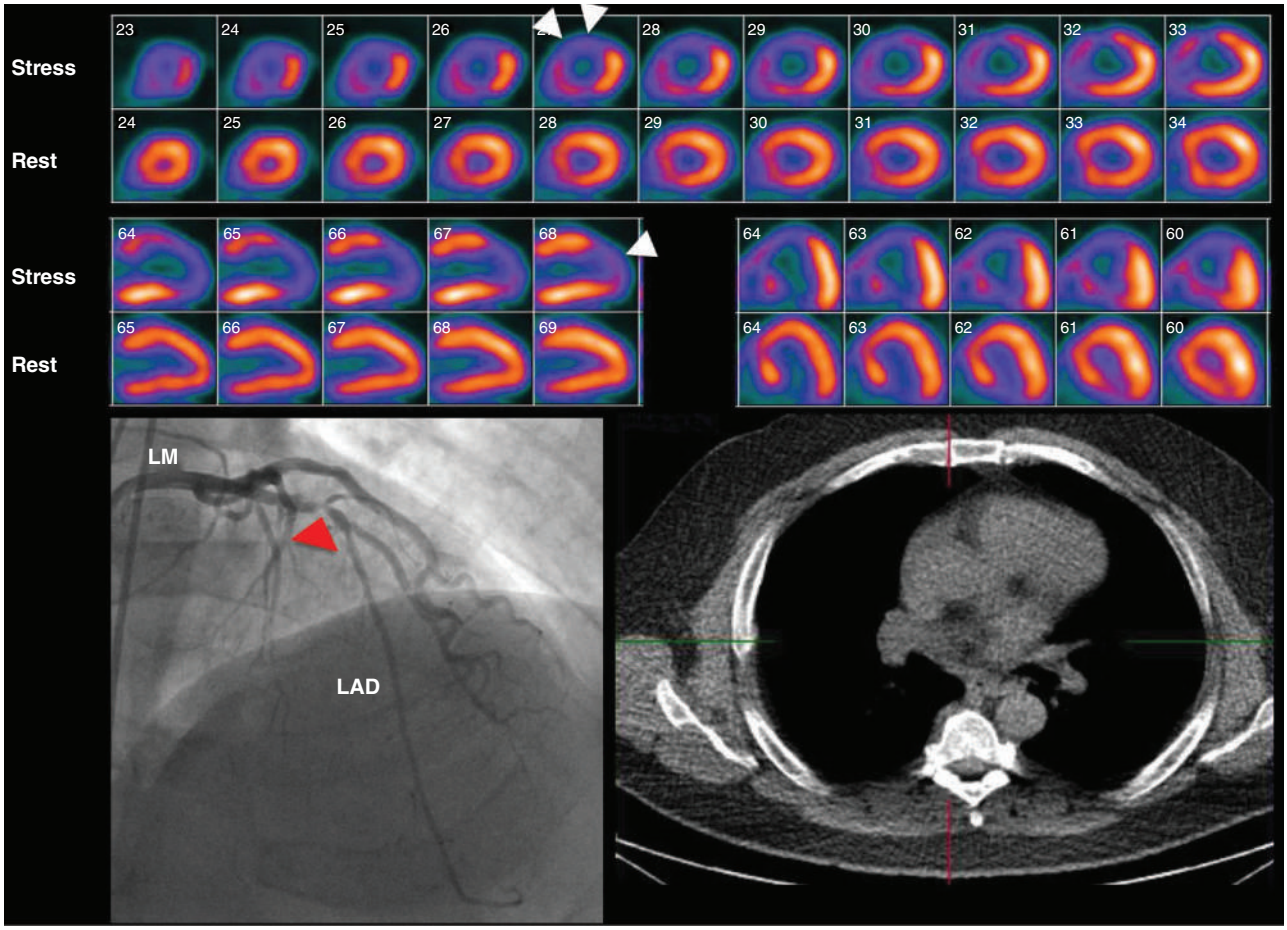

FIGURE 248-12 Stress and rest rubidium-82 myocardial perfusion positron emission tomography images (*top*), noncontrast gated computed tomography images (*lower right*), and selected coronary angiographic images obtained on a 59-year-old male patient with atypical angina. Despite the absence of significant coronary calcifications (Agatston calcium score = 0), the perfusion images demonstrated a dense and reversible perfusion defect involving the anterior and anteroseptal walls (*arrows*), reflecting significant obstructive disease in the left anterior descending coronary artery (LAD), confirmed on angiography. LM, left main artery.

atherosclerosis with coronary CTA. The extremely high sensitivity of this approach offers a very effective means for excluding the presence of CAD (high negative predictive value) (Table 248-3). In the setting of high coronary calcium scores (e.g., >400), however, specificity is reduced because the blooming artifact of calcium does not allow one to evaluate the vessel lumen accurately. Given the high negative predictive value of CTA, a normal scan result effectively excludes obstructive CAD and abolishes the need for further investigation. As discussed below, this may be quite useful in patients with low-intermediate clinical risk presenting to the emergency room for chest pain. However, the limited capability of this technique to determine which coronary plaques are flow limiting can make abnormal scan results more difficult to interpret, especially in terms of the possible need of revascularization. There are emerging data suggesting that by adding a stress myocardial perfusion CT evaluation (similar to stress perfusion CMR) **(Fig. 248-13, *top panel*)** or an estimated fractional flow reserve (so-called FFR_{CT}) **(Fig. 248-13, *lower panel*)**, one can define the hemodynamic significance of anatomic stenosis. FFR_{CT} is beginning to enter routine clinical practice. However, CT myocardial perfusion remains an emerging technology.

As with invasive coronary angiography, assessments of the extent of CAD by CTA can also provide useful prognostic information. A low 1-year cardiac event rate has been reported for patients without coronary atherosclerosis on CTA. For patients with obstructive CAD, the risk of adverse cardiac events increases proportionally with the extent of angiographically obstructive CAD. There is new evidence that even the presence of nonobstructive atherosclerosis increases the risk of adverse cardiac events.

Although CTA can be helpful in assessing patency of bypass grafts, the assessment of stents is somewhat more challenging because the limited spatial resolution of CT and stent diameter (<3 mm being associated with the highest number of partial lumen visualization and nondiagnostic scans) both contribute to limited clinical results.

CMR Imaging CMR evaluates for ischemia from CAD by assessing regional myocardial perfusion or regional wall motion at rest and during pharmacologic stress with an intravenous infusion of vasodilator agent or dobutamine. Myocardial perfusion is evaluated by injecting a GBCA bolus followed by imaging data acquisition as the contrast passes through the cardiac chambers and into the myocardium. Relative perfusion deficits are recognized as regions of low signal intensity (black) within the myocardium **(Video 248-4)**. Several minutes after GBCA injection, LGE imaging allows detection of bright areas of myocardial scar (white), which permits comparison of regions of hypoperfusion and infarction to quantify myocardial ischemia **(Fig. 248-14)**.

With better delineation of the endocardial borders, dobutamine CMR has better diagnostic accuracy than dobutamine echocardiography for detection of CAD, especially in patients with poor acoustic window (Table 248-3). High-dose dobutamine carries the risk of serious ventricular arrhythmias (~1%), but most cases can be prevented with proper monitoring of vital signs and regional cine function. The advantages of stress perfusion CMR over SPECT include its higher spatial resolution, which allows detection of subendocardial ischemia or infarction that may be missed by SPECT. As with other imaging modalities, stress CMR studies also provides robust risk stratification in practice. In a recent randomized controlled trial, a stress CMR-guided strategy was shown to improve the guidance toward the use of invasive investigation and coronary revascularization.

Selecting a Testing Strategy in Patients without Known CAD

As discussed above, there are many options for the evaluation of a patient with suspected CAD presenting with chest pain symptoms. The critical questions to be answered by a testing strategy include the

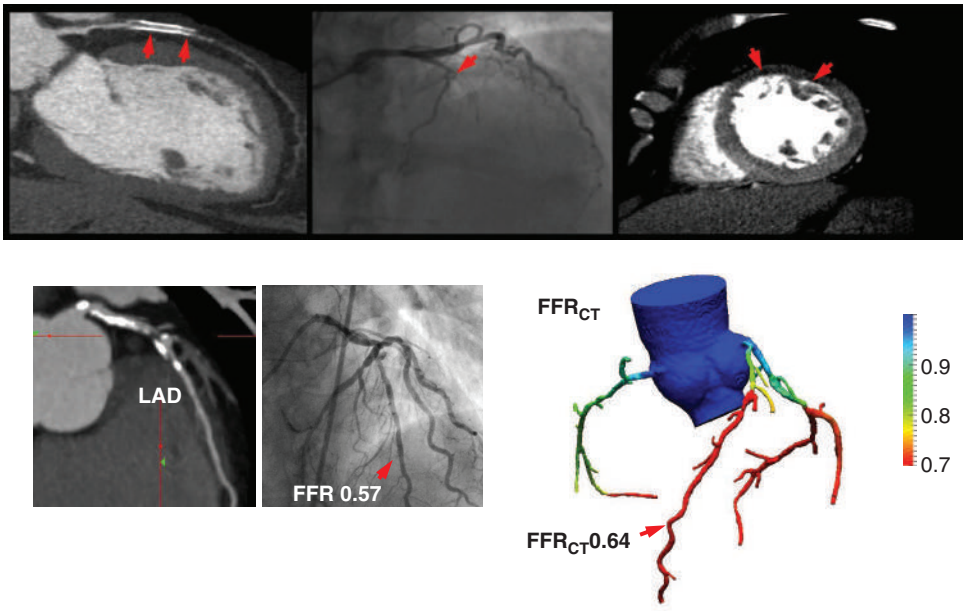

FIGURE 248-13 Examples of novel approaches to the assessment of flow-limiting coronary artery disease (CAD) with cardiac computed tomography (CT). In the *top panel*, representative views of a coronary CT angiogram (CTA; *left*), coronary angiogram (*middle*), and stress myocardial perfusion CT (*right*) images in a patient with CAD and prior stenting of the left anterior descending coronary artery (LAD) are presented. On the CTA, the stent (*arrows*) is totally occluded as evidenced by the loss of contrast enhancement distal to the stent. The coronary angiogram demonstrates a concordant total occlusion of the LAD. On the perfusion CT images, there is a black rim (*arrows*) involving the anterior and anterolateral walls, indicating the lack of contrast opacification during stress consistent with myocardial ischemia. *(Images courtesy of CORE 320 investigators.)* The *lower panel* illustrates an example of fractional flow reserve (FFR) estimates with coronary CTA (*left*) compared to the reference standard of invasive FFR. The FFR reflects the pressure differential between a coronary segment distal to a stenosis and the aorta. In normal coronary arteries, there is no gradient, and FFR is 1. An FFR <0.80 is consistent with a hemodynamically significant stenosis. *(Images courtesy of Dr. James Min, Cornell University, New York.)*

following: (1) Does the chest pain reflect obstructive CAD? (2) What are the short- and long-term risks? (3) Does the patient need to be considered for revascularization? Large-scale clinical trials have demonstrated the benefits of guideline-directed medical therapies where the majority of the patients with stable CAD are at low risk of serious cardiac events on guideline-directed medical therapy alone, and coronary revascularization is best reserved for patients with severe symptoms despite adequate medical therapy. However, imaging will continue to play a significant role in diagnosing the etiology of chest pain and risk assessment of individual patients.

FIGURE 248-14 The image shows the late gadolinium enhancement image of a mid short-axis view. There is no evidence of infarction in the anterior wall, which would be seen as bright white areas, indicating that the stress perfusion defect primarily represents myocardial ischemia. This patient had a significant stenosis of the left anterior descending coronary artery.

For symptomatic patients without a prior history of CAD, the 2021 American College of Cardiology/American Heart Association chest pain guidelines assigned a class I recommendation for stress imaging testing and coronary CTA. Most common stress imaging strategies include stress echocardiography and radionuclide imaging. However, CMR and PET have both been shown to have higher test accuracy than SPECT. In patients with intermediate clinical risk, stress imaging with either SPECT or echocardiography has been shown to reclassify patients accurately who are initially classified as intermediate risk by exercise treadmill testing (ETT) as low or high risk. ETT as the initial testing strategy is still valuable for patients with a normal or nearly normal resting ECG who can exercise.

The use of exercise testing in women presents difficulties that are not seen in men, reflecting the differences in the lower prevalence of obstructive CAD in women and the different accuracy of exercise testing in men and women. Compared with men, the lower pretest probability of disease in women means that more test results are false positive. In some of these patients, a positive ETT may reflect true myocardial ischemia caused by microvascular coronary artery dysfunction (so-called *microvascular disease*). In addition, the inability of many women to exercise to maximum aerobic capacity, the greater prevalence of mitral valve prolapse and microvascular disease, and possibly other reasons may contribute to the differences with men as well. The difficulties of using exercise testing for diagnosing obstructive CAD in women have led to speculation that stress imaging may be preferred over standard stress testing. However, recent data from the WOMEN study suggest that in symptomatic, low-risk women who can exercise, standard ETT is a very effective initial diagnostic strategy as compared to stress radionuclide imaging. Indeed, the 2-year outcomes were similar in both diagnostic strategies, and the ETT-first approach resulted in 48% lower costs compared to exercise radionuclide imaging.

An imaging strategy is the recommended first step for patients who are unable to exercise to an adequate workload and/or those with abnormal resting ECGs (e.g., left ventricular hypertrophy with strain, left bundle branch block). Importantly, the most recent documents regarding appropriate use of imaging also considered that an imaging

strategy may be an appropriate first step in patients with intermediate-high likelihood of CAD (e.g., diabetics, renal impairment) due to increased overall sensitivity for diagnosis of CAD and improved risk stratification. In considering an imaging strategy, the evidence supporting the role of ischemia assessment versus anatomy must be considered. From the discussion above, for patients with atypical chest pain and a low-pretest risk of CAD, a normal coronary CTA is helpful because it effectively excludes the presence of obstructive CAD and the need for further testing, defines a low clinical risk, and makes management decisions regarding referral to coronary angiography straightforward. However, in patients with an intermediate or higher pretest risk, coronary CTA is less effective in excluding obstructive CAD because of its limited accuracy to define stenosis severity and predict ischemia; however, abnormal CTA results are more problematic to interpret and to use as the basis for defining the potential need of invasive coronary angiography and revascularization. In such patients, a follow-up stress test is usually required to determine the possible need of revascularization **(Fig. 248-15)**.

The justification of stress imaging in testing strategies has hinged on the identification of which patients may benefit from a revascularization strategy by means of noninvasive estimates of jeopardized myocardium rather than angiography-derived anatomic stenoses. However, recent evidence from the ISCHEMIA trial suggests that optimal medical therapy provides comparable prognostic benefit to an early invasive strategy in patients with moderate or severe myocardial ischemia. Coronary revascularization is reserved for patients with very extensive evidence of ischemia by stress imaging and/or inadequate symptom control by optimal medical therapy. While the available data suggest similar diagnostic accuracy for SPECT and echocardiography but higher accuracy for PET and CMR, the choice of strategy depends on availability and local expertise.

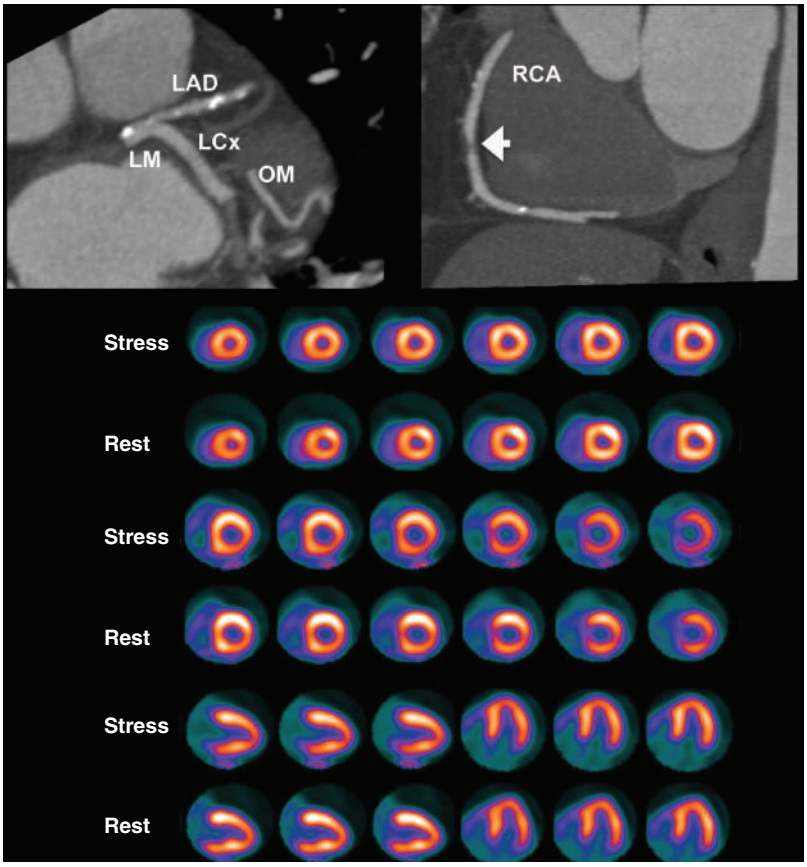

FIGURE 248-15 Selected views from coronary computed tomography angiographic (CTA) images (*top panel*) and stress and rest rubidium-82 myocardial perfusion positron emission tomography images (*lower panel*) obtained on a 64-year-old male patient with atypical angina. The CTA images demonstrate dense focal calcifications in the left main (LM) and left anterior descending (LAD) coronary arteries and a significant noncalcified plaque in the mid right coronary artery (RCA; *arrow*). The myocardial perfusion images demonstrated no evidence of flow-limiting stenosis. LCx, left circumflex artery; OM, obtuse marginal branch.

Selecting a Testing Strategy in Patients with Known CAD

Use and selection of testing strategies in symptomatic patients with established CAD (i.e., prior angiography, prior myocardial infarction, prior revascularization) differ from those in patients without prior CAD. Although standard ETT may help distinguish cardiac from noncardiac chest pain, exercise ECG has several limitations following myocardial infarction and revascularization (especially coronary artery bypass grafting). These patients frequently have rest ECG abnormalities. In addition, there is a clinical need to document both the magnitude and localization of ischemia to be able to direct therapy, especially the potential need for targeted revascularization. Consequently, imaging tests are preferred for evaluating patients with known CAD.

There are also important differences in the effectiveness of imaging tests in these patients. As discussed above, coronary CTA is limited in patients with prior revascularization. While CTA provides excellent visualization of the bypass grafts, the native circulation tends to get heavily calcified and is generally not a good target for imaging with CTA. Likewise, blooming artifacts from metallic stents also limit the application of coronary CTA in patients with prior percutaneous coronary intervention. If an anatomic strategy is indicated, direct referral to invasive angiography is preferred.

Stress imaging approaches are especially useful and preferred in symptomatic patients with established CAD. As in patients without prior CAD, normal imaging studies in symptomatic patients with established CAD also identify a low-risk cohort. In those with abnormal stress imaging studies, the degree of abnormality relates to posttest risk. In addition, stress imaging approaches can localize and quantify the magnitude of ischemia, thereby assisting in planning targeted revascularization procedures. As in patients without prior CAD, the choice of stress imaging strategy depends on availability and local expertise.

Testing Strategy Considerations in Patients Presenting with Chest Pain to the Emergency Department

Although acute chest pain is a frequent reason for patient visits to the emergency department (ED), only a small minority of those presentations represent an acute coronary syndrome (ACS). Strategies used in the evaluation of these patients include novel cardiac biomarkers (e.g., serum troponins), conventional stress testing (ETT), and noninvasive cardiac imaging. It is generally accepted that the primary goal of this evaluation is exclusion of ACS and other serious conditions rather than detection of CAD.

The routine evaluation of acute chest pain in most centers in the United States includes admission to a chest pain unit to rule out ACS with the use of serial ECGs and cardiac biomarkers. In selected patients, stress testing with or without imaging may be used for further risk stratification. Stress echocardiography and radionuclide imaging are among the most frequently used imaging approaches in these patients. Multiparametric CMR imaging has also been used successfully in patients with acute chest pain **(Video 248-5)**. Due to its ability to probe multiple aspects of myocardial physiology, cardiac anatomy, and tissue characterization with LGE imaging, CMR is useful in diagnosing conditions that mimic ACS (e.g., acute myocarditis, takotsubo cardiomyopathy, pericarditis) **(Fig. 248-16)**.

As discussed above, coronary CTA is a rapid and accurate imaging technique to exclude the presence of CAD and is well suited for the evaluation of patients with acute chest pain **(Fig. 248-17)**. Four randomized clinical trials have demonstrated the feasibility, safety, and accuracy of coronary CTA in the ED as compared to usual care (which typically includes stress imaging). Patients in these trials had a very low clinical

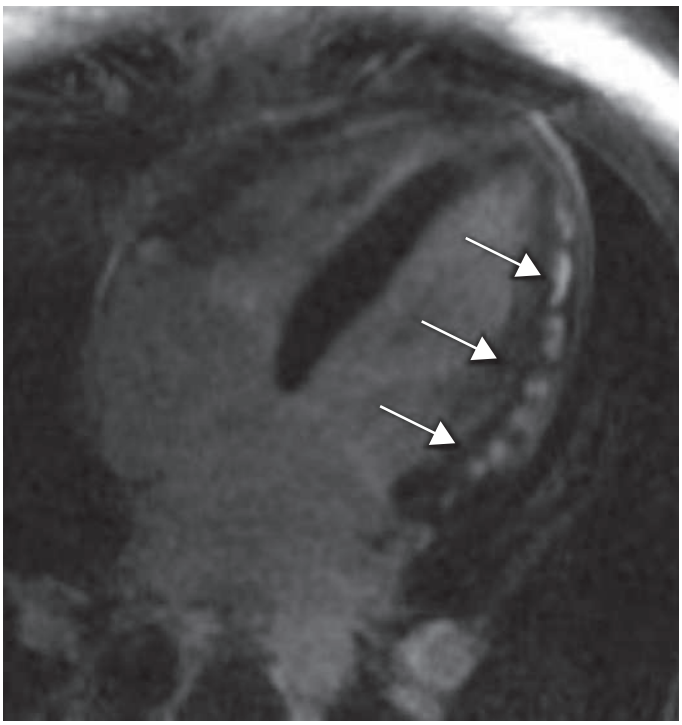

FIGURE 248-16 A four-chamber long-axis late gadolinium enhancement (LGE) image of a patient with acute myocarditis. Note that the LGE primarily involved the epicardial aspect of the myocardium (*arrows*), sparing the endocardium, which is a feature that distinguishes myocarditis from myocardial infarction, which affects the endocardium. Also note the multiple foci of LGE in this case affecting the lateral wall of the left ventricle. Viral myocarditis often presents with this pattern.

risk. Overall, there were no deaths and very few myocardial infarctions without differences between the groups. Likewise, there were no differences in postdischarge ED visits or rehospitalizations. These studies showed decreased length of stay with coronary CTA, and most but not all reported cost savings. An observation from a recent meta-analysis was that, compared to usual care, more patients assigned to coronary CTA underwent cardiac catheterization (6.3 vs 8.4%, respectively) and revascularization (2.6 vs 4.6%, respectively). The relative increased frequency in the referral to cardiac catheterization and revascularization after coronary CTA compared to stress imaging testing strategies has also been observed in patients with stable chest pain syndromes.

Taken together, the available data clearly suggest that not all patients presenting with acute chest pain require specialized imaging testing. Patients with very low clinical risk and negative biomarkers (especially high-sensitivity troponin assays) can be safely triaged. The use of imaging tests in patients with low-intermediate risk should be carefully considered, especially given the trade-offs discussed above.

VALVULAR HEART DISEASE

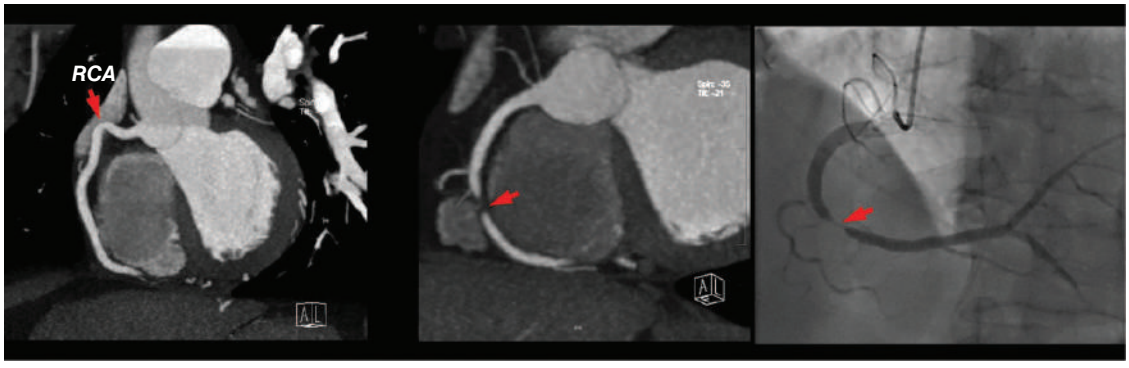
Abnormalities of any of the four valvular structures in the heart can lead to significant cardiac dysfunction, heart failure, or even death. Echocardiography, CMR, and cardiac CT can be used for the evaluation of valvular heart disease, although echocardiography is generally considered the first imaging test for the assessment of valvular heart disease. In addition, echocardiography is the most cost-effective screening method for valvular heart disease. In some cases, CMR can complement echocardiography when echocardiographic acoustic window is inadequate, by quantifying blood flow data more precisely or providing complimentary assessment of adjacent vascular structures relevant to the valvular condition.

Echocardiography can be used to assess both regurgitant and stenotic lesions of any of the cardiac valves. Typical indications for echocardiography to assess valvular heart disease include cardiac murmurs identified on physical examination, symptoms of breathlessness that may represent valvular heart disease, syncope or presyncope, and preoperative exams in patients undergoing bypass surgery. A standard echocardiographic examination should include qualitative and quantitative assessment of all valves regardless of indication and should serve as an adequate screening test for significant valvular disease.

Assessment of Aortic Stenosis Aortic stenosis, one of the most common forms of valvular heart disease, most often occurs because of gradual progression of valvular calcification in both normal and congenitally abnormal valves. Assessment of aortic stenosis is most commonly performed with echocardiography, although techniques for quantitative assessment of aortic stenosis with CMR have been developed and increasingly used over the past decade. Echocardiographic assessment generally begins with visual inspection of the valve. This allows for assessment of valvular morphology, whether it is tricuspid, bicuspid, or some variant; degree of leaflet calcification; and leaflet excursion.

The normal aortic valve consists of three leaflets or cusps: the right coronary, the left coronary, and the noncoronary cusps. Abnormalities of cusp development are some of the most common congenital heart anomalies, the most common of which is bicuspid aortic valve, with two opening leaflets rather than three **(Fig. 248-18)**. The aortic valve can be visualized on echocardiography, although sometimes it can be difficult to distinguish true bicuspid aortic valve from variants, including the presence of a vestigial commissure (raphe). Bicuspid aortic valve, one of the most common congenital anomalies, predisposes to both aortic stenosis and aortic insufficiency.

The degree of aortic stenosis is assessed by estimating both the pressure gradient across the valve and the valve area. Patients with moderate aortic stenosis or higher generally have peak instantaneous velocities of 3.0 m/s and higher, and often higher than 4.0 m/s, corresponding to pressure gradients of 36 and 64 mmHg, respectively. Because pressure gradients across the aortic valve can be underestimated in patients with severe left ventricular dysfunction, estimation of



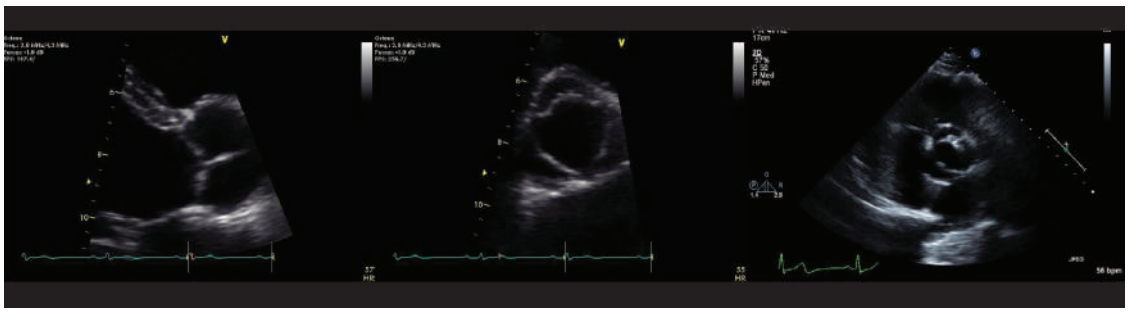


FIGURE 248-17 Representative coronary computed tomography angiographic (CTA) images of two patients presenting to the emergency department with chest pain and negative biomarkers. The patient in ***A*** had angiographically normal coronary arteries; the panel shows a representative view of the right coronary artery (RCA). ***B*** and ***C*** show a corresponding significant stenosis in the mid portion of the RCA on both the CTA (***B***) and invasive angiographic view (***C***). *(Images used with permission from Dr. Quynh Truong, Massachusetts General Hospital, Boston, MA.)*

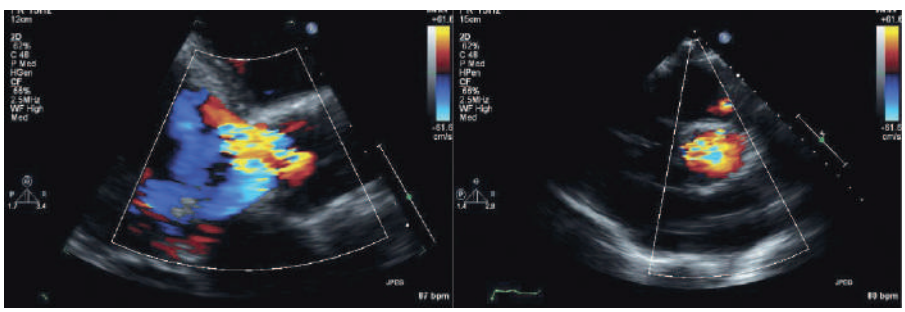
A B C

FIGURE 248-18 Normal aortic valve in the parasternal long-axis view (***A***) and short-axis view (***B***), and bicuspid aortic valve showing typical 10 o'clock to 4 o'clock leaflet orientation (***C***).

valve area by the continuity principle is the most accurate technique for assessing the severity of the stenosis. However, evaluation of the patient with so-called low-flow or low-gradient aortic stenosis can be challenging and sometimes require provocative testing such as dobutamine echocardiography. In these cases, it is important to distinguish whether the valve is indeed capable of opening further or simply behaving like a stenotic valve because of the low-pressure gradient.



Aortic valve areas <1.0 cm^2 are generally considered severe, and valve areas <0.6 cm^2 are considered critical. Because patients with good left ventricular function can often tolerate severe aortic stenosis for a considerable period of time, valve areas or gradients alone should not be used to determine whether an individual patient should undergo aortic valve surgery, as this remains a clinical decision.

Some patients with apparent aortic stenosis have subvalvular or even supravalvular obstruction. Hypertrophic cardiomyopathy represents the classic form of subvalvular aortic stenosis, but this is usually easily distinguished from aortic stenosis on echocardiography as the valve leaflets can be seen opening during systole. Subaortic membranes can behave very similarly to leaflet aortic stenosis, and the membranes themselves can be very thin and difficult to visualize, although the presence of a murmur, a gradient across the valve with aortic leaflets that appear to open normally, is highly suggestive of a membrane. Supravalvular aortic stenosis, although exceedingly rare, also occurs.

The emergence of transcatheter aortic valve intervention as a therapeutic option for patients with severe aortic stenosis who are not optimal candidates for surgical replacement has resulted in a very important clinical role for multimodality imaging. Imaging plays a critical role in preprocedural planning, intraprocedural implantation optimization, and follow-up of these patients. CT plays an important role in defining the eligibility of the proposed access site (CTA of the aorta and iliac arteries) and in defining the anatomic relationships between the aortic valve and aortic root, left ventricle, and coronary ostia. Cardiac CT and transesophageal echocardiography are also used to define the device size. Transesophageal echocardiography is used during the device implantation to ensure the best prosthesis–patient match, to assess prosthesis position and function after deployment, and to identify immediate complications (e.g., aortic insufficiency, paravalvular leak resulting from patient–prosthesis mismatch). Echocardiography is the imaging modality of choice for long-term surveillance.

Assessment of Aortic Regurgitation Assessment of aortic regurgitation requires qualitative assessment of the aortic valve structure. Aortic regurgitation is common with congenital abnormalities of the aortic valve, the most common of which is bicuspid aortic valve. Aortic regurgitation often coexists with aortic stenosis, and it is not uncommon for patients to have both severe aortic stenosis and regurgitation. Congenital abnormalities of the aortic leaflets, such as bicuspid aortic valve, are common causes of aortic insufficiency. Dilatation of the aortic root, as occurs in patients with hypertension and other disorders in which aortic dilatation can occur, can also lead to aortic regurgitation even when the valve leaflets are intrinsically normal due to malcoaptation of the leaflets. Aortic root dilatation is common in patients with aortic regurgitation, both as a cause or coexisting lesion, and the aortic root and ascending aorta should be measured and followed in these patients **(Fig. 248-19)**.

Because aortic regurgitation can result in dilatation of the left ventricle over time with ultimate reduction in ventricular function, caring for the patient with aortic regurgitation requires serial assessment of ventricular size and function. Patients whose ventricles dilate beyond an end-systolic diameter of 5.5 cm or whose LVEF declines below normal are at significantly higher risk of death or heart failure, and these measures are often used to decide the need for valve surgery. Quantitation of regurgitation itself can be performed using a number of methods. Semiquantitative visual assessment of aortic regurgitant jet width and depth by color flow Doppler remains the most used. The jet diameter as a ratio of the left ventricular outflow tract diameter proximal to the valve represents one of the most reliable indices of severity and correlates well with angiographic assessment. Similarly, the vena contracta, which represents the smallest diameter of the regurgitant flow at the level of the valve, can be used to assess the severity of aortic regurgitation. Other Doppler-based methods include assessing the pressure half-time, or rate of decline of the pressure gradient between the aorta and left ventricle, a measure of acuity of aortic regurgitation, and assessing aortic flow reversal in the descending aorta.

A B

FIGURE 248-19 Aortic regurgitation visualized by color flow Doppler in the parasternal long-axis view (***A***) and the parasternal short-axis view (***B***).

The regurgitant volume can be calculated by comparing the flow across the aortic and pulmonic valves, assuming the pulmonic valve is competent. Central or perivalvular aortic regurgitation is common in patients following transcatheter aortic valve replacement and is generally assessed immediately after the procedure and on follow-up echocardiography.

CMR offers several advantages over echocardiography in the assessment of aortic regurgitation. CMR is more accurate than echocardiography for assessing small changes in cardiac size or function longitudinally in patients with aortic insufficiency. In addition, CMR can accurately quantify aortic regurgitant volume secondary to aortic insufficiency better than echocardiography. CMR can also capture aortic size in 3D that may be helpful in determining the etiology of the aortic regurgitation or in monitoring progression of the condition **(Fig. 248-20 and Video 248-6)**. For this reason, CMR is often used for serial follow-up of patients with aortic regurgitation.

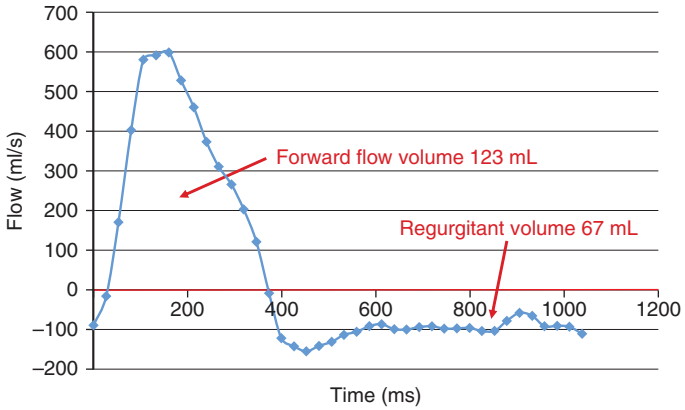


FIGURE 248-20 The resultant flow curve generated from phase contrast imaging demonstrates a forward flow of 123 mL and a regurgitant volume of 67 mL, yielding a regurgitant fraction of 54% indicating severe aortic regurgitation.

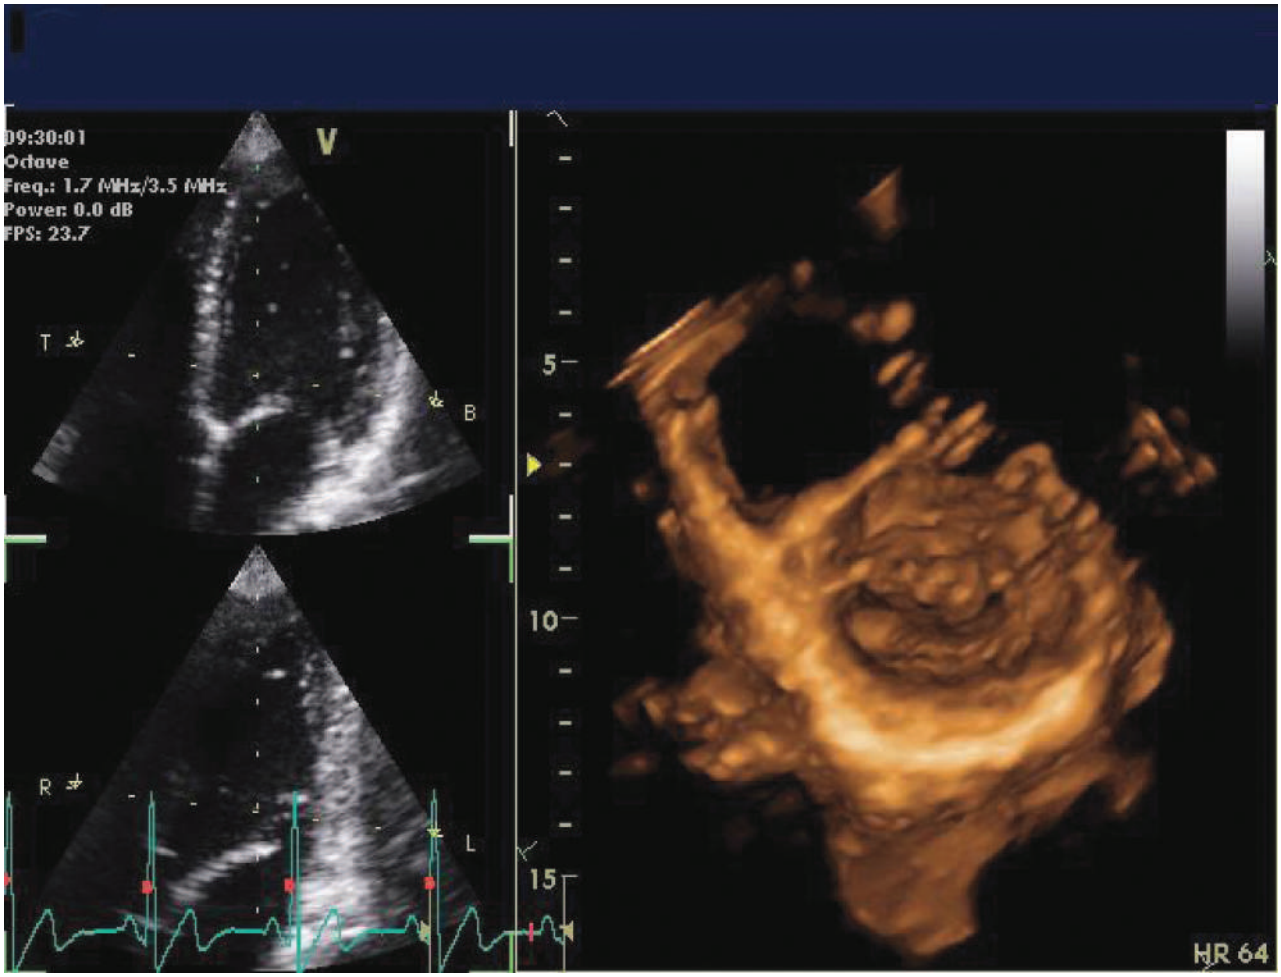
Assessment of Mitral Regurgitation The normal mitral valve consists of an anterior and posterior leaflet in a saddle shape configuration **(Fig. 248-21)**. The leaflets are attached to the papillary muscles via chordae tendineae that insert on the ventricular side of the leaflets. Mitral regurgitation can occur due to abnormalities of the leaflets, the chordal structures, or the ventricle, or any combination of these **(Fig. 248-22)**.

Mitral valve prolapse, in which one leaflet moves behind the plane of the other leaflet, can be due to myxomatous degeneration of the valves and leaflet redundancy, disruption of chordal structures secondary to degenerative disease, or papillary muscle rupture or dysfunction following myocardial infarction. Regurgitant jets can be visualized using color flow Doppler. The velocity of regurgitant jets is driven by the pressure gradient between the two chambers. This velocity will thus be quite high for left-sided regurgitant lesions, including mitral regurgitation and aortic regurgitation, resulting in turbulent jets on color flow Doppler (Fig. 248-22). Visual estimation of color flow Doppler is generally sufficient for qualitative assessment of regurgitant severity but can dramatically under- or overestimate regurgitation severity, particularly when regurgitant jets are quite eccentric. For this reason, quantitative assessment is generally recommended, especially when making clinical decisions about surgical intervention. The proximal isovelocity surface area (PISA) method is generally used for quantitative assessment of severity of mitral regurgitation. This method relies on estimation of the velocity of flow acceleration at a specific distance proximal to the valve with the assumption that the flow accelerates in concentric hemispheres.



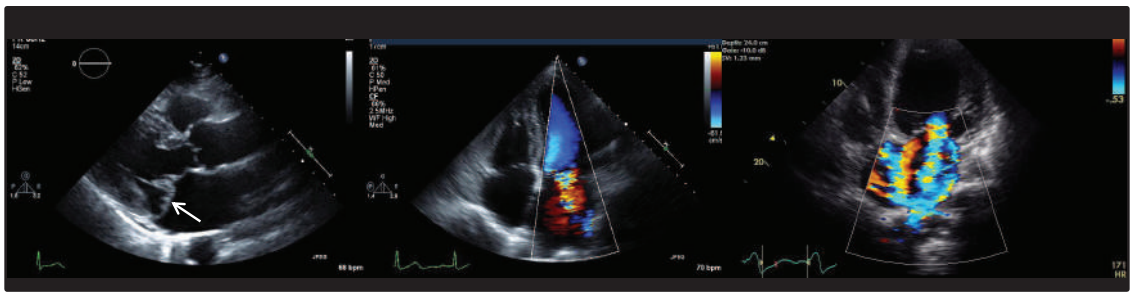


FIGURE 248-21 Normal mitral valve in two-dimensional views (*left*) and with three-dimensional imaging (*right*).

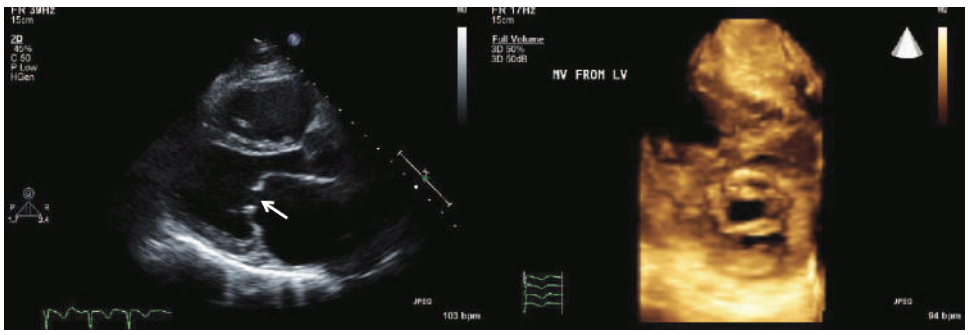
A B C

FIGURE 248-22 ***A.*** Mitral valve prolapse with posterior leaflet visualized prolapsing behind the plane of the anterior leaflet (*arrow*). ***B.*** Color flow Doppler showing mitral regurgitation in a patient with mitral valve prolapse. ***C.*** Severe functional mitral regurgitation in a patient with a dilated left ventricle.

As with aortic insufficiency, assessment of ventricular structure and function is also integral in the evaluation of mitral regurgitation. Although some patients have mitral regurgitation due to intrinsic abnormalities of the valve itself, in others, the valve can be relatively normal, but the mitral regurgitation can be secondary to dilatation and remodeling of the left ventricle. So-called functional mitral regurgitation is generally secondary to apical displacement of the papillary muscles in a dilated ventricle, resulting in the leaflets of the mitral valve being pulled toward the apex of the heart, resulting in poor coaptation during systole and resultant relatively central mitral regurgitation. This type of mitral regurgitation can generally be distinguished from intrinsic mitral valve disease, and the surgical or procedural treatment of these conditions can be different. Knowledge of the etiology of mitral regurgitation can be important for a surgeon planning mitral valve surgery. Moreover, new procedural approaches to mitral valve disease may be different depending on the etiology.

Ventricular dilatation is an important predictor of outcome in patients with mitral regurgitation of any cause. It is important to realize that in a patient with significant mitral regurgitation, a large portion of the blood being ejected from the left ventricle with every beat is regurgitant, thus artificially increasing the ejection fraction. Thus, an ejection fraction of 55% in a patient with severe mitral regurgitation may represent substantial reduction in myocardial systolic function.

CMR can be helpful in evaluating mitral regurgitation in a subset of patients when echocardiographic assessment is inadequate. CMR can directly quantify regurgitant volume of the mitral regurgitant jet or indirectly quantify regurgitant volume by measuring the difference of left ventricular stroke volume and aortic forward flow.



Assessment of Mitral Stenosis Rheumatic mitral disease remains the most common cause of mitral stenosis, although mitral stenosis can also result from severe calcification of the mitral leaflets. Rheumatic mitral stenosis has a distinct appearance characterized by tethering at the leaflet tips and relative pliability of the leaflets themselves, resulting in a hockey stick–type deformation particularly of the anterior leaflet (Fig. 248-23). Narrowing of the mitral orifice impedes flow from the left atrium to the left ventricle, resulting in increased pressures in the left atrium, which are then transmitted backward into the pulmonary vasculature and the right side of the heart. When mitral stenosis is suspected, echocardiography can be useful for determining etiology (specifically whether it is rheumatic or not), estimating the valve areas and gradients across the valve, assessing the left atrium, and assessing right ventricular size and function. Assessment of left atrial size and right ventricular size and function is particularly useful in helping determine the severity of the mitral stenosis.

MYOCARDIAL INFARCTION AND HEART FAILURE

Role of Imaging after Myocardial Infarction Imaging can be useful in the immediate and long-term follow-up of patients with myocardial infarction. As discussed earlier in the chapter, LGE imaging by CMR is the best technique for imaging for presence or the extent of infarcted myocardium. In a recent multicenter study, LGE imaging identified infarct location accurately and detected acute and chronic infarcts at a sensitivity of 99 and 94%, respectively. In addition, regions of microvascular obstruction (no-reflow) can be seen as dense hypoenhanced areas within the core of a bright region of infarction (Fig. 248-24). Both the presence of LGE and microvascular obstruction are markers of increased clinical risk.

While echocardiography is often used to assess myocardial function immediately after myocardial infarction, myocardial stunning is common in the early post–myocardial infarction period, especially in patients who undergo reperfusion therapy. In these patients, either partial or complete recovery of ventricular function is common within several days, so that early estimation of ejection fraction may be misleading. In patients with uncomplicated myocardial infarction, imaging can generally be deferred for several days so that a more accurate assessment of cardiac function, including regional wall motion, can be assessed (Fig. 248-25).

Echocardiography is the best method for assessment of patients with suspected mechanical complications after myocardial infarction. These include mitral regurgitation secondary to either papillary muscle dysfunction or rupture of papillary muscle head, ventricular septal defect, or cardiac rupture. A new severe systolic murmur should raise

A B

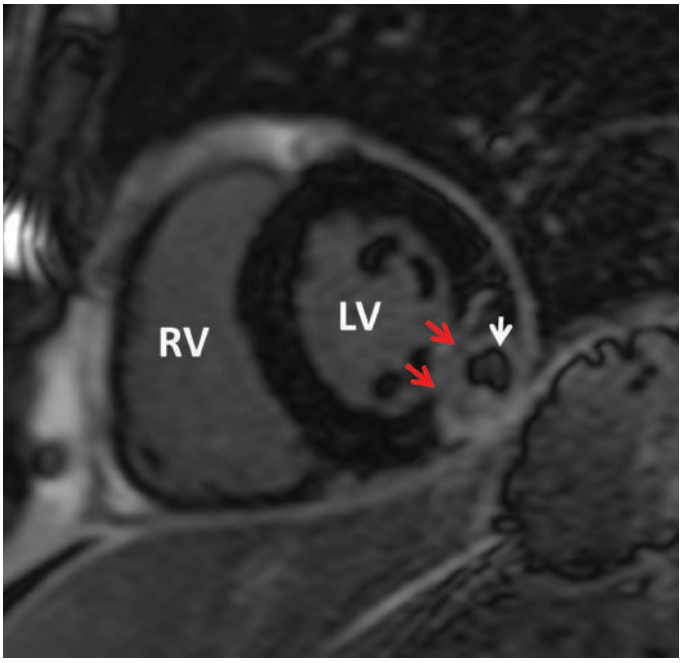

FIGURE 248-24 Example of a patient who presented with inferior ST-segment elevation myocardial infarction (MI) after several days of intermittent chest pain. Magnetic resonance imaging (MRI) confirmed an inferior MI by the location of late gadolinium enhancement (LGE; *red arrows*). In addition, there is a central area of microvascular obstruction (dark region surrounded by the bright LGE, *white arrow*). LV, left ventricle; RV, right ventricle.

suspicions for either severe mitral regurgitation or ventricular septal defect. While cardiac rupture is often catastrophic, contained ruptures, in the form of pseudoaneurysms, can occur, and early diagnosis and surgical treatment are the best way to maximize survival. The presence of thrombus within the pericardial space following myocardial infarction should immediately raise suspicion of myocardial rupture and represents a surgical emergency.

Some patients demonstrate progressive left ventricular dilatation and dysfunction, known as cardiac remodeling, after myocardial infarction. Assessment of cardiac function and regional wall motion is useful in the follow-up period, generally between 1 and 6 months following infarction. The persistence of left ventricular systolic dysfunction following infarction is used to determine the type of therapy (e.g., angiotensin-converting enzyme inhibitors or angiotensin receptor blockers are typically used in patients with systolic dysfunction following myocardial infarction).

In patients with acute or subacute myocardial infarction, investigation of residual ischemia and/or viability is occasionally an important clinical question, especially among those with recurrent symptoms after

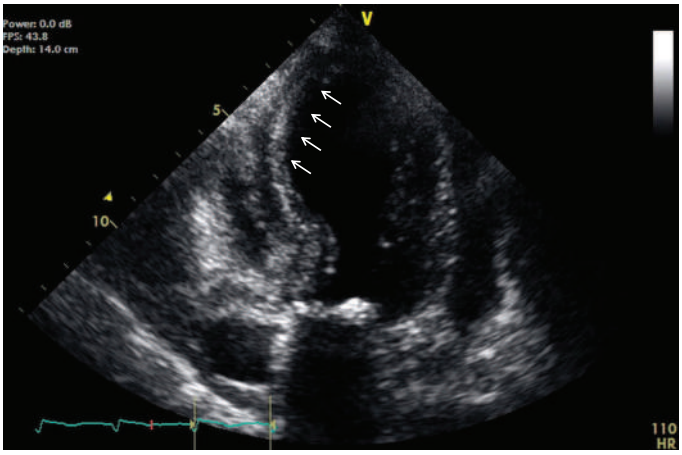

FIGURE 248-25 Acute left anterior descending artery distribution myocardial infarction at end systole showing akinetic region (*arrows*).

myocardial infarction **(Fig. 248-26)**. All cardiac imaging techniques can provide information regarding myocardial viability and ischemia. The available data suggest that radionuclide imaging, especially PET, is highly sensitive, with higher negative predictive value than dobutamine echocardiography. In contrast, dobutamine echocardiography tends to be associated with higher specificity and positive predictive accuracy than the radionuclide imaging methods. The experience with CMR suggests that it offers similar predictive accuracies as those seen with dobutamine echocardiography.

Role of Imaging in New-Onset Heart Failure Echocardiography is usually a first-line test in patients presenting with new-onset heart failure. As discussed above, this test provides a direct assessment of ventricular function and can help distinguish patients with reduced from those with mildly reduced or preserved ejection fraction, particularly important because of the different therapeutic options available for patients with each of these types of heart failure. In addition, it provides additional structural information including an assessment of valves, myocardium, and pericardium.

Although coronary angiography is commonly performed in patients with reduced ejection fraction, the determination of heart failure etiology in an individual patient may be difficult even if angiographically obstructive CAD is present. Indeed, patients with heart failure and no angiographic CAD may have typical angina or regional wall motion abnormalities on noninvasive imaging, whereas patients with angiographically obstructive CAD may have no symptoms of angina or history of myocardial infarction. Thus, the appropriate classification for any given patient is not always clear, and it often requires the complementary information of coronary angiography and noninvasive imaging. As discussed above, stress radionuclide imaging and echocardiography can be helpful in delineating the extent and severity of inducible myocardial ischemia and viability. Multiparametric CMR can be quite helpful in the differential diagnosis of heart failure etiologies. Apart from quantifying left and right ventricular volumes and function, CMR can provide information about myocardial ischemia and scar. The pattern of LGE helps differentiate infarction (typically starting in the subendocardium and involving a coronary territory) from other forms of infiltrative or inflammatory cardiomyopathies (typically involving the mid- or subepicardial layers without following a coronary distribution) **(Fig. 248-27)**. In addition, it can assess the presence of myocardial edema using T1 or T2 tissue mapping methods to inform toward chronicity of acute coronary syndromes or noncoronary inflammatory conditions (e.g., myocarditis). Other methods such as T2* mapping of myocardial iron deposition assess for the extent of iron infiltration that leads to cardiac toxicity. Infiltrative cardiomyopathy such as amyloidosis typically has a restrictive cardiomyopathy pattern characterized by biventricular increased wall thickness and bilateral atrial enlargement, as assessed by both echocardiography and CMR. CMR of patients with cardiac amyloidosis often also demonstrates a characteristic pattern of diffuse endocardial infiltration of the left ventricle and the atria (Fig. 248-27). On strain echocardiography, patients with cardiac amyloidosis show reduction in systolic function which typically spares the apical left ventricular segments. Bone scintigraphy complements the use of echocardiography and CMR in cardiac amyloidosis by allowing accurate noninvasive distinction of transthyretin (ATTR) from light chain (AL) cardiac amyloidosis. ATTR typically shows intense ^{99m}Tc tracer uptake compared to patients with AL amyloidosis **(Fig. 248-28)**. Hypertrophic cardiomyopathy has variable degree of increased ventricular thickness and often is seen to have outflow obstruction and intense LGE in regions with marked hypertrophy **(Fig. 248-29)**. CMR also can quantify myocardial iron content in patients at risk of iron-overload cardiomyopathy **(Video 248-7)**.

PET metabolic imaging has a complementary role in the evaluation of inflammatory cardiomyopathies, especially sarcoidosis where the presence of focal and/or diffuse glucose uptake can help identify areas of active inflammation. In addition, for patients undergoing immunosuppressive therapy, PET is frequently used to monitor therapeutic response **(Fig. 248-30)**. In patients with ischemic cardiomyopathy,

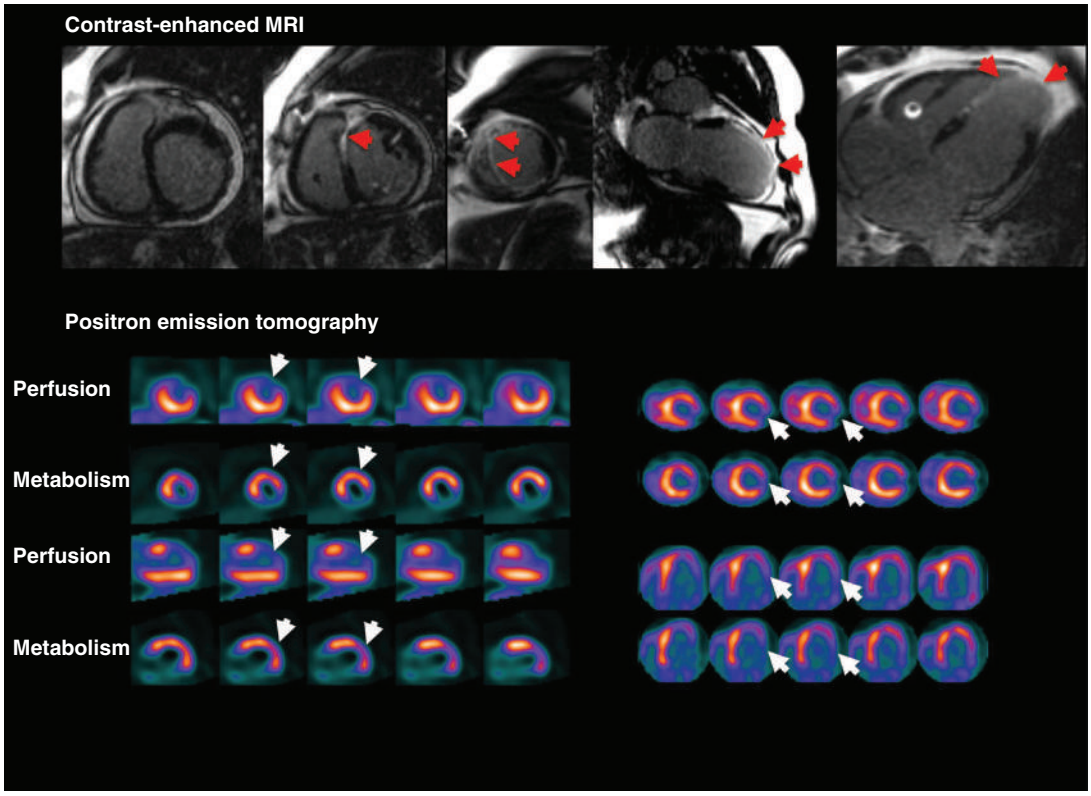

FIGURE 248-26 Examples of myocardial viability patterns obtained with cardiac magnetic resonance imaging (MRI) and positron emission tomography (PET) in three different patients with coronary artery disease. The *top panel* demonstrates extensive late gadolinium enhancement (*bright white areas*) involving the anterior, anteroseptal, and apical left ventricular walls (*arrows*), consistent with myocardial scar and nonviable myocardium. The *lower left panel* demonstrates rubidium-82 myocardial perfusion and ^{18}F-fluorodeoxyglucose (FDG) images showing a large and severe perfusion defect in the anterior, anterolateral, and apical walls, indicating preserved glucose metabolism (so-called *perfusion-metabolic mismatch*) consistent with viable myocardium. The *right lower panel* shows similar PET images demonstrating concordant reduction in perfusion and metabolism (so-called *perfusion-metabolic match*) in the lateral wall, consistent with nonviable myocardium.

radionuclide imaging in general and PET in particular are frequently used to quantify the presence and extent of myocardial ischemia and viability to assist with clinical decision-making related to myocardial revascularization (Fig. 248-25).

ASSESSING CARDIAC FUNCTION IN PATIENTS UNDERGOING CANCER TREATMENT

Therapies used to treat cancer can adversely affect the cardiovascular system. As the efficacy of cancer treatment and survival improve, many patients are presenting with late adverse consequences from chemotherapy and/or radiation therapy on cardiovascular function. Thus, the morbidity and mortality from late cardiovascular complications threaten to offset the early gains in cancer survival, especially among children and young adults. Early recognition and treatment of cardiomyocyte injury are critical for successful application of preventative therapies, but difficult because the adverse effects on cardiac function are a relatively late manifestation after exposure to anticancer therapy.

The accepted standard for clinical diagnosis of cardiotoxicity is defined as a >5% reduction in LVEF to <55% with symptoms of heart failure, or a >10% drop in LVEF to <55% in patients who are asymptomatic. Thus, noninvasive imaging plays a major role in diagnosing and monitoring for cardiac toxicity in patients undergoing cancer treatment. Radionuclide angiography has been the technique of choice for quite some time. However, echocardiography now plays a major role in this application.

Recently, more novel imaging approaches have been advocated, including deformation imaging with echocardiography and fibrosis imaging with CMR. These techniques have shown promising results in experimental animal models and in humans. In addition, there are also proof-of-concept studies in animal models using molecular imaging approaches targeting the mechanisms of cardiac toxicity (e.g., apoptosis and oxidant stress), which can presumably provide the earliest signs of the off-target effects of these therapies. However, these techniques are currently considered experimental.

PERICARDIAL DISEASE

The fibroelastic pericardial sac surrounding the heart consists of a visceral, or epicardial, layer and a parietal layer, with a generally small amount of pericardial fluid in between layers. The pericardium is generally quite pliable and moves easily with the heart during contraction and relaxation. Abnormalities of the pericardium can affect cardiac function primarily by impairing the heart's ability to fill. Inflammation of the pericardium can lead to an accumulation of fluid between the two layers, or *pericardial effusion*, which can be visualized by echocardiography, CMR, or CT. Other reasons for accumulation of pericardial fluid include infection, malignancy, and bleeding into the pericardium. The latter can be the result of catastrophic processes such as trauma, cardiac rupture, perforation in the setting of a cardiac procedure, cardiac surgery, or dissection of the aorta with extension in the pericardium.

Echocardiography remains the initial test of choice for assessing pericardial disease, especially effusions **(Fig. 248-31)**. Moreover, echocardiography can be useful in evaluating for pericardial constrictive physiology, in which a thick noncompliant pericardium impairs cardiac filling. The location, size, and physiologic consequences of accumulated pericardial effusion can generally easily be determined by echocardiography. Pericardial tamponade occurs when enough pericardial fluid accumulates so that the intrapericardial pressure exceeds filling pressures of the heart, generally the right ventricle. The balance between intrapericardial pressure and ventricular pressure is more important than the extent of fluid accumulation. Conditions in which pericardial effusions accumulate over a long period of time, as can be the case in the setting of malignant effusions, can lead to large pericardial fluid accumulations without the classic hemodynamic findings associated with pericardial tamponade. In contrast, rapid accumulations of pericardial fluid, such as those that occur due to cardiac rupture or perforation, can lead to tamponade physiology without very large effusions. In patients with suspected pericardial effusion or tamponade, echocardiography can usually be performed rapidly, at the

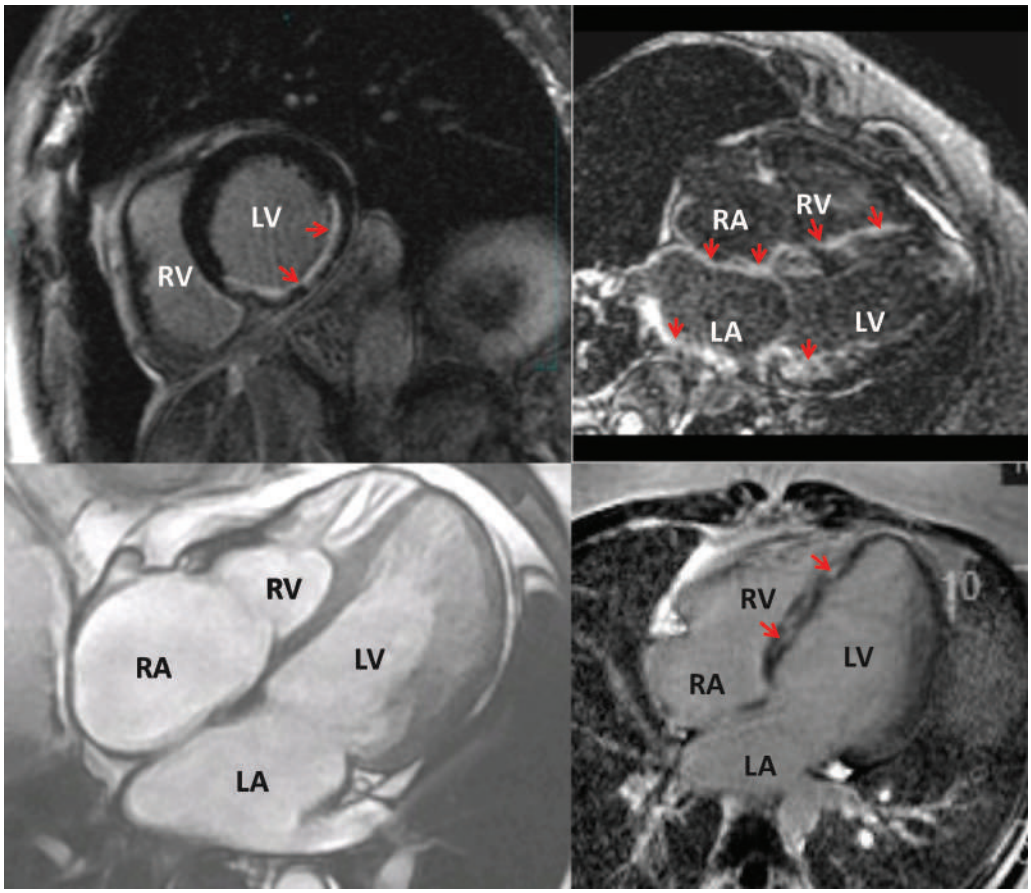

FIGURE 248-27 Differentiation of various cardiomyopathies by cardiac magnetic resonance (CMR). The *left upper panel* shows the short-axis late gadolinium enhancement (LGE) imaging of a patient who suffered an acute myocardial infarction. Note LGE of the endocardial myocardium in the inferior wall extending from the septum to the lateral wall associated with myocardial thinning (*arrows*). The *right upper panel* shows the long-axis LGE imaging of a patient who has cardiac amyloidosis. Note the diffuse LGE throughout left ventricular myocardium, the left atrium, and the interatrial septum (*arrows*). In addition, the blood pool is characteristically dark in signal, indicating sequestration of gadolinium contrast out of the blood pool after injection due to a high burden of amyloidosis in other organs. The *left lower panel* shows a cine diastolic long-axis image of a patient with a nonischemic dilated cardiomyopathy. Note that there is extensive sponge-like noncompacted myocardium of the LV as well as dilatation of all four cardiac chambers. This patient has a nonischemic dilated cardiomyopathy secondary to LV noncompaction. The *right lower panel* shows a 22-year-old female patient with a recent episode of acute chest pain and troponin elevation. Note the multiple mid-wall foci of LGE, which suggests acute myocarditis (*arrows*). LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

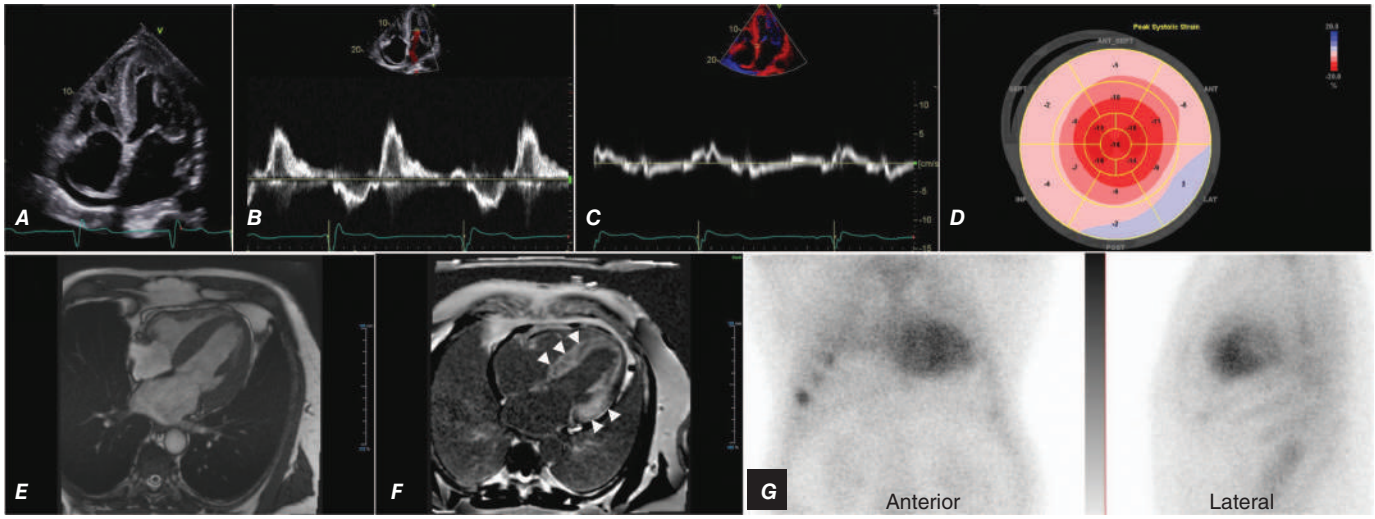

FIGURE 248-28 Multimodality cardiac imaging in a 71-year-old man with history of atrial fibrillation, heart failure with preserved ejection fraction, numbness in his fingers, a history of bilateral carpal tunnel surgery, and remote history of back surgery with L3 and S1 fusion. *A.* Two-dimensional echocardiogram demonstrating moderate increase in left ventricular thickness with a visually estimated left ventricular ejection fraction of 45–50% and small pericardial effusion. ***B, C.*** Mitral inflow and tissue Doppler demonstrating abnormal diastolic function (E/e' was >20, consistent with elevated left ventricular filling pressure). ***D.*** Bull's-eye strain map demonstrating abnormal global longitudinal strain at the basal segments (*pink and blue colors*) with characteristic apical sparing (*red color*). ***E.*** Cardiac magnetic resonance imaging (MRI) study showing normal left ventricular (LV) cavity size and mildly increased LV mass and mildly enlarged right and left atria. ***F.*** The MRI shows a large amount of diffuse late gadolinium enhancement of all myocardial LV segments but more prominent in a circumferential subendocardial pattern (*arrowheads*). ***G.*** The ^{99m}Tc-pyrophosphate images demonstrate increased myocardial uptake of the radiotracer (uptake in the heart is greater than ribs, grade 3). *(Images courtesy of Dr. Sarah Cuddy, Brigham and Women's Hospital.)*

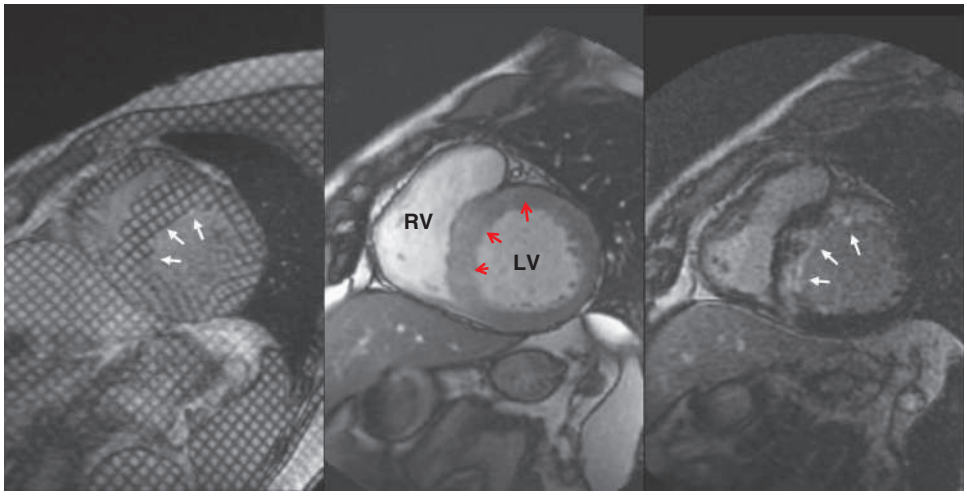

FIGURE 248-29 This figure demonstrates three pulse sequence techniques by cardiac magnetic resonance that are often used to assess patients with hypertrophic cardiomyopathy, all displayed in the mid short-axis scan plane. The *center panel* demonstrates that the left ventricle (LV) was markedly thickened in its wall thickness especially in the LV septum (*red arrows*). This finding was matched by marked regions of late gadolinium enhancement (LGE), which was consistent with fibrosis in these segments (*right panel, white arrows*). The *left panel* was cine myocardial tagging in the same slice plane. Myocardial tagging is used to assess the normal intramyocardial strain by assessing distortion of the myocardial grids during systole. In this case, despite normal-appearing systolic radial wall thickening, the myocardial strain as assessed by the distortion of grids was markedly reduced (*left panel, white arrows*). This finding is consistent with substantial myofibril disarray in the anterior and anteroseptal segments in this patient. RV, right ventricle.

bedside, and even by operators with limited skill. The distance from the parietal to the visceral pericardial layer can be measured, and when this exceeds ~1 cm, an effusion is considered significant. Echocardiographic features suggestive of tamponade include diastolic collapse of the right ventricular free wall, suggestive of pericardial pressures that exceed right ventricular filling pressures, and Doppler evidence of respiratory flow variation, which is the Doppler equivalent of pulsus paradoxus. Despite the benefits of echocardiography in suspected pericardial tamponade, the diagnosis of tamponade remains a clinical diagnosis, and other important features, such as patient's blood pressure in the presence of pulsus paradoxus, need to be considered when weighing therapeutic options.

Chronic inflammation of the pericardium leads to thickening and calcification of the parietal pericardium, resulting in pericardial constriction in which diastolic filling can be severely impaired. In these cases, filling of the ventricles comes to an abrupt halt when the volume of ventricular filling is impaired by the constricting pericardium. Assessment of pericardial thickness in these patients is important, but it is just as important to note that approximately one in five patients with severe pericardial constriction have no significant pericardial thickening by imaging or at surgery. Thus, a lack of thickened pericardium does not rule out pericardial constriction, and patients' signs and symptomatology and physiologic evidence of constriction should be assessed independently. Pericardial constriction typically demonstrates

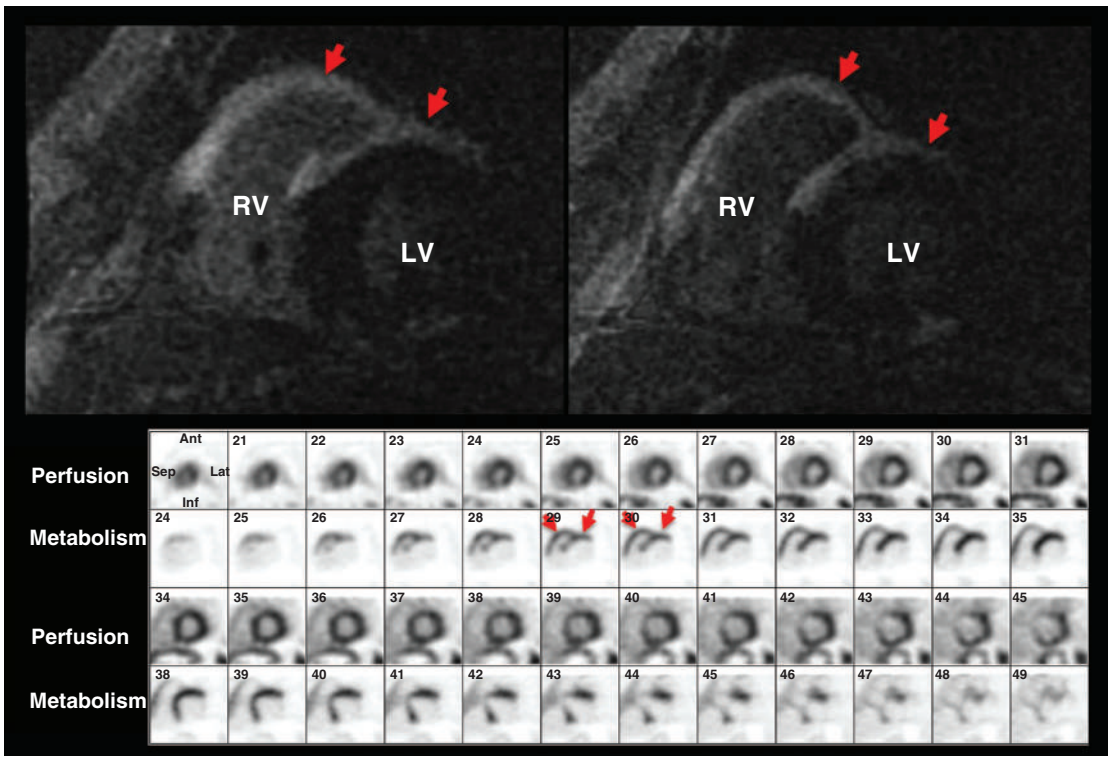

FIGURE 248-30 Representative cardiac magnetic resonance (CMR; *top panel*) and positron emission tomography (PET; *lower panel*) images from a 45-year-old male presenting with complete heart block. The CMR images demonstrate extensive late gadolinium enhancement in the subepicardial left ventricular (LV) anterior and anteroseptal walls and also in the right ventricular (RV) free wall (*arrows*). The PET images demonstrate extensive fluorodeoxyglucose uptake in the same areas, most consistent with active inflammation due to sarcoidosis.

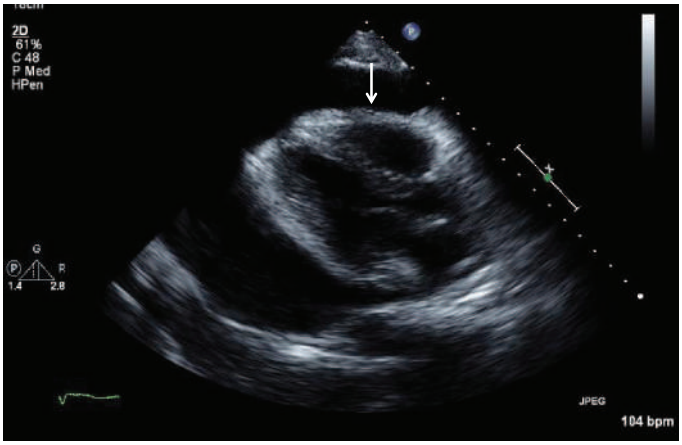

FIGURE 248-31 Pericardial effusion with tamponade physiology. The right ventricle (*arrow*) is small and collapsing in end diastole due to increased pericardial pressure.

marked respiratory changes in diastolic flow on Doppler echocardiography, in contrast to restrictive cardiomyopathy, but substantial overlap exists. CT and CMR offer tomographic, whole-heart assessment of pericardial thickening and other anatomy abnormalities in pericardial constriction enlarged atria, vena cava, and pleural and pericardial effusions **(Figs. 248-32 and 248-33, and Videos 248-8 and 248-9)**. CMR offers the additional information of pericardial fibrosis and inflammation by LGE imaging and evidence of constrictive physiology (e.g., regional relaxation concordance due to myocardial adhesions, abnormal septal bounce with Valsalva maneuver) (Fig. 248-33).

CARDIAC THROMBUS AND MASS

Echocardiography is usually the modality that first detects a cardiac mass with differential diagnoses including thrombus, tumor, or vegetation. Given their unrestricted tomographic views and multiplanar 3D imaging, CMR and CT can complement echocardiography by further characterizing the physical features of the cardiac mass. Compared to CT, CMR has the advantage of higher tissue contrast differentiation, more robust cine imaging, and the use of multifaceted techniques within the same imaging session to determine the physiologic characteristics of the mass. Gadolinium contrast enhancement patterns of increased capillary perfusion can detect vascularity within a mass that differentiates a tumor from a thrombus. Structures that are known to mimic a cardiac mass include (1) anatomic variants, such as the Eustachian valve, Chiari network, crista sagittalis or terminalis, and the right ventricular moderator band, and (2) "pseudotumors," such as interatrial septal aneurysm, coronary or aortic aneurysm, lipomatous hypertrophy of interatrial septum, hiatal hernia, or a catheter/pacemaker lead. Coexisting abnormalities that raise the likelihood of a cardiac thrombus **(Fig. 248-34)** include regional wall motion abnormality from an infarction or ventricular aneurysm, atrial fibrillation leading to slow flow in the left atrial appendage, or presence of venous catheters or recent endovascular injury. CMR has the advantage of being able to assess regional wall motion and infarction or ventricular aneurysm in matching scan planes, adjacent to the cardiac thrombus, using cine and LGE imaging, respectively. For ventricular thrombus, gadolinium-enhanced LGE imaging can detect thrombus at a higher sensitivity than echocardiography by depicting high-contrast difference between the dark thrombus and its adjacent structures and by imaging in three dimensions. In addition, mural thrombus does not enhance on first-pass perfusion and often has a characteristic "etched" appearance (black border surrounding a bright center) on LGE imaging, thus providing higher diagnostic specificity than anatomic information alone **(Fig. 248-35)**. Comparing the signal intensities of a mass before and after contrast injection may confirm the lack of tissue vascularity (i.e., thrombus) by the lack of signal enhancement after contrast administration. Like intracardiac thrombus, regions of microvascular obstruction also appear dark, but microvascular obstruction is confined within the myocardium and surrounded by infarction and thus can be differentiated from intracardiac thrombus. Cardiac CT imaging is ideally suited for small thrombus in the left atrial appendage especially in cases where transesophageal echocardiography is suboptimal or not feasible.

Metastatic cardiac malignancy is about 20-fold more common than primary cardiac tumors. However, with the exception of involvement of the pericardium, even metastatic tumors of the heart are rare. Metastasis to the heart can be the result of direct invasion (e.g., lung and breast), lymphatic spread (e.g., lymphomas and melanomas), or hematogenous spread (e.g., renal cell carcinoma). Primary benign cardiac tumors are seen mostly in children and young adults and include atrial myxoma, rhabdomyoma, fibroma, and endocardial fibroelastoma **(Fig. 248-36)**. Atrial myxomas are often seen as a round or multilobar mass in the left atrium (75%), right atrium (20%), or ventricles or mixed chambers (5%). They typically have inhomogeneous brightness in the center on cine steady-state free precession imaging due to their gelatinous contents and may have a pedunculated attachment to the fossa ovalis. Primary malignant cardiac tumors are rare and may include angiosarcoma, fibrosarcoma, rhabdomyosarcoma, and liposarcoma.

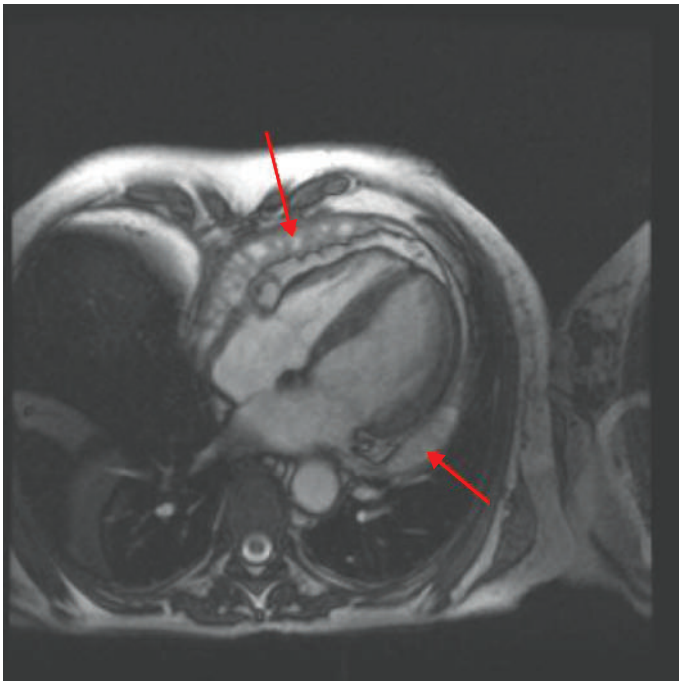

FIGURE 248-32 A female patient developed pericardial constriction and right heart failure, secondary to radiation therapy for breast cancer. Note the multiple pericardial adhesions (*red arrows*).

ROLE OF IMAGING IN INFECTIOUS AND INFLAMMATORY DISEASE

Patients with suspected endocarditis often undergo echocardiography for the purpose of identifying vegetations or intramyocardial abscesses. Vegetations are generally highly mobile structures that most typically are attached to valves or present in areas of the heart with turbulent flow. The absence of a vegetation on echocardiography does not rule out endocarditis, because small vegetations below the resolution of the imaging techniques can be present. Echocardiography remains the best technique for assessment of vegetations because its high temporal resolution allows visualization of the typical oscillating motion, although large vegetations can be visualized with other techniques **(Fig. 248-37)**. The size and location of a vegetation do not necessarily provide any specific information about the type of infection. Abscesses, particularly around the aortic and mitral annuli, are particularly concerning in patients with endocarditis and should be suspected in patients with prolongation of cardiac intervals in the setting of endocarditis. Visualization of both vegetations and possible abscesses is best done with transesophageal echocardiography, particularly in patients with prosthetic valves. Indeed, transesophageal echocardiography is the first test of choice in a patient with a mechanical mitral or aortic valve and

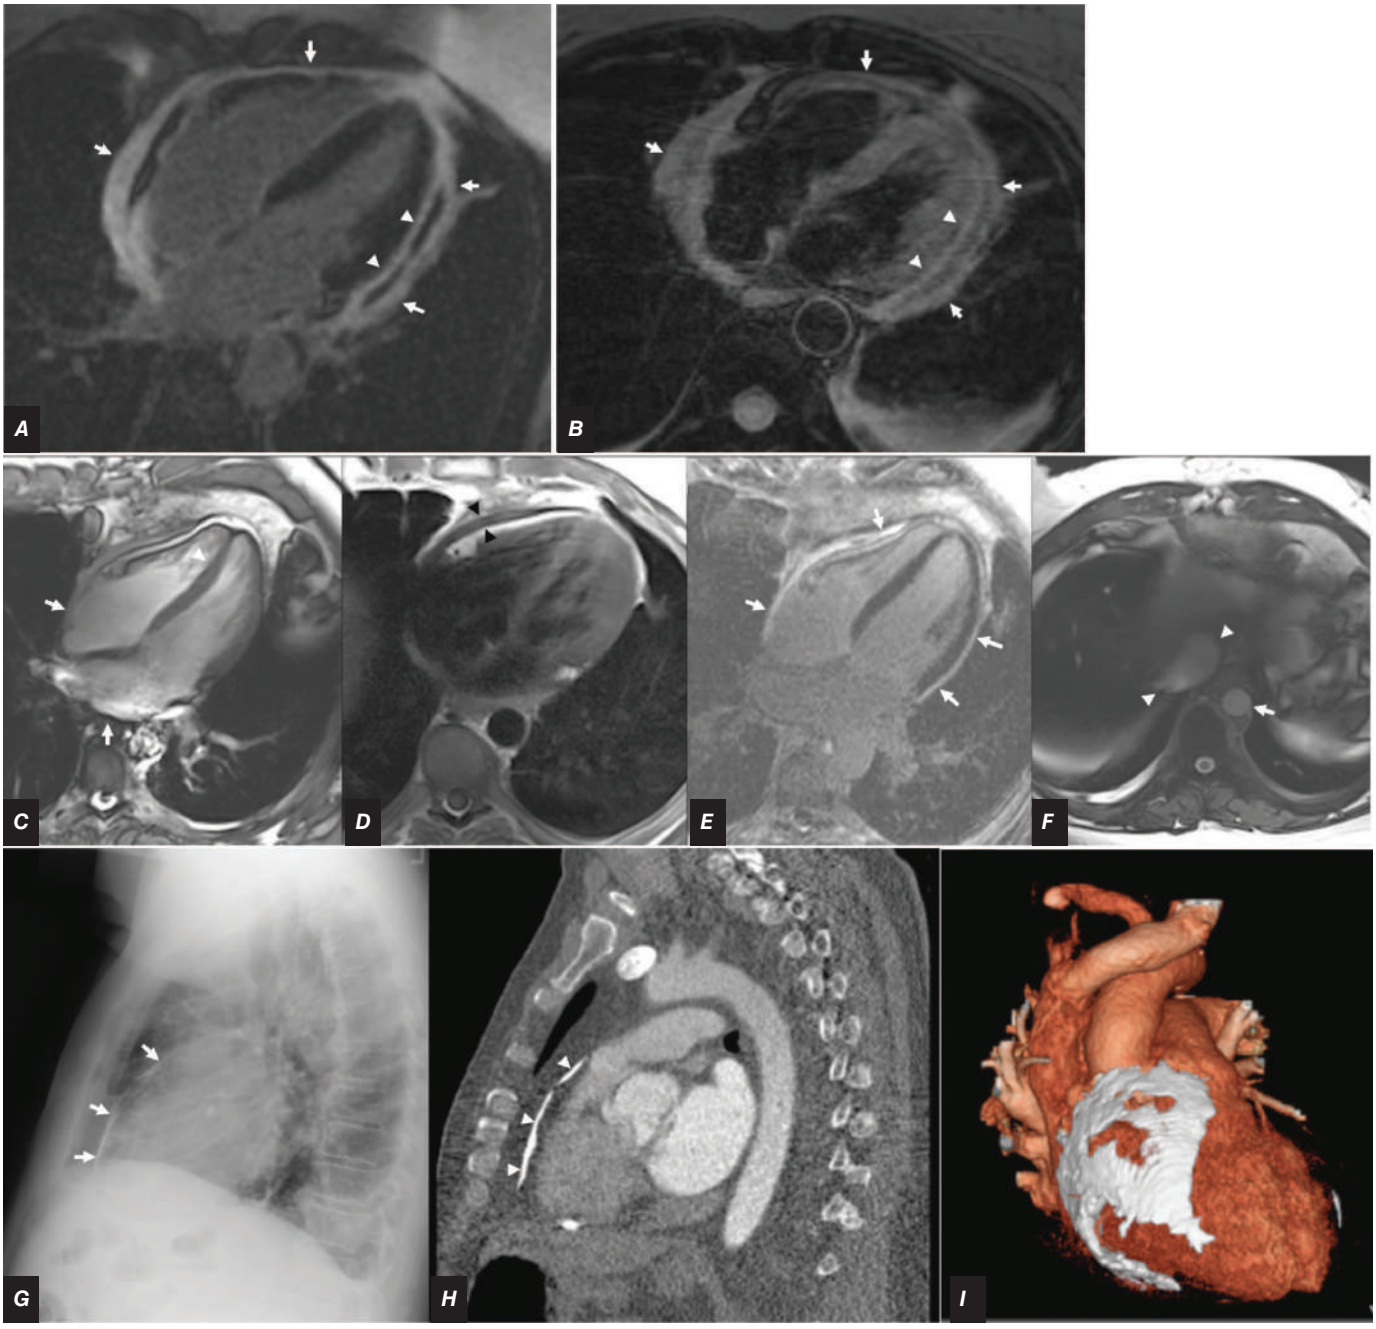

FIGURE 248-33 Representative cardiac magnetic resonance (CMR) and computed tomography (CT) features of pericardial disease. ***A.*** Four-chamber late gadolinium-enhanced image showing severe diffuse enhancement of both the visceral (*arrowheads*) and parietal (*arrows*) layers of the pericardium. The black signal between the two layers represents effusion. ***B.*** Axial T2-weighted image showing severe thickening and increased signal of both the visceral (*arrowheads*) and parietal (*arrows*) layers of the pericardium. ***C.*** Four-chamber steady-state free precession (bright-blood) image in early diastole showing the apical interventricular septum bowed to the left (*white arrowhead*) due to the increased right-sided ventricular volume at the expense of the left ventricular volume. Dilated atria (*white arrows*) are also a feature of constriction. ***D.*** Axial T1-weighted double inversion recovery (black-blood) image showing increased thickness of the pericardium >4 mm (*black arrowhead*). ***E.*** Four-chamber late gadolinium-enhanced image showing diffuse enhancement of the thickened pericardium (*white arrows*). ***F.*** Axial steady-state free precession (bright-blood) image showing dilated inferior vena cava (IVC; *white arrowheads*) that is greater than twice the size of the normal aorta (*white arrow*). Under normal conditions, the IVC should be similar in size to the aorta. ***G.*** Lateral chest radiograph showing calcification of the pericardium anteriorly (*arrows*). ***H.*** Corresponding sagittal view from CT angiography (CTA) showing the calcified pericardium (*arrowheads*). ***I.*** Three-dimensional rendered segmented image from the CTA showing the extent of the pericardial calcification. *(Images courtesy of Dr. Michael Steigner, Brigham and Women's Hospital.)*

suspected endocarditis (Fig. 248-37). Vegetations should be measured because their size has prognostic importance and can be used to decide whether a patient should be taken to surgery.

PET metabolic imaging is emerging as a potentially useful imaging technique to identify the source of infection in patients with prosthetic valves, vascular grafts, and implantable pacemakers/defibrillators, especially in patients in whom echocardiography and/or blood cultures are negative. There is an emerging literature documenting the potential value of macrophage-targeted metabolic imaging with ^{18}F-FDG and PET (Fig. 248-38). Likewise, FDG-PET is also useful to identify vascular inflammation and monitor the response to immunosuppressive therapy (Fig. 248-39).

EVALUATION OF COMMON CONGENITAL ABNORMALITIES IN THE ADULT

While a discussion of complex congenital heart disease is beyond the scope of this chapter, several common congenital abnormalities are present in adults, and cardiac imaging is essential to diagnosing and managing these conditions. Abnormalities of the interatrial septum probably represent the most common adult congenital cardiac

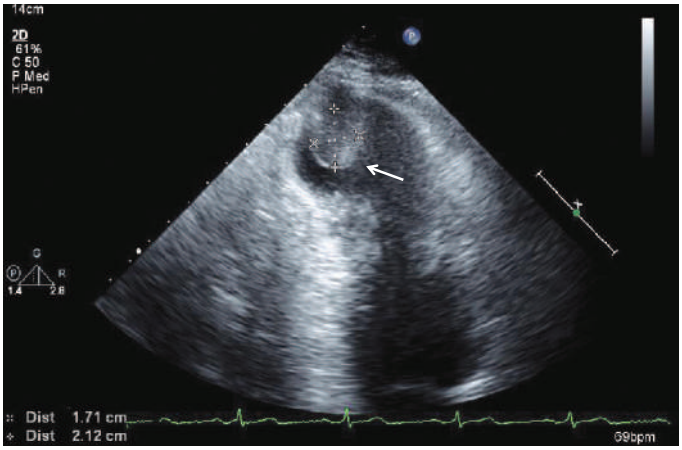

FIGURE 248-34 Cardiac thrombus (*arrow*) in an apical aneurysmal region following acute myocardial infarction.

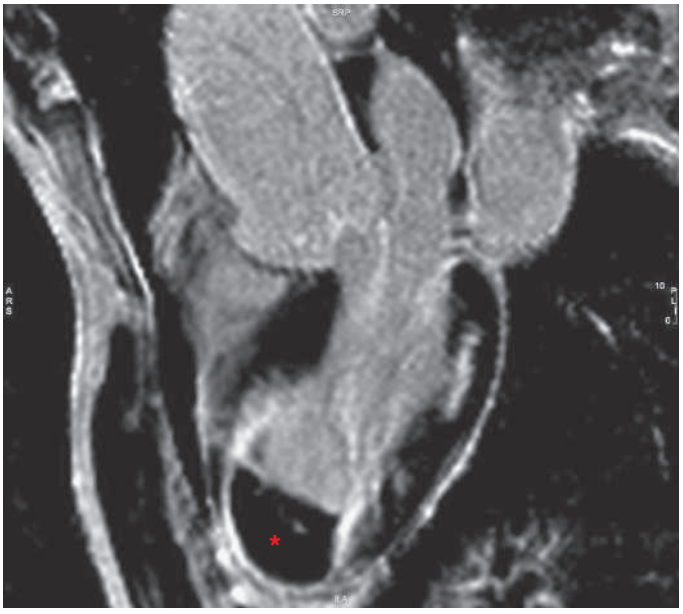

FIGURE 248-35 Late gadolinium enhancement image of a massive anterior infarction complicated by a dyskinetic left ventricular aneurysm and intracavitary thrombus (*red asterisk*).

abnormalities. Patent foramen ovale (PFO) can be identified in almost 25% of patients. In patients with PFO, a one-way flap in the region of the fossa ovalis is normally kept close by the left atrial pressure, which is generally higher than right atrial pressure for much of the cardiac cycle. However, right-to-left flow through a PFO can occur any time the right atrial pressure exceeds the left atrial pressure, including with maneuvers or conditions in which intrathoracic pressure is increased. The presence of a PFO can increase the likelihood of the paradoxical embolus, and thus the presence of a PFO should be determined in patients with stroke or systemic embolus of unknown etiology. Because the one-way flap of the PFO will be closed during much of the cardiac cycle, color flow Doppler will usually not reveal a PFO. Instead, agitated saline (bubble study) is the best way to assess for PFO or atrial septal defect. Saline is agitated and injected peripherally and then enters the right atrium. If no shunt is present, only the right side of the heart will be pacified because the air bubbles will be too small to traverse the lungs. Because PFO is a one-way flap, maneuvers should be used to temporarily increase right atrial pressure. Either a Valsalva maneuver or sniff maneuver can be effective.

Atrial septal defects occur most commonly in the region of the fossa ovalis, referred to as secundum-type defects **(Fig. 248-40)**. Additional atrial septal defects include defects of the sinus venosus and atrium primum. Color flow Doppler echocardiography is usually sufficient for diagnosis of a secundum-type atrial septal defect, but agitated saline is generally needed for the diagnosis of other types of atrial septal defects.

Ventricular septal defects can generally be visualized by color flow Doppler as turbulent high-velocity jets from the left to the right ventricle. In cases where the jet origin is unclear, continuous wave Doppler can estimate the velocities. These would be expected to be extremely high to reflect the pressure gradient between the left and right ventricles. Defects can occur in both the muscular and membranous portions of the ventricular septum.

In patients with either atrial or ventricular septal defects, estimation of the severity of the left-to-right shunt is essential and can be an important determinant in management decisions. Shunts are generally assessed by echocardiography by assessing the relationship between pulmonary flow and aortic flow, the Qp/Qs ratio. Shunts and cardiac anatomy of most congenital heart diseases can also be accurately evaluated by CMR **(Fig. 248-41)**.

ARTIFICIAL INTELLIGENCE IN CARDIAC IMAGING

Artificial intelligence (AI) is poised to revolutionize cardiac imaging over the next decade. AI methods have been applied to image acquisition, especially in echocardiography where a probe needs to

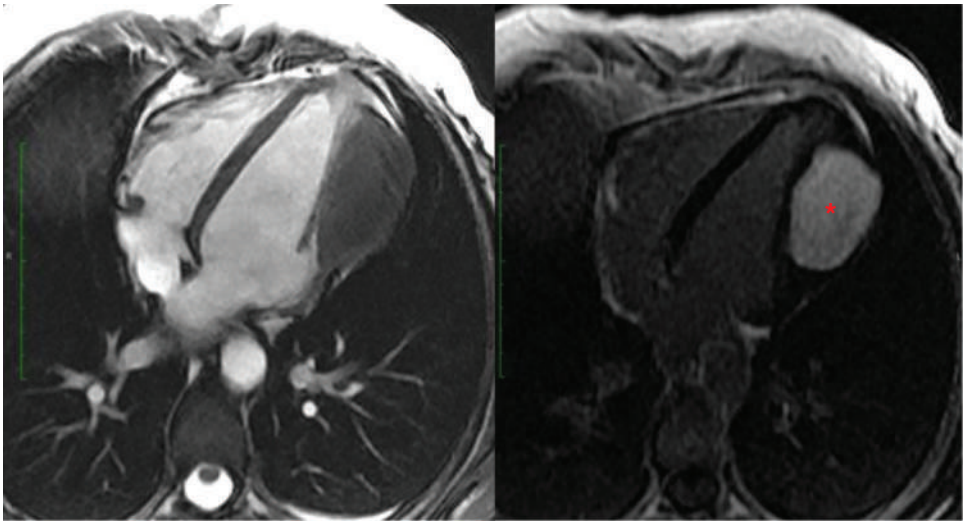

FIGURE 248-36 A case of a cardiac fibroma. A patient presented with shortness of breath and was found to have a large myocardial mass on echocardiography. Cine cardiac magnetic resonance imaging confirmed the large myocardial mass involving the anterolateral wall. Shortly after gadolinium contrast was injected, the myocardial mass demonstrated intense accumulation of contrast on late gadolinium enhancement imaging (*right panel, asterisk*). This is a case of cardiac fibroma. The patient also has gingival hyperplasia and bifid thoracic ribs, a part of the rare Gorlin's syndrome.

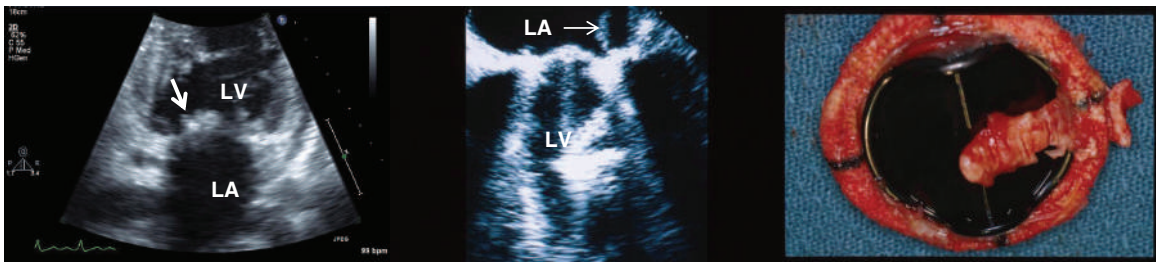

FIGURE 248-37 Vegetation on native mitral valve (*left panel, arrow*). Left atrium (LA) and left ventricle (LV) are indicated. *Middle panel* shows a vegetation on a mechanical prosthesis (St. Jude) indicated by an *arrow*; *right panel* shows vegetation on prosthesis after excision.

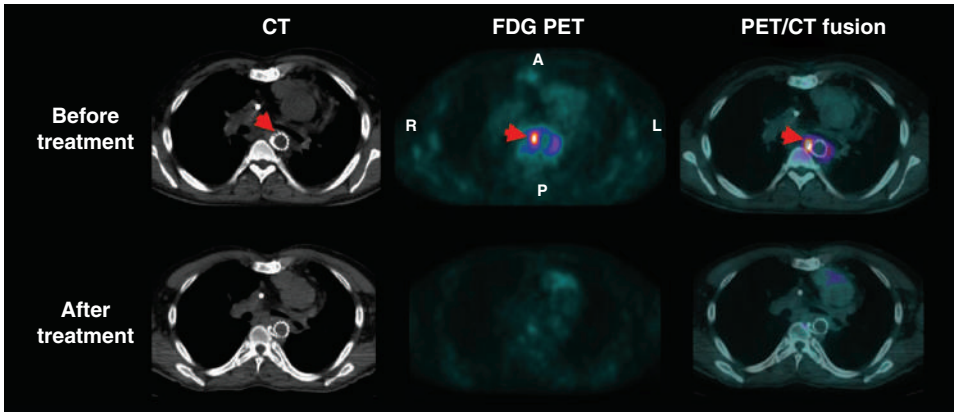

FIGURE 248-38 Representative cross-sectional computed tomography (CT; *left*), fluorodeoxyglucose (FDG) positron emission tomography (PET; *middle*), and fused CT and PET (*right*) images before and after antibiotic treatment in a patient with fever and suspected infection of the stent placed in the descending portion of the aortic arch (*arrow*) for treatment of aortic coarctation. The FDG images before treatment demonstrate intense glucose uptake within the stent, consistent with inflammation/infection. The *lower panel* demonstrates significant attenuation of the FDG signal after treatment. *(Images used with permission from Dr. Sharmila Dorbala, Brigham and Women's Hospital.)*

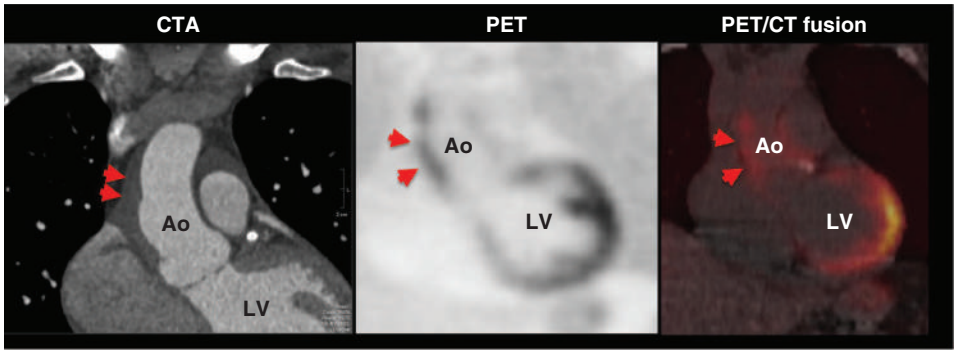

FIGURE 248-39 Representative coronal computed tomography (CT) angiographic (CTA; *left panel*), fluorodeoxyglucose (FDG) positron emission tomography (PET; *middle panel*), and fused CT and PET (*right panel*) images in a patient with suspected aortitis. The CTA images demonstrate thickening of the ascending aorta (Ao), which correlates with intense, focal FDG uptake consistent with active inflammation. LV, left ventricle.

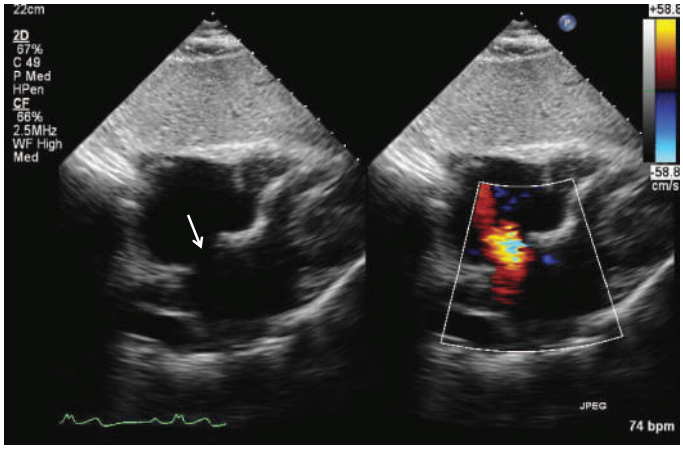

FIGURE 248-40 Large secundum-type atrial septal defect (*arrow*) noted in the subcostal view with color flow Doppler showing flow through the defect (*right*).

be manually applied to a patient's chest and the images acquired. AI software can direct a user to obtain optimal images. Likewise, cardiac MRI is a multicomponent examination that consists of numerous pulse sequences, and it is limited by the availability of an experienced scanning operator, the need for manual contouring and analysis, and a relatively long scan time of 45–60 min. FDA-approved commercial AI solutions are now available to guide the cardiac MRI scanning procedure, greatly reducing the complexities of image acquisition and reconstruction, and improving patient throughput and image quality.

AI is also being embedded in postprocessing and routine quantification. This includes image segmentation and routine measurements of cardiac dimension/volumes and function with echocardiography and CMR, quantification of CAC on nongated CT images (e.g., PET/CT and SPECT/CT), and plaque burden on coronary CTA. There is also growing evidence that AI may be able to refine risk prediction by integrating imaging markers of risk.

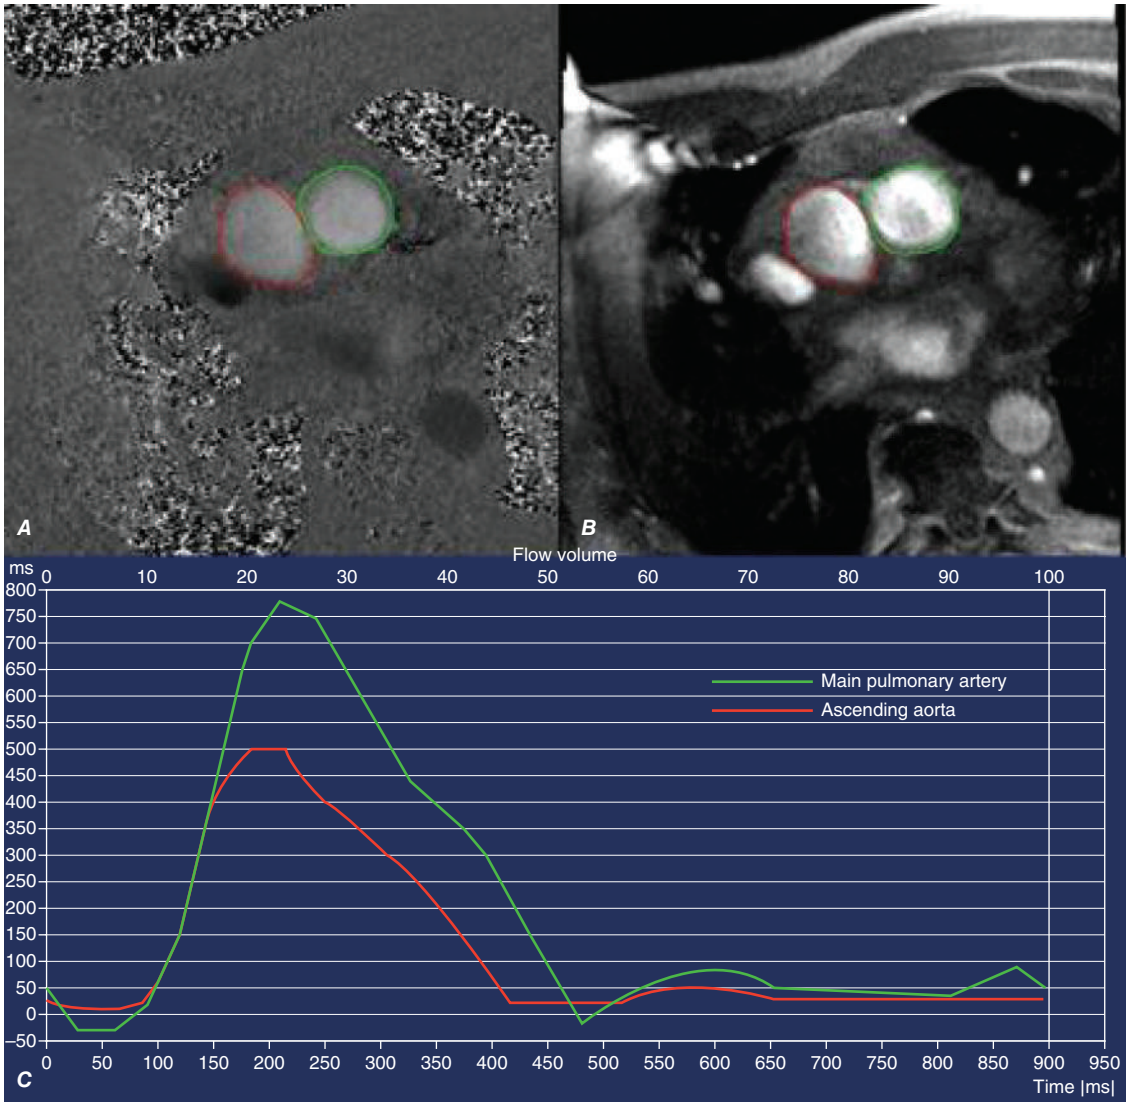

FIGURE 248-41 ***A*** and ***B*** are phase contrast images that display blood flow (phase images on ***A***) and anatomy (structural images on ***B***) of the aorta (*red*) and pulmonary artery (*green*). ***C*** demonstrates the flow curves of the aorta (*red*) and the pulmonary artery (*green*). Note that the total flow (area under the curve) was substantially higher in the pulmonary artery than the aorta, indicative of a marked elevated pulmonary-to-systemic shunt ratio, as a result of the partial anomalous pulmonary venous return that drained into the superior vena cava.

VIDEO 248-1 Cine steady-state free precession (SSFP) imaging (*left*) in short axis in a patient who had a large anterior myocardial infarction. Only one cut of a stack of short axis is shown. This method allows quantification of left ventricular (LV) and right ventricular (RV) volumes in diastole and systole and calculation of the LV ejection fraction, stroke volumes, and cardiac output (a product of LV stroke volume and heart rate). Note that in this case there is anterior and anteroseptal akinesia (lack of systolic wall thickening, as shown by the left cine movie, *red arrows*) matching by a near-transmural myocardial infarction as seen by the matching late gadolinium enhancement (LGE) image (*right picture, white arrows*).

VIDEO 248-2 This is cine cardiac magnetic resonance (CMR) imaging of a patient in the long-axis four-chamber view. Note that the basal aspect of the right ventricular (RV) free wall is thickened, aneurysmal, and akinetic (*red arrows*). The global RV systolic function is mildly reduced, and the RV is dilated. CMR can image the RV using tomographic views and can quantify the RV volumes and ejection fraction volumetrically. This is a patient who presented with syncopal spells and inducible ventricular tachycardia on subsequent workup. He was diagnosed to have arrhythmogenic right ventricular dysplasia.

VIDEO 248-3 Exercise echocardiogram showing rest images on left and poststress images on right, with parasternal long-axis, upper panel, and apical four-chamber, lower panel, end-systolic frames. Following exercise, the distal septal/apical region becomes akinetic. A = upper left (UL); B = upper right (UR); C = lower left (LL); D = lower right (LR).

VIDEO 248-4 The video shows cardiac magnetic resonance (CMR) myocardial perfusion imaging during vasodilating stress, in three parallel short-axis views. A bolus of gadolinium contrast was injected intravenously while rapid imaging acquisition occurred. The contrast enhances the right ventricle first, then travels through the pulmonary circulation, enters the left ventricle (LV), and then perfuses the LV myocardium. Myocardial perfusion defects with this technique show as black subendocardial rims, reflecting lack of contrast accumulation due to ischemia and/or scar. In this case, the anterior wall has a severe perfusion defect (*red arrow*). Figure 248-14 shows the late gadolinium enhancement (LGE) image of a mid short-axis view. There is no evidence of infarction in the anterior wall, which would be seen as bright white areas, indicating that the stress perfusion defect primarily represents myocardial ischemia. This patient had a significant stenosis of the left anterior descending coronary artery.

VIDEO 248-5 A 60-year-old female presented with intermittent chest pain of 3 days in duration but was pain-free at the time of assessment in the emergency room. Admission electrocardiogram (ECG) demonstrated T-wave inversion in the anterior

precordial lead, but cardiac enzymes were normal. A resting cardiac magnetic resonance (CMR) study reviewed a large area of anteroseptal hypokinesia (*left picture*, region of hypokinesia shown by the *red arrows*), matching with a large resting perfusion defect (*middle picture*, perfusion defect shown by the *blue arrows*). Late gadolinium enhancement (LGE) imaging (*right picture*), however, did not show any enhancement to indicate any infarction in the anteroseptal wall, suggesting that the hypocontractile and hypoperfused anteroseptal wall was viable. Urgent coronary angiography demonstrated an acute thrombus in the mid left anterior descending coronary artery, which required coronary stenting. This case represents an example of acute coronary syndrome with hibernating but viable myocardium in the anteroseptal wall. The anteroseptal wall recovered contractile function when reassessed 6 months later.

VIDEO 248-6 A patient with severe aortic regurgitation quantified by cardiac magnetic resonance (CMR). Notice the dark flow jet during diastolic across the aortic valve. For quantitation of the aortic regurgitation severity, a cross-sectional cut was made just below the aortic valve, perpendicular to the aortic regurgitation jet, using phase contrast flow imaging. Apart from aortic regurgitation fraction and volume, CMR also can volumetrically quantify ventricular sizes and dimensions of the aorta, which are useful in monitoring patients with aortic valve diseases.

VIDEO 248-7 These are T2* images of the heart (*left panel*) and the liver (*right panel*) of a patient who has hemochromatosis. Note that iron and the liver are markedly darkened in these movies, indicating high load of iron in the heart muscle and liver. The rate of signal reduction (decay) in the myocardium and liver can be calculated as T2* value expressed in milliseconds. In this case, the T2* was at 10 ms. T2* <20 ms in patients with cardiomyopathy has been shown to indicate iron toxicity as the etiology of the cardiomyopathy, and it carries prognostic valve for such patients at risk of cardiac iron toxicity.

VIDEO 248-8 This video shows the heart in long and short axis. Note the large atria, thickened pericardium, and extensive pericardial adhesions. Given the extensive pericardial adhesions, there is little shearing motion of the ventricles against the parietal pericardium.

VIDEO 248-9 This video shows the heart in long axis with a 4-chamber view. The steady-state free precession (bright-blood) cine show the early diastolic filling bounce of the apical interventricular septum due to constrictive physiology.

249 Diagnostic Cardiac Catheterization and Coronary Angiography

Jane A. Leopold, Ajar Kochar

Diagnostic cardiac catheterization and coronary angiography are considered the gold standard in the assessment of the anatomy and physiology of the heart and its associated vasculature. In 1929, Forssmann demonstrated the feasibility of cardiac catheterization in humans when he passed a urological catheter from a vein in his arm to his right atrium and documented the catheter's position in the heart by x-ray. In the 1940s, Cournand and Richards applied this technique to patients with cardiovascular disease to evaluate cardiac function. These three physicians were awarded the Nobel Prize in 1956. In 1958, Sones inadvertently performed the first selective coronary angiography when a catheter in the left ventricle slipped back across the aortic valve, engaged the right coronary artery, and power-injected 40 mL of contrast down the vessel. The resulting angiogram provided superb anatomic detail of the artery, and the patient suffered no adverse effects. Sones went on to develop selective coronary catheters, which were modified further by Judkins, who developed preformed catheters and allowed coronary artery angiography to gain widespread use as a diagnostic tool. In the United States, cardiac catheterization is the second most common operative procedure, with more than 1.0 million procedures performed annually.

CARDIAC CATHETERIZATION

INDICATIONS, RISKS, AND PREPROCEDURE MANAGEMENT

Cardiac catheterization and coronary angiography are indicated to evaluate the extent and severity of cardiac disease in symptomatic patients and to determine if medical, surgical, or catheter-based interventions are warranted (Table 249-1). They are also used to exclude

TABLE 249-1 Indications for Cardiac Catheterization and Coronary Angiography

Asymptomatic or Symptomatic Coronary Artery Disease
High risk for adverse outcome based on noninvasive testing
Sudden cardiac death
Sustained (>30 s) monomorphic ventricular tachycardia
Nonsustained (<30 s) polymorphic ventricular tachycardia
Symptomatic Coronary Artery Disease
Canadian Cardiology Society Class II, III, or IV stable angina on medical therapy
Acute coronary syndrome (unstable angina and non-ST-segment elevation myocardial infarction)
Chest-pain syndrome of unclear etiology and equivocal findings on noninvasive tests
Acute Myocardial Infarction
Reperfusion with primary percutaneous coronary intervention
Persistent or recurrent ischemia
Pulmonary edema and/or reduced ejection fraction
Cardiogenic shock or hemodynamic instability
Risk stratification or positive stress test after acute myocardial infarction
Mechanical complications—mitral regurgitation, ventricular septal defect
Valvular Heart Disease
Suspected severe valve disease in symptomatic patients—dyspnea, angina, heart failure, syncope
Infective endocarditis with need for cardiac surgery
Asymptomatic patients with aortic regurgitation and cardiac enlargement or ↓ ejection fraction
Prior to cardiac surgery or transcatheter aortic valve replacement or other percutaneous valvular interventions in patients with suspected coronary artery disease
Congestive Heart Failure
New-onset angina or suspected undiagnosed coronary artery disease
New-onset cardiomyopathy of uncertain cause or suspected to be due to coronary artery disease
Congenital Heart Disease
Prior to surgical correction or percutaneous interventions, when symptoms or noninvasive testing suggests coronary disease
Suspicion for congenital coronary anomalies
Pericardial Disease
Symptomatic patients with suspected cardiac tamponade or constrictive pericarditis
Cardiac Transplantation
Preoperative and postsurgical evaluation
Other Conditions
Hypertrophic cardiomyopathy with angina
Diseases of the aorta when knowledge of coronary artery involvement is necessary for management
Pulmonary hypertension
Unexplained dyspnea

severe disease in symptomatic patients with equivocal findings on noninvasive studies and in patients with chest-pain syndromes of unclear etiology for whom a definitive diagnosis is necessary for management. Cardiac catheterization is not mandatory prior to cardiac surgery in some younger patients who have uncomplicated congenital or valvular heart disease that is well defined by noninvasive imaging and who do not have symptoms or risk factors that suggest concomitant coronary artery disease.

The risks associated with elective cardiac catheterization are relatively low, with a reported risk of <0.1% for myocardial infarction, 0.01% for stroke, and 0.05% for death. For elective and emergent procedures, the in-hospital mortality is 1.4%. These risks increase substantially if the catheterization is performed emergently, during acute myocardial infarction, or in hemodynamically unstable patients. Additional risks of the procedure include tachy- or bradyarrhythmias that require countershock, temporary pacing or pharmacologic therapy, acute renal failure leading to transient or permanent dialysis, air embolus, hemodynamic compromise, acute pulmonary edema, aortic dissection or other peripheral vascular complications that necessitate surgical repair or percutaneous intervention, and significant access-site bleeding. Of these risks, vascular access-site bleeding is the most common complication, occurring in 1.5–2.0% of patients, with major bleeding events associated with a worse short- and long-term outcome. These vascular access site bleeding complications are less common with the radial approach as compared with the femoral access site.

In patients who understand and accept the risks associated with cardiac catheterization, there are no absolute contraindications when the procedure is performed in anticipation of a life-saving intervention. Relative contraindications for elective procedures do, however, exist; these include decompensated congestive heart failure; acute renal failure; severe chronic renal insufficiency, unless dialysis is planned; bacteremia; acute stroke; active gastrointestinal bleeding; excessive anticoagulation or recent lytic administration; severe, uncorrected electrolyte abnormalities; a history of an anaphylactic/anaphylactoid reaction to iodinated contrast agents without premedication; and a history of allergy/anaphylaxis/bronchospasm to aspirin in patients for whom progression to a percutaneous coronary intervention is likely and aspirin desensitization has not been performed. For right heart catheterization, contraindications include right heart tumor, endocarditis, thrombus, or clot in transit.

Contrast allergy and contrast-induced acute kidney injury merit further consideration because these adverse events may occur in otherwise healthy individuals and prophylactic measures exist to reduce risk. Allergic reactions to contrast agents occur in <5% of cases, with severe anaphylactoid (clinically indistinguishable from anaphylaxis, but not mediated by an IgE mechanism) reactions occurring in 0.1–0.2% of patients. Mild reactions manifest as nausea, vomiting, and urticaria, while severe anaphylactoid reactions lead to hypotensive shock, pulmonary edema, and cardiorespiratory arrest. Patients with a history of significant contrast allergy should be premedicated prior to planned coronary angiography with corticosteroids (prednisone 50 mg orally 13, 7, and 1 hour prior to the procedure) and antihistamines (H_1-blockers), and studies performed with nonionic, low-osmolar contrast agents that have a lower reported rate of allergic reactions.

Contrast-induced acute kidney injury, defined as an increase in creatinine >0.5 mg/dL or 25% above baseline that occurs 48–72 h after contrast administration, occurs in ~2–7% of patients, with rates of 20–30% reported in high-risk patients. Risk factors for contrast-induced kidney injury are diabetes mellitus, congestive heart failure, chronic kidney disease, anemia, older age, and ST-segment elevation myocardial infarction. Dialysis is required in 0.3–0.7% of patients and is associated with a fivefold increase in in-hospital mortality. For all patients, adequate intravascular volume expansion with intravenous 0.9% saline (1.0–1.5 mL/kg per hour) for 3–12 h before and continued 6–24 h after the procedure limits the risk of contrast-induced acute kidney injury by >50%. Other strategies to decrease risk include the administration of sodium bicarbonate (3 mL/kg per hour) 1 h before and 6 h after the procedure (similar outcome to saline infusion); use of low- or iso-osmolar contrast agents; and limiting the volume of contrast to <50 mL per procedure. Diabetic patients treated with metformin should stop the drug 24 h prior to the procedure and not restart until 48 h after contrast administration to limit the associated risk of lactic acidosis.

Cardiac catheterization is performed after the patient has fasted for 6 h and has received intravenous conscious sedation to remain awake but sedated during the procedure. Diabetic patients who have a tendency to develop hypoglycemia should hold oral hypoglycemic medications. All patients with suspected coronary artery disease are pretreated with 325 mg of aspirin. In patients in whom the procedure is likely to progress to a percutaneous coronary intervention, an additional $P2Y_{12}$ antiplatelet inhibitor agent should be started: clopidogrel (600-mg loading dose and 75 mg daily), prasugrel (60-mg loading dose and 10 mg daily), or ticagrelor (180-mg loading dose and 90 mg twice daily). Prasugrel should not be selected for individuals with prior stroke or transient ischemic attack and is not recommended for patients 75 years of age or older. Ticagrelor should not be chosen for patients with bradycardia; additionally, up to 10% of patients treated with ticagrelor may experience dyspnea. For those patients who will be treated with an oral anticoagulant after the procedure, clopidogrel is the antiplatelet agent of choice. Intravenous cangrelor may be used for patients who are unable to tolerate an oral $P2Y_{12}$ inhibitor medication. Warfarin is held starting 2–3 days prior to the catheterization to allow the international normalized ratio (INR) to fall to <1.8 and limit access-site bleeding complications. For patients at high risk of thrombotic complications (mechanical heart valve, ventricular assist device), a heparin bridge may be necessary. The direct oral anticoagulants (DOACs) should be stopped 24–48 h prior to the test. Cardiac catheterization is a sterile procedure, so antibiotic prophylaxis is not required.

TECHNIQUE

Cardiac catheterization and coronary angiography provide a detailed hemodynamic and anatomic assessment of the heart and coronary arteries. The selection of procedures is dependent on the patient's symptoms and clinical condition, with some direction provided by noninvasive studies.

Vascular Access Cardiac catheterization procedures are performed using a percutaneous technique to enter the femoral, radial, or ulnar artery and femoral, brachial, or internal jugular vein as the access sites for left and right heart catheterization, respectively. A flexible sheath is inserted into the vessel over a guidewire, allowing diagnostic catheters to be introduced into the vessel and advanced toward the heart using fluoroscopic guidance. The radial artery (or rarely the ulnar or brachial artery) access site is advantageous in patients with peripheral arterial disease that involves the abdominal aorta, iliac, or femoral vessels; severe iliac artery tortuosity, morbid obesity, or preference for early postprocedure ambulation. Use of radial artery access is the preferred access route due to a lower rate of access-site bleeding complications and improved patient comfort. The femoral artery should be accessed using a micropuncture needle with ultrasound guidance to ensure that the insertion site is above the bifurcation of the profunda femoris and superficial femoral artery and below the inferior epigastric artery. Femoral artery access outside this zone increases the risk of retroperitoneal hemorrhage, pseudoaneurysm formation, and/or arteriovenous fistula. Complications associated with radial artery access include severe radial vasospasm that may result in device entrapment, forearm hematoma, and rarely, compartment syndrome. The internal jugular or antecubital veins serve as the preferred access sites to the right heart when the patient has an inferior vena cava filter in place or requires prolonged hemodynamic monitoring.

Right Heart Catheterization This procedure measures pressures in the right heart and pulmonary artery. Right heart catheterization is no longer a routine part of diagnostic cardiac catheterization, but it is reasonable in patients with unexplained dyspnea, pulmonary hypertension, valvular heart disease, pericardial disease, right and/or left ventricular dysfunction, congenital heart disease, and suspected intracardiac shunts. Right heart catheterization most commonly uses a balloon-tipped flotation catheter that is advanced sequentially to the right atrium, right ventricle, pulmonary artery, and pulmonary

wedge position (as a surrogate for left atrial pressure) using fluoroscopic guidance; in each cardiac chamber, pressure is measured and blood samples are obtained for oxygen saturation analysis to screen for intracardiac shunts and calculate a cardiac output.

Left Heart Catheterization This procedure measures pressures in the left heart as a determinant of left ventricular performance. With the aid of fluoroscopy, a catheter is guided to the ascending aorta and across the aortic valve into the left ventricle to provide a direct measure of left ventricular pressure. In patients with a tilting-disc prosthetic aortic valve, crossing the valve with a catheter is contraindicated, and the left heart may be accessed via a transseptal technique from the right atrium using a needle-tipped catheter to puncture the atrial septum at the fossa ovalis. Once the catheter crosses from the right to the left atrium, it can be advanced across the mitral valve to the left ventricle. This technique is also used for mitral valvuloplasty. Heparin is given for prolonged procedures to limit the risk of stroke from embolism of clots that may form on the catheter. For patients with heparin-induced thrombocytopenia, the direct thrombin inhibitors bivalirudin (0.75 mg/kg bolus, 1.75 mg/kg per hour for the duration of the procedure) or argatroban (350 μg/kg bolus, 15 μg/kg per min for the duration of the procedure) may be used.

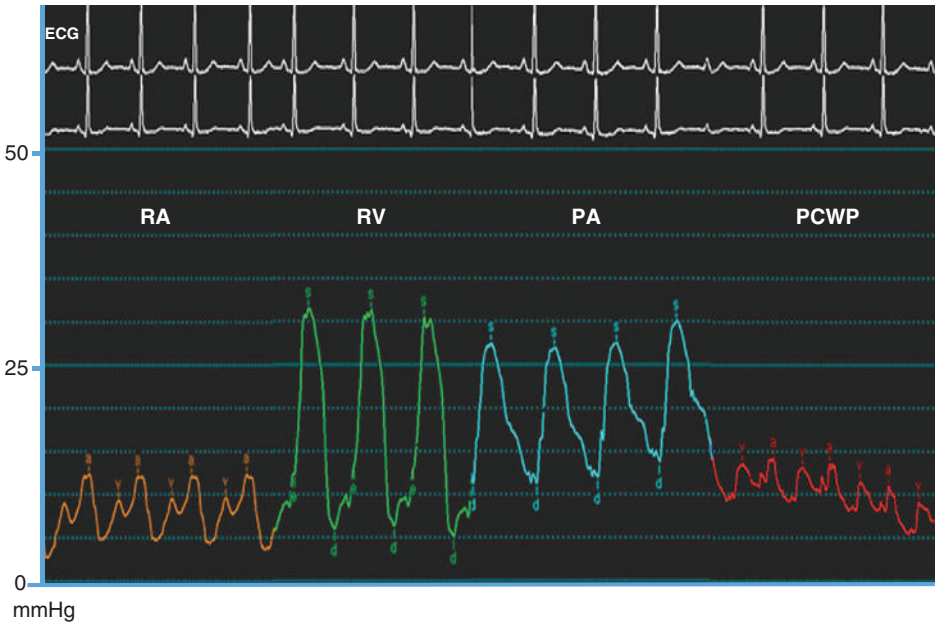

FIGURE 249-1 Normal hemodynamic waveforms recorded during right heart catheterization. Atrial pressure tracings have a characteristic "*a*" wave that reflects atrial contraction and a "*v*" wave that reflects pressure changes in the atrium during ventricular systole. Ventricular pressure tracings have a low-pressure diastolic filling period and a sharp rise in pressure that occurs during ventricular systole. d, diastole; PA, pulmonary artery; PCWP, pulmonary capillary wedge pressure; RA, right atrium; RV, right ventricle; s, systole.

HEMODYNAMICS

A comprehensive hemodynamic assessment involves obtaining pressure measurements in the right and left heart and peripheral arterial system and determining the cardiac output (Table 249-2). The shape and magnitude of the pressure waveforms provide important diagnostic information; an example of normal pressure tracings is shown in Fig. 249-1. In the absence of valvular heart disease, the atria and ventricles are "one chamber" during diastole when the tricuspid and mitral valves are open, whereas in systole, when the pulmonary and aortic valves are open, the ventricles and their respective outflow tracts are considered "one chamber." These concepts form the basis by which hemodynamic measurements are used to assess valvular stenosis. When aortic stenosis is present, there is a systolic pressure gradient between the left ventricle and the aorta; when mitral stenosis is present, there is a diastolic pressure gradient between the pulmonary capillary wedge (left atrial) pressure and the left ventricle (Fig. 249-2). Hemodynamic measurements also discriminate between aortic stenosis and hypertrophic obstructive cardiomyopathy where the asymmetrically hypertrophied septum creates a dynamic intraventricular pressure gradient during ventricular systole. The magnitude of this obstruction is measured using an end-hole catheter positioned at the left ventricular apex that is pulled back while recording pressure; once the catheter has passed the septal obstruction and is positioned in the apex of the left ventricle, a gradient can be measured between the left ventricular apex and the aorta. Hypertrophic obstructive cardiomyopathy is confirmed by the Brockenbrough-Braunwald sign: following a premature ventricular contraction, there is an increase in the left ventricular–aorta pressure gradient with a simultaneous decrease in the aortic pulse pressure. The finding of a decrease in pulse pressure is absent in aortic stenosis.

Regurgitant valvular lesions increase volume (and pressure) in the "receiving" cardiac chamber. In severe mitral and tricuspid regurgitation, the increase in blood flow to the atria takes place during ventricular systole, leading to an increase in the *v* wave (often two times greater than the mean pressure). The size of the *v* wave is a measure of the compliance of the left atrium but is not a reliable measure of the severity of the mitral regurgitation. Severe aortic regurgitation leads to a decrease in aortic diastolic pressure with a concomitant rise in left ventricular end-diastolic pressure, resulting in equalization of pressures between the two chambers at end diastole.

Hemodynamic measurements are also used to differentiate between cardiac tamponade, constrictive pericarditis, and restrictive cardiomyopathy (Table 249-3). In cardiac tamponade, right atrial pressure is increased with a decreased or absent "y" descent, indicative of impaired right atrial emptying in diastole, and there is diastolic equalization of pressures in all cardiac chambers. In constrictive pericarditis, right atrial pressure is elevated with a prominent "y" descent, indicating rapid filling of the right ventricle during early diastole. A diastolic dip and plateau, or "square root sign," in the ventricular waveforms due to an abrupt halt in ventricular filling during diastole, elevated right

TABLE 249-2 Normal Values for Hemodynamic Measurements

Pressures (mmHg)	
Right atrium (mean)	1–8
Right ventricle	
Peak systolic/end diastolic	15–30/1–8
Pulmonary artery	
Peak systolic/end diastolic	15–30/4–12
Mean	9–19
Pulmonary capillary wedge (mean)	4–12
Left atrium (mean)	4–12
Left ventricle	
Peak systolic/end diastolic	90–129/5–12
Aorta	
Peak systolic/end diastolic	90–129/60–79
Mean	70–100
Resistances ([dyn-s]/cm^5)	
Systemic vascular resistance	900–1400
Pulmonary vascular resistance	40–120
Oxygen Consumption Index ([L-min]/m^2)	**115–140**
Arteriovenous oxygen difference (vol %)	3.5–4.8
Cardiac index ([L-min]/m^2)	2.8–4.2

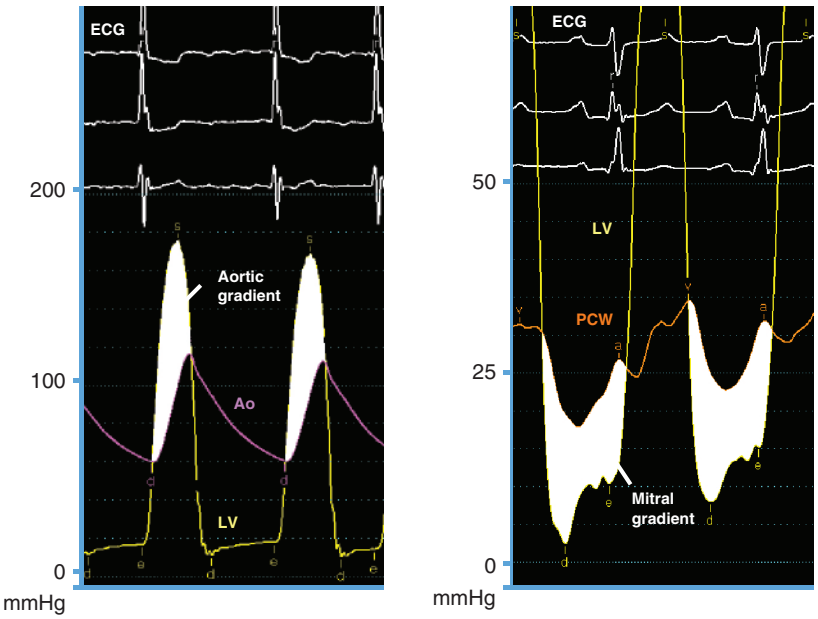

FIGURE 249-2 Severe aortic and mitral stenosis. Simultaneous recording of left ventricular (LV) and aortic (Ao) pressure tracings demonstrates a 62-mmHg mean systolic gradient (*shaded area*) that corresponds to an aortic valve area of 0.6 cm^2 (*left*). Simultaneous recording of LV and pulmonary capillary wedge (PCW) pressure tracings reveals a 14-mmHg mean diastolic gradient (*shaded area*) that is consistent with critical mitral stenosis (mitral valve area = 0.5 cm^2). d, diastole; e, end diastole; s, systole.

ventricular and pulmonary artery pressures, and discordant pressure changes in the right and left ventricles with inspiration (right ventricular systolic pressure increases while left ventricular systolic pressure decreases) are observed. In the absence of constriction, the two ventricular pressures are concordant. The latter hemodynamic phenomenon is the most specific for constriction. Restrictive cardiomyopathy may be distinguished from constrictive pericarditis by a marked increase in right ventricular and pulmonary artery systolic pressures (usually >60 mmHg), a separation of the left and right ventricular diastolic pressures by >5 mmHg (at baseline or with acute volume loading), and concordant changes in left and right ventricular diastolic filling pressures with inspiration (both increase).

Cardiac Output Cardiac output is measured by the Fick method or the thermodilution technique. Typically, the Fick method and thermodilution technique are both performed during cardiac catheterization, although the Fick method is considered more reliable in the presence of tricuspid regurgitation and in low-output states. The Fick method uses oxygen as the indicator substance and is based on the principle that the amount of a substance taken up or released by an organ (oxygen consumption) is equal to the product of its blood flow (cardiac output) and the difference in the concentration of the substance in the arterial and venous circulation (arterial-venous oxygen difference). Thus, the formula for calculating the Fick cardiac output is:

$$\text{Cardiac output (L/min)} = \frac{\text{(oxygen consumption [mL/min])}}{\text{(arterial-venous oxygen difference [mL/L])}}$$

If oxygen consumption is not measured directly, then it is estimated as 125 mL oxygen/minute × body surface area, and the arterial-venous oxygen difference is determined by first calculating the oxygen-carrying capacity of blood (hemoglobin [g/100 mL] × 1.36 [mL oxygen/g hemoglobin] × 10) and multiplying this product by the fractional oxygen saturation. The indicator dilution method measures the concentration of a substance that is injected proximally, adequately mixes with blood, and is then sampled distally. In contemporary practice, thermodilution cardiac outputs are measured using temperature as the indicator. Measurements are made with a thermistor-tipped catheter that detects temperature deviations in the pulmonary artery after the injection of 10 mL of room-temperature normal saline into the right atrium.

Vascular Resistance Resistance across the systemic and pulmonary circulations is calculated by extrapolating from Ohm's law of electrical resistance and is equal to the mean pressure gradient divided by the mean flow (cardiac output). Therefore, systemic vascular resistance is ([mean aortic pressure − mean right atrial pressure]/cardiac output) multiplied by 80 to convert the resistance from Wood units to dyn-s-cm^{-5}. Similarly, the pulmonary vascular resistance is ([mean pulmonary artery − mean pulmonary capillary wedge pressure]/cardiac output) × 80. Pulmonary vascular resistance is lowered by oxygen, nitroprusside, calcium channel blockers, prostacyclin infusions, and inhaled nitric oxide; these therapies may be administered during catheterization to determine if increased pulmonary vascular resistance is fixed or reversible.

Valve Area Hemodynamic data may also be used to calculate the valve area using the Gorlin formula that equates the area to the flow

TABLE 249-3 Hemodynamic Findings in Tamponade, Constrictive Pericarditis, and Restrictive Cardiomyopathy

	CARDIAC TAMPONADE	CONSTRICTIVE PERICARDITIS	EFFUSIVE-CONSTRICTIVE PERICARDITIS	RESTRICTIVE CARDIOMYOPATHY
Pericardial pressure	↑	↑	↑	Normal
Right atrium pressure	↑	↑	↑ (Fails to decrease by 50% or to <10 mmHg after pericardiocentesis)	↑
Right atrium pressure waveform	Prominent "x" descent Diminished or absent "y" descent	Prominent "x" descent Prominent "y" descent	Prominent "x" descent "y" descent less prominent than expected	Prominent "y" descent
Right ventricle systolic pressure	<50 mmHg	<50 mmHg	<50 mmHg	>60 mmHg
Right ventricle end-diastolic pressure	Equals left ventricular end-diastolic pressure within 5 mmHg	>1/3 right ventricular systolic pressure Equals left ventricular end-diastolic pressure within 5 mmHg	>1/3 right ventricular systolic pressure Equals left ventricular end-diastolic pressure within 5 mmHg	<1/3 right ventricular systolic pressure Less than left ventricular end-diastolic pressure by ≥5 mmHg
Right ventricle pressure waveform		Dip and plateau or "square root" sign	Dip and plateau or "square root" sign	Dip and plateau or "square root" sign
Right ventricle–left ventricle systolic pressure relationship with inspiration	Discordant	Discordant	Discordant	Concordant

across the valve divided by the pressure gradient between the cardiac chambers surrounding the valve. The formula for the assessment of valve area is: Area = (cardiac output [cm^3/min]/[systolic ejection period or diastolic filling period][heart rate])/44.3 C × square root of the pressure gradient, where C = 1 for aortic valve and 0.85 for the mitral valve. A valve area of <1.0 cm^2 and a mean gradient of >40 mmHg indicate severe aortic stenosis, while a valve area of <1.5 cm^2 and a mean gradient >5–10 mmHg are consistent with moderate-to-severe mitral stenosis; in symptomatic patients with a mitral valve area >1.5 cm^2, a mean gradient >15 mmHg, pulmonary artery pressure >60 mmHg, or a pulmonary artery wedge pressure >25 mmHg after exercise is also considered significant and may warrant intervention. The modified Hakki formula has also been used to estimate aortic valve area. This formula calculates the valve area as the cardiac output (L/min) divided by the square root of the pressure gradient. Aortic valve area calculations based on the Gorlin formula are flow-dependent, and therefore, for patients with low cardiac outputs, it is imperative to determine if a decreased valve area actually reflects a fixed stenosis or is overestimated by a low cardiac output and stroke volume that is insufficient to open the valve leaflets fully. In these instances, cautious hemodynamic manipulation using dobutamine to increase the cardiac output and recalculation of the aortic valve area may be necessary.

Intracardiac Shunts In patients with congenital heart disease or unexplained hypoxemia, detection, localization, and quantification of the intracardiac shunt should be evaluated. A shunt should be suspected when there is unexplained arterial desaturation or increased oxygen saturation of venous blood. A "step up" or increase in oxygen content indicates the presence of a left-to-right shunt while a "step down" indicates a right-to-left shunt. The shunt is localized by detecting a difference in oxygen saturation levels of 5–7% between adjacent cardiac chambers. The severity of the shunt is determined by the ratio of pulmonary blood flow (Q_p) to the systemic blood flow (Q_s), or Q_p/Q_s = ([systemic arterial oxygen content − mixed venous oxygen content]/pulmonary vein oxygen content − pulmonary artery oxygen content). For an atrial septal defect, a shunt ratio of 1.5 is considered significant and factored with other clinical variables to determine the need for intervention. When a congenital ventricular septal defect is present, a shunt ratio of ≥1.5 with evidence of left ventricular volume overload is a strong indication for surgical correction.

VENTRICULOGRAPHY AND AORTOGRAPHY

Ventriculography to assess left ventricular function may be performed during cardiac catheterization. A pigtail catheter is advanced retrograde across the aortic valve into the left ventricle, and 30–45 mL of contrast is power-injected to visualize the left ventricular chamber during the cardiac cycle. The ventriculogram is usually performed in the right anterior oblique projection to examine wall motion and mitral valve function. Normal wall motion is observed as symmetric contraction of all segments; hypokinetic segments have decreased contraction, akinetic segments do not contract, and dyskinetic segments appear to bulge paradoxically during systole (Fig. 249-3). Ventriculography may also reveal a left ventricular aneurysm, pseudoaneurysm, or diverticulum, or an apical ballooning pattern consistent with takotsubo cardiomyopathy, and can also be used to assess mitral valve prolapse and the severity of mitral regurgitation. The degree of mitral regurgitation is estimated by comparing the density of contrast opacification of the left atrium with that of the left ventricle. Minimal contrast reflux into the left atrium is considered 1+ mitral regurgitation, while contrast density in the left atrium that is greater than that in the left ventricle with reflux of contrast into the pulmonary veins within three beats defines 4+ mitral regurgitation. When it takes more than three beats but fully fills the atrium, it is 3+. Both 3+ and 4+ are considered severe regurgitation. Ventriculography performed in the left anterior oblique projection can be used to identify a ventricular septal defect. Calculation of the ventricular volumes in systole and diastole allows calculation of stroke volume and cardiac output.

Aortography in the cardiac catheterization laboratory visualizes abnormalities of the ascending aorta, including aneurysmal dilation and involvement of the great vessels, as well as dissection with compression of the true lumen by an intimal flap that separates the true and false lumina. Aortography can also be used to identify patent saphenous vein grafts that elude selective cannulation, identify shunts that involve the aorta such as a patent ductus arteriosus, evaluate the takeoff or proximal anatomy of the great vessels, and provide a qualitative assessment of aortic regurgitation using a 1+–4+ scale similar to that used for mitral regurgitation.

CINEFLUOROSCOPY OF PROSTHETIC MECHANICAL VALVES

Prosthetic valve leaflet dysfunction may occur as a result of thrombus or obstruction of leaflet excursion by pannus (Fig. 249-4). The incidence of prosthetic valve thrombosis in left-sided valves is 0.1–6.0% per patient-year with differences in rates attributable to valve type, position, anticoagulation status, and left ventricular function. Prosthetic valve dysfunction should be suspected in patients with subtherapeutic anticoagulation with a low mean INR, a prothrombotic state, recent-onset heart failure, cardiogenic shock, cardiac arrest, thromboembolic

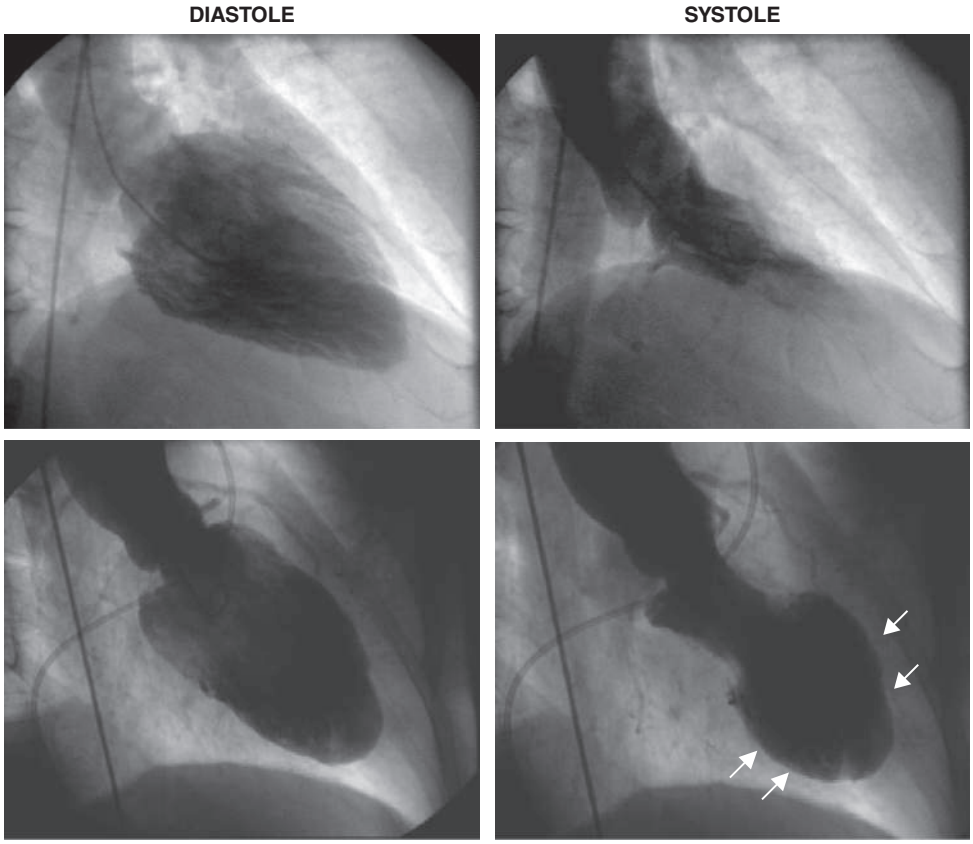

FIGURE 249-3 Left ventriculogram at end diastole (left) and end systole (right). In patients with normal left ventricular function, the ventriculogram reveals symmetric contraction of all walls (*top*). Patients with coronary artery disease may have wall motion abnormalities on ventriculography as seen in this 60-year-old male following a large anterior myocardial infarction. In systole, the anterior, apical, and inferior walls are akinetic (*white arrows*) (*bottom*).

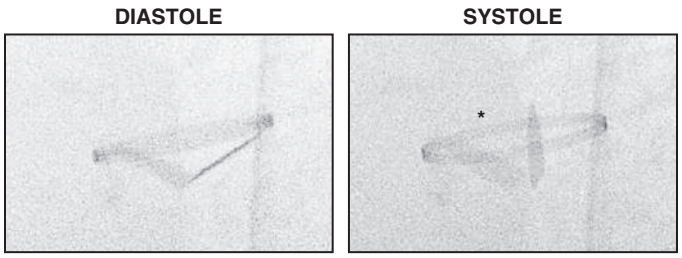

FIGURE 249-4 Cinefluoroscopic detection of mechanical valve leaflet dysfunction. Images of a bileaflet mechanical valve in the aortic position taken during diastole (*left*) and systole (*right*) show that one leaflet opens normally during systole while the other leaflet (below asterisk) remains immobile and fixed consistent with valve leaflet thrombosis.

event, or, in asymptomatic patients, an increasing gradient across the valve. Cinefluoroscopy visualizes the motion of mechanical valve leaflets, is noninvasive, is available in most centers, and can be performed rapidly with minimal radiation exposure. Prosthetic mechanical valves should be imaged *en face* and at a 90° angle over several cardiac cycles to document opening and closing of the valve leaflets as well as motion of the base ring. Each type of prosthetic valve has leaflet opening and closing angles that are reported by the manufacturer and can be used to determine if movement or closure of the valve leaflets is restricted, suggestive of mechanical obstruction.

CORONARY ANGIOGRAPHY

Selective coronary angiography is almost always performed during cardiac catheterization and is used to define the coronary anatomy and determine the extent of epicardial coronary artery and coronary artery bypass graft disease. Specially shaped coronary catheters are used to engage the left and right coronary ostia. Injection of radiopaque contrast agents by hand or automated contrast injector system creates a coronary "luminogram" that is recorded as radiographic images (cine angiography). Because the coronary arteries are three-dimensional objects that are in motion with the cardiac cycle, angiograms of the vessels using several different orthogonal projections are taken to best visualize the vessels without overlap or foreshortening.

The normal coronary anatomy is highly variable between individuals, but, in general, there are two coronary ostia and three major coronary vessels—the left anterior descending, the left circumflex, and the right coronary arteries with the left anterior descending and left circumflex arteries arising from the left main coronary artery **(Fig. 249-5)**. When the right coronary artery is the origin of the atrioventricular nodal branch, the posterior descending artery, and the posterior lateral vessels, the circulation is defined as right dominant; this is found in ~85% of individuals. When these branches arise from the left circumflex artery, as occurs in ~5% of individuals, the circulation is defined as left dominant. The remaining ~10% of patients have a codominant circulation with the posterior descending vessel arising from both the right coronary and the posterior lateral vessels from left coronary circulation. In some patients, a ramus intermedius branch arises directly from the left main coronary artery that trifurcates into the left anterior descending, ramus, and circumflex arteries; this finding is a normal variant. Coronary artery anomalies occur in 1–2% of patients, with separate ostia for the left anterior descending and left circumflex arteries (0.41%), ectopic origin of the right coronary artery from the left coronary sinus (0.92%), ectopic origin of the left circumflex artery from the right coronary sinus (0.67%), and fistulas between the coronary arteries and cardiac chambers or the pulmonary artery or vein (0.87%) being the most common. Certain anomalous coronary artery patterns increase the risk of sudden cardiac death, especially if the artery travels between the pulmonary artery and aorta.

Coronary angiography visualizes coronary artery stenoses as luminal narrowings on the cine angiogram. The degree of narrowing is referred to as the percent stenosis and is determined visually by comparing the most severely diseased segment with a proximal or distal "normal segment;" a stenosis >50% is considered significant **(Fig. 249-6)**. Online quantitative coronary angiography can provide a more accurate assessment of the percent stenosis and lessen the tendency to overestimate lesion severity visually. The presence of a myocardial bridge, which most commonly involves the left anterior descending artery, may be mistaken for a significant stenosis; this occurs when a portion of the vessel dips below the epicardial surface into the myocardium and is subject to compressive forces during ventricular systole. The key to differentiating a myocardial bridge from a fixed stenosis is that the "stenosed" part of the vessel returns to normal during diastole. Coronary angiography may also reveal spontaneous coronary artery dissections that appear similar to a stenosis but tends to occur in an angiographically normal-appearing coronary artery; a linear dissection flap may be present. Coronary spasm appears similar to a fixed stenosis but resolves with the administration of intracoronary nitroglycerin. Coronary calcification is also seen during angiography prior to the injection of contrast agents. Collateral blood vessels may be seen traversing from one vessel to the distal vasculature of a severely stenosed or totally occluded vessel. Thrombolysis in myocardial infarction (TIMI) flow grade, a measure of the relative duration of time that it takes for contrast to opacify the coronary artery fully, may provide an additional clue to the degree of lesion severity, and the presence of TIMI grade 1 (minimal filling) or 2 (delayed filling) suggests that a severe coronary artery stenosis is present.

INTRAVASCULAR ULTRASOUND, OPTICAL COHERENCE TOMOGRAPHY, FRACTIONAL FLOW RESERVE, AND CORONARY FLOW RESERVE

During coronary angiography, intermediate stenoses (40–70%), indeterminate findings, or anatomic findings that are incongruous with the patient's symptoms may require further interrogation. In these cases, intravascular ultrasound (IVUS) provides a more accurate anatomic

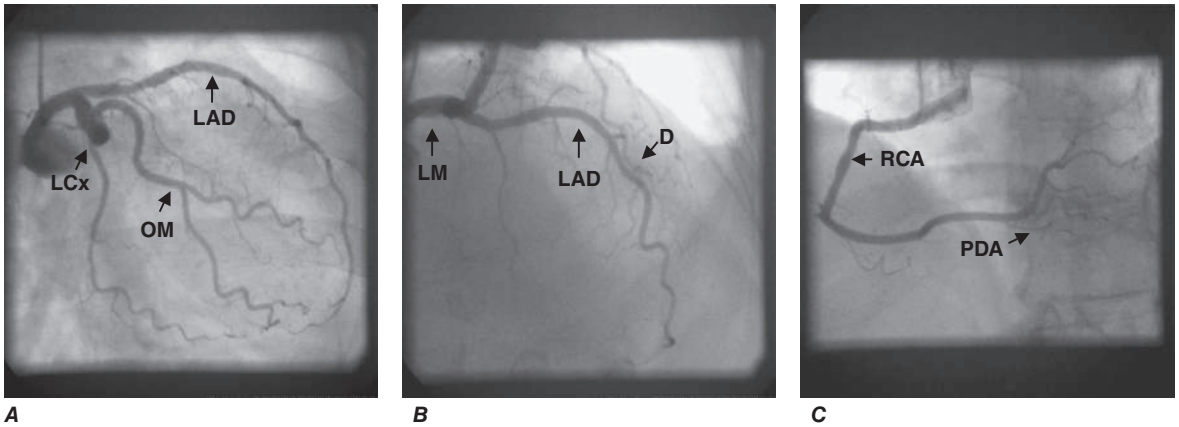

FIGURE 249-5 Normal coronary artery anatomy. ***A.*** Coronary angiogram showing the left circumflex (LCx) artery and its obtuse marginal (OM) branches. The left anterior descending (LAD) artery is also seen but may be foreshortened in this view. ***B.*** The LAD and its diagonal (D) branches are best seen in cranial views. In this angiogram, the left main (LM) coronary artery is also seen. ***C.*** The right coronary artery (RCA) gives off the posterior descending artery (PDA), so this is a right dominant circulation.

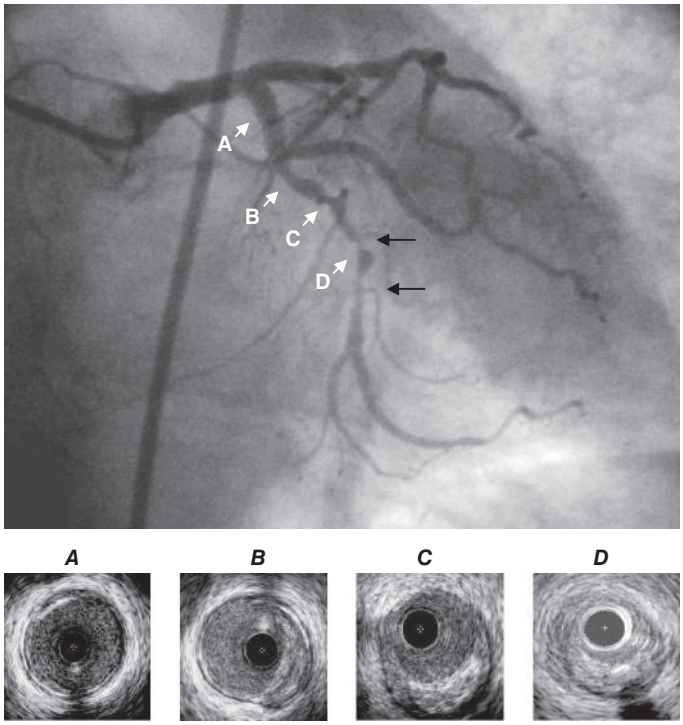

FIGURE 249-6 Coronary stenoses on cine angiogram and intravascular ultrasound. Significant stenoses in the coronary artery are seen as narrowings (*black arrows*) of the vessel. Intravascular ultrasound shows a normal segment of artery (***A***), areas with eccentric plaque (***B, C***), and near total obliteration of the lumen at the site of the significant stenosis (***D***). Note that the intravascular ultrasound catheter is present in the images as a black circle.

assessment of the coronary artery and the degree of coronary atherosclerosis (Fig. 249-6). IVUS is performed using a small flexible catheter with a transducer at its tip that is advanced into the coronary artery over a guidewire. Data from IVUS studies may be used to image atherosclerotic plaque precisely, determine luminal cross-sectional area, characterize plaque, including quantifying the arc and length of calcium, and measure vessel size. It is also used during or following percutaneous coronary intervention to assess the stenosis and determine the adequacy of the stent implantation procedure (stent expansion, apposition, geographic miss, or edge dissection). Optical coherence tomography (OCT) is a catheter-based imaging technique that uses near-infrared light to generate images with better spatial resolution than IVUS (10–15 microns vs 100–150 microns); however, the depth of field is smaller. The advantage of OCT imaging over IVUS lies in its ability to image characteristics of the atherosclerotic plaque (lipid, fibrous cap, plaque rupture or erosion, thrombus) with high definition and to assess coronary stent placement, apposition, and patency **(Fig. 249-7)**.

Measurement of the fractional flow reserve provides a functional assessment of the stenosis and is more accurate in predicting long-term clinical outcome than imaging techniques. The fractional flow reserve is the ratio of the pressure in the coronary artery distal to the stenosis divided by the pressure in the artery proximal to the stenosis at maximal vasodilation. Fractional flow reserve is measured using a coronary pressure–sensor guidewire at rest and at maximal hyperemia following the infusion of adenosine **(Fig. 249-8)**. A fractional flow reserve of <0.80 indicates a hemodynamically significant stenosis that would benefit from intervention. The instantaneous wave-free ratio, which measures the gradient across the stenosis during the latter part of diastole, does not require the use of adenosine and may be preferred for some patients with asthma or documented allergy to adenosine. An instantaneous wave-free ratio of <0.89 is considered positive for ischemia. Resting gradients have also been shown to predict a significant stenosis.

Microvascular dysfunction can be evaluated by assessing coronary flow reserve, the ratio between coronary blood flow at maximal hyperemia and rest. Coronary flow reserve is measured using a Doppler wire– or pressure wire–based thermodilution technique in patients with unexplained chest pain or ischemia and no obstructive coronary artery disease. A coronary flow reserve <2.0 is considered abnormal. An index of microcirculatory resistance can also be calculated by multiplying the pressure wire thermodilution-derived mean transit time by the distal pressure. An index of microcirculatory resistance of <25 is considered normal. Studies have shown this derivative parameter to be an important predictor of outcome as well.

POSTPROCEDURE CARE

Once the procedure is completed, vascular access sheaths are removed. If the femoral approach is used, direct manual compression or vascular closure devices that immediately close the arteriotomy site with a staple/clip, collagen plug, or sutures are used to achieve hemostasis. These devices decrease the length of supine bed rest (from 6 h to 2–4 h) and improve patient satisfaction but have not been shown definitively to be superior to manual compression with respect to access-site complications. The overall risk of complications for vascular closure devices is low, but potential complications include infection, embolization, and limb ischemia. Vascular closure devices should be avoided in heavily diseased vessels where the risk of complications is increased. With radial-artery access, the sheath is removed and a plastic wristband with an air pillow is used to keep pressure on the access site while maintaining flow through the radial artery. Bed rest is needed for only 2 hours while the air in the wristband is released. When cardiac catheterization is performed as an elective outpatient procedure, the patient completes postprocedure bed rest in a monitored setting and is discharged home with instructions to liberalize fluids because contrast agents promote an osmotic diuresis, to avoid strenuous activity, and to observe the vascular access site for signs of complications. Overnight hospitalization may be required for high-risk patients with significant comorbidities, patients with complications occurring during the catheterization, or patients who have undergone a complicated percutaneous coronary intervention. Hypotension early after the procedure may be due to inadequate fluid replacement or retroperitoneal bleeding from the femoral access site. Patients who received >2 Gy of radiation during the procedure should be examined for signs of erythema. For patients who received higher doses (>5 Gy), clinical follow-up within 1 month to assess for skin injury is recommended.

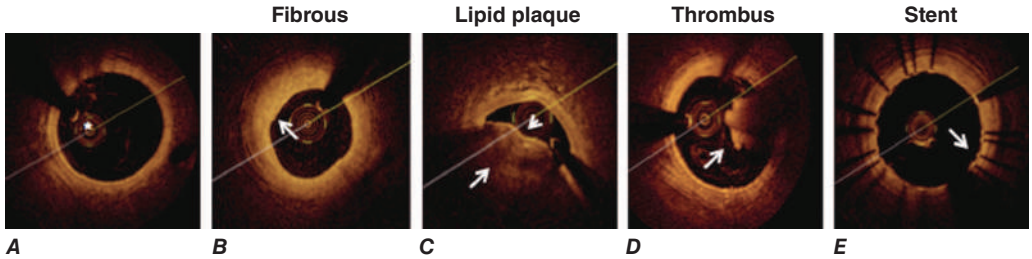

FIGURE 249-7 Optical coherence tomography imaging. ***A.*** The optical coherence tomography (OCT) catheter (*) in the lumen of a coronary artery with limited neointima formation. The intima is seen with high definition, but unlike intravascular ultrasound imaging, the vessel media and adventitia are not well visualized. ***B.*** A fibrous plaque (*arrow*) is characterized by a bright signal. ***C.*** A large, eccentric, lipid-rich plaque obscures part of the vessel lumen. Because lipid in the plaque absorbs light, the lipid-rich plaque appears as a dark area with irregular borders (*arrow*). The plaque is covered by a thin fibrous cap (*arrowhead*) typical of a vulnerable plaque. ***D.*** A thrombus (*arrow*) adherent to a ruptured plaque that is protruding into the vessel lumen. ***E.*** A coronary stent is that is well apposed to the vessel wall. The stent struts appear as short bright lines with dropout behind the struts (*arrow*).

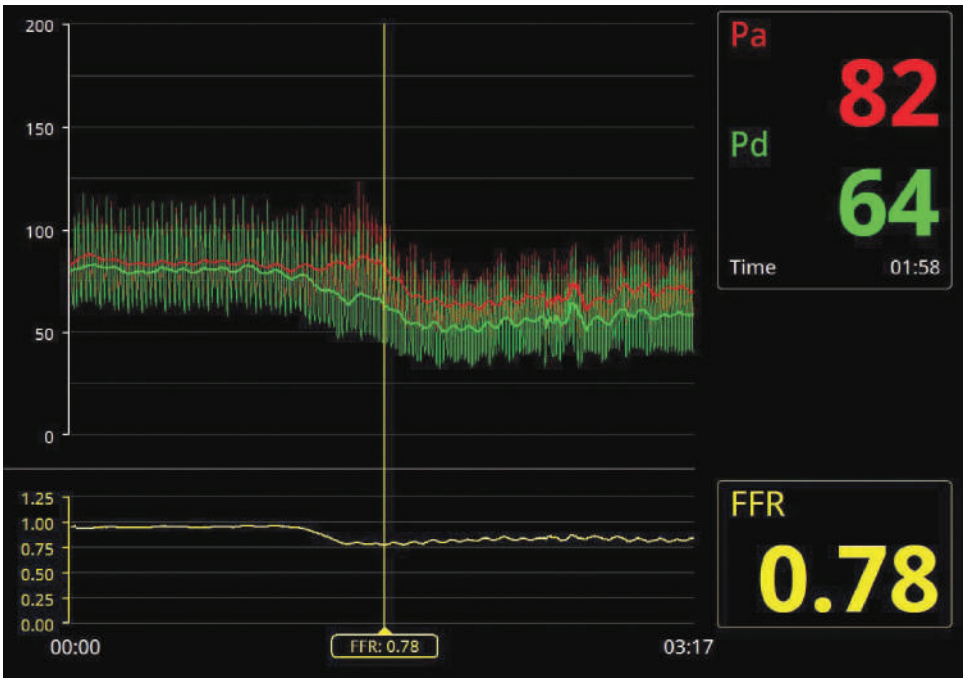

FIGURE 249-8 Fractional flow reserve. The fractional flow reserve is measured using a coronary pressure-sensor guidewire that measures the ratio of the pressure in the coronary artery distal to the stenosis (Pd, *green*) divided by the pressure in the artery proximal to the stenosis (Pa, *red*) at maximal hyperemia following the injection of adenosine. A fractional flow reserve of <0.80 indicates that revascularization would be beneficial.

250 Principles of Clinical Cardiac Electrophysiology

William H. Sauer, Bruce A. Koplan, Paul C. Zei

HISTORICAL PERSPECTIVE

Clinical cardiac electrophysiology is the subspecialty of cardiology that focuses on the study and management of heart rhythm disorders. The development of the modern surface electrocardiogram (ECG) by Willem Einthoven more than 100 years ago enabled an understanding of the relationship between cardiac electrical potentials, mechanical cardiac function, and pathophysiology of cardiac arrhythmias. In the mid-twentieth century, the recording of cellular membrane currents enabled the understanding that the surface ECG represents the sum of cellular cardiac electrical activity. An understanding of cellular electrophysiology also ushered in the development of antiarrhythmic drugs utilized by cardiac electrophysiologists.

The modern era of clinical cardiac electrophysiology began with the first recordings of human intracardiac electrograms in the 1960s. Initially, invasive electrophysiology studies were limited to diagnostic tools. This included serial electrophysiologic testing to evaluate arrhythmia mechanisms and evaluate arrhythmia suppression by antiarrhythmic drugs, and programmed stimulation of the ventricle for risk stratification of sudden cardiac death. In the 1960s and 1970s, cardiac surgery was the only available invasive treatment for cardiac arrhythmias. The subsequent development of radiofrequency catheter ablation in the 1980s ushered in the era of interventional cardiac electrophysiology. In addition, with the development of implanted cardiac rhythm management devices including pacemakers and defibrillators, clinical cardiac electrophysiology became a distinct medical subspecialty. Developments in catheter ablation techniques, cardiac resynchronization and conduction system pacing, subcutaneous defibrillator implantation, leadless pacemaker implantation, left atrial appendage closure, and laser-assisted lead extraction have broadened the procedural aspects of the specialty over the past 30 years; however, the principles of arrhythmia patient management have remained the same.

CELLULAR ELECTROPHYSIOLOGY

The cardiac action potential (AP) drives the electrophysiologic behavior of all cardiac myocytes. The AP is characterized morphologically by five distinct phases, termed phases 0–4, as shown in **Fig. 250-1**. Moreover, as ventricular electrophysiologic activity accounts for the QRS and T complexes of the surface ECG, each AP phase in ventricular tissues corresponds to distinct phases in the surface ECG: Phase 0, the rapid upstroke, corresponds to the QRS deflection; phases 1–2 account for the ST segment; phase 3 accounts for the T wave; while phase 4 corresponds to the segment between the end of the T wave and the subsequent QRS deflection. In addition, the P wave corresponds to atrial depolarization, while the PR interval corresponds to the time between

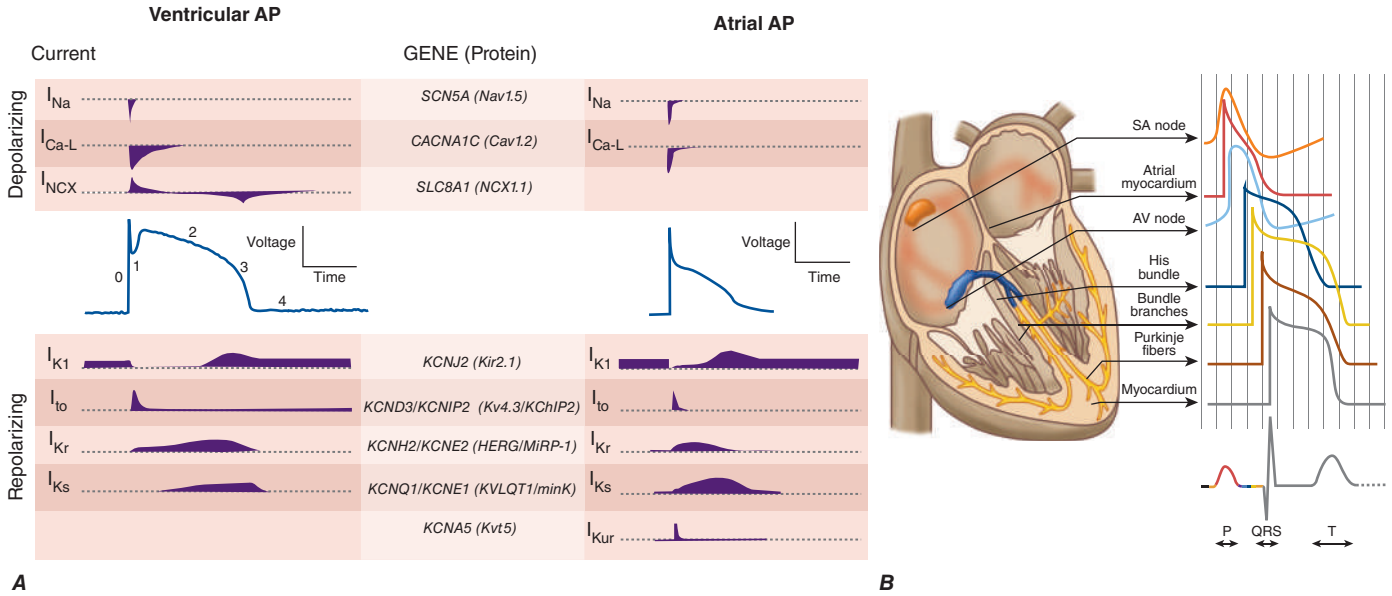

FIGURE 250-1 ***A.*** Cellular atrial and ventricular action potentials. Phases 0–4 are the rapid upstroke, early repolarization, plateau, late repolarization, and diastole, respectively. The ionic currents and their respective genes are shown above and below the action potentials. The currents that underlie the action potentials vary in atrial and ventricular myocytes. Potassium current (I_{K1}) is the principal current during phase 4 and determines the resting membrane potential of the myocyte. Sodium current generates the upstroke of the action potential (phase 0); activation of I_{to} with inactivation of the Na current inscribes early repolarization (phase 1). The plateau (phase 2) is generated by a balance of repolarizing potassium currents and depolarizing calcium current. Inactivation of the calcium current with persistent activation of potassium currents (predominantly I_{Kr} and I_{Ks}) causes phase 3 repolarization. Currents that result in membrane depolarization are grouped at the top of the figure above the action potentials, while repolarizing currents are shown below the action potentials. ***B.*** A surface electrocardiogram (ECG) representation of sinus rhythm is shown with respective intracardiac action potentials that are active during each phase of the ECG. Each cardiac conduction region's action potential is shown in the upper portion of the panel, with colors reflected in the ECG segment shown in the lower portion of the panel. Note that during the P wave, atrial depolarization is active. During the PR interval, the atrioventricular (AV) nodal, His, bundle branches, and Purkinje fibers are active (in sequence), although these action potentials are not discernible on the surface ECG. During the QRS interval, ventricular action potentials are active, with the QRS morphology most reflective of the sequence of ventricular tissue action potential activation. The ST segment is predominantly determined by the plateau phase 2 of the ventricular action potential. The T wave is determined largely by ventricular repolarization (phase 3), while the isoelectric segment is the result of the electrically neutral phase 4 of the ventricular action potential.

the initiation of atrial depolarization to the initiation of ventricular depolarization, comprised (typically) for the most part by the conduction time through the atrioventricular (AV) node.

AP morphologies are the result of the precise and carefully timed sequences of opening, closing, and inactivation of an array of membrane ion channels in response to cellular membrane potential changes, ligands that bind to the ion channel complex, or membrane stretch in a time-dependent fashion. The open ion channel allows flux of specific charged ions through a central pore, resulting in electrical (ionic) currents that drive the AP. The activity of different subsets of ion channels drives the different phases of the AP. Specific ionic currents that flux through an open channel are driven by the electrochemical gradient of that particular ion across the membrane, which in turn are driven by ion pumps or transporters/exchangers, which in turn are catalyzed by ATP **(Fig. 250-2)**.

Ion channels are complex, multi-subunit transmembrane glycoproteins that contain a central pore that is selective for particular ionic species (selectivity); a "gating" apparatus that regulates the opening, closing, and inactivation apparatus; and often one or more regulatory subunits. Most channels gate in response to changes in membrane potential, a specific ligand, or mechanical deformation. The molecular underpinnings of these specific functional properties of channels have become well understood through decades of basic electrophysiologic study using the tools of voltage clamp and patch clamp techniques, and more recently, molecular, genetic, and structural/crystallographic techniques.

The structural makeup of most ion channels contains several common motifs. All channels form a central conducting pore, with ionic selectivity determined by specific amino acids that line the central pore. The central pore of most channels is formed by the P domain, a series of hydrophilic amino acid residues, with one of several structural variants: four separate homologous alpha subunits, each with homologous P domains (voltage-gated K channels); a single alpha subunit with four internally homologous P domains (voltage-gated Na or Ca channels); or two internally homologous P domains from two separate subunits (most ligand-gated K channels). A series of one or more transmembrane segments surrounds the central pore. In voltage-gated channels, the fourth of six segments, the S4 segment, contains a series of charged amino acid residues that functions as a voltage sensor, responding to changes in membrane potential by facilitating protein conformational changes that result in channel opening or closing (gating). In ligand-activated channels, the binding of a ligand (transmitters, molecules, or other ions) results in channel opening or closing, while deformations in membrane shape determine gating in stretch-activated channels. In addition, in many ion channels, a complex of auxiliary proteins is associated with the primary alpha subunit; most auxiliary subunits appear to facilitate regulation of ion channel expression and activity. A distinct type of transmembrane protein complex is the gap junction complex. A large multimeric complex of connexin subunits forms a large, nonselective pore that spans and thereby connects adjacent myocytes. This allows free flux of ions between adjacent myocytes, facilitating impulse propagation across myocardial tissues.

Due to the physiologic gradient of their respective ions across the cell membrane, Na and Ca channels account for most inward, or depolarizing, currents in cardiac myocytes, and these channels respond to membrane depolarization with rapid opening, relatively rapid closing, and inactivation. Na and Ca currents therefore drive phase 0 depolarization of the AP. Potassium channels, on the other hand, account for most of the repolarizing currents seen in cardiac myocytes. Relatively slow K channel opening, as well as Na and Ca channel closing and inactivation, drives the plateau of phases 1–2 as well as the repolarizing phase 3 of the AP. Mutations in K channel subtypes are causative of many inherited channelopathies. Mutations that either inherently delay the closing or inactivation of K channels result in prolongation of the QT interval, leading to many forms of inherited long QT syndrome.

The morphologic and functional properties of APs vary across different regions of the heart. These variations are the result of variations in the active ionic currents during each phase of the AP, which in turn reflects regional variation in ion channel expression. In atrial and ventricular myocytes, Na currents dominate the rapid upstroke

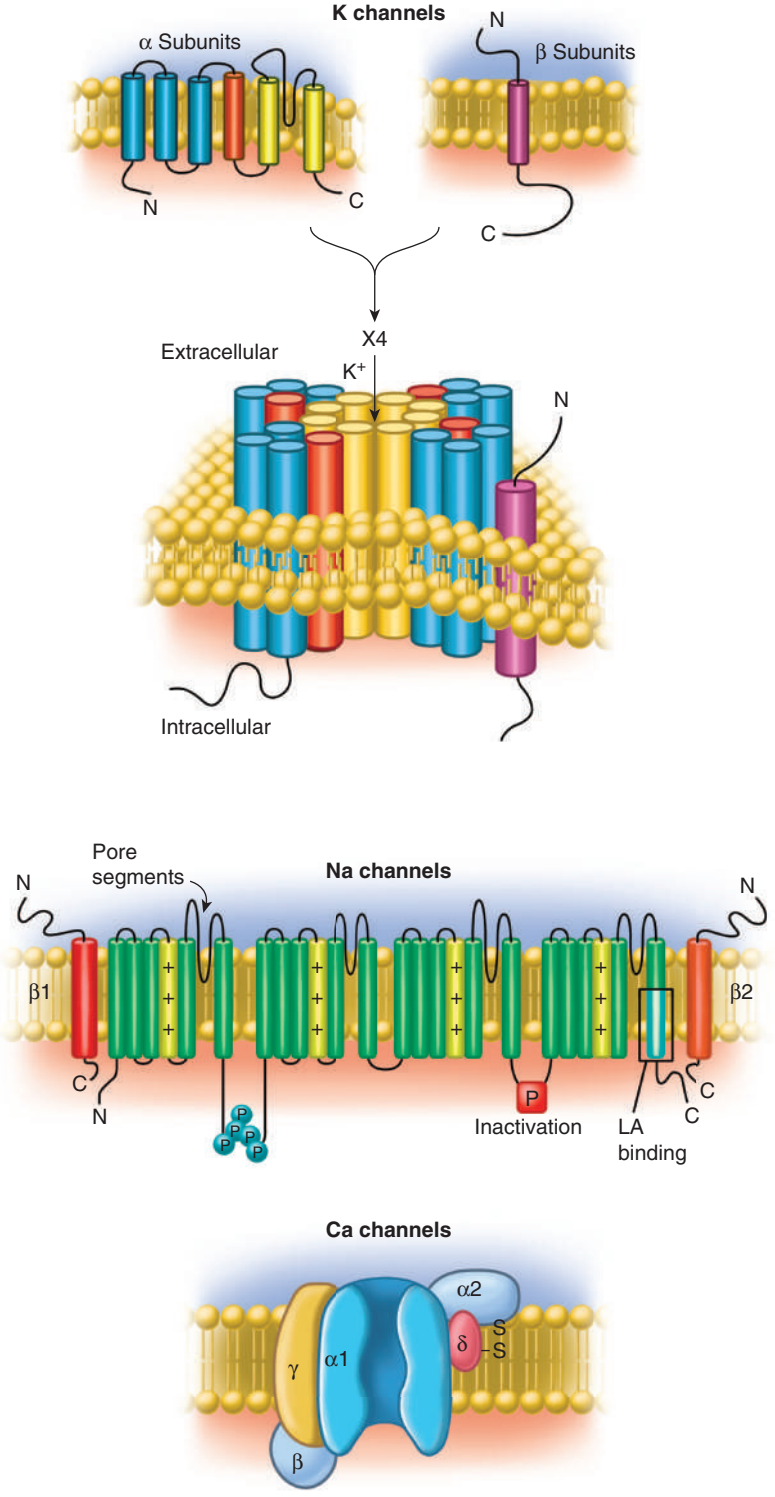

FIGURE 250-2 Topology and subunit composition of the voltage-dependent ion channels. Potassium channels are formed by the tetramerization of α or pore-forming subunits and one or more β subunits; only single β subunits are shown for clarity. Sodium and calcium channels are composed of α subunits with four homologous domains and one or more ancillary subunits. In all channel types, the loop of protein between the fifth and sixth membrane-spanning repeat in each subunit or domain forms the ion-selective pore. In the case of the sodium channel, the channel is a target for phosphorylation, the linker between the third and fourth homologous domain is critical to inactivation, and the sixth membrane-spanning repeat in the fourth domain is important in local anesthetic antiarrhythmic drug binding. The Ca channel is a multi-subunit protein complex with the α_1 subunit containing the pore and major drug-binding domain.

(phase 1) of the AP, while in nodal tissues, Ca currents, which activate more slowly, dominate phase 1. Hence, for instance, drugs that bind and block the cardiac Na channel demonstrate efficacy in treating tachyarrhythmias arising from the atria and ventricles, whereas Ca channel blocking agents demonstrate efficacy at nodal tissues. During the pre-depolarizing phase 4 of the AP, ionic currents remain relatively quiescent in atrial and ventricular myocytes as they await local depolarization that triggers the next AP. In contrast, in sinus nodal tissues, which possess the property of automaticity, or intrinsic rhythmic depolarization, there is gradual depolarization observed during phase 4, until a threshold is reached that initiates the next AP. In these nodal tissues, this depolarizing phase 4 current is generated by a semiselective Na/Ca channel, termed the "funny current" or I_f, which is the target for the medication ivabradine.

NORMAL CARDIAC IMPULSE PROPAGATION

The normal cardiac impulse initiates and travels through specialized conduction fibers, often referred to as the cardiac conduction system. Each impulse is initiated in the sinoatrial (SA) node, located at the lateral junction between the superior vena cava (SVC) and right atrium (RA). SA nodal tissues exhibit automaticity, such that a reliable, rhythmic impulse emanates from the SA node. The SA node (along with the AV node) is richly innervated by autonomic fibers, allowing precise and dynamic control of heart rate and overall function by the central nervous system. The normal impulse then travels across the RA then the LA across preferential conduction pathways, initiating atrial systole. Once the impulse reaches the AV node, conduction occurs in a relatively slow time frame through the AV nodal tissues. This conduction time not only serves to provide physiologic AV synchrony but also is reflected in the surface ECG as the PR interval, or time between the atrial inscription and the subsequent ventricular, or QRS, complex. In normal hearts, the AV node serves as the only electrical connection between atria and ventricles. Both the SA and AV nodes respond exquisitely to autonomic input; for instance, with exercise and increased adrenergic tone, the PR interval physiologically shortens. After the AV node, the impulse travels through a network of specialized conduction fibers: the bundle of His divides into a right and left bundle branch, which transmit conduction to the right and left ventricles, respectively. The left bundle then divides further into the left anterior and posterior fascicles. The fascicles then further divide into a network of Purkinje fibers. The conduction velocity of electrical impulses is much higher in Purkinje fibers (2–3 m/s) than in myocardial cells (0.3–0.4 m/s). Different connexins in gap junctions of Purkinje networks are partially responsible for more rapid conduction. This network of conductive Purkinje fibers is located endocardially and serves to rapidly transmit depolarization throughout the ventricles, such that myocardial depolarization, and hence mechanical contraction, occur rapidly and in a coordinated, synchronized fashion, optimizing mechanical contraction of the ventricles. Repolarization of the ventricular myocardium, on the other hand, occurs relatively slowly and progresses from the epicardial surface back toward the endocardium. Hence, the T wave inscription in most ECG leads is concordant with the QRS complex.

MECHANISMS OF CARDIAC ARRHYTHMIAS

Cardiac arrhythmias are the manifestation of abnormalities in the initiation and/or propagation of the cardiac electrical impulse. Bradyarrhythmias result most commonly from abnormalities in the specialized conduction tissues. Abnormal function of the SA node may result in pathologic sinus bradycardia; AV node disease may result in conduction block; pathology in the His-Purkinje system may result in conduction block as well. Tachyarrhythmias may arise from not only

TABLE 250-1 Overview of the Mechanisms of Cardiac Tachyarrhythmias

TACHYARRHYTHMIA CATEGORY	MECHANISM	PROTOTYPICAL ARRHYTHMIAS
Abnormal automaticity	Enhanced (acceleration of phase 4 repolarization)	Idiopathic VT; AT
	Suppressed (absent or decelerated phase 4 repolarization)	Sinus node dysfunction
Triggered activity	EADs	TdP in long QT syndrome, PVCs
	DADs	Reperfusion PVCs/VT, AT and VT with digitalis toxicity
Reentry	(1) Anatomic or functional confinement of a circuit (i.e., scar, accessory pathway); (2) unidirectional block after a premature impulse; (3) wave of excitation that travels in a single direction returning to its point of origin	AVNRT, AVRT, atrial flutter, scar-related VT

Abbreviations: AT, atrial tachycardia; AVRT, atrioventricular reentry tachycardia; AVNRT, atrioventricular nodal reentry tachycardia; DADs, delayed afterdepolarizations; EADs, early afterdepolarizations; PVC, premature ventricular contraction; TdP, torsades des pointes; VT, ventricular tachycardia.

nearly every location within the conduction tissues, but also within atrial or ventricular tissues. Tachyarrhythmias are typically classified by mechanism: enhanced automaticity refers to abnormal spontaneous depolarization, which can occur along the conduction system, the atria, or ventricles; triggered arrhythmias result from abnormal afterdepolarizations that occur in either phase 2/3 (early afterdepolarizations) or phase 4 (delayed afterdepolarizations) of the AP; reentry results from circus movement of an electrical impulse **(see Table 250-1 and Fig. 250-3)**.

ENHANCED AUTOMATICITY

Automaticity, defined as spontaneous depolarizations occurring during phase 4 of the AP, is a normal property of several myocardial tissues, including the SA node, AV node, and the His-Purkinje system. The automaticity of the SA node triggers the normal cardiac impulse. When the automaticity of a more proximal conduction system tissue is unreliable or slow, the automaticity of a more distal aspect of the conduction system may result in an "escape rhythm" that may maintain cardiac output. Automaticity in these tissues results from phase 4 depolarization of cellular membranes driven by several ionic currents. In the SA node, the nonselective Na/Ca I_f current drives this depolarization, while in other tissues, K currents, Ca currents, or even the Na/Ca and ATP-driven Na/K exchangers contribute.

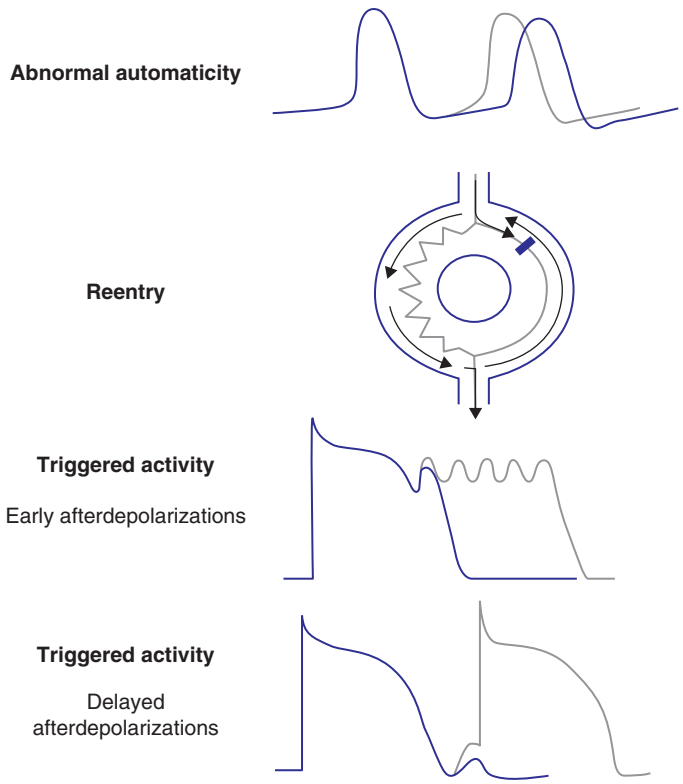

FIGURE 250-3 Schematic action potentials with early afterdepolarizations (EADs) and delayed afterdepolarizations (DADs).

The rate of depolarization during phase 4 drives the frequency of APs and hence automaticity rate of these tissues. In nodal tissues, this rate of depolarization is highly regulated by the autonomic system. Parasympathetic input results in local acetylcholine (ACh) release, which then binds the IKACh potassium channel complex (specifically via a G protein–mediated mechanism). The opening of IKACh channels, resulting in K efflux, hyperpolarizes these cells, resulting in slowing of phase 4 depolarization, thereby slowing the automaticity rate. Sympathetic input, via catecholamines, activates both alpha- and beta-adrenergic receptors. Beta-1 adrenergic stimulation results in activation of L-type Ca channels, Ca influx, and as a result, enhanced depolarization rates during phase 4, and increased automaticity rates. The normal range of SA automaticity rates is between 30 and 220 beats/min, corresponding to the normal range of rates during sinus rhythm. The sinus rate at any instant is therefore a dynamic balance between sympathetic and parasympathetic input, with the latter dominating in the restful state. The intrinsic heart rate (IHR) is defined as the "native" automaticity rate of the SA node, absent any autonomic input.

Abnormally enhanced automaticity may occur at any site that exhibits automaticity, including the SA node, AV node, or His-Purkinje system, resulting in pathologic tachycardia. In addition, in pathologic states, other stereotyped regions in the heart may exhibit enhanced automaticity, including the pulmonary veins, coronary sinus superior vena cava, and ventricular outflow tracts. Injury to myocardium, whether through ischemia or other mechanisms, may alter its cellular membrane properties, resulting in automaticity in these tissues. For instance, the border zones of infarcted ventricular myocardium, or rapidly reperfused ischemic myocardium, often exhibit automatic arrhythmias including premature ventricular contractions (PVCs) or automatic idioventricular rhythms (AIVR). Abnormal automaticity in the pulmonary veins is believed to underpin the triggers that drive paroxysmal atrial fibrillation, while automaticity elsewhere in the atria drives atrial tachycardias.

AFTERDEPOLARIZATIONS AND TRIGGERED ARRHYTHMIAS

Afterdepolarizations and triggered arrhythmias refer to abnormal depolarizations that occur in the late phases of the AP (afterdepolarizations) that can initiate sustained arrhythmias. Early afterdepolarizations (EADs) occur typically during phases 2–3 of the AP and may be facilitated by intracellular Ca loading. When the QT interval prolongs, typically in a heterogeneous fashion across the ventricles, EADs may trigger wavefronts of abnormal depolarizations, resulting in torsades des pointes (TdP), a nonsustained or sustained ventricular arrhythmia that may result in cardiac arrest. Medications that prolong QT interval, as well as other QT-prolonging factors including hypokalemia, hypomagnesemia, and bradycardia, predispose the ventricles to EADs, leading to TdP. Electrical remodeling in cardiomyopathies may also predispose to QT prolongation and risk of EADs and TdP.

Delayed afterdepolarizations (DADs) are abnormal depolarizations occurring in phase 4 of the AP. The mechanism underlying DADs is increased intracellular Ca, which then enhances repetitive depolarizations during the late phases of the AP. As a result, repetitive depolarizations ensue, including the well-described phenomenon of bidirectional ventricular tachycardia (VT). Digitalis glycoside toxicity, ischemia, and catecholamines are the most commonly described causes for DADs.

REENTRY

Reentry refers to the circus movement of a wavefront of electrical activation. Reentry can occur around a fixed anatomic barrier, referred to as anatomic reentry, or around a functionally blocked or

refractory barrier or anchor, termed functional reentry. Initiation and maintenance of a reentrant arrhythmia require (1) unidirectional block, where the electrical wavefront can only propagate in one direction, and (2) slow conduction, a zone within the reentrant circuit where conduction is relatively slow, allowing the remainder of the circuit to repolarize and recover from refractoriness (the inability to reexcite).

The more common form of reentry is anatomic, which requires a defined electrical/anatomic circuit with a pathway around a fixed barrier. A wavefront of depolarization encounters a barrier to conduction that allows propagation in only one direction (unidirectional block), forcing activation preferentially along one limb or pathway. Due to slow conduction, the depolarization wavefront travels through the remaining circuit and continually encounters tissues that have recovered from refractoriness and are hence excitable. This results in perpetual circus movement. Moreover, if the total length of the circuit exceeds a distance determined by the product of the conduction velocity (theta) of the tissue and the refractory period (duration) of that tissue (tr), referred to as the wavelength of tachycardia (lambda = theta × tr), an excitable gap, where tissue is recovered from refractory and able to depolarize, is created, allowing reentry. Reentry is the mechanism for several clinically important and common cardiac arrhythmias, including atrial flutter, AV nodal reentry, AV reciprocating tachycardia utilizing an accessory pathway, and scar-based reentrant VT.

When reentry occurs in the absence of a fixed anatomic barrier, it is termed *functional reentry*. A nidus of partially refractory tissue anchors the depolarization wavefront, resulting in a circular or rotational reentrant wavefront. In this case, the reentrant circuit or activity tends to be less stable than that from anatomic reentry, resulting in variations in depolarization rate and propensity to easily terminate and/or reinitiate. There is evidence that functional reentry is the underlying mechanism for perpetuation and maintenance of both atrial fibrillation (AF) and ventricular fibrillation (VF). In both of these apparently chaotic and disorganized arrhythmias, multiple wavefronts resulting from multiple functional reentrant circuits appear to drive arrhythmia in many, if not most, instances. Underlying pathology of the myocardium resulting in heterogeneous electrophysiologic properties, altered activation, and repolarization properties predispose myocardial tissues to initiation and propagation of functional reentry-based arrhythmias.

In addition to intrinsic alterations in cellular membrane electrophysiologic properties that underpin most arrhythmias, extrinsic factors may precipitate other architectural and tissue changes that contribute to proarrhythmia. Ischemia and infarct may create regions of heterogeneous fibrosis, resulting in islands of scar surrounded by injured tissue. This creates the anatomic substrate that can sustain anatomic reentry, which underlies scar-based VT, as well as many macroreentrant atrial arrhythmias. Peri-infarct border zones often contain injured myocardium as well, and the resultant alterations in cellular membrane properties may promote enhanced automaticity or triggered arrhythmias. Chronic ischemia also results in downregulation of connexin proteins and gap junctions, resulting in slowed impulse propagation, which is one of the factors required for reentrant arrhythmias. Alterations in ion channel function, either through inherited mutations or through drug effect, can promote arrhythmias. QT prolongation can occur when the closing of potassium channels that should hyperpolarize cells is delayed or slowed, or when the closing or inactivation of Na channels is impaired.

UNDERPINNINGS OF THE TREATMENT OF ARRHYTHMIAS

Pharmacologic therapies for arrhythmias are directed toward the specific underlying mechanism. For enhanced automaticity-based arrhythmia, medications that target phase 4 depolarization, including Ca channel blockers, beta-adrenergic blockers (via indirect action on adrenergic input), or ivabradine may be used. For triggered activity-based arrhythmia, correcting the precipitating factor is most effective. This includes, among other therapies, removal of digitalis glycosides from the body, discontinuation of QT-prolonging medications, or even increasing heart rate, thereby shortening QT interval. For reentrant arrhythmia, medications that increase the refractory period, in particular K channel blocking agents, will increase the wavelength of conduction beyond the circuit length of tachycardia, resulting in the inability to sustain reentry. Medications that slow conduction velocity may have the paradoxical effect of promoting reentrant arrhythmias due to the creation of a larger excitable gap. This explains much of the proarrhythmic effect of many antiarrhythmic medications. Therefore, for these agents, which typically include Na channel blockers, sufficient dosing is required to slow conduction velocity to the point of extinguishing meaningful arrhythmia circuit conduction.

A major aspect of clinical cardiac electrophysiology that has evolved over several decades is the ability to disrupt arrhythmic substrates through catheter-based (or rarely surgical) myocardial ablation. For automaticity-based arrhythmias, precise localization and elimination or isolation through ablation of the site of focal automaticity is effective in eliminating arrhythmia. For anatomically bound reentrant arrhythmias, interruption of the reentrant circuit with a series of ablation lesions is effective. In contrast, given the lack of a fixed anatomic circuit, and perhaps also due to the presence of multiple, often migratory, circuits, it appears that mechanical disruption, typically through catheter-based ablation, of identified sites of functional reentry appears to be ineffective in eliminating arrhythmia.

CARE OF THE ARRHYTHMIA PATIENT

EVALUATION AND DIAGNOSIS

The evaluation of a patient with suspected arrhythmia begins with a directed history and physical examination, which must include an ECG. The history and examination should focus on determining the nature of symptoms attributable to the arrhythmia itself and clues to potential underlying cardiac, medical, or metabolic conditions that may predispose to specific arrhythmias, and hence direct further studies and evaluations, ultimately directing appropriate therapy, prognosis, and counseling. Family history may also provide clues toward possible inherited arrhythmia syndromes. Symptoms attributable to arrhythmia can vary from a vague sensation of fatigue, chest pain, dyspnea, or lightheadedness to more specific sensations of rapid, slow, or irregular heart rate. Premature contractions, whether atrial or ventricular, may be sensed as extra beats, or if these extrasystoles result in diminished stroke volume for that particular beat, a sensation of a missed beat. Second, the hemodynamic sequelae of impaired cardiac output may result in symptoms, from presyncope to frank syncope, dyspnea, chest discomfort, or generalized weakness. Importantly, as the cadence and duration of arrhythmia episodes are highly variable, the temporal manifestations of arrhythmia symptoms may vary significantly. Sporadic episodes of arrhythmia will result in intermittent symptoms, including syncope if hemodynamic compromise is significant; protracted episodes of arrhythmia may cause persistent symptoms. In patients with underlying compromise in cardiac function, most typically in patients with structural heart disease, arrhythmia leading to diminished cardiac output may trigger or exacerbate symptoms associated with the underlying condition such as angina, congestive heart failure, or hypoxia-associated symptoms.

Inciting factors or associations may also provide clues to the diagnosis. Arrhythmias associated with activities that increase adrenergic tone, such as exercise, stimulant intake, or emotional stress, may suggest not only tachyarrhythmias but also automaticity-triggered arrhythmias. However, keep in mind that exceptions will occur. Medication use may be highly suggestive of an etiology: use of Ca channel blockers or beta blockers may suggest bradycardia exacerbated by these medications. Medications known to potentially prolong QT interval may suggest a malignant ventricular arrhythmia, specifically TdP. Eliciting a thorough family history, not only for known arrhythmia diagnoses, but of unexplained sudden death, may point toward a heritable syndrome. Demographic factors may point toward or away from certain diagnoses. For instance, AF rarely occurs in children and young

adults, save rare familial forms, or AF associated with structural heart disease; a strong male predominance, as well as a higher prevalence in certain ethnic populations such as Southeast Asians, is seen in Brugada syndrome; inappropriate sinus tachycardia is nearly exclusively a condition affecting young women; degenerative conduction system disease leading to symptomatic bradycardia is most commonly a condition seen in older patients.

Arrhythmias may run the gamut from benign to malignant, life-threatening etiologies. Therefore, an important aspect of the evaluation of suspected arrhythmia is to discern patient prognosis, which then informs treatment. Arrhythmias that result in more significant hemodynamic compromise, and therefore more profound symptoms, tend to correlate with more malignant disease. In turn, the higher the suspicion for a malignant arrhythmia, the more aggressive the evaluation will likely be. Loss of consciousness, which may be the result of cardiac arrhythmia but also other etiologies that may be more benign, presents a particularly challenging yet common diagnostic dilemma. Therefore, careful thought into the appropriate evaluation for a patient with syncope is critical. In general, the presence of underlying structural abnormality of ventricular myocardium favors more malignant arrhythmias, both due to the increased risk of lethal ventricular arrhythmias and to potential inability to hemodynamically tolerate any particular arrhythmia. A careful history of circumstances, symptoms, and associated findings during the syncopal episode(s) can be very helpful in formulating a differential diagnosis.

The ECG is the cornerstone and most important diagnostic test that should be performed on every patient with suspected arrhythmia. A 12-lead resting ECG may offer clues to the diagnosis. Most simply, if active arrhythmia is captured on the ECG, a definitive diagnosis can be made. In addition, evidence suggesting underlying cardiac disease, such as prior myocardial infarction, left ventricular hypertrophy and possible hypertrophic cardiomyopathy, atrial disease, or baseline conduction system disease, may suggest a diagnosis. A subset of conditions that predispose to arrhythmia, both inherited or acquired, may be discerned as well, including ventricular preexcitation, prolonged or shortened QT interval, or ECG findings suggestive of specific inherited conditions such as Brugada syndrome or right ventricular cardiomyopathy.

However, the ECG typically records only 6 s of cardiac electrical activity, and therefore more intermittent and transient arrhythmias, particularly those not typically associated with abnormalities on the resting ECG, may not be seen. Many arrhythmias, including forms of both supraventricular tachycardia (SVT) and VT, can only be diagnosed definitively if an ECG is performed during active arrhythmia and/or symptoms from arrhythmia or, alternatively, provoked in the electrophysiology laboratory. Therefore, various forms of ambulatory monitoring may be performed to attempt to capture ECG activity during active arrhythmia. A growing variety of monitoring options are available; the most appropriate option should be primarily guided by the cadence of suspected arrhythmia episodes. For instance, if daily symptoms occur, a 24- or 48-h continuous Holter monitor is appropriate. On the other hand, a patient-activated event recorder is inappropriate in a patient with syncope, as the arrhythmic event will likely have passed once the patient reawakens.

Attempts at provoking arrhythmia may be warranted in the appropriate circumstances. An ECG-monitored treadmill test may elicit exercise-induced arrhythmias, or if long QT is suspected, a QT interval that fails to shorten appropriately with increased heart rate may be helpful. Pharmacologic provocation may be indicated for certain suspected diagnoses, such as Brugada syndrome. Judicious and appropriate use of carotid sinus massage or other means to enhance vagal tone may be helpful to diagnose carotid hypersensitivity or overall vagally mediated syncope.

Tilt table testing (TTT) involves having a patient strapped to a tiltable table. While monitoring heart rate and blood pressure, the patient is moved from a supine to upright position. In patients with suspected autonomic dysfunction–mediated syncope or presyncope, this provocation may elicit a paradoxical vagal response, resulting in bradycardia and/or sinus pauses as well as hypotension, and perhaps frank syncope. However, given the significant lack of both sensitivity and specificity, the current role of TTT is unclear, and it is seldom indicated after a careful history elucidates a neurally mediated cause for syncope.

Invasive electrophysiologic (EP) testing is the most useful diagnostic modality for many arrhythmias. Catheter-based recordings of intracardiac electrograms, with or without provocative pacing or pharmacologic maneuvers, may elicit the clinical arrhythmia. This will, in turn, help to define the mechanism of arrhythmia. However, one must keep in mind that for certain arrhythmia mechanisms, such as automaticity-driven tachycardia, EP study may fail to elicit arrhythmia due to the often transient and multifactorial nature of initiation of these arrhythmias. The nature of arrhythmia elicited will aid in determination of the patient's prognosis. In a typical EP study, catheters are placed within the heart via femoral venous access. Baseline conduction properties are measured. Provocative maneuvers including electrical pacing maneuvers, programmed stimulation, and pharmacologic provocation are performed. In the modern era, the vast majority of invasive EP studies are performed in conjunction with planned catheter ablation, although programmed ventricular stimulation for risk stratification of sudden death may still be utilized. EP study during catheter ablation is performed to confirm the diagnosis, localize appropriate ablation targets, and evaluate the efficacy of ablation performed during the procedure.

Depending on the suspected arrhythmia diagnosis, further testing may be indicated. If structural heart disease is suspected, echocardiography is most often the best next test, as it can assess for underlying structural disease, evaluate left ventricular function, and assess atrial dimensions and mitral valve function if AF is suspected, both of which are fair prognostic indicators. In patients in whom underlying coronary artery disease is suspected, an evaluation for coronary ischemia is indicated. Further evaluation for underlying structural heart disease will be directed based on the differential diagnosis. Cardiac computed tomography provides broad diagnostic utility, depending on the scanning protocol, including evaluation for ischemia, ventricular scar, anatomic evidence of coronary artery disease, congenital anomalies, and left atrial anatomy. Cardiac magnetic resonance imaging provides significant resolution of soft-tissue characteristics and may be used to assess for ischemia, infarct, cardiomyopathy, or infiltrative disease. Cardiac positron emission tomography can also discern underlying ischemia, as well as metabolic/inflammatory/infiltrative conditions.

TREATMENT

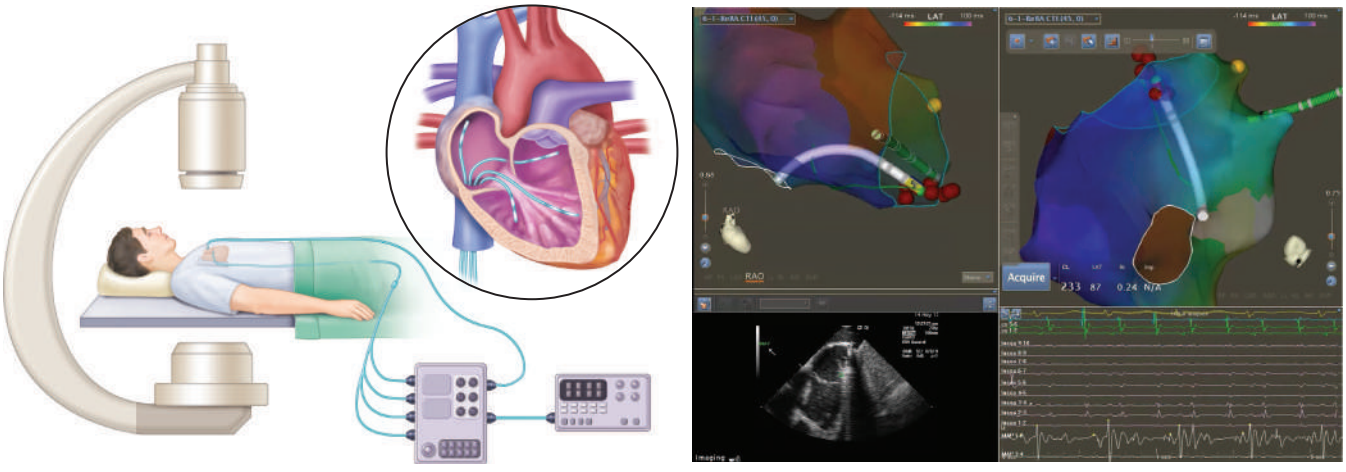
Cardiac Arrhythmias

ANTIARRHYTHMIC DRUG THERAPY

The effects of pharmacologic agents on cardiac electrophysiologic properties are often complex and, in some instances, remain incompletely understood. The complexity is the result of complex pharmacodynamics and pharmacokinetics, in particular significant cross-reactivity of certain drugs across different targets as well as variable effects on drug targets across drugs within the same category. There are regional differences in drug effect within the myocardium, and interpatient variations in drug metabolism play important roles. This has, in part, led to many instances of harm that have come from the adverse effects of many agents used over the years. In fact, many antiarrhythmic agents currently in use carry significant risks of side effects, some of which may be significant and even lethal. Therefore, judicious use of antiarrhythmic medications by those with appropriate knowledge base and experience is warranted. The practical result of the narrow therapeutic index of this class of medications has rendered their use increasingly as ancillary options **(Table 250-2)**.

The traditional nomenclature of antiarrhythmic drugs (AADs) is known as the Vaughan-Williams classification schema. In this schema, there are four classes (I–IV; Table 250-2). Class I AADs primarily target the Na channel, class II agents target the

TABLE 250-2 Antiarrhythmic Drug Actions



DRUG	CLASS ACTIONS I	II	III	IV	OTHER ACTIONS/COMMON SIDE EFFECTS
Quinidine	++		++		Anticholinergic
Flecainide	+++		+		Can promote reentrant arrhythmias (atrial flutter, ventricular tachycardia)
Propafenone	++	+			Mild beta-blocker effect
Amiodarone	++	++	+++	+	Multiorgan toxicity with long-term use
Sotalol		++	+++		Prominent beta-blocker effect
Dofetilide			+++		Prolongation of QT at slower heart rates
Dronedarone	+	+	+	+	Mild effect
Ibutilide			+++		Used only for acute cardioversion
Ranolazine	++		++		Late sodium channel blockade
Lidocaine	++				Used for reperfusion arrhythmias

beta-adrenergic receptor, class III agents target potassium channels, and class IV agents target Ca channels. Class I agents are further subdivided into three subclasses based on the kinetics of drug to Na channel interactions. Class IA agents, including procainamide and quinidine, possess intermediate binding kinetics and potency. Class IB agents, including lidocaine and mexiletine, possess rapid binding kinetics and relatively low potency. Class IC agents (flecainide, propafenone) possess slow kinetics and high potency. Class II agents consist entirely of beta-adrenergic blocking agents. Class III agents (sotalol, dofetilide, ibutilide) specifically target the Kv11.1 potassium channel (encoded by the *KCNH2* gene) and risk prolongation of the QT interval through these effects on phases 2/3 of the AP and hence ventricular repolarization. Class IV agents are cardioselective Ca channel blockers including verapamil and diltiazem. This classification has significant limitations, however. Many AADs interact with multiple ion channels, and as a result, many exhibit behavior consistent with multiple classes. Amiodarone, in particular, exhibits properties of all AAD classes. Adenosine, with primary antiarrhythmic effects as an acute and transient, intravenously administered AV nodal blocking agent, as well as digitalis glycoside, which blocks the Na^+/K^+ pump, which in turn inhibits the Na^+/Ca^{++} exchanger, resulting in antiarrhythmic effect, do not neatly fit into this classification schema.

CATHETER ABLATION

The rationale that underlies catheter ablation for cardiac arrhythmia is that an anatomic substrate can be identified and localized, and disruption or isolation of that substrate will eliminate the cardiac arrhythmia. For automaticity-driven arrhythmias, a focal source of automaticity is identified, localized, and ablated. For anatomic reentrant arrhythmias, a critical zone of slow conduction that sustains arrhythmia and can be reasonably targeted is ablated. Moreover, the ablation target must be in a location deemed at acceptable risk of not damaging critical structures such as the native conduction system, coronary arteries, or extracardiac structures including the esophagus and phrenic nerve. Advances in electroanatomic mapping, a technology that uses alterations in electrical impedance and a magnetic field as measured by an intracardiac mapping catheter, have allowed for real-time reconstruction of cardiac chambers and identification of arrhythmogenic tissue to be targeted for ablation while safely avoiding nontargeted critical structures. Intracardiac echocardiography has also been used to enhance the safety and efficacy of invasive electrophysiologic procedures with real-time visualization of cardiac structures **(Fig. 250-4)**.

In the 1950s–1960s, as the underlying anatomic substrates for arrhythmias became better understood, open surgical disruption of arrhythmia circuits was the only available interventional and curative therapy for many arrhythmias. Surgical ligation of accessory pathways or resection of ischemic VT substrates was performed at specialized surgical centers. The first attempts at clinical catheter ablation utilized direct current (DC) electrical energy. This resulted in a high-voltage pulse of electrical energy that would ablate cardiac tissue, but with a difficult-to-control scope, often leading to significant complications. Radiofrequency (RF) energy was adapted to catheter-based cardiac ablation in the 1980s. RF alternating electrical current (300–550 kHz) delivered through a catheter tip results in local tissue heating and permanent injury, rendering the targeted tissue electrically inert. This type of ablation is similar to the technology used in electrosurgical techniques using a Bovie electrocautery device. For >35 years, RF delivery via catheters has been iteratively optimized such that it has become the most common and mainstay energy source for catheter ablation. Catheter ablation is indicated for a wide variety of clinical arrhythmias, including SVT, accessory pathways, atrial flutter, AF, PVCs, and VT. Alternative

FIGURE 250-4 Catheter ablation of cardiac arrhythmias. ***A.*** A schematic of the catheter system and generator in a patient undergoing radiofrequency catheter ablation (RFCA); the circuit involves the catheter in the heart and a dispersive patch placed on the body surface (usually the back). The inset shows a diagram of the heart with a series of intracardiac catheters placed via the inferior vena cava (IVC), typically through femoral venous access. Catheters are located at the high right atrium, His bundle location, right ventricular (RV) apex, and through a transseptal puncture within the left atrium. ***B.*** Images from an electroanatomic mapping system are shown during mapping and ablation of typical cavo-tricuspid isthmus-dependent atrial flutter. This system allows three-dimensional real-time localization and annotation of catheter position and cardiac anatomy to guide mapping and ablation. In this instance, two projections of the map are shown at the top of the right atrium (RA), a right anterior oblique (RAO) and left anterior oblique (LAO) caudal view. Annotations of ablation lesion delivery are shown as *red dots*. In the left lower aspect of this panel, a simultaneous image from intracardiac echocardiography (ICE) is shown of the RA, with the ablation catheter in view in all three images. In the lower right aspect of this panel, surface electrocardiogram and intracardiac electrograms acquired in real time are shown.

ablative energy sources have been explored over the years, including cryothermy, light spectrum (laser), microwave, ultrasound, and more recently pulsed field electroporation, which injures targeted myocardium through high-energy, ultra-short pulses of electrical current that disrupts the lipid cell membrane, resulting in permanent cell death. Recently, the well-established ablative technique of stereotactic (focused and directed) external beam ionizing radiation has been applied to the heart to treat various arrhythmias, including VT and AF. This particular treatment modality holds promise given its ability to target regions of the heart that may be inaccessible to catheters, as well as the completely noninvasive nature of the procedure.

A widely applied non-RF ablative energy source today is cryothermy, where an ablative catheter tip is cooled to a temperature range (typically below –40°C) that results in permanent tissue death. Cryothermy is most widely applied to ablation of paroxysmal atrial ablation, via an expandable balloon introduced sequentially into each pulmonary vein and cooled to produce a circumferential ablative lesion at the ostium/antrum of each pulmonary vein. Similar catheter-based tools utilizing pulsed field ablation (PFA) have also been introduced for the purpose of electrically isolating pulmonary veins during AF ablation.

IMPLANTED ELECTRICAL DEVICE THERAPY

Implanted cardiac rhythm management devices are commonly utilized to manage arrhythmia. The first definitive pacemaker was implanted in 1958, and this technology has evolved to be the mainstay in the management of bradyarrhythmias. Sinus node dysfunction and AV conduction disease, particularly with symptoms, are the primary indications for most implanted pacemakers. Pacemakers are typically implanted percutaneously, with insulated wires, or leads, inserted through the upper extremity venous system into the right atrial and/or ventricular myocardium, with the lead tip secured to the myocardium mechanically. The leads are connected to a pulse generator placed in the prepectoral space, which contains electronic circuitry and a battery, allowing sensing and/or delivery of pacing stimuli to maintain adequate heart rate. More recently, a completely leadless pacemaker inserted through a large femoral venous sheath directly into the RA or right ventricle endocardium has become available. Although these devices possess more limited pacing options, they likely reduce the risks associated with transvenous lead systems, including infection or lead fracture requiring extraction.

Implanted cardioverter-defibrillators (ICDs) are placed in a similar fashion to pacemakers. However, ICDs have the ability to sense abnormal ventricular arrhythmias and deliver either antitachycardia pacing or defibrillation to prevent sudden death. In patients who experience a potentially lethal ventricular arrhythmia, ICD therapy may be lifesaving. Indications for ICD therapy are considered for either primary prevention of sudden cardiac death (SCD) due to arrhythmia in an at-risk patient or as secondary prevention in a patient who has survived an SCD event. More recently, a completely subcutaneous ICD system has become available, avoiding intravenous leads that increase risk for systemic infection, and potentially the procedure to extract a potentially fibrosed lead in cases of lead malfunction or endovascular infection.

251 The Bradyarrhythmias: Disorders of the Sinoatrial Node

William H. Sauer, Bruce A. Koplan

The sinoatrial (SA) node serves as the natural pacemaker of the heart and has variable rates in response to parasympathetic and sympathetic stimulation. If the sinus node is dysfunctional or suppressed, a subsidiary pacemaker in the atrioventricular node or specialized conduction system will take over, leading to a junctional or ventricular rhythm. Symptoms of sinus node dysfunction can vary but typically present as fatigue, exercise intolerance, or dyspnea. The diagnostic evaluation includes an investigation into reversible causes of sinus bradycardia, confirmation of sinus node dysfunction with outpatient telemetry monitoring or exercise testing, and possibly cardiac imaging if structural heart disease is suspected. Once irreversible sinus node dysfunction is confirmed, permanent pacemaker implantation is the only reliable long-term therapy for symptomatic bradycardia.

STRUCTURE AND PHYSIOLOGY OF THE SA NODE

The SA node region is complex in structure. Clusters of myocytes with pacemaker activity are surrounded by fibroblasts, endothelial cells, and transitional cells. These clusters of small fusiform cells in the sulcus terminalis on the epicardial surface of the heart at the right atrial–superior vena cava junction envelop the SA nodal artery. The SA node is structurally heterogeneous, but the central prototypic nodal cells have fewer distinct myofibrils than does the surrounding atrial myocardium, no intercalated disks visible on light microscopy, a poorly developed sarcoplasmic reticulum, and no T tubules. Cells in the peripheral regions of the SA node are transitional in both structure and function. The SA nodal artery arises from the right coronary artery in 55–60% and the left circumflex artery in 40–45% of persons. This feature, along with a protective extracellular matrix of connective tissue, insulates the SA node from the hyperpolarizing influence of the larger atrium. In addition, the alignment of this complex matrix is associated with nearly unidirectional electrical propagation to the atrium **(Fig. 251-1)**.

Pacemaker cells spontaneously depolarize in a continuous manner setting the natural rate of depolarization and myocardial contraction. Action potential depolarization in the SA node is normally at a resting rate of 60–100 beats/min. The autonomic nervous system exhibits control over the sinus node, with a preponderance of parasympathetic innervation at baseline. Removal of parasympathetic tone or an increase in sympathetic innervation leads to an increase in rate of depolarization. In denervated hearts, the rate of electrical depolarization (intrinsic heart rate) is approximately 100 beats/min, reflecting the rate of automaticity of the sinus node uninhibited by parasympathetic tone. The complement of ionic currents present in nodal cells results in a less negative resting membrane potential compared with atrial or ventricular myocytes. Electrical diastole in nodal cells is characterized by slow diastolic depolarization (phase 4), which generates an action potential as the membrane voltage reaches threshold. The action potential upstrokes (phase 0) are slow compared with atrial or ventricular myocytes, being mediated by calcium rather than sodium current.

Cells with properties of SA nodal tissue are electrically connected to the remainder of the myocardium by cells with an electrophysiologic phenotype between that of nodal cells and that of atrial or ventricular myocytes. Cells in the SA node exhibit the most rapid phase 4 depolarization and thus are the dominant pacemakers in a normal heart.

Myocytes within the SA node complex include specialized cells surrounded by fibrous tissue. Unlike atrial and ventricular cells, sinus node pacemaker cells have no true resting potential, but instead depolarize automatically and repetitively after the end of an action potential, and the depolarizing current in the SA node myocytes results primarily from slow calcium currents instead of fast sodium channels, which are

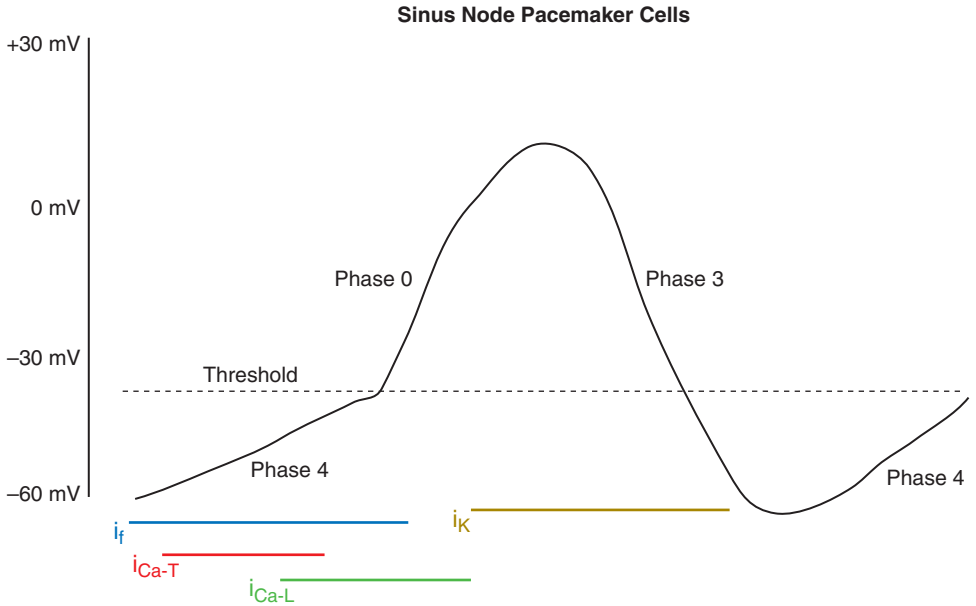

FIGURE 251-1 Cellular ion currents involved in depolarization and automaticity of sinoatrial (SA) nodal pacemaker cells. Phase 4 spontaneous depolarization results from i_f (funny) current, along with T- and L-type calcium channels. Phase 0 is the depolarization phase of the action potential. This is followed by phase 3 repolarization, which results from the outward directed hyperpolarizing K+ currents. i_f, funny current; i_{Ca-T}, T-type calcium current; i_{Ca-L}, L-type calcium current; i_K, potassium current.

absent in SA node cells. Spontaneous phase 4 depolarization results from a combination of slow inward depolarizing sodium current (I_f, "funny current"), along with inward calcium current controlled by T-type and L-type calcium channels. The upstroke of depolarization in SA node myocytes is slower and lower in amplitude than in ventricular myocytes.

In patients <85 years of age, the resting heart rate is strongly influenced by parasympathetic tone at baseline. The absence or elimination of autonomic influence on the SA node (e.g., after atropine administration) leads to an intrinsic heart rate that is normally 100–110 beats/min. The myocytes within the SA node that initiate pacing will change with different rates with a superior shift at higher heart rates and an inferior shift at lower rates. This shift may lead to a slightly different P wave inscribed on electrocardiograms (ECGs) recorded during different rates of sinus rhythm.

In addition, a progressive decline in maximum heart rate occurs with age, although the resting heart rate normally remains unchanged. Intrinsic heart rate declines 5–6 beats/min for each decade of age. However, the constancy of resting heart rate is associated with a gradual decrease in parasympathetic tone and a transition to predominant sympathetic tone by the ninth decade.

DIAGNOSIS OF SA NODAL DISEASE

Intrinsic sinus node disease is sometimes referred to as sick sinus syndrome or sinus node dysfunction (SND) and can manifest as fatigue, exercise intolerance, or syncope resulting from either reduced heart rate or pauses. Electrocardiographic recording plays a central role in the diagnosis and management of SA node dysfunction. The correlation between symptoms and slow heart rate or pauses is essential in determining whether bradycardia may be considered pathologic and necessitating intervention. Baseline ECG can detect baseline sinus bradycardia but may not indicate symptom correlation in certain settings. To address the limitations of the resting ECG, longer-term recording employing mobile telemetry devices such as Holter monitors or mobile cardiac telemetry can also be helpful in correlating symptoms with rate abnormalities **(Fig. 251-2)**.

In addition, commercially available wearable devices, such as watches with ECG recording capabilities, can have electrograms with excellent fidelity that may also be utilized. Contemporary event monitors may be automatically triggered to record the ECG when certain programmed heart rate criteria are met and implantable monitors permit very long-term recording (years) in particularly challenging patients. Treadmill testing can be utilized to assess for maximum heart rate. It is worth noting, however, that standard Bruce protocol treadmill testing may be helpful in detecting abnormalities in maximum heart rate, but more insidious chronotropic incompetence that manifests as abnormalities of rate increase during submaximal exercise may be more evident with treadmill protocols that have more gradual effort increases.

Once there is evidence of SND, it is important to rule out reversible causes of resting sinus bradycardia or chronotropic incompetence. **Table 251-1** lists the potentially reversible causes of sinus node disease and includes hypothyroidism and rate-slowing medications. Many patients with sleep apnea will have high vagal tone during sleep, especially during apneic events. Sinus bradycardia and sinus pauses frequently are seen if a patient is being monitored during this period. Sleep apnea, a common reversible cause, should be suspected if marked sinus bradycardia and prolonged sinus pauses are observed in a telemetry monitoring period during sleep. It is also worth noting that asymptomatic sinus bradycardia and pauses during sleep are typically not an indication for pacing, and it is, therefore, important when interpreting a wearable monitor to determine the timing of bradycardia events with regard to the sleep versus awake periods.

If structural heart disease is suspected, transthoracic echocardiography should be used to detect potential cardiac abnormalities associated with SND **(Fig. 251-3)**. Advanced cardiac imaging is indicated for evaluation of possible myocardial diseases such as amyloidosis, infiltrative cardiomyopathy, or myocarditis. Invasive electrophysiology testing solely to assess sinus node function is rarely utilized beyond the noninvasive techniques mentioned. In patients who are undergoing electrophysiology studies (EPS) for other indications, evaluation of sinus node function as part of the EPS may be considered. In symptomatic patients with suspected SND, EPS may rarely be considered when the diagnosis remains uncertain and after initial noninvasive evaluation is inconclusive. Investigation of the sinus node during EPS can consist of determination of sinus node recovery time (SNRT) and sinoatrial conduction time (SACT). In addition, the intrinsic heart rate [118.1 – (0.57 × age)] can be assessed via pharmacologic blockade of autonomic tone with intravenous propranolol and atropine. EPS is not widely used, however, as there is no evidence that abnormal SNRT or SACT alone can be used as an absolute indication for permanent pacing (PPM). There is no indication for EPS in asymptomatic patients with sinus bradycardia.

SA NODAL DYSFUNCTION SUBTYPES

SND can be categorized into problems with impulse formation and problems with impulse conduction. The term *sick sinus syndrome* may be used interchangeably with SND and refers to a group of related

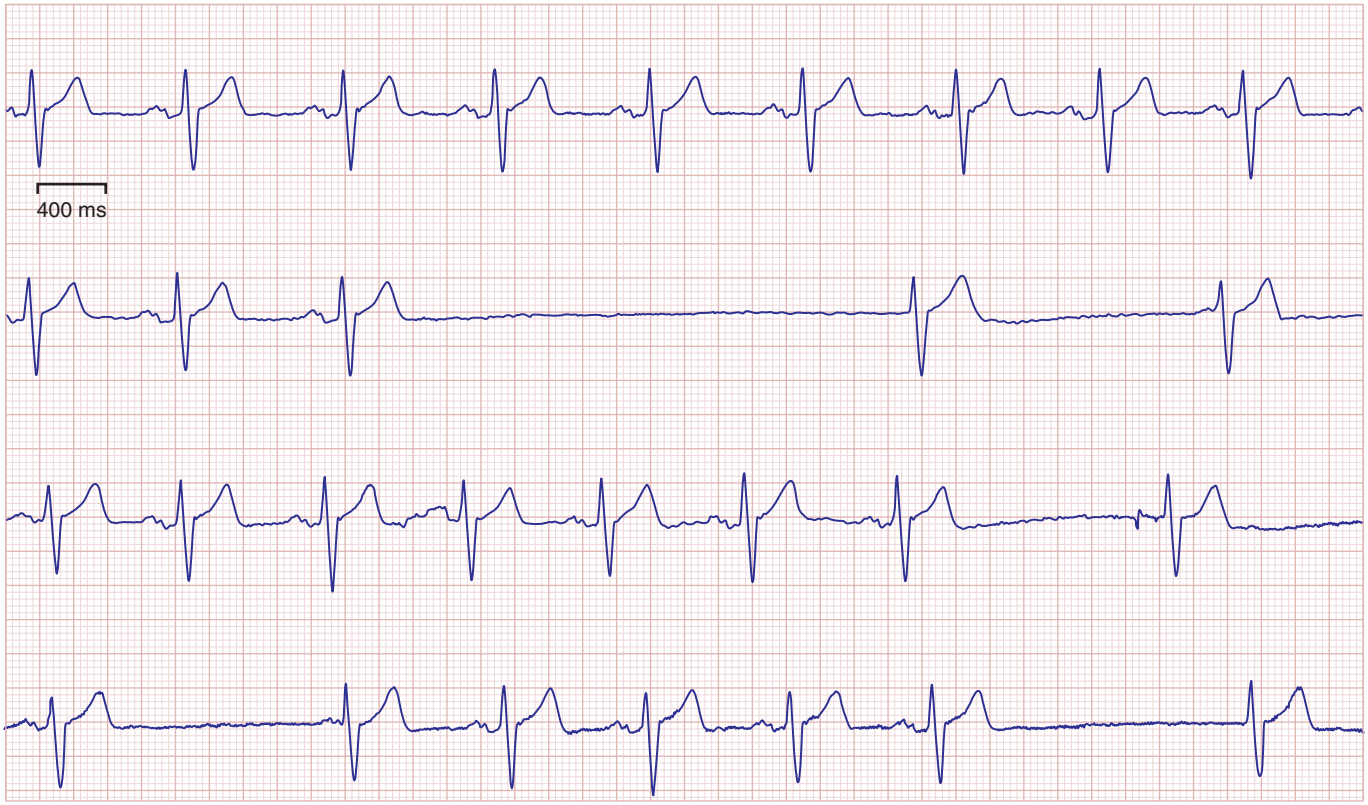

FIGURE 251-2 Sinoatrial exit block. A pause in the heart rhythm is seen that results from a sinus pause. On the second line of the tracing, there is a pause that results from the absence of a sinus beat (absent P wave) and no subsequent QRS. This is followed by a junctional escape beat and eventually recovery of the presence of sinus rhythm P waves.

conditions comprising problems of both impulse formation and impulse conduction.

Sinus Node Exit Block (See Fig. 251-4) "Sinus arrest" results from failure of impulse formation within the sinus node. Sinoatrial exit block results from failure of sinus node activity to propagate to the atrium. Sinoatrial exit block can have similar pattern characteristics of types of atrioventricular (AV) node block. It can manifest as complete SA block. Type I SA block involves fixed delay out of the sinus node. Type II SA block can occur with either progressive delay and then intermittent failure to propagate to the atrium (Mobitz I type) or fixed delay with intermittent failure to conduct (Mobitz II). The mass of the sinus node is not large enough to have an appearance on the ECG. Instead, the P waves that result from atrial depolarization can provide information that reflects the health of the sinus node. Type II second-degree SA block can be inferred on the ECG if the sinus rate abruptly transitions to a sinus rate that is half the previous rate (every other sinus depolarization is blocked from exiting to the atrium). Sinoatrial Wenckebach can be inferred from the ECG in the setting of progressive shortening of the P-P interval leading up to a sinus pause. This is due to progressive prolongation of SA conduction, but to a lesser extent with each successive prolongation. This is similar to the typical progressive shortening of the R-R interval that is observed with AV nodal Wenckebach. Other types of SA block require invasive EPS to decipher. The exercise of determining the type of SA block with invasive electrophysiology testing is typically not necessary because it does not alter management.

Tachy-Brady Syndrome Tachycardia-bradycardia (tachy-brady) syndrome is a subset of sick sinus syndrome/sinus node disease that consists of high heart rates (most commonly atrial fibrillation) with alternating symptomatic bradycardia or offset pauses **(Fig. 251-5)**. Commonly, medications that are needed for rate control of tachycardia exacerbate bradycardia episodes, and thus the presence of tachy-brady syndrome is often a reason to consider pacemaker implantation.

Chronotropic Incompetence Chronotropic incompetence (CI) is broadly defined as the inability of the heart to increase its rate to meet activity or demand. Compared to an increased stroke volume, the increase in heart rate is a stronger contributor to the increase in oxygen uptake (VO_2) during aerobic exercise. Therefore, CI can be the primary cause of severe exercise intolerance and increased cardiovascular events and overall morality. Unfortunately, CI lacks a consistent definition, leading to a lack of clarity on its overall prevalence. CI can take many forms, including failure to achieve a percentage (e.g., 85%) of age-predicted maximal heart rate [(220 – age) × 0.85] during stress testing. Other definitions that have been used include an overall a maximum heart rate [208 – (0.7 × age)], heart rate instability with exercise, or failure to achieve submaximal heart rate. Due to this latter category, standard exercise testing can, at times, fail to recognize a patient with CI because some patients can achieve an appropriate maximum heart rate but may exhibit heart rate instability or inadequate heart rate during activities of daily living (ADLs). Ambulatory heart rate monitoring along with a diary can be helpful to correlate symptoms with abnormally slow heart rates. Because CI can be insidious and multiple definitions exist, it can be easily overlooked.

Sinus Node Fibrosis Clinical SND is most common in older adults. This is due to normally occurring age-associated increase in fibrotic tissue in the SA node, which can exacerbate any degree of SND. A loss of pacemaker cells in the sinus node is also seen with age. It is worth noting, however, that while increased fibrosis in the SA node and decreased numbers of pacemaker myocytes are part of a normal process of aging, SND is pathologic and there are many elderly patients with extensive fibrosis and normal heart rate.

SA Nodal Ischemia and Infarction Sinus bradycardia is common in patients with acute inferior or posterior myocardial infarction (MI) and can be exacerbated by increased vagal tone (Bezold-Jarisch reflex) or with the use of drugs such as morphine and beta blockers. Ischemia of the SA nodal artery occurs in acute coronary syndromes

TABLE 251-1 Reversible Causes of Sinus Node Dysfunction

Medical Conditions Associated with Sinus Bradycardia

- Hypothyroidism
- Sleep apnea
- Hypoxia
- Hypothermia
- Increased intracranial pressure
- Lyme disease
- Myocarditis
- COVID-19
- Vagal reflex (cough, pain, etc.)

Medications Associated with Sinus Node Dysfunction

Antihypertensive Medications

- Beta-adrenergic receptor blockers
- Clonidine
- Methyldopa
- Nondihydropyridine calcium channel blockers

Antiarrhythmic Medications

- Amiodarone
- Dronedarone
- Flecainide
- Procainamide
- Propafenone
- Quinidine
- Sotalol
- Ivabradine

Psychiatric Medications

- Donepezil
- Lithium
- Opioid analgesics
- Phenothiazine antiemetics and antipsychotics
- Phenytoin
- Selective serotonin reuptake inhibitors
- Tricyclic antidepressants

Other

- Anesthetic drugs (propofol)
- Cannabis
- Digoxin
- Muscle relaxants

more typically with involvement with the right coronary artery, and even with infarction, the effect on SA node function most often is transient. However, there are rare cases where SA infarction can affect sinus node function. One potential rare complication of atrial fibrillation catheter ablation is the inadvertent injury to the SA nodal artery that may be coursing over a targeted ablation region in the right and left atrium. SND and arrest have been described following ablation of atrial fibrillation and flutter.

Carotid Sinus Hypersensitivity and Neurally Mediated Bradycardia Sinus bradycardia is a prominent feature of carotid sinus hypersensitivity and neurally mediated bradycardia associated with the cardioinhibitory variant of vasovagal syncope. Carotid hypersensitivity with recurrent syncope or presyncope associated with a predominant cardioinhibitory component responds to pacemaker implantation. Although the vasodepressor effect of the enhanced vagal tone may be unaffected by the pacing support, the lack of bradycardia often prevents injury with this subtype of vasovagal syncope. Several randomized trials have investigated the efficacy of permanent pacing in patients with drug-refractory vasovagal syncope, with mixed results. Although initial trials suggested that patients undergoing pacemaker implantation have fewer recurrences and a longer time to recurrence of symptoms, at least one follow-up study did not confirm these results.

TREATMENT

SA Nodal Disease

TEMPORARY PACING FOR TRANSIENT SUPPORT

In symptomatic patients presenting with sinus node disease, removing any possible reversible cause remains the initial strategy. Acute myocardial infarction, electrolyte abnormalities, medications, and hypothyroidism should all be considered as potentially reversible causes. Unnecessary medications that may be causing bradycardia should be eliminated. Beta blockers, calcium channel blockers, and digoxin are some of the more common medications in use that may cause bradycardia. These drugs may have a wide range of indications in patients after MI and with chronic systolic dysfunction. If stopping the medication or decreasing the dose is an option, this should be tried first. If the medication is felt to be unavoidable, a pacemaker may be indicated.

In patients with tachy-brady syndrome, alleviation of the tachycardia, whether it is atrial fibrillation or other forms of supraventricular tachyarrhythmias, can prevent bradycardia events. Treatment of the tachycardia can sometimes be accomplished with antiarrhythmic drug therapy or catheter ablation. If arrhythmia control cannot be achieved, permanent pacing may be necessary.

Hypoxia from decrease in blood flow to the SA node, which can occur with cardiac ischemia or MI, can lead to slowing of phase 4 depolarization and resultant bradycardia. Further ischemia and necrosis of pacemaker cells can cause irreversible sinus node disease. On occasion, reversal of ischemia with revascularization can alleviate bradycardia. Sinus pauses in the setting of tachy-brady syndrome may be eliminated if atrial tachyarrhythmias can be successfully treated. It is also important to recognize when bradycardia may be transient. Acute illness associated with episodes of extreme vagal tone may lead to transient SA node abnormalities. Typically, this may be observed as sinus slowing, followed by transient sinus arrest and/or AV block. Although a pacemaker may be needed in extreme instances of prolonged arrest, recovery from the acute illness may make the pacemaker unnecessary in follow-up.

Sinus bradycardia may also be observed after heart transplantation and cardiac surgery. Due to cardiac denervation, a normal resting heart rate in heart transplant recipients is generally 90–110 beats/min. Therefore, a heart rate that may be normal in a non-transplant patient may represent CI in a transplanted patient. In the case of heart transplantation, sinus bradycardia may be due to accumulated drugs such as amiodarone that affect the donor heart or ischemic injury to the SA node upon transplantation. If the SA nodal artery is injured at the time of right atriotomy during cardiac surgery, sinus arrest with junctional rhythm may be observed. Temporary pacing or pharmacologic support with beta-1 adrenergic agonists may be needed in these circumstances while awaiting SA nodal recovery.

In addition, sinus bradycardia and sinus pauses are common after spinal cord injury. The mechanism of bradycardia is enhanced parasympathetic tone and autonomic dysreflexia. Common triggers can be tracheal suctioning and turning the patient. Atropine and inotropes have shown mixed success. Adenosine blockade with theophylline or aminophylline can sometimes be successful. Temporary and sometimes permanent pacing may be necessary in extreme circumstances.

PERMANENT PACEMAKER IMPLANTATION

Pacing in SA nodal disease is indicated to alleviate symptoms of bradycardia. Consensus guidelines published by the American Heart Association (AHA)/American College of Cardiology (ACC)/Heart Rhythm Society (HRS) outline the indications for the use of pacemakers and categorize them by class based on levels of evidence **(Fig. 251-6)**. Since the first implementation of permanent pacing in the 1950s, many advances in technology have resulted in miniaturization, increased longevity of pulse generators, improvement in leads, and increased functionality. To better understand

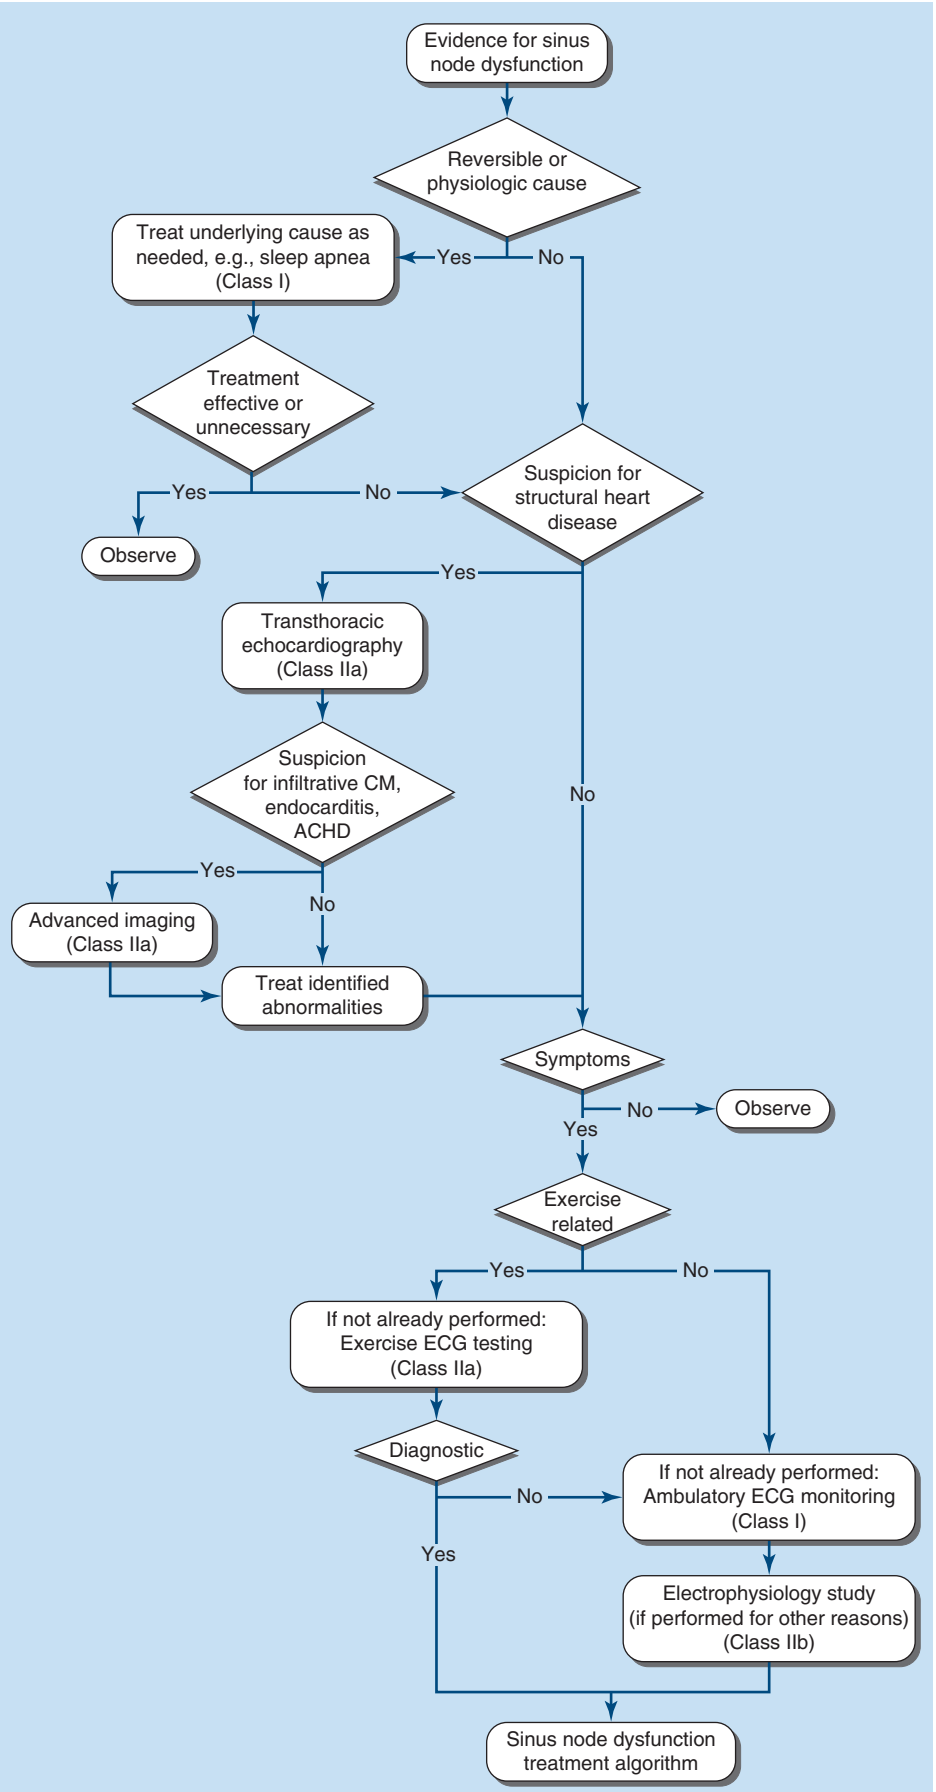

FIGURE 251-3 Evaluation of bradycardia and conduction disease. In patients with sinus node dysfunction, reversible causes should be identified and eliminated when possible. If no reversible cause can be identified, structural heart disease should be considered and evaluated for, if appropriate. If no symptoms are present, an observation strategy is appropriate. In patients who are symptomatic, further evaluation with ambulatory monitoring or exercise testing to identify symptom-rhythm correlation should be considered. ACHD, adult congenital heart disease; CM, cardiomyopathy. *(Reproduced with permission from FM Kusumoto et al: 2018 ACC/AHA/HRS guideline on the evaluation and management of patients with bradycardia and cardiac conduction delay. Heart Rhythm 16:e128, 2019.)*

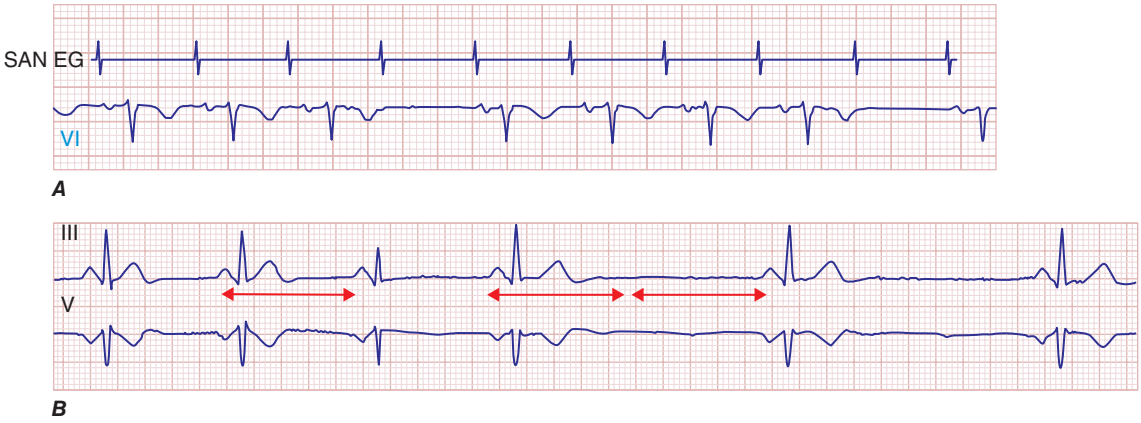

FIGURE 251-4 ***A.*** Mobitz type I sinoatrial (SA) nodal exit block. A theoretical SA node electrogram (SAN EG) is shown. Note that there is grouped beating producing a regularly irregular heart rhythm. The SAN EG rate is constant with progressive delay in exit from the node and activation of the atria, inscribing the P wave. This produces subtly decreasing P-P intervals before the pause, and the pause is less than twice the cycle length of the last sinus interval. ***B.*** Mobitz type II SA nodal exit block. This panel shows sinus rhythm in the first four beats followed by a sinus pause with the absence of a P wave. The interval comprising the absent P wave is exactly twice as long as the preceding P-P interval consistent with type II SA exit block.

pacemaker therapy for bradycardias, it is important to be familiar with the fundamentals of pacemaker function.

There is no established heart rate below which pacemaker treatment is indicated (Table 251-2). Well-conditioned athletes can have resting sinus rates below 40 beats/min, and some individuals can have similar levels of bradycardia during sleep. Permanent pacing is typically not indicated for sleep-related pauses felt secondary to high vagal tone in the absence of other symptoms. Asymptomatic sinus bradycardia has not been associated with adverse outcomes and does not typically warrant permanent pacing. In situations such as asymptomatic sinus bradycardia, sinus pauses secondary to physiologically elevated parasympathetic tone, transient pauses during sleep, or asymptomatic SND where symptoms have been documented to occur in the absence of bradycardia, a pacemaker is generally not indicated.

Medications to improve heart rate in order to avoid PPM are very rarely utilized. Medications such as methylxanthines (e.g., theophylline) or beta agonists (e.g., terbutaline) are sometimes utilized on a temporary basis when a pacemaker may need to be delayed due to unique circumstances such as active infection. In addition, oral theophylline may be considered to determine if an increase in heart rate is associated with improvement in symptoms in a patient with sinus bradycardia to suggest that a PPM may be beneficial. This latter strategy is rarely utilized in more equivocal situations.

PPM is the principal treatment for SND, and the decision to pursue this treatment is largely driven by a correlation between symptoms and bradycardia. The stronger the correlation between symptoms and bradycardia, the greater is the likelihood of improvement. PPM is most commonly achieved through transvenous implantation of one or more leads through the left or right subclavian veins into the cardiac chambers. The leads are attached to a pacemaker generator that is placed subcutaneously in the pectoral chest region. Less commonly, pacing leads can be placed in the epicardium via surgical approaches including sternotomy or thoracotomy. This latter approach can be accomplished as a standalone procedure but is more commonly performed concomitantly

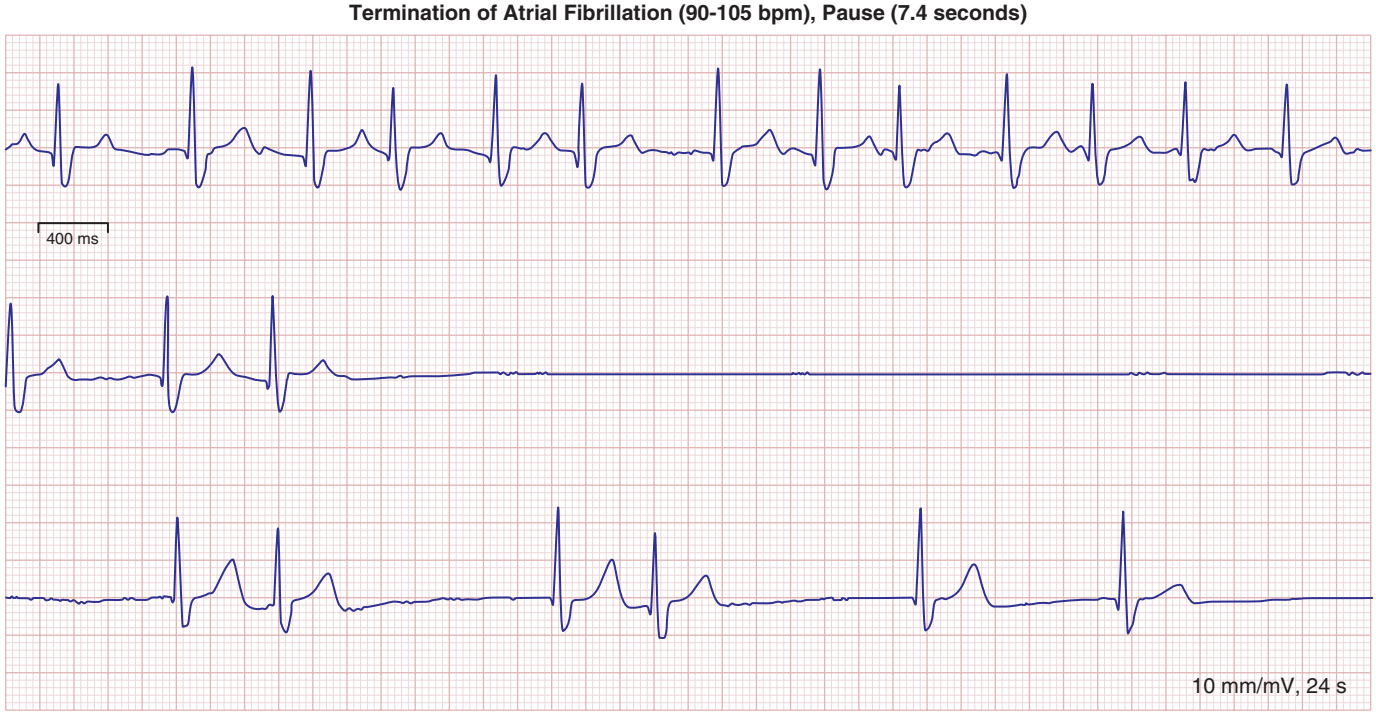

FIGURE 251-5 Offset pause and tachy-brady syndrome. An offset pause after termination of atrial fibrillation is seen and is consistent with tachy-brady syndrome.

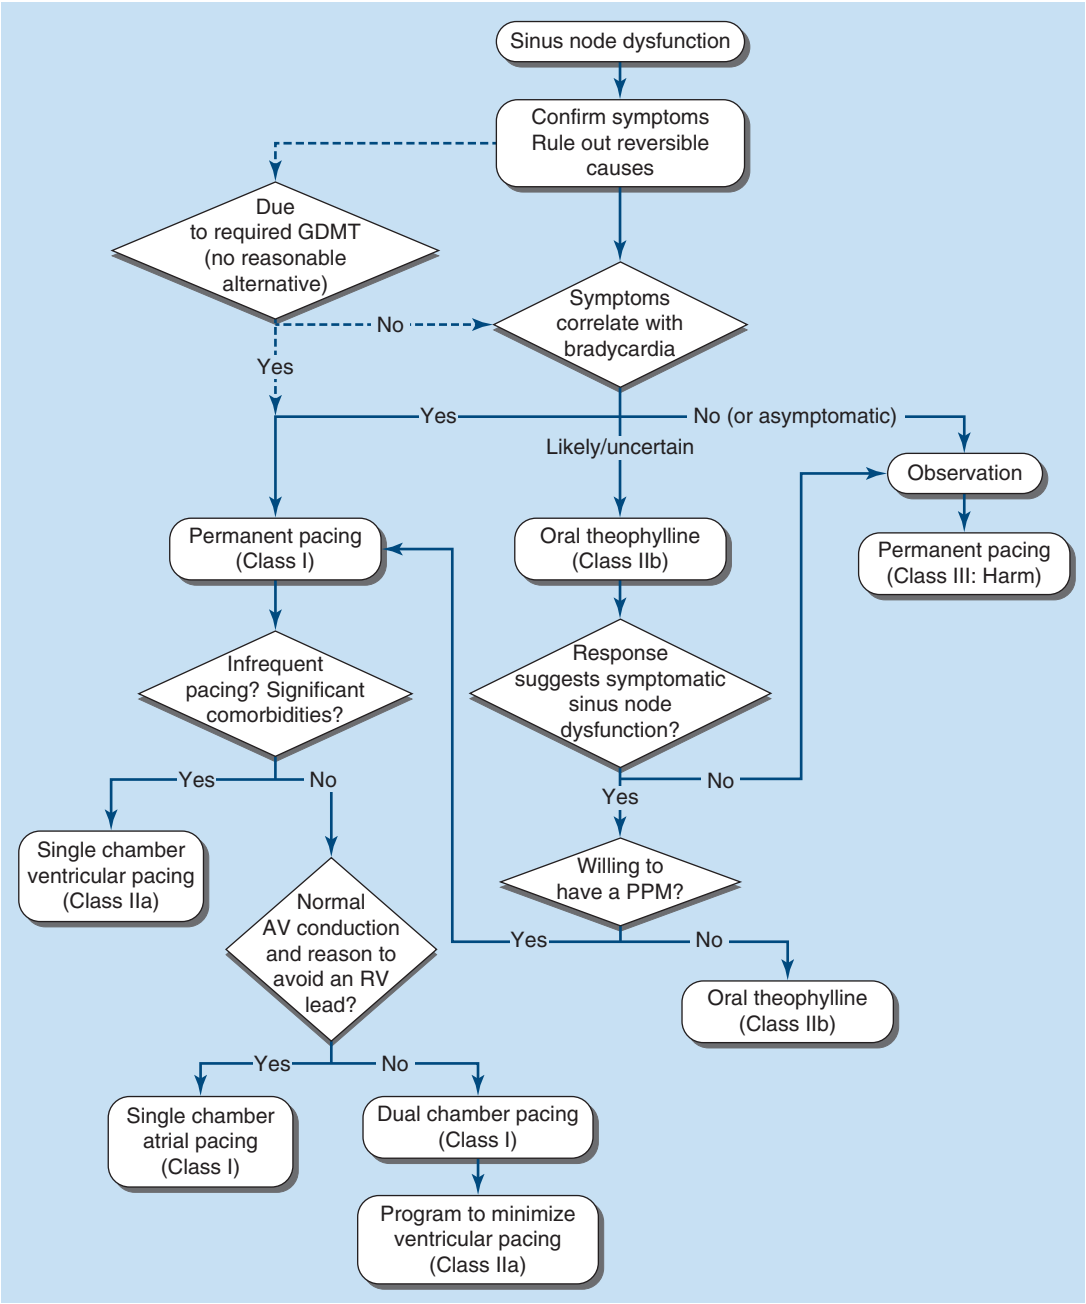

FIGURE 251-6 Management of sinus node dysfunction. Management of sinus node dysfunction begins with eliminating reversible causes and confirming whether symptoms correlate with bradycardia. If symptoms are clearly correlated, permanent pacing should be offered. If it is unclear, a trial of oral theophylline can be considered diagnostically. If there is no correlation between symptoms and bradycardia, then observation is appropriate. Class I recommendations should be performed or are indicated. Class IIa recommendations are considered reasonable to perform. Class IIb recommendations may be considered. Class III recommendations are associated with harm more than benefit. AV, atrioventricular; GDMT, guideline-directed management and therapy; PPM, permanent pacemaker; RV, right ventricular. *(Reproduced with permission from FM Kusumoto et al: 2018 ACC/AHA/HRS guideline on the evaluation and management of patients with bradycardia and cardiac conduction delay. Heart Rhythm 16:e128, 2019.)*

TABLE 251-2 Indications for Permanent Pacing in Sinus Node Dysfunction (SND)

- Symptoms that are directly attributable to SND
- Symptomatic sinus bradycardia because of essential medication therapy for which there is no alternative treatment
- Tachy-brady syndrome and symptoms attributable to bradycardia
- Symptomatic chronotropic incompetence
- In patients with symptoms that are possibly attributable to SND, a trial of oral theophylline may be considered to increase heart rate and determine if permanent pacing may be beneficial

during another primary cardiac surgery. Leadless pacemakers that are totally self-contained pacing devices can also be placed in the right atrium and right ventricle to provide dual chamber pacing. Some leadless pacemakers can also incorporate technology to sense atrial activity to attempt to coordinate atrial sensing with ventricular pacing.

A standard nomenclature for pacing mode programming utilizes a four-letter code. The first letter indicates the chamber(s) paced (O, none; A, atrium; V, ventricular; D, dual; S, single). The second letter indicates the chamber(s) sensed. The third letter is the response to a sensed event (O, none; I, inhibited; T, triggered;

D, inhibition and triggered). The fourth letter refers to whether rate response (R) is turned on. Therefore, a dual-chamber pacemaker programmed in a DDDR mode provides atrial and ventricular pacing, A and V sensing, can be inhibited or triggered by a sensed beat, and is programmed to provide rate responsiveness to activity via either a built-in accelerometer, minute ventilation sensor, or both. Rate response is essential for the treatment of CI as it attempts to mimic the natural physiologic increase in heart rate in response to exertion.

A single-chamber atrial pacemaker can be a consideration in patients with pure SND who are felt to be at low risk for developing AV nodal block. However, fibrosis of the sinus node is associated with fibrosis of the AV node on pathology series in older patients and many patients with SND will develop AV node disease. Therefore, although a single-chamber atrial pacemaker can be a consideration in younger patients with pure SND, a majority of patients receiving a pacemaker for sinus node disease (particularly older individuals) often receive a dual-chamber pacemaker with backup ventricular pacing if needed.

Class I indications for pacing in SA node dysfunction include documented symptomatic bradycardia, SND-associated long-term drug therapy for which there is no alternative, and symptomatic CI. Class IIa indications include those outlined previously in which SND is suspected but not documented and for syncope of unexplained origin in the presence of major abnormalities of SA node dysfunction. Mildly symptomatic individuals with heart rates consistently <40 beats/min constitute a class IIb indication for pacing. Pacing is not indicated in patients with SA node dysfunction who do not have symptoms and in those in whom bradycardia is associated with the use of nonessential drugs.

COMPLICATIONS RELATED TO PACEMAKER IMPLANTATION

Although pacemakers are highly reliable, they are subject to a number of complications related to implantation and electronic function. In adults, permanent pacemakers are most commonly implanted with access to the heart by way of the subclavian superior vena cava venous system. Rare but possible acute complications of transvenous pacemaker implantation include infection, hematoma, pneumothorax, cardiac perforation, diaphragmatic/phrenic nerve stimulation, and lead dislodgment. Limitations of chronic pacemaker therapy include infection, erosion, lead failure, and abnormalities resulting from inappropriate programming or interaction with the patient's native electrical cardiac function. Rotation of the pacemaker pulse generator in its subcutaneous pocket, either intentionally or inadvertently, often referred to as "twiddler's syndrome," can wrap the leads around the generator and produce dislodgment with failure to sense or pace the heart. The small size and light weight of contemporary pacemakers make this a rare complication. Transvenous leads are considered the least reliable component of permanent pacing systems. Enhancements in battery technology and component design have produced a pacing system small enough to be implanted in the heart without the need for a transvenous lead. The first "leadless" pacemakers were only appropriate for patients with indications for single-chamber ventricular (right ventricle) pacing. More recently, these devices have been modified to detect mechanical atrial contraction and thus can be programmed to preserve AV synchrony in patients with heart block but without SND. Dual-chamber leadless pacemakers can also be implanted to preserve AV synchrony in patients with AV block.

252 The Bradyarrhythmias: Disorders of the Atrioventricular Node

William H. Sauer, Bruce A. Koplan

Impulses generated in the sinoatrial (SA) node are conducted to the ventricles through the electrically and anatomically complex atrioventricular (AV) node. The AV node is specialized for slow conduction of the action potential to create a delay between atrial and ventricular activation. There is a similar pattern of arrangement of gap junctions and expression of connexins in the AV node as in the sinus node. This allows for weak electrical coupling in the center of the node to slow conduction and protect it from the periphery. This unique arrangement of gap junctions, along with extracellular matrix and fibroblasts and a lack of conductance in adjacent valvular tissue, allow the AV node to slow conduction and serve as the electrical "gatekeeper" to the ventricle.

As described in previous chapters, cells located in the AV node sit at a relatively higher resting membrane potential than surrounding atrial and ventricular myocytes, exhibit spontaneous depolarization during phase 4 of the action potential, and have slower phase 0 depolarization (mediated by calcium influx in nodal tissue with a lack of the type of fast sodium channels found in atrial and ventricular myocytes) compared to ventricular tissue (mediated by sodium influx). Although the AV node has the potential for pacemaker activity, the normal automaticity rate is 20–60 beats/min, which is overridden by the higher intrinsic rate of the SA node (60–100 beats/min). Therefore, the AV node can provide a backup heart rate when the SA node fails to depolarize. There is a progressive decrease in the frequency of spontaneous depolarization down the His and Purkinje fibers. This progressive decrease in rate of depolarization allows for unidirectional flow of impulses through the conduction system.

Bradycardia may occur when conduction across the AV node is compromised, resulting in slow ventricular rates. The consequences can be fatigue, syncope, and, if a reliable escape rhythm does not occur, death from asystole. Transient AV conduction block is common in the young and is most likely the result of high vagal tone found in up to 10% of young adults. Acquired and persistent failure of AV conduction is rare in healthy adult populations, with an estimated incidence of 1 per 5000 in the U.S. population per year. In the setting of myocardial ischemia, aging and fibrosis, or cardiac infiltrative diseases, however, persistent AV block is much more common. As with symptomatic bradycardia arising from SA node dysfunction, permanent pacing is the only reliable therapy for symptoms arising from AV conduction block. While pacemakers for sinus node dysfunction are mainly indicated when symptoms correlate with bradycardia, pacemakers may be indicated in some forms of AV block in the absence of symptoms if the type of AV block is lower in the conduction system (infra-Hisian block) due to an increased risk of life-threatening asystole even if symptoms are not present leading up to such an event.

STRUCTURE AND PHYSIOLOGY OF THE AV NODE

The normal AV junctional area can be divided into a transition cell zone (which results from approaches from the atrium to the AV node), the compact AV node, and the penetrating part of the His bundle. Conduction from the SA node to the AV node occurs in a preferential manner via intra-atrial pathways with higher conduction velocity than the remainder of atrial tissue. The AV node itself is a small region (~1 × 3 × 5 mm) that lies beneath the right atrial endocardium at the apex of the triangle of Koch, a region defined by three landmarks: the coronary sinus ostium posteriorly, the septal tricuspid valve annulus anteriorly, and the tendon of Todaro superiorly. The AV node can be further

subdivided into the lower nodal bundle and compact node. A rightward inferior node extension spreads along the tricuspid valve toward the coronary sinus, and the leftward nodal extension spreads from the compact node along the tendon of Todaro. In some people, there are two functional pathways in the AV node: a slow pathway located in the inferior node extension and a fast pathway that is less well defined but is superior to the slow pathway. The role of these pathways in supraventricular tachycardia is described in another chapter.

The compact AV node continues anteriorly and superiorly as the penetrating AV bundle where it traverses the central fibrous body in close proximity to the aortic, mitral, and tricuspid valve annuli. The penetrating AV bundle continues through the annulus fibrosis and emerges as the His bundle along the ventricular septum. The right bundle branch (RBB) emerges from the distal AV bundle and terminates to a band that traverses the right ventricle (moderator band). In contrast, the left bundle branch (LBB) is a broad subendocardial sheet of tissue on the septal left ventricle. The Purkinje fiber network emerges from the RBB and LBB and extensively ramifies on the endocardial surfaces of the right and left ventricles, respectively.

The cells that constitute the AV node complex are heterogeneous with a range of action potential profiles. The AV junction has distinct regions including a transitional cell zone (atrionodal cells), the compact AV node, and the cells of the penetrating part of the His bundle. In the transitional zones, the cells have an electrical phenotype between those of atrial myocytes and cells of the compact node. Atrionodal transitional connections exhibit *decremental conduction*, defined as slowing of conduction with increasingly rapid rates of stimulation. Myocytes that constitute the compact AV node are similar to sinus node myocytes, having a resting membrane potential of ~–60 mV; exhibit action potentials with low amplitudes, slow upstrokes of phase 0 (<10 V/s), and spontaneous phase 4 diastolic depolarization; and have high-input resistance and relative insensitivity to external $[K^+]$. The action potential phenotype is explained by the complement of ionic currents expressed. AV nodal cells lack a robust inward rectifier potassium current (I_{K1}) and fast sodium current (I_{Na}); L-type calcium current ($I_{Ca\text{-}L}$) is responsible for phase 0; and phase 4 depolarization reflects the composite activity of the depolarizing currents—funny current (I_f), $I_{Ca\text{-}L}$, T-type calcium current ($I_{Ca\text{-}T}$), and sodium-calcium exchanger current (I_{NCX})—and the repolarizing currents—delayed rectifier (I_{Kr}) and acetylcholine-gated (I_{KACh}) potassium currents. Electrical coupling between cells in the AV node is tenuous due to the relatively sparse expression of gap junction channels (predominantly connexin-40) and increased extracellular volume.

The His bundle and the bundle branches are insulated from ventricular myocardium. The most rapid conduction in the heart is observed in Purkinje cells (1–3 m/s), with action potentials exhibiting a very rapid upstroke (phase 0), prolonged plateau (phase 2), and modest automaticity (phase 4 depolarization). Gap junctions, composed largely of connexin-40, are abundant, but bundles are not connected transversely to ventricular myocardium. The AV node is innervated by both sympathetic and parasympathetic autonomic input that can either slow or enhance conduction.

The blood supply to the penetrating AV bundle is from the AV nodal artery and first septal perforator of the left anterior descending coronary artery. The AV node artery arises from the right coronary artery (80–90% of the time) or the left circumflex (10%) with the assigned artery associated with the dominance of the coronary artery circulation. The bundle branches also have a dual blood supply from the septal perforators of the left anterior descending coronary artery (LBB and proximal RBB) and branches of the posterior descending coronary artery. The AV node is highly innervated with postganglionic sympathetic and parasympathetic nerves; however, the bundle of His and distal conducting system are not influenced by autonomic tone.

ELECTROCARDIOGRAPHIC DEFINITIONS OF AV CONDUCTION BLOCK (TABLE 252-1)

Conduction block in the AV node is classified based on the appearance on electrocardiography (ECG), which may also be a reflection of the location of block along the AV conduction axis. First-degree AV block involves a fixed prolongation of the PR interval (>200 ms). In first-degree AV block, delay usually occurs within the AV node, although the atria, His bundle, and Purkinje system may also be involved. Although the term *block* is a misnomer of sorts because electrical conduction is delayed and not interrupted, it remains commonly in use. Second-degree AV block involves intermittent failure of conduction between the atrium and ventricle. There are two subtypes of second-degree AV block. Type I (Mobitz I, Wenckebach) AV block manifests as progressive prolongation of the PR interval prior to one or more "dropped" QRS complexes. Progressive shortening of the RR interval and grouped beating of QRS complexes are classically seen in Mobitz I AV block. In addition, comparison of the last PR interval before and the first PR interval after the absent QRS complex will often reveal the greatest discrepancy of PR interval, making the diagnosis of Mobitz I AV block most evident. Mobitz I AV block typically involves the AV node, is hemodynamically stable, and in the absence of symptoms, does not typically warrant pacing. Type II second-degree AV block manifests on ECG as failed AV conduction preceded by fixed PR interval (no prolongation of PR interval prior to a dropped beat). Type II block has more serious implications, including a risk of sudden death. It is infranodal in location and associated with a less reliable escape rhythm, and thus, permanent pacing is required even in the absence of symptoms. In the setting of 2:1 AV block, ECG differentiation of type I versus type II block is not possible. If the PR interval is <160 ms prior to the AV conduction and QRS is wider than normal, infranodal (type II) block is most likely. Complete heart block (third-degree block) involves complete AV dissociation with a ventricular rate that is slower than the atrial rate **(Fig. 252-1)**.

TABLE 252-1 Electrocardiographic Classification of Atrioventricular (AV) Block

First-Degree AV Block
All atrial impulses are conducted to the ventricle
PR interval is abnormally long (>200 ms)
AV delay usually occurs within the AV node
Second-Degree AV Block (intermittent failure of conduction between atrium and ventricle)
Two subtypes
Type I/Mobitz I/Wenckebach block: progressive prolongation of the PR interval until loss of conduction occurs
Type II/Mobitz II: fixed PR interval precedes loss of conduction
Usually associated with QRS widening
Third-Degree AV Block (complete heart block)
Complete interruption of conduction between atria and ventricles

In the absence of a preexisting bundle branch block, a wide QRS escape rhythm implies a block in the distal His or bundle branches; in contrast, a narrow QRS rhythm implies a block in the AV node or proximal His and an escape rhythm originating in the AV junction. Narrow QRS escape rhythms are typically faster and more stable than wide QRS escape rhythms and originate more proximally in the AV conduction system.

ETIOLOGY OF AV CONDUCTION DISEASE

There are numerous causes of intrinsic AV node dysfunction. Fibrosis and sclerosis of the conduction system are the most common causes of acquired conduction disease, accounting for ~50% of AV block. Numerous conditions that may not be distinguishable from one another can lead to conduction system fibrosis. Senile degeneration of the conduction system is most commonly seen in the elderly and results from idiopathic fibrosis and calcification. Lev's disease results from proximal bundle branch fibrosis. Lenègre's disease results from a sclerodegenerative process that occurs in a younger age group and involves the more distal portions of the bundle branches. Calcification of the aortic valve annulus can encroach on the conduction system. Compared to aortic valve calcification, mitral calcification is less commonly a cause of AV block **(Table 252-2)**.

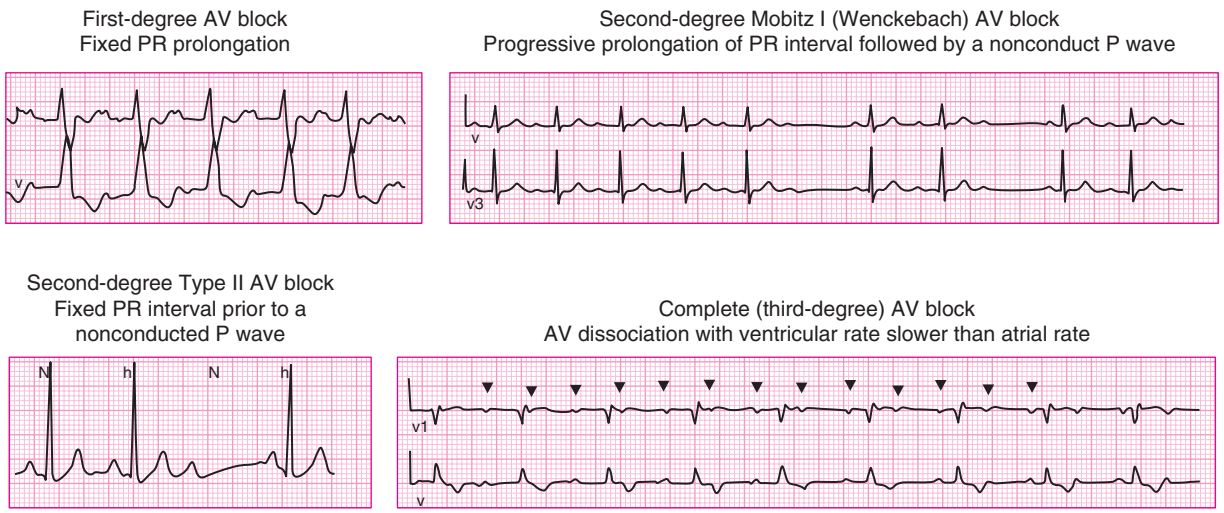

FIGURE 252-1 Types of atrioventricular (AV) block. The *upper left* figure displays fixed prolongation of the PR interval. The *upper right* figure demonstrates Mobitz I block (Wenckebach AV block) manifested as progressive prolongation of the PR interval followed by a nonconducted P wave ("dropped beat"). The *lower left* figure displays AV block with P wave with no QRS complex and no associated PR prolongation prior to the dropped beat (Mobitz type II AV block). The *lower right* figure demonstrates complete heart block manifested as dissociation between P waves and QRS complexes (AV dissociation).

IATROGENIC CAUSES

AV block may also be from iatrogenic causes. Cardiac surgery, most commonly cardiac valve surgery, can result in damage to the AV conduction system, with the highest risk occurring in aortic valve and tricuspid valve surgery. Percutaneous transcatheter aortic valve replacement, septal myectomy, and alcohol septal ablation also carry a risk of AV block. Percutaneous catheter ablation for atrial arrhythmias, particularly AV nodal reentry tachycardia ablation, is associated with a small (<1%) risk of AV block. Medications, including beta blockers, verapamil, diltiazem, and digoxin, are also common iatrogenic causes of AV block. Many patients with drug-induced AV block have preexisting conduction system disease. Iatrogenic AV block may occur rarely in the setting of thoracic radiation or chemotherapy. AV block is a rare complication of the surgical repair of ventricular septal defects (VSDs) or atrial septal defects (ASDs) but may complicate repairs of transposition of the great arteries.

TABLE 252-2 Causes of AV Block

Fibrosis/sclerosis/calcification of the conduction system
Senile degeneration of the conduction system (Lev's disease)
Lenègre's disease
Calcification of the aortic valve annulus (mitral—less common)
Iatrogenic
After cardiac surgery (including valve surgery)
TAVR/alcohol septal ablation
Complication from catheter ablation
Medication (beta blockers, verapamil, diltiazem, digoxin)
Toxin/overdose/poisoning
Acute MI/coronary ischemia
Infectious causes
Lyme carditis
Bacterial endocarditis with perivalvular abscess
Viral myocarditis
Chagas' disease
Toxoplasmosis
Infiltrative heart disease/inflammatory disease
Sarcoidosis
Amyloid
Rheumatologic disease: reactive arthritis (Reiter's syndrome), SLE, RA, systemic sclerosis
Congenital AV block
Maternal lupus
Idiopathic congenital AV block
Congenital heart defects
Genetic
Endocrine (e.g., thyroid disease, hypoadosteronism)
Autoimmune disease
Neuromuscular disease (e.g., myotonic dystrophy, Kearns-Sayre syndrome, Erb's dystrophy)
Lymphoma
Enhanced vagal tone/neurocardiogenic

Abbreviations: AV, atrioventricular; MI, myocardial infarction; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; TAVR, transcatheter aortic valve replacement.

AV BLOCK IN THE SETTING OF MYOCARDIAL ISCHEMIA

Coronary artery disease may produce transient or persistent AV block. In the setting of coronary spasm, ischemia, particularly in the right coronary artery distribution, may produce transient AV block. In acute myocardial infarction (MI), AV block transiently develops in 10–25% of patients; most commonly, this is first- or second-degree AV block, but complete heart block (CHB) may also occur. Second-degree and higher-grade AV block tends to occur more often in inferior than in anterior acute MI; however, the level of block in inferior MI tends to be in the AV node with more stable, narrow escape rhythms. In contrast, acute anterior MI is associated with block in the distal AV nodal complex, His bundle, or bundle branches and results in wide complex, unstable escape rhythms and a worse prognosis with high mortality rates.

AV conduction abnormalities may be caused by either direct ischemia to the conduction system or enhanced autonomic tone (Bezold-Jarisch reflex). Conduction abnormalities can be considered based on infarct location, and this may also predict which conduction abnormalities may be reversible. High-grade AV block associated with inferior MI is often located proximal to the His bundle in 90% of patients. Narrow junctional escape typically occurs with rates >40 beats/min, and a temporary pacemaker is typically not required as the AV block is often reversible and successfully managed with pharmacologic therapy. High-grade AV block in the setting of anterior MI is typically indicative of extensive infarction, is more often distal to the AV node, and is associated with an increased mortality. Temporary pacing in this circumstance is typically indicated. CHB in the setting of anterior MI may also be preceded by RBB block due to the arterial supply of the proximal RBB.

INFECTIOUS CAUSES OF AV BLOCK

Infection can also cause AV block. AV block is a common manifestation of Lyme carditis due to infection with *Borrelia burgdorferi*.

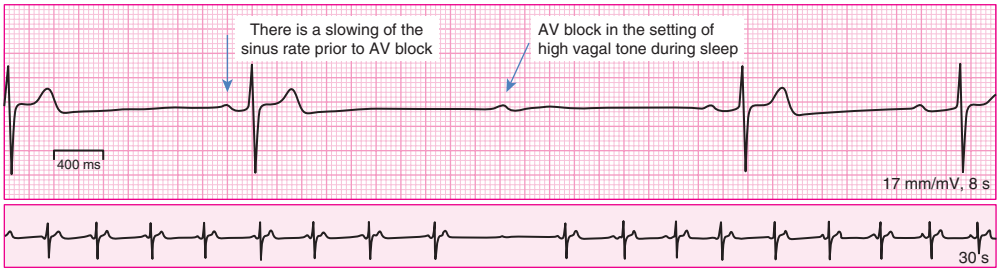

FIGURE 252-2 Evidence of atrioventricular (AV) block during sleep. During sleep, increased vagal tone leads to sinus bradycardia with associated Mobitz I (Wenckebach) AV block. See Fig. 252-1 for an explanation of Mobitz I block.

AV block is typically at the level of the AV node with narrow junctional escape rhythm >40 beats/min. Less commonly, conduction abnormalities can occur below the level of the AV node or in the sinus node. In Lyme carditis, AV block typically improves within 1 week of antibiotic therapy, although a longer time frame can occur in some patients. AV block in the setting of infective endocarditis should raise concern for perivalvular abscess, which requires urgent surgical consultation. Viral myocarditis, Chagas' disease, and toxoplasmosis are less common infectious causes of AV block. Infiltrative heart disease such as cardiac sarcoid, amyloid, and hemochromatosis can also present as AV block. Autoimmune diseases, including systemic lupus erythematosus (SLE), rheumatoid arthritis, mixed connective tissue disease, and scleroderma, may cause AV block due to infiltration of the conduction system. Rare malignancies also may impair AV conduction.

AUTONOMIC AND FUNCTIONAL CAUSES OF AV BLOCK

Functional causes of AV block (autonomic, metabolic/endocrine, and drug-related) tend to be reversible. Most other etiologies produce structural changes, typically fibrosis, in segments of the AV conduction axis that are generally permanent. Heightened vagal tone during sleep or in well-conditioned individuals can be associated with all grades of AV block **(Fig. 252-2)**.

Carotid sinus hypersensitivity, vasovagal syncope, and cough and micturition syncope may be associated with SA node slowing and AV conduction block. Transient metabolic and endocrinologic disturbances and a number of pharmacologic agents also may produce reversible AV conduction block.

ACQUIRED AV BLOCK FROM FIBROSIS AND INFILTRATIVE CARDIOMYOPATHIES

Idiopathic progressive fibrosis of the conduction system is one of the more common and degenerative causes of AV conduction block. Aging is associated with degenerative changes in the summit of the ventricular septum, central fibrous body, and aortic and mitral annuli and has been described as "sclerosis of the left cardiac skeleton." The process typically begins in the fourth decade of life and may be accelerated by atherosclerosis, hypertension, and diabetes mellitus. Accelerated forms of progressive familial heart block have been identified in families with mutations in the cardiac sodium channel gene (*SCN5A*) and other loci that have been mapped to chromosomes 1 and 19.

AV conduction block has been associated with heritable neuromuscular diseases, including the nucleotide repeat disease myotonic dystrophy, the mitochondrial myopathy Kearns-Sayre syndrome, and several of the monogenic muscular dystrophies. Patients with these neuromuscular diseases and evidence of AV block should be considered for permanent pacing support.

CONGENITAL AV BLOCK

Congenital AV block may be observed in complex congenital cardiac anomalies, such as transposition of the great arteries, ostium primum ASDs, VSDs, endocardial cushion defects, and some single-ventricle defects. Congenital AV block in the setting of a structurally normal heart can occur sporadically and can also be seen in children born to mothers with SLE and other autoimmune diseases.

DIAGNOSTIC TESTING

Patients with conduction abnormalities should be evaluated for the presence or absence of structural heart disease. Physical exam may reveal valvular heart disease. ECG may suggest concomitant disease that predisposes to conduction abnormalities. Echocardiography is also indicated to evaluate for structural heart disease including valvular abnormalities, ejection fraction, and ventricular wall motion. Because age-dependent progressive fibrosis of the conduction system is the most common cause, AV node block that develops at a younger age (≤60 years) warrants advanced imaging such as chest computed tomography (CT), cardiac magnetic resonance imaging (MRI), or CT/positron emission tomography (PET) scan to further evaluate for infiltrative heart disease such as sarcoidosis. Advanced imaging may also be warranted based on other factors in the history and testing that suggest the need for evaluation of infiltrative heart disease. Evaluation for cardiac ischemia should be driven by the clinical suspicion at presentation (e.g., symptoms of ischemia, ECG abnormalities, etc.) **(Fig. 252-3)**.

Diagnostic testing in the evaluation of AV block is aimed at determining the level of conduction block, particularly in asymptomatic patients, since the prognosis and therapy depend on whether the block is in or below the AV node. Vagal maneuvers, carotid sinus massage, exercise, and administration of drugs such as atropine and isoproterenol may be diagnostically informative. Owing to the differences in the innervation of the AV node and infranodal conduction system, vagal stimulation and carotid sinus massage slow conduction in the AV node but have less of an effect on infranodal tissue and may even appear to improve conduction due to a reduced rate of activation of distal tissues. Conversely, atropine, isoproterenol, and exercise improve conduction through the AV node and may appear to impair infranodal conduction. In patients with congenital CHB and a narrow QRS complex, exercise typically increases heart rate; by contrast, those with acquired CHB, particularly with wide QRS, do not respond to exercise with an increase in heart rate.

Additional diagnostic evaluation, including electrophysiologic testing, may be indicated in patients with syncope and suspected high-grade AV block. This is particularly relevant if noninvasive testing does not reveal the cause of syncope or if the patient has structural heart disease with ventricular tachyarrhythmias as a cause of symptoms. Electrophysiologic testing provides more precise information regarding the location of AV conduction block and permits studies of AV conduction under conditions of pharmacologic stress and exercise. Recording of the His bundle electrogram by a catheter positioned at the superior margin of the tricuspid valve annulus provides information about conduction at all levels of the AV conduction axis. A properly recorded His bundle electrogram reveals local atrial activity, the His electrogram, and local ventricular activation; when it is monitored simultaneously with recorded body surface ECG traces, intra-atrial, AV nodal, and infranodal conduction times can be assessed. The time from the most rapid deflection of the atrial electrogram in the His bundle recording to the His electrogram (*AH interval*) represents conduction through the AV node and is normally <130 ms. The time from the His electrogram to the earliest onset of the QRS on the surface ECG (*HV interval*) represents the conduction time through the His-Purkinje system and is normally ≤55 ms **(Fig. 252-4)**.

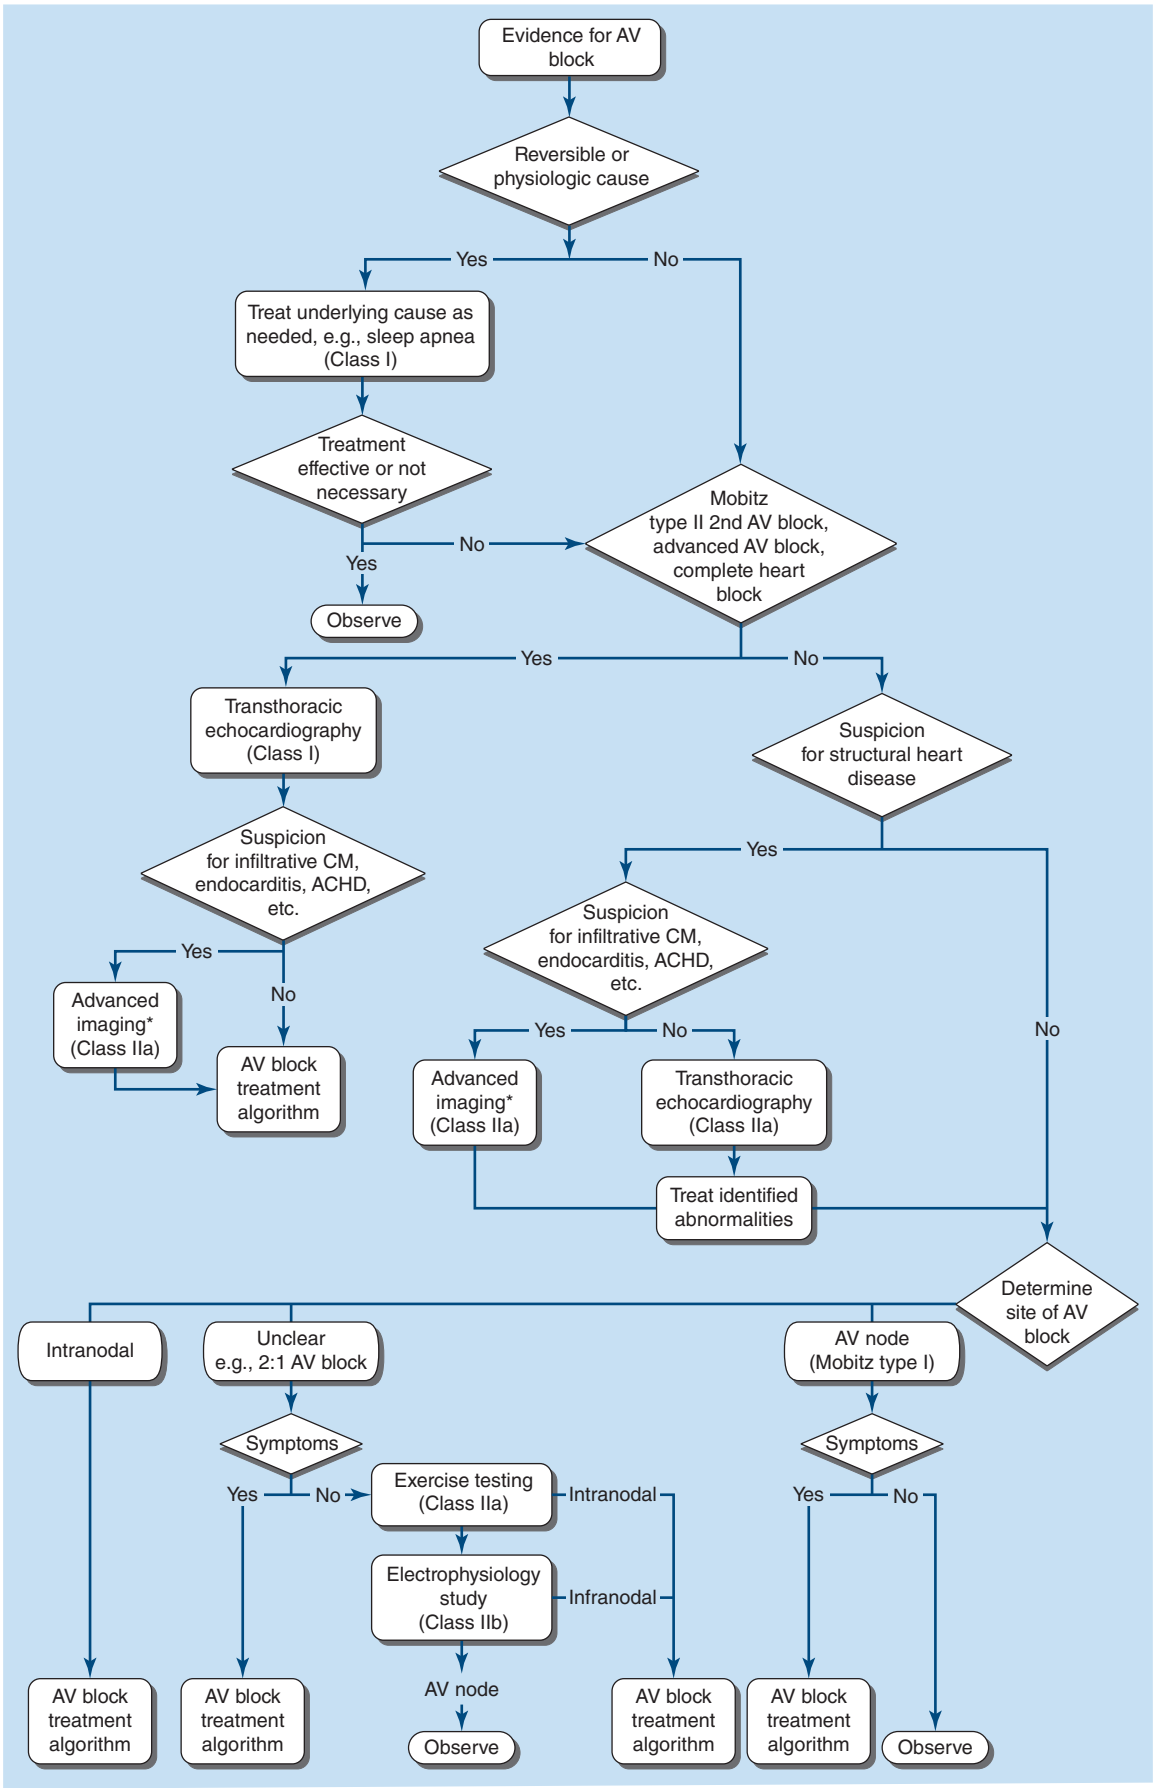

FIGURE 252-3 Initial evaluation of suspected atrioventricular (AV) block algorithm. *Targeted advanced imaging—magnetic resonance imaging (MRI): amyloidosis, myocarditis, hemochromatosis, sarcoidosis, congenital heart disease (CHD), sinus of Valsalva aneurysm, aortic dissection, arrhythmogenic right ventricular cardiomyopathy; fluorodeoxyglucose-positron emission tomography (FDG-PET): sarcoidosis; technetium-99m pyrophosphate (Tc PYP) or 99m technetium 3,3-diphosphono-1,2-propanodicarboxylic acid (TC-DPD): transthyretin (TTR) amyloidosis; cardiac computed tomography (CT): CHD, sinus of Valsalva. ACHD, adult CHD; CM, cardiomyopathy. *(Reproduced with permission from FM Kusumoto et al: 2018 ACC/AHA/HRS guideline on the evaluation and management of patients with bradycardia and cardiac conduction delay. Heart Rhythm 16:e128, 2019.)*

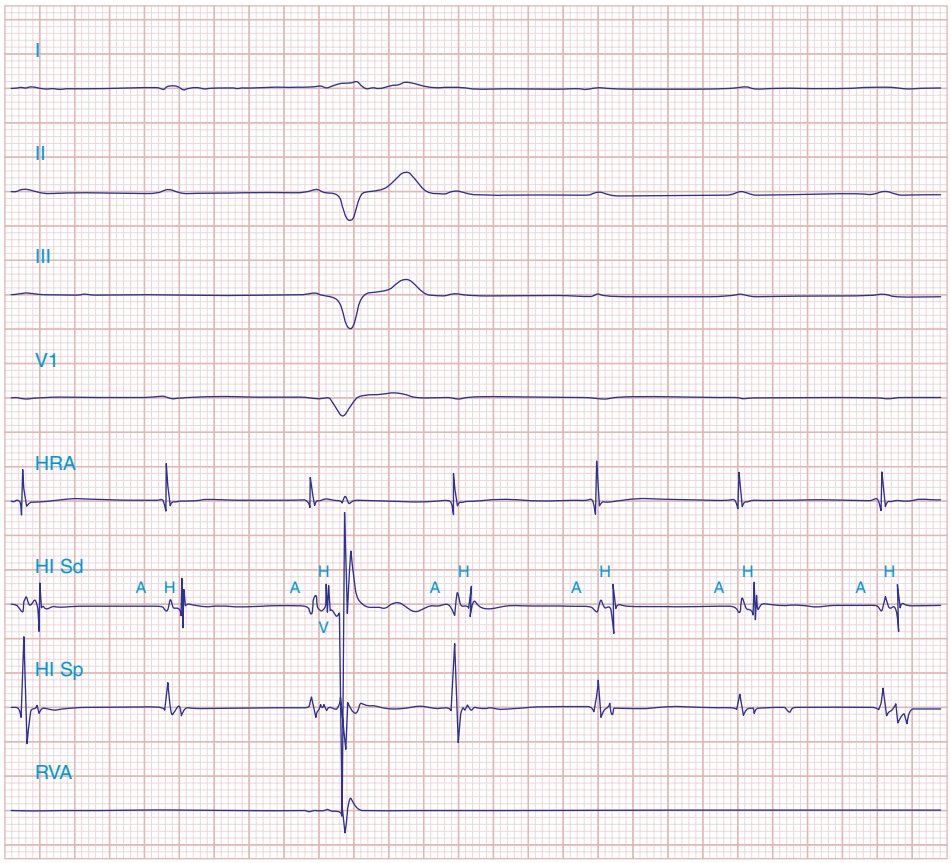

FIGURE 252-4 High-grade atrioventricular (AV) block below the His. The AH interval is normal and is not changing before the block. Atrial and His bundle electrograms are recorded consistent with block below the distal AV junction. I, II, III, and V_1 are surface electrocardiogram leads. HISp, HISd, and RVA are the proximal HIS, distal HIS, and right ventricular apical electrical recordings, respectively. A, H, and V represent the atrial, His, and ventricular electrograms on the His bundle recording, respectively. *(Courtesy of Dr. Joseph Marine.)*

Rate stress produced by pacing can unmask abnormal AV conduction. Mobitz I second-degree AV block at short atrial paced cycle lengths is a normal response. However, when it occurs at atrial cycle lengths >500 ms (<120 beats/min) in the absence of high vagal tone, it is abnormal. Typically, type I second-degree AV block is associated with prolongation of the AH interval, representing conduction slowing and block in the AV node. AH prolongation occasionally is due to the effect of drugs (beta blockers, calcium channel blockers, digitalis) or increased vagal tone. Atropine can be used to reverse high vagal tone; however, if AH prolongation and AV block at long pacing cycle lengths persist, intrinsic AV node disease is likely. Type II second-degree block is typically infranodal, often in the His-Purkinje system. Block below the node with prolongation of the HV interval or a His bundle electrogram with no ventricular activation is abnormal unless it is elicited at fast pacing rates or short coupling intervals with extra stimulation. It is often difficult to determine the type of second-degree AV block when 2:1 conduction is present; however, the finding of a His bundle electrogram after every atrial electrogram indicates that block is occurring in the distal conduction system.

Intracardiac recording at an electrophysiologic study that reveals prolongation of conduction through the His-Purkinje system (i.e., long HV interval) is associated with an increased risk of progression to higher grades of block and is generally an indication for pacing. In the setting of bundle branch block, the HV interval may reveal the condition of the unblocked bundle and the prognosis for developing more advanced AV conduction block. Prolongation of the HV interval in patients with asymptomatic bundle branch block is associated with an increased risk of developing higher-grade AV block. The risk increases with greater prolongation of the HV interval such that in patients with an HV interval >100 ms, the annual incidence of complete AV block approaches 10%, indicating a need for pacing. In patients with acquired CHB, even if intermittent, there is little role for electrophysiologic testing, and pacemaker implantation is almost always indicated.

TREATMENT

Acute Management of AV Conduction Block

The first-line strategies for management of AV block should be to eliminate reversible causes and to determine the immediate safety and reliability of the heart rhythm (e.g., escape rhythm) and whether or not temporary or permanent pacing is warranted. The need for temporary pacing is determined by the symptoms of the patient, hemodynamic status, and the estimate of the level at which AV block is present. In a general sense, the lower in the conduction system that an escape rhythm is occurring, the lower is the reliability of the escape rhythm. A narrow-complex junctional escape of 45 beats/min with no symptoms does not warrant urgent temporary pacing, whereas a wide-complex (implying block lower in the conduction system) escape rhythm at 30 beats/min does. Elimination of unnecessary medications known to slow AV conduction (e.g., beta blockers, diltiazem, verapamil, digoxin), correction of electrolyte abnormalities, ischemia, and inhibition of excessive vagal tone may increase the heart rate. Adjunctive pharmacologic treatment with atropine or isoproterenol may be useful if the block is in the AV node. When pacing is indicated, the most expeditious technique is the use of transcutaneous pacing, where pacing patches are placed anteriorly over the cardiac apex (cathode) and posteriorly between the spine and the scapula or above the right nipple (anode). Acutely, transcutaneous pacing is highly effective, but its duration is limited by patient discomfort and longer-term failure to capture the ventricle owing to changes in lead impedance. Transvenous temporary pacing is more reliable, and a pacing wire can be placed from the jugular, subclavian, or femoral venous system and advanced to the right ventricle, permitting stable temporary pacing.

AV conduction abnormalities may be reversible in certain circumstances including removal of unnecessary medication or toxins,

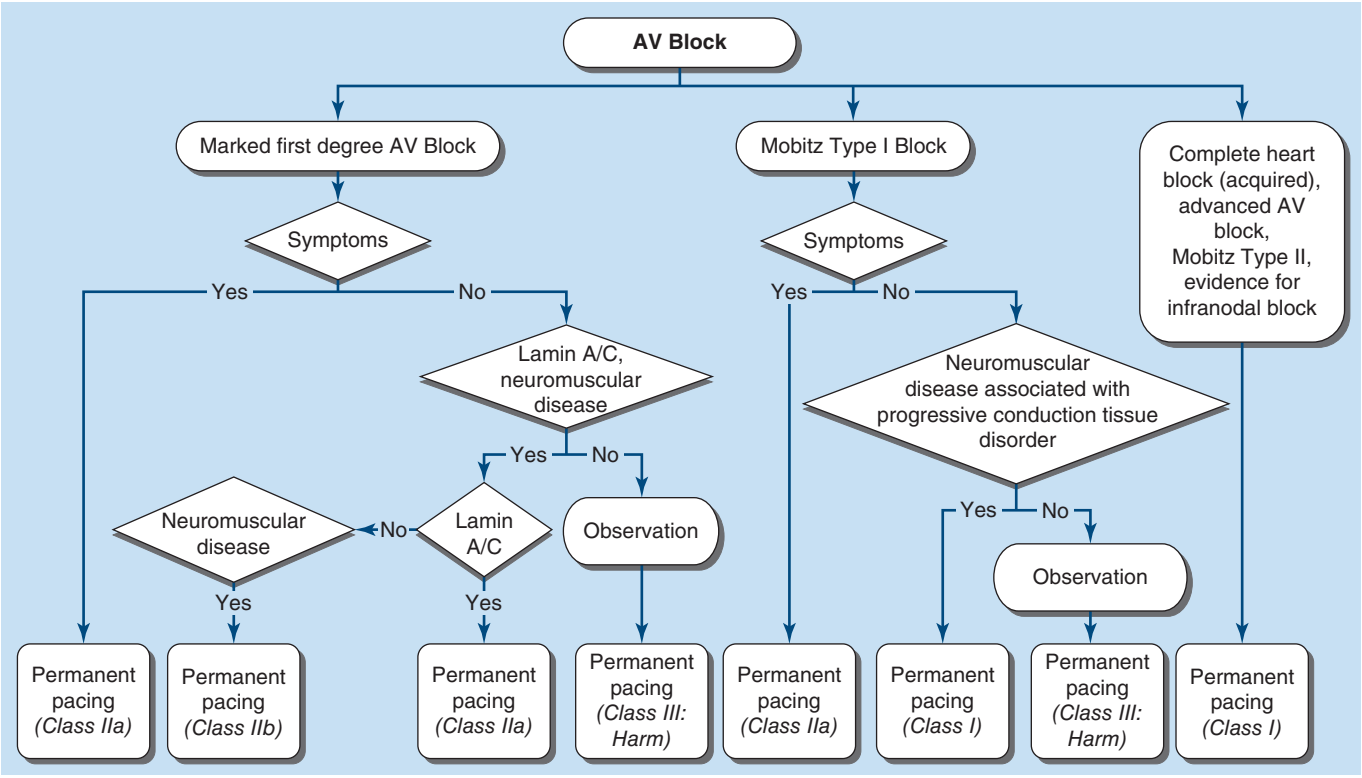

FIGURE 252-5 Indications for pacing in patients with atrioventricular (AV) block. In patients presenting with AV block, the category of AV block should be determined (first-degree, second-degree, or complete heart block). In first-degree AV block, permanent pacing may be indicated in the setting of symptoms or higher-risk systemic disease such as neuromuscular disease or Lamin A/C cardiomyopathy. In Mobitz I AV block, pacing may be considered in the setting of symptoms or the additional disease mentioned with first-degree AV block. In complete heart block or Mobitz II AV block, permanent pacing is generally indicated. Class I recommendations should be performed or are indicated. Class IIa recommendations are considered reasonable to perform. Class IIb recommendations may be considered. Class III recommendations are associated with harm more than benefit. *(Reproduced with permission from FM Kusumoto et al: 2018 ACC/AHA/HRS guideline on the evaluation and management of patients with bradycardia and cardiac conduction delay. Heart Rhythm 16:e128, 2019.)*

correction of electrolyte abnormalities, relief of ischemia, treatment of certain infiltrative heart disease (e.g., immunosuppression in cardiac sarcoidosis), and treatment of sleep apnea in patients with nocturnal vagally mediated AV block. When symptomatic or infranodal AV block is not reversible, which is often the case, permanent pacing is warranted.

PERMANENT PACEMAKER IMPLANTATION

The indications for pacing in AV conduction block are shown in **Fig. 252-5**. In patients with acquired Mobitz type II AV block, high-grade AV block, or third-degree AV block that is not reversible or physiologic, permanent pacing is recommended regardless of symptoms. For all other types of AV block, in the absence of conditions associated with progressive AV conduction abnormalities, permanent pacing should generally be considered only in the presence of symptoms that correlate with block. In patients with neuromuscular disease and other progressive cardiomyopathies affecting the conduction system, permanent pacemaker implantation is recommended for marked first-degree AV block and Mobitz I AV block. Pacemaker implantation should be performed in any patient with symptomatic bradycardia and irreversible second- or third-degree AV block, regardless of the cause or level of block in the conducting system. Symptoms may include those directly related to bradycardia and low cardiac output or to worsening heart failure, angina, or intolerance to an essential medication. Pacing in patients with asymptomatic AV block should be individualized; situations in which pacing should be considered are patients with acquired CHB, particularly in the setting of cardiac enlargement; left ventricular dysfunction; and waking heart rates ≤40 beats/min. Patients who have asymptomatic second-degree AV block of either type should be considered for pacing if the block is demonstrated to be intra- or infra-His or is associated with a wide QRS complex. Pacing may be indicated in asymptomatic patients in special circumstances, in patients with profound first-degree AV block and left ventricular dysfunction in whom a shorter AV interval produces hemodynamic improvement, and in the setting of milder forms of AV conduction delay (first-degree AV block, intraventricular conduction delay) in patients with neuromuscular diseases that have a predilection for the conduction system, such as myotonic dystrophy and other muscular dystrophies and Kearns-Sayre syndrome.

AV block in acute MI is often transient, particularly in inferior infarction. The circumstances in which pacing is indicated in acute MI are persistent second- or third-degree AV block, particularly if symptomatic, and transient second- or third-degree AV block associated with bundle branch block. Pacing is generally not indicated in the setting of transient AV block in the absence of intraventricular conduction delays or in the presence of fascicular block or first-degree AV block that develops in the setting of preexisting bundle branch block. Fascicular blocks that develop in acute MI in the absence of other forms of AV block also do not require pacing.

Distal forms of AV conduction block may require pacemaker implantation in certain clinical settings. Patients with bifascicular or trifascicular block and symptoms, particularly syncope that is not attributable to other causes, should undergo pacemaker implantation. Permanent pacemaker implantation is indicated in asymptomatic patients with bifascicular or trifascicular block who experience intermittent third-degree block, type II second-degree AV block, or alternating bundle branch block. In patients with fascicular block who are undergoing electrophysiologic study, a markedly prolonged HV interval or block below the His at long cycle lengths also may constitute an indication for permanent pacing. Patients with fascicular block and the neuromuscular diseases previously described should also undergo pacemaker implantation.

SELECTION OF PACING MODE AND SYSTEM

In general, a pacing mode that maintains AV synchrony reduces complications of pacing such as pacemaker syndrome and pacemaker-mediated tachycardia. This is particularly true in younger patients; the importance of dual-chamber pacing in the elderly, however, is

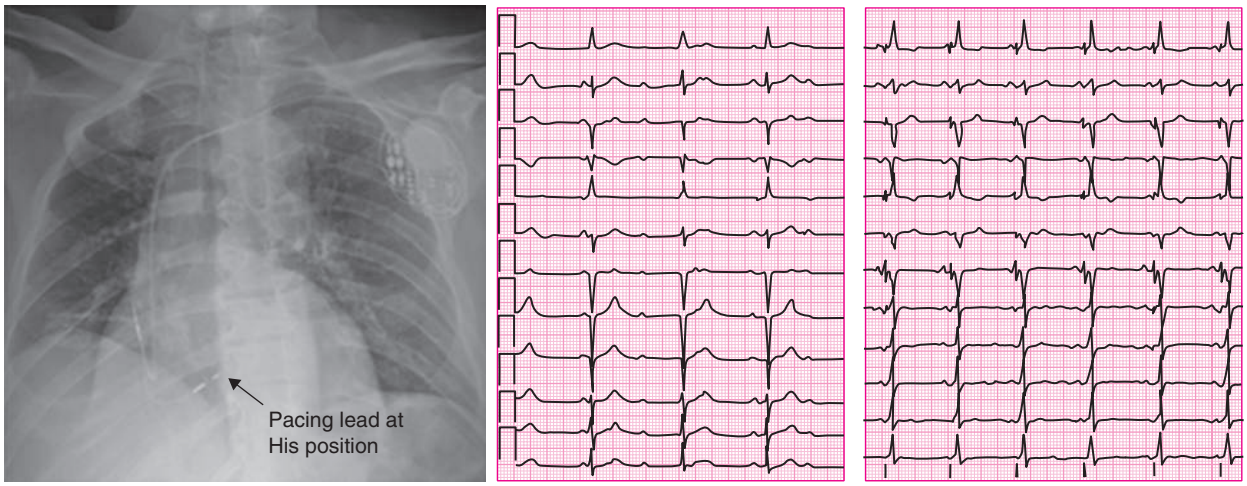

FIGURE 252-6 Left bundle branch area pacing. The chest radiograph on the left shows a dual-chamber pacemaker with a pacing lead in the right atrium (*upper left*) and a pacing lead in the region of proximal ventricular septum to achieve physiologic pacing by pacing deep enough in the septum to achieve left bundle branch area pacing. The electrocardiograms demonstrated intrinsic conduction with complete heart block on the left and atrial sensed, ventricular paced rhythm with a narrow QRS complex by capturing the specialized conduction system of the heart.

less well established, although AV synchrony in patients with sinus rhythm and AV block is typically desired.

Physiologic Ventricular Pacing In patients with left ventricular ejection fraction <50% and AV block who have an indication for permanent pacing and are expected to require ventricular pacing >40% of the time, techniques to provide more physiologic ventricular activation are preferred to right ventricular pacing to prevent heart failure. Cardiac resynchronization therapy (CRT) involves placement of an additional pacing lead in a lateral or anterolateral branch of the coronary sinus to allow for simultaneous right ventricle and lateral left ventricle pacing leading to a more physiologic left ventricular contraction. CRT pacing has been shown to improve outcomes and mortality in appropriately selected patients. Physiologic ventricular pacing has also been achieved with placement of a ventricular pacing lead in the region of the His bundle. His bundle pacing recruits the specialized conduction system, leading to a more physiologic cardiac contraction. In addition to His bundle pacing, left bundle branch area pacing in the proximal interventricular septal region has also been shown to achieve a more physiologic pacing response. The selection of pacing lead location should be individualized based on expected pacing requirements, underlying heart disease, and level of conduction block **(Fig. 252-6)**.

The availability of leadless miniaturized pacing systems may be appropriate in selected patients. Leadless pacemakers are completely self-contained devices that are implanted via the femoral vein into the right atrium and ventricle. The technology for these devices continues to evolve, and the most recent models are capable of detecting atrial mechanical contraction to allow for the preservation of AV synchrony. The device can provide single- or dual-chamber pacing in addition to containing technology that can sense atrial activity (utilizing the accelerometer in the pacemaker) to coordinate an atrial sensed, ventricular paced rhythm. Leadless pacemakers can be particularly useful in patients with vascular access limitations. Because there is no intravascular pacing wire or implanted subcutaneous pacemaker generator, the long-term infection rate is lower and there is no risk of lead fracture **(Fig. 252-7)**.

Several studies have failed to demonstrate a difference in mortality rate in older patients with AV block treated with a single- (VVI) compared with a dual- (DDD) chamber pacing mode. In some of the studies that randomized pacing mode, the risk of chronic atrial fibrillation and stroke risk decreased with physiologic pacing. In patients with sinus rhythm and AV block, the very modest increase in risk with dual-chamber pacemaker implantation appears to be justified to avoid the possible complications of single-chamber pacing.

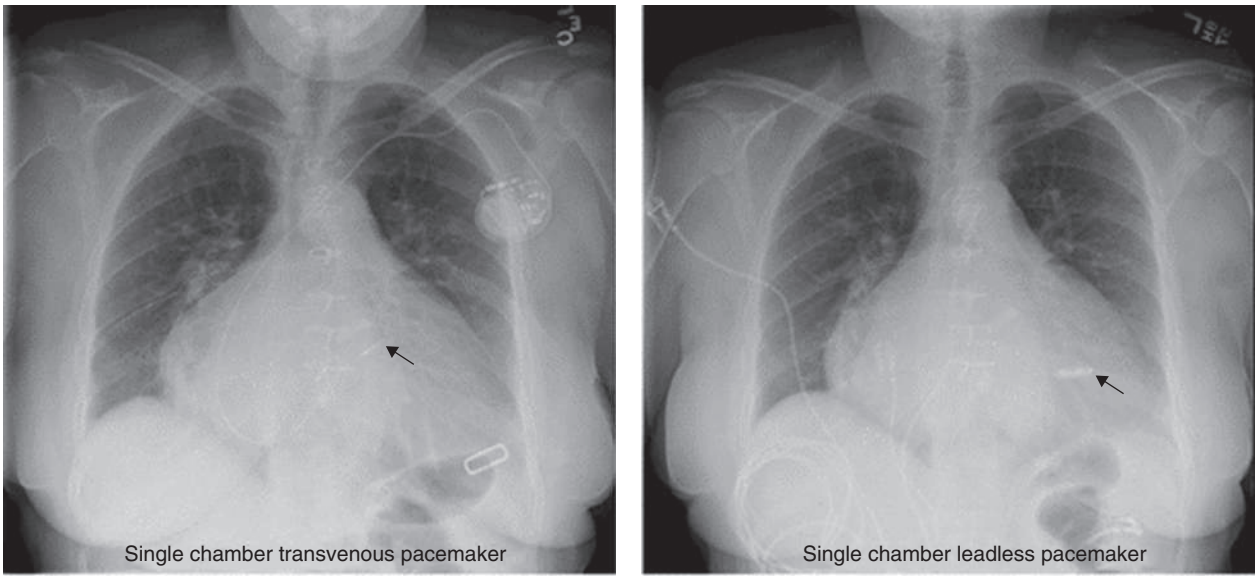

FIGURE 252-7 Types of pacemakers. A single-chamber pacemaker with the pacing lead in the right ventricular outflow tract (*arrow*) is shown on the left. A single-chamber leadless pacemaker (*arrow*) is shown on the right.

253 Approach to Supraventricular Arrhythmias

William H. Sauer, Paul C. Zei

Supraventricular arrhythmias refer to all abnormal heart rhythms originating above the level of the ventricle including the atria and the atrioventricular (AV) junction. Supraventricular arrhythmias include premature atrial contractions (PACs), wandering atrial pacemaker, sinus arrhythmia, nonphysiologic sinus tachycardia, atrial tachycardia, junctional tachycardia, atrial flutter, and atrial fibrillation. Supraventricular arrhythmias that result in an elevated heart rate (>100 beats/min) are broadly defined as *supraventricular tachycardias* (SVTs). SVTs originate from or are dependent on conduction through the atrium or AV node to the ventricles. Most produce narrow QRS complex tachycardia (QRS duration <120 ms) characteristic of ventricular activation over the Purkinje system and, thus, are sometimes referred to as a narrow-complex tachycardias. The QRS morphology of the SVT is usually identical to the sinus rhythm QRS. Conduction block in the left or right bundle branch or activation of the ventricles from an accessory pathway produces a wide QRS complex during SVT that must be distinguished from ventricular tachycardia (VT). Mechanisms of supraventricular tachyarrhythmia can be divided into physiologic sinus tachycardia and pathologic tachycardia **(Table 253-1)**.

Pathologic tachycardia can be further subclassified by mechanism as reentrant arrhythmias dependent on AV nodal conduction (e.g., AV nodal reentry tachycardia), large reentry circuits within the atrial tissue alone (e.g., atrial flutter), or focal atrial tachycardias that can be due to automaticity or small reentry circuits. The prognosis and treatment vary considerably depending on the mechanism and underlying heart disease. SVT can be of brief duration, termed *nonsustained*, or can be sustained such that an intervention, such as cardioversion, catheter ablation, or drug administration, is required for termination and maintenance of sinus rhythm. Episodes that occur with sudden onset and termination are referred to as paroxysmal. *Paroxysmal supraventricular tachycardia* (PSVT) refers to a family of tachycardias including AV node reentry, AV reciprocating tachycardia using an accessory pathway, and atrial tachycardia described in subsequent chapters **(Fig. 253-1)**.

Other supraventricular arrhythmias that may or may not be symptomatic include PACs, sinus arrhythmia, ectopic atrial rhythm, and accelerated junctional rhythm. Atrial flutter and atrial fibrillation may present as a tachycardia or may be adequately rate controlled with or without AV nodal blocking agents; these entities are discussed separately **(see Chaps. 255, 256, 257, and 258)**.

TABLE 253-1 Mechanisms of Supraventricular Arrhythmias

Physiologic Sinus Tachycardia

Defining feature: normal sinus mechanism precipitated by exertion, stress, exogenous or endogenous stimulants, concurrent illness

Pathologic Supraventricular Tachycardia (SVT)

A. Tachycardias originating from the atrium

Defining feature: tachycardia may continue despite beats that fail to conduct to the ventricles, indicating that the atrioventricular (AV) node is not participating in the tachycardia circuit

1. Inappropriate sinus tachycardia

Defining feature: tachycardia from the normal sinus node area that occurs without an identifiable precipitating factor as a result of dysfunctional autonomic regulation

2. Focal atrial tachycardia (AT)

Defining feature: regular atrial tachycardia with defined P wave; may be sustained, nonsustained, paroxysmal, or incessant; frequent sites of origin occur along the valve annuli of left or right atrium, pulmonary veins, coronary sinus musculature, superior vena cava

3. Atrial flutter and macroreentrant atrial tachycardia

Defining feature: macroreentry reflected as organized atrial activity on an electrocardiogram (ECG), commonly seen as sawtooth flutter waves at rates typically faster than 200 beats/min

4. Atrial fibrillation

Defining feature: chaotic rapid atrial electrical activity with variable ventricular rate; the most common sustained cardiac arrhythmia in older adults

5. Multifocal atrial tachycardia

Defining feature: multiple discrete P waves often seen in patients with pulmonary disease during acute exacerbations of pulmonary insufficiency

B. AV nodal reentry tachycardia (AVNRT)

Defining feature: paroxysmal regular tachycardia with P waves visible at the end of the QRS complex or not visible at all; the most common paroxysmal sustained tachycardia in healthy young adults; more common in women

C. Tachycardias associated with accessory atrioventricular pathways

1. Orthodromic AV reciprocating tachycardia (AVRT)

Defining feature: paroxysmal sustained tachycardia similar to AV nodal reentry; during sinus rhythm, evidence of ventricular preexcitation may be present (Wolff-Parkinson-White syndrome) or absent (concealed accessory pathway)

2. Preexcited tachycardia

Defining feature: wide QRS tachycardia with QRS morphology similar to ventricular tachycardia

a. Antidromic AV reciprocating tachycardia—regular paroxysmal tachycardia

b. Atrial fibrillation with preexcitation—irregular wide-complex or intermittently wide-complex tachycardia, some with dangerously rapid rates faster than 250/min

c. Atrial tachycardia or flutter with preexcitation

Other Supraventricular Arrhythmias

A. Premature atrial contractions (PACs)

Defining feature: sinus rhythm with an early atrial complex distinct from the sinus P wave resulting in an irregular rhythm. A pattern of ectopy (i.e., trigeminy, bigeminy) is sometimes seen with PACs

B. Sinus arrhythmia

Defining feature: irregular rhythm with a sinus P wave and with P-P intervals varying with respiration

C. Accelerated junctional rhythm

Defining feature: paroxysmal regular rhythm with P waves visible at the end of the QRS complex or not visible at all

D. Ectopic atrial rhythm

Defining feature: regular rhythm with a rate <100 beats/min but usually faster than sinus rhythm and with a P wave distinct from sinus that may or may not sustain

CLINICAL PRESENTATION

Symptoms of supraventricular arrhythmia vary depending on the rate, duration, associated heart disease, and comorbidities and include palpitations, chest pain, dyspnea, diminished exertional capacity, and occasionally syncope. Rarely, a supraventricular arrhythmia precipitates cardiac arrest in patients with Wolff-Parkinson-White (WPW) syndrome or severe heart disease, such as hypertrophic cardiomyopathy. Asymptomatic supraventricular arrhythmias are often captured on routine electrocardiographic (ECG) recordings and sometimes prompt

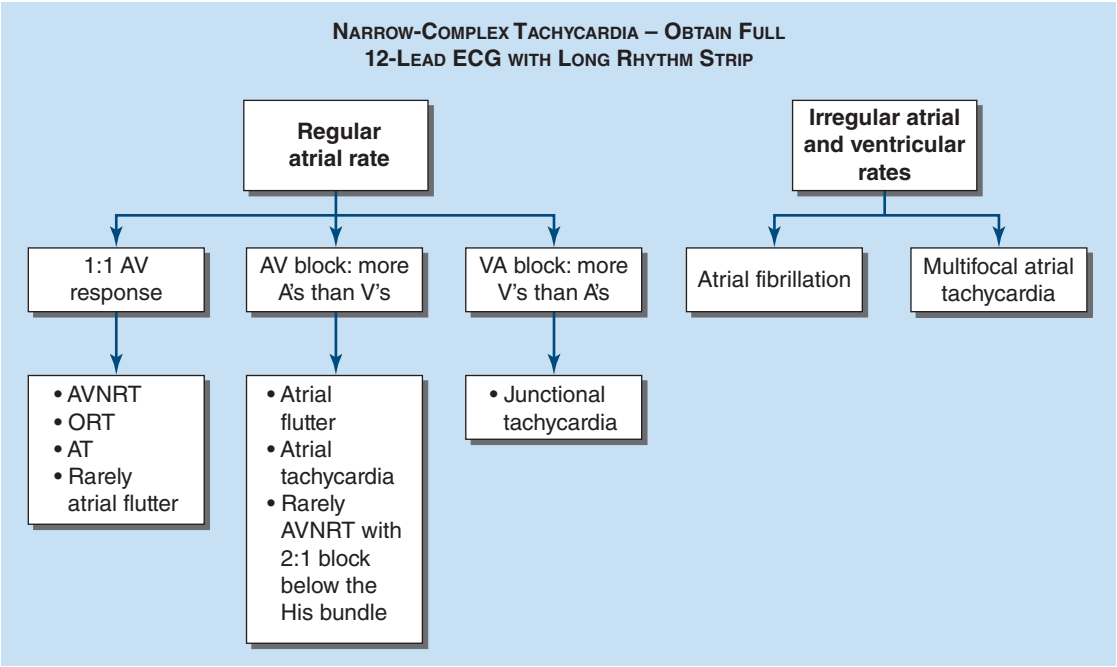

FIGURE 253-1 Diagnostic possibilities based on the appearance of the 12-lead electrocardiogram (ECG) recorded during an episode of supraventricular tachycardia (SVT). AT, focal atrial tachycardia; AVNRT, atrioventricular (AV) nodal reentry tachycardia; ORT, orthodromic AV reentry tachycardia.

referral to a cardiologist. Most asymptomatic supraventricular arrhythmias do not require treatment or further evaluation.

INITIAL EVALUATION

The diagnosis of SVT is most often entertained when evaluating a patient for arrhythmia-related symptoms or when evidence of ventricular preexcitation is seen on an ECG as an outpatient. Diagnosis of SVT requires obtaining an ECG at the time of symptoms **(Fig. 253-2)**. Ventricular preexcitation on the resting ECG suggests AV reciprocating tachycardia using an accessory pathway. When the arrhythmia is ongoing at the time of recording, the ECG usually establishes or suggests the diagnosis. In the urgent care or inpatient setting, treatment of SVT will often involve vagal maneuvers or carotid sinus massage (CSM) to achieve AV block **(Table 253-2)**. In the appropriate patient, CSM should be used cautiously, if at all, if there is concern for carotid atherosclerosis that may be embolized during manipulation. If this is unsuccessful, the administration of 6 or 12 mg of adenosine to cause transient AV block is usually successful in terminating an AV nodal–dependent SVT or diagnosing a non-AV nodal–dependent SVT such as atrial tachycardia or atrial flutter. There are some atrial tachycardias that are adenosine sensitive, and thus, termination of an SVT with adenosine does not exclude this potential diagnosis.

For transient arrhythmias, ambulatory ECG recording is warranted. Patients will often have access to ECG recording devices, such as a watch or smartphone-enabled ECG recording electrode pair. Therefore, a patient may have an ECG diagnosis before seeing a physician **(Fig. 253-3)**.

Exercise testing is useful for assessing exercise-related symptoms and potentially evoking the arrhythmia. Additional evaluation for underlying cardiac disease and to exclude potentially dangerous arrhythmias should be performed based on the clinical scenario. Occasionally, an invasive electrophysiology study is warranted to provoke the arrhythmia with pacing, confirm the mechanism, and risk stratify the patient, but most commonly, this is performed at the time of intended catheter ablation to treat the arrhythmia.

Paroxysmal SVT is most commonly encountered in patients who do not have structural heart disease. Other supraventricular arrhythmias, particularly atrial fibrillation, are often associated with a variety of heart diseases. At initial evaluation, history and examination should assess possible underlying heart disease. Any abnormal findings may warrant further cardiac evaluation.

Heart Rate Over 120 —♥ 200 BPM Average

This ECG was not checked for AFib because your heart rate was over 120 BPM.

If you repeatedly get this result or you're not feeling well, you should talk to your doctor.

Reported Symptoms

- Rapid pounding, or fluttering heartbeat
- Chest tightness or pain
- Fainting

25 mm/s, 10 mm/mV, Lead I, 511Hz, iOS 12.1.4, watchOS 5.1.3, Watch4,2 — The waveform is similar to a Lead I ECG. For more information, see Instructions for Use.

FIGURE 253-3 Narrow-complex tachycardia recorded by a consumer wearable monitor (Apple watch). Afib, atrial fibrillation; ECG, electrocardiogram.

The most common SVT is sinus tachycardia in response to physiologic stress, such as exercise, but it can also be a manifestation of acute illness. The first step in diagnosis of SVT is to consider the possibility of sinus tachycardia. Therapy is then determined by the clinical findings and probable diagnosis. If sinus tachycardia is diagnosed, treatment of the underlying inciting cause is the primary approach. If the arrhythmia is ongoing and is not due to sinus tachycardia, initial assessment determines whether immediate therapy is needed to terminate the arrhythmia or slow the rate. Arrhythmias that cause hypotension, impaired consciousness, angina, or heart failure warrant immediate therapy, guided by the type of arrhythmia. Treatment options for specific types of SVT are discussed in more detail in subsequent chapters and include pharmacologic and procedural interventions.

254 Physiologic and Nonphysiologic Sinus Rhythm

William H. Sauer, Paul C. Zei

The sinus node is composed of a group of cells located in the lateral superior aspect of the junction between the right atrium and superior vena cava, within the superior aspect of the thick ridge of muscle known as the crista terminalis where the posterior smooth atrial wall derived from the sinus venosus meets the trabeculated anterior portion of the right atrium. Patients with sinus tachycardia will often seek medical attention with the uncomfortable awareness of their heartbeat as their chief complaint. Often, an arrhythmia is suspected because of the similar constellation of symptoms that accompanies supraventricular and ventricular tachycardia or atrial and ventricular ectopy. However, a careful review of the 12-lead electrocardiogram (ECG) reveals a characteristic P wave originating from the superior and lateral aspect of the right atrium with a positive deflection in leads I, II, and III and a biphasic morphology in lead V_1. Sinus P waves are characterized by a frontal plane axis directed inferiorly and leftward, with positive P waves in leads II, III, and aVF; a negative P wave in aVR; and an initially positive biphasic P wave in V_1. Normal sinus rhythm has a range of rates between 60 and 100 beats/min **(Fig. 254-1)**.

SINUS ARRHYTHMIA

Sinus arrhythmia is a common finding that is usually asymptomatic and related to normal physiology in healthy individuals. The rhythm is defined as arising from a sinus node origin but with irregularity between P-P intervals of >120 ms. When there is an irregularity in the heart rhythm and there are different P-wave morphologies observed, then this arrhythmia is most likely due to premature atrial contractions (PACs) and not sinus arrhythmia. Sinus arrhythmia usually occurs at rest and is often eliminated with higher rates observed with exertion due to removal of vagal tone. The three types of sinus arrhythmias observed are respirophasic, ventriculophasic, and nonphasic. Respirophasic sinus arrhythmia occurs when vagal tone is inhibited reflexively during inspiration and is restored with expiration. A similar phenomenon is seen with breath-holding leading to exaggerated pauses most often seen with obstructive sleep apnea. Ventriculophasic sinus arrhythmia is most often observed with heart block or after a premature ventricular contraction (PVC). The P-P interval is shortened when there is an interposed ventricular complex seen in these conditions possibly related to the triggered baroreceptor reflex from the subsequent beat after a longer ventricular filling time and increased stroke volume. Nonphasic sinus arrhythmia refers to variations in sinus P-P intervals unrelated to the cardiac or respiratory cycle. Regardless of the mechanism, asymptomatic sinus arrhythmia does not warrant further cardiac evaluation and is not considered pathogenic.

AVN, atrioventricular node; CS Os, coronary sinus ostium; FO, fossa ovalis; IVC, inferior vena cava; TVA, tricuspid valve annulus.

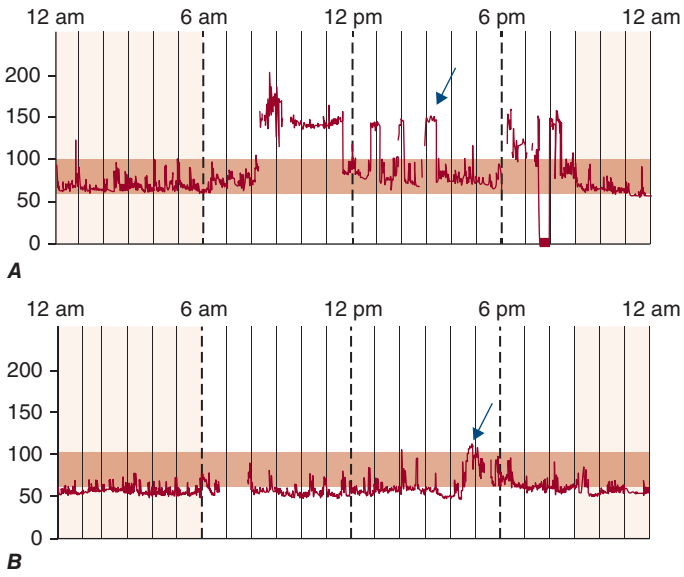

FIGURE 254-2 Outpatient telemetry monitor in a patient with intermittent atrial tachycardia (***A***) and normal physiologic sinus tachycardia (***B***).

PHYSIOLOGIC SINUS TACHYCARDIA

Sinus tachycardia (>100 beats/min) typically occurs in response to sympathetic stimulation and/or vagal withdrawal, whereby the rate of spontaneous depolarization of the sinus node increases and the focus of earliest activation within the node typically shifts more leftward and closer to the superior septal aspect of the crista terminalis, thus producing taller P waves in the inferior limb leads when compared to normal sinus rhythm. Sinus bradycardia is defined as rates <60 beats/min; however, bradycardia can be normal during sleep and in fit individuals.

Sinus tachycardia is considered physiologic when it is an appropriate response to exercise, stress, or illness. Sinus tachycardia can be difficult to distinguish from focal atrial tachycardia (see below) that originates near the sinus node. A causative factor (e.g., exertion) and a gradual rate increase favor a diagnosis of sinus tachycardia, whereas abrupt tachycardia onset and offset favor atrial tachycardia **(Fig. 254-2)**.

The distinction can be difficult and occasionally requires extended ECG monitoring or invasive electrophysiology study. Treatment for physiologic sinus tachycardia is aimed at the underlying condition, but frequently, no therapy is necessary. Consideration to abnormal thyroid conditions and anemia should be given in patients with sinus tachycardia as these represent reversible causes. In addition, structural and functional cardiovascular abnormalities can present as sinus tachycardia, especially pulmonary embolism, and thus must be ruled out in the appropriate clinical scenario before considering sinus tachycardia as nonphysiologic. Finally, as sinus rate varies widely between individuals, a relatively elevated sinus rate (whether at rest or during exercise) without underlying cause, particularly without symptoms, typically does not warrant treatment **(Table 254-1)**.

TABLE 254-1 Common Causes of Sinus Tachycardia

Physiologic Causes
Emotion, physical exercise, sexual intercourse, pain, pregnancy
Pathologic Causes
Anxiety, panic attack, anemia, fever, dehydration, infection, malignancies, hyperthyroidism, hypoglycemia, pheochromocytoma, Cushing's disease, diabetes mellitus with evidence of autonomic dysfunction, pulmonary embolus, myocardial infarction, pericarditis, valve disease, decompensated heart failure, shock, alcohol withdrawal
Drugs
Epinephrine, norepinephrine, dopamine, dobutamine, atropine, β_2-adrenergic receptor agonists (salbutamol), methylxanthines, doxorubicin, daunorubicin, beta blocker withdrawal, caffeine, alcohol
Illicit Drugs
Amphetamines, cocaine, lysergic acid diethylamide, psilocybin, ecstasy, cocaine

NONPHYSIOLOGIC SINUS TACHYCARDIA

Inappropriate sinus tachycardia is an uncommon condition in which the sinus rate increases spontaneously at rest or out of proportion to physiologic stress or exertion and is within a spectrum of ill-defined conditions associated with autonomic dysregulation. The underlying mechanism remains elusive, but it may be related to imbalance between sympathetic and parasympathetic inputs to the sinus node, altered membrane automaticity of sinus node cells, or a combination of both. Affected individuals are often women in the third or fourth decade of life. Fatigue, dizziness, and even syncope may accompany palpitations, which can be disabling. Additional symptoms of chest pain, headaches, and gastrointestinal upset are common. Inappropriate sinus tachycardia must be distinguished from appropriate sinus tachycardia and from focal atrial tachycardia arising from a region near the sinus node. The distinction between physiologic sinus tachycardia due to an anxiety disorder and inappropriate sinus tachycardia can be difficult. Therapy is often ineffective or poorly tolerated. Careful titration of beta blockers may reduce symptoms. Clonidine and serotonin reuptake inhibitors have also been used. Ivabradine, a drug that blocks the I_f current that causes spontaneous sinus node depolarization, is approved in the United States for use in heart failure but has also been effective in the treatment of inappropriate sinus tachycardia. Catheter ablation of the sinus node to modify and thereby decrease the sinus rate has been performed, but long-term control of symptoms is usually poor and can result in a permanent pacemaker requirement due to resultant symptomatic sinus bradycardia or arrest, or chronotropic incompetence **(Fig. 254-3)**.

Postural orthostatic tachycardia syndrome (POTS) is characterized by symptomatic sinus tachycardia that occurs with postural change from a supine position to standing. The sinus rate increases by 30 beats/min or to >120 beats/min within 10 min of standing and in the absence of hypotension. Symptoms are often similar to those in patients with inappropriate sinus tachycardia. POTS is sometimes due to autonomic dysfunction following a viral illness and may resolve spontaneously over 3–12 months. Prolonged postviral symptoms after COVID-19 infection, sometimes referred to as "long COVID," have been ascribed to autonomic dysfunction and a POTS-like presentation. Volume expansion with salt supplementation, oral fludrocortisone, compression stockings, and the α-agonist midodrine, often in combination, can be helpful. Exercise training has also been shown to improve symptoms

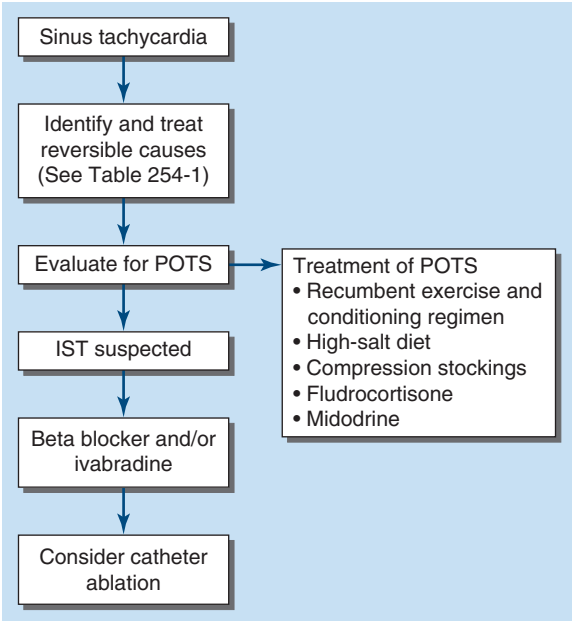

FIGURE 254-3 Evaluation and treatment of sinus tachycardia. For the patient who presents with sinus tachycardia, reversible causes of appropriate sinus tachycardia must be excluded and treated as indicated. Otherwise, evaluation for a spectrum of syndromes resulting in inappropriate sinus tachycardia should be undertaken. Potential directed therapies are shown. IST, inappropriate sinus tachycardia; POTS, postural orthostatic tachycardia syndrome.

and should be a part of a treatment strategy to reduce symptoms. While it is sometimes difficult to differentiate inappropriate sinus tachycardia from POTS, recognition of these distinct clinical syndromes is critical for treatment. Sinus node modification will be ineffective for the treatment of POTS and will possibly exacerbate the nontachycardia components of the condition. Likewise, treatment strategies aimed at increasing blood pressure will not be appropriate for inappropriate sinus tachycardia.

255 Focal Atrial Tachycardia

William H. Sauer, Paul C. Zei

The underlying mechanisms of focal atrial tachycardia (AT) include abnormal automaticity, triggered automaticity, or a small reentry circuit in diseased atrial tissue. The term *focal* is used to differentiate this form of AT from typical and atypical atrial flutter but does not define a mechanism of the arrhythmia. ATs can originate from most regions of the atria, including atrial tissue extending into a pulmonary vein, the coronary sinus, or vena cava. It can be sustained, nonsustained, paroxysmal, or incessant. Focal AT accounts for ~10% of paroxysmal supraventricular tachycardia (PSVTs) in patients referred for catheter ablation. Nonsustained focal AT is commonly observed on ambulatory electrocardiogram (ECG) recordings, and the prevalence increases with age. Asymptomatic nonsustained ATs are often labeled as "SVT" on monitor reports, prompting patients to seek advice on catheter ablation. However, treatment is not recommended for asymptomatic nonsustained AT identified on ECG monitoring. Frequent atrial ectopy and nonsustained AT are often precursors to more significant arrhythmias such as atrial fibrillation and atrial flutter. Occasionally, nonsustained, frequent atrial ectopy or short bursts of AT may be symptomatic and require therapy similar to that required for focal AT **(Fig. 255-1)**.

AT can occur in the absence of structural heart disease or may be associated with any condition that causes atrial fibrosis, including atrial tissue targeted with prior catheter ablation. Areas of fibrosis can act as a nidus for abnormal automaticity from injured but partially living cells or microreentry in zones of slow conduction within and on the border of fibrotic areas. Sympathetic stimulation is a promoting factor, and the emergence of AT can be a sign of underlying illness or drug toxicity. In particular, AT with atrioventricular (AV) block is characteristic of digitalis toxicity. Symptoms from AT are highly variable but similar to other supraventricular tachycardias (SVTs), and incessant AT can cause tachycardia-induced cardiomyopathy.

AT typically presents with 1:1 AV conduction or with AV block in a Wenckebach or fixed (e.g., 2:1 or 3:1) pattern. Because it is not dependent on AV nodal conduction, AT will not terminate with AV block, and the atrial rate will not be affected, which distinguishes AT from most AV nodal–dependent SVTs, such as AV nodal reentry and AV reentry using an accessory pathway (see below). A so-called warm-up phase when the atrial activation rate increases after initiation or a cool-down phase when the rate slows prior to termination also favors AT rather than AV nodal–dependent SVT, as this is a common observation with enhanced automaticity. P waves are often discrete, with an intervening isoelectric segment, in contrast to atrial flutter and macroreentrant AT because atrial activation from a focal source occurs through a small portion of the tachycardia cycle **(Fig. 255-2)**.

When 1:1 conduction to the ventricles is present, the arrhythmia can resemble sinus tachycardia typically with a P-R interval shorter than the R-P interval, *particularly when sympathetic tone results in rapid AV nodal conduction*. It can be distinguished from sinus tachycardia by the P-wave morphology, which usually differs from sinus P waves depending on the location of the focus. Focal AT tends to originate in areas of complex atrial anatomy, such as the crista terminalis, valve annuli, atrial septum, and atrial muscle extending along cardiac thoracic veins (superior vena cava, coronary sinus, and pulmonary veins), and the location can often be approximated by the P-wave morphology. AT from the atrial septum will frequently have a narrower P-wave duration than sinus rhythm. AT from the left atrium will usually have a monophasic, positive P wave in lead V_1 and negative P waves in I and aVL, indicating an activation wavefront away from the left atrial free wall. AT that originates from superior atrial locations, such as the superior vena cava or superior pulmonary veins, will be positive in the inferior limb leads II, III, and aVF, whereas AT from a more inferior location, such as the ostium of the coronary sinus, will inscribe negative P waves in these same leads. When the focus is in the superior aspect of the crista terminalis, close to the sinus node, however, the P wave will resemble that of sinus tachycardia. Abrupt onset and offset then favor AT rather than sinus tachycardia. Depending on the atrial rate, the P wave may fall on top of the T wave, or during 2:1 conduction,

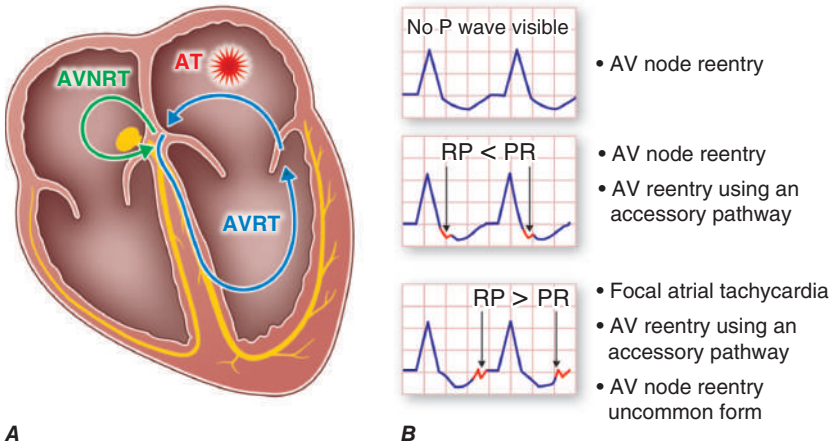

FIGURE 255-1 Common mechanisms underlying paroxysmal supraventricular tachycardia along with typical R-P relationships. *A.* Schematic showing a four-chamber view of the heart with atrioventricular (AV) node and specialized conduction tissue (His-Purkinje) in *yellow*. Atrial tachycardia (AT; *red circuit*) is confined completely to atrial tissue. Atrioventricular nodal reentry tachycardia (AVNRT; *green circuit*) uses AV nodal and perinodal atrial tissue. Atrioventricular reentry tachycardia (AVRT; *blue circuit*) uses atrial and ventricular tissue, accessory pathway between the ventricle and atrium, AV node, and His-Purkinje tissue as part of the reentry circuit. ***B.*** Typical relation of the P wave to QRS, commonly described as the R-P to P-R relationship, for the different tachycardia mechanisms.

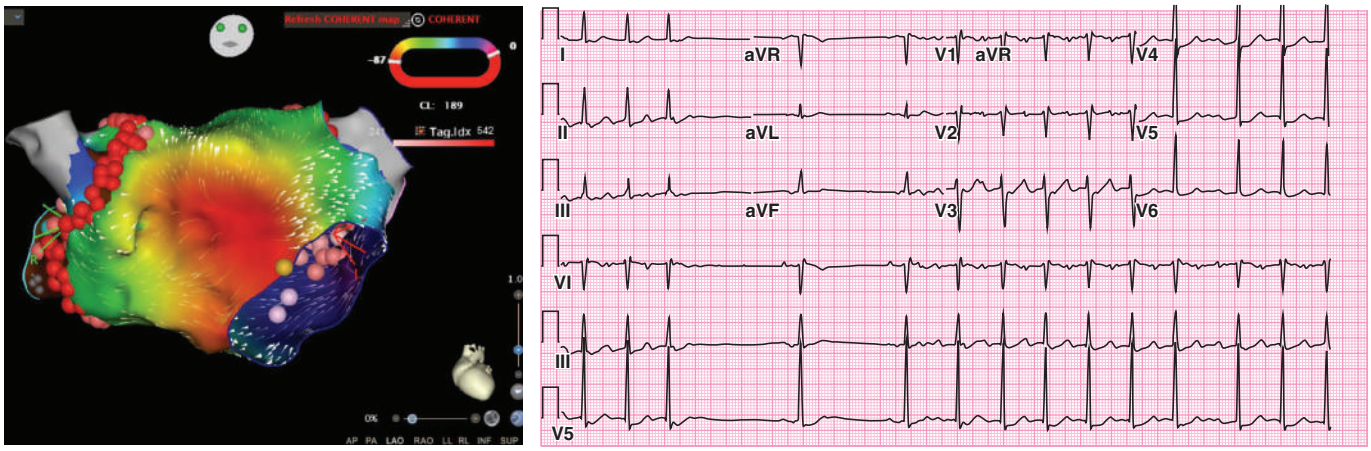

FIGURE 255-2 Focal atrial tachycardia. In the right panel, a surface 12-lead electrocardiogram shows focal intermittent atrial tachycardia. Note the discrete P waves, with isoelectric segments between, as well as the sinus rhythm. The left panel shows an electroanatomic map of the same focal atrial tachycardia originating from the anterior interatrial septum, as viewed in an anterior-posterior (AP) view of the left atrium obtained during electrophysiology study and ablation. The colors represent the timing of local electrical activation during each tachycardia atrial activation, showing a focal early (*red*) site. Additional markers of *white "flecks"* represent conduction direction, demonstrating activation of the atrium dispersing from this focal site. Of note, the *pink* and *red dots* represent ablation lesions, in this case, for pulmonary vein isolation. *(Adapted from J Brugada et al: 2019 ESC Guidelines for the management of patients with supraventricular tachycardia. The Task Force for the management of patients with supraventricular tachycardia of the European Society of Cardiology (ESC). Eur Heart J 41:655, 2020.)*

every other P wave may fall coincident with the QRS. Maneuvers that increase AV block, such as carotid sinus massage, Valsalva maneuver, or administration of AV nodal–blocking agents, such as adenosine, are useful to create AV block that will expose the P wave.

Acute management of sudden-onset, sustained AT is the same as for other forms of PSVT, but the response to pharmacologic therapy is variable, likely depending on the mechanism **(Fig. 255-3)**.

For AT due to reentry, administration of adenosine or vagal maneuvers may transiently increase AV block without terminating tachycardia. Some ATs terminate with a sufficient dose of adenosine, consistent with triggered activity as the mechanism. Cardioversion can be effective in some but fails in others because of immediate recurrence, suggesting automaticity as the mechanism in these cases. Beta blockers and calcium channel blockers may slow the ventricular rate by increasing AV block, which can improve tolerance of the arrhythmias, but large doses are sometimes required. Potential precipitating factors and intercurrent illness should be sought and corrected. Underlying heart disease should be considered and excluded.

For patients with recurrent episodes, beta blockers, calcium channel blockers such as diltiazem or verapamil, and antiarrhythmic drugs such as flecainide, propafenone, disopyramide, sotalol, and amiodarone can be effective, but potential toxicities and adverse effects often warrant avoidance of long-term use.

Catheter ablation targeting the AT focus is effective in >80% of patients and is recommended for recurrent symptomatic AT when drugs fail or are not desired or for incessant AT causing tachycardia-induced cardiomyopathy. Although AT is often a precursor to atrial fibrillation or atrial flutter, the associated risk for stroke and, hence, indications for long-term anticoagulation are unclear but not considered equivalent.

256 Paroxysmal Supraventricular Tachycardias

William H. Sauer, Paul C. Zei

In this chapter, sustained supraventricular tachycardias (SVTs) dependent on the atrioventricular (AV) node are discussed. These include AV nodal reentry tachycardia (AVNRT), junctional tachycardia, AV reciprocating tachycardia (AVRT) utilizing an accessory pathway, and a group of additional various SVTs that involve an accessory

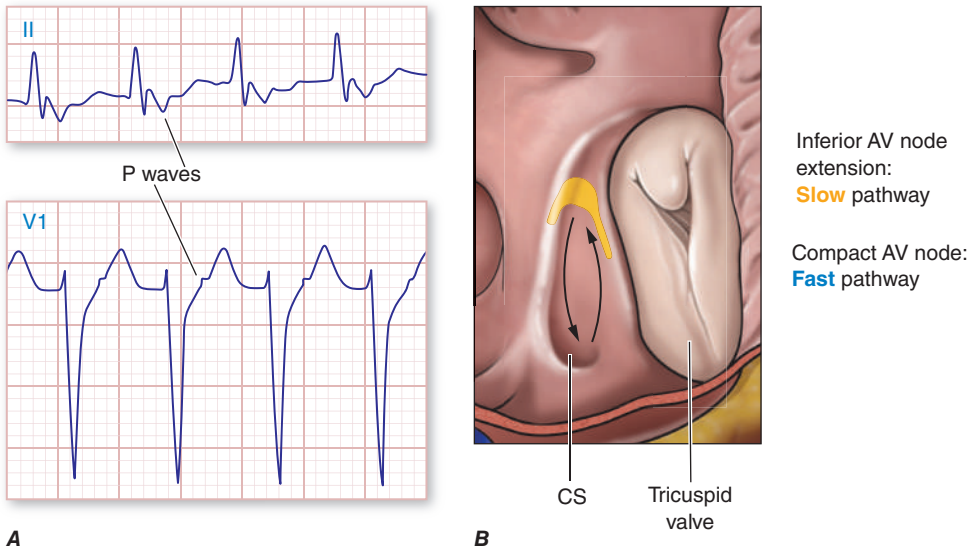

FIGURE 256-1 Atrioventricular (AV) node reentry. ***A.*** Leads II and V_1 are shown. P waves are visible at the end of the QRS complex and are negative in lead II and may give the impression of S waves in the inferior limb leads II, III, and aVF and an R′ in lead V_1. ***B.*** Stylized version of the AV nodal reentry circuit within the triangle of Koch (see **Fig. 254-1**) that involves AV node and its extensions along with perinodal atrial tissue. CS, coronary sinus.

pathway, termed *preexcited tachycardias*. The term *SVT* encompasses a broad group of tachyarrhythmias based on anatomic origin and technically includes sinus tachycardia, atrial tachycardia (AT), atrial flutter, and atrial fibrillation; however, for the purposes of describing an organized approach to diagnosis and treatment of SVT, a separate discussion for these non-AV nodal–dependent SVTs are discussed elsewhere.

ATRIOVENTRICULAR NODAL REENTRY TACHYCARDIA

AVNRT is the most common form of paroxysmal supraventricular tachycardia (PSVT), representing ~60% of cases referred for catheter ablation. It most commonly manifests in the second to fourth decades of life, more often in women. It is usually well tolerated, but rapid tachycardia, particularly in the elderly, may cause angina, pulmonary edema, hypotension, or syncope. It is not usually associated with structural heart disease. In patients without associated heart disease, AVNRT is not a life-threatening arrhythmia; however, it may cause significant symptoms.

The mechanism is reentry involving the AV node and the perinodal atrium, made possible by the existence of multiple pathways for conduction from the atrium into the AV node that are capable of conduction in two directions **(Fig. 256-1)**.

Most forms of AVNRT utilize a slowly conducting AV nodal pathway (right inferior extension) that extends from the compact AV node near the His bundle, inferiorly along the tricuspid valve annulus to the floor of the coronary sinus. The reentry wavefront propagates up this slowly conducting pathway to the compact AV node and then exits from the fast pathway at the top of the AV node. The path back to the slow pathway probably involves the left atrial septum, which has connections to the coronary sinus musculature. More unusual forms of AVNRT utilize a left inferior extension that connects to the compact AV node through the roof of the coronary sinus or, in extremely rare cases, directly from the mitral valve annulus avoiding the coronary sinus musculature altogether. In typical forms, the conduction time from the compact AV node region to the atrium is similar to that from the compact node to the His bundle and ventricles, such that atrial activation occurs at about the same time as ventricular activation. The P wave is therefore inscribed during, slightly before, or slightly after the QRS and can be difficult to discern. Often the P wave is seen at the end of the QRS complex as a pseudo-r′ in lead V_1 and pseudo-S waves in leads II, III, and aVF **(Fig. 256-2)**.

More unusual forms of AVNRT have P waves falling later, anywhere between QRS complexes, in which case, an inverted P wave is seen in the inferior limb leads with the inverted P wave seen in the subsequent T wave. The rate can vary with sympathetic tone through its effect on the conduction time of AV nodal tissues. Simultaneous atrial and ventricular contraction results in atrial contraction against a closed tricuspid valve, producing a cannon A wave visible in the jugular venous pulse often perceived as a fluttering sensation in the neck. Elevated venous pressures may also lead to release of natriuretic peptides that cause post-tachycardia diuresis. In contrast to ATs, maneuvers or medications that produce AV nodal block terminate the arrhythmia. Acute treatment is the same as for other forms of PSVT (discussed below). Whether ongoing therapy is warranted depends on the severity of symptoms and frequency of episodes. Reassurance and instruction as to how to perform the Valsalva maneuver or other vagal

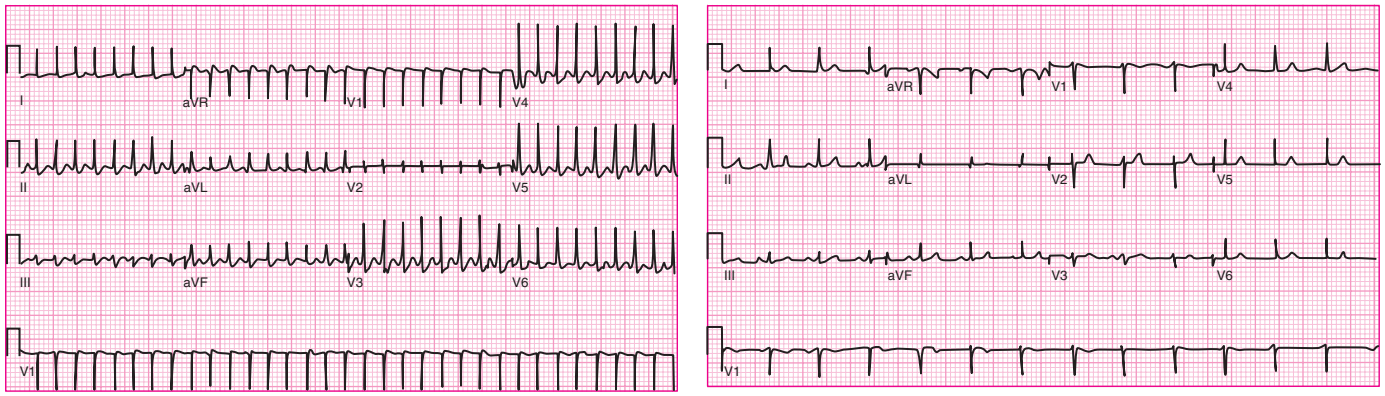

FIGURE 256-2 Atrioventricular nodal reentry tachycardia with retrograde P waves before and after adenosine termination.

nerve–stimulating maneuvers to terminate episodes are sufficient for many patients. Administration of an oral beta blocker, verapamil, or diltiazem at the onset of an episode can be used to facilitate termination. Chronic therapy with these medications or flecainide is an option if prophylactic therapy is needed. Catheter ablation of the slow AV nodal pathway is recommended for patients with recurrent or severe episodes or when drug therapy is ineffective, not tolerated, or not desired by the patient. Catheter ablation is curative in >95% of patients. The major risk is AV block requiring permanent pacemaker implantation, which occurs in <1% of patients.

JUNCTIONAL TACHYCARDIA

Junctional ectopic tachycardia (JET) is due to automaticity within the AV node. It is rare in adults and more frequently encountered as an incessant tachycardia in children, often in the perioperative period of surgery for congenital heart disease. It presents as a narrow QRS tachycardia, often with ventriculoatrial (VA) block, such that AV dissociation is present. JET can occur as a manifestation of increased adrenergic tone and may be seen after administration of isoproterenol, particularly after catheter ablation in the perinodal region. It may also occur for a short period of time after ablation for AVNRT. *Accelerated junctional rhythm* is a junctional automatic rhythm between 50 and 100 beats/min. Initiation may occur with gradual acceleration in rate, suggesting an automatic focus, or after a premature ventricular contraction, suggesting a focus of triggered automaticity. VA conduction is usually present, with P-wave morphology and timing such that it resembles AVNRT at a slow rate. It can be related to increased sympathetic tone and may produce palpitations. It usually does not require specific therapy.

ACCESSORY PATHWAYS AND THE WOLFF-PARKINSON-WHITE SYNDROME

Accessory pathways (APs) occur in 1 in 1500–2000 people and are associated with a variety of arrhythmias including narrow-complex PSVT, wide-complex tachycardias, and, rarely, sudden death. Most patients have structurally normal hearts, but APs are associated with Ebstein's anomaly of the tricuspid valve and forms of hypertrophic cardiomyopathy including *PRKAG2* mutations, Danon's disease, and Fabry's disease **(Fig. 256-3)**.

APs are abnormal connections that allow conduction between the atrium and ventricles across the AV ring. They are present from birth and are due to failure of complete partitioning of atrium and ventricle by the fibrous AV rings. They occur across either an AV valve annulus or the septum, most frequently between the left atrium and free wall of the left ventricle, followed by posteroseptal, right free wall, and anteroseptal locations. If the impulse from the sinus node conducts through the AP to the ventricle (antegrade) before the impulse conducts through the AV node and His bundle, then the ventricles are preexcited during sinus rhythm, and the electrocardiogram (ECG) shows a short P-R interval (<0.12 s), slurred initial portion of the QRS (delta wave), and prolonged QRS duration produced by slow conduction through direct activation of ventricular myocardium over the AP. The morphology of the QRS and delta wave is determined by the AP location and associated site of earliest ventricular activation, and the degree of fusion between the excitation wavefronts from conduction over the AV node and conduction over the AP **(Fig. 256-4)**.

Right-sided pathways preexcite the right ventricle, producing a left bundle branch block–like configuration in lead V_1, and often create marked preexcitation because of their relatively close proximity of the AP to the sinus node (Fig. 256-4). Left-sided pathways preexcite the left ventricle and may produce a right bundle branch–like configuration in lead V_1 and a negative delta wave in aVL, indicating initial depolarization of the lateral portion of the left ventricle that can mimic Q waves of lateral wall infarction (Fig. 256-4). Because of the relatively large distance between the sinus node and left free wall APs, preexcitation may be minimal or absent on 12-lead ECG. Preexcitation due to an AP at the diaphragmatic surface of the heart, typically in the paraseptal region, produces delta waves that are negative in leads III and aVF,

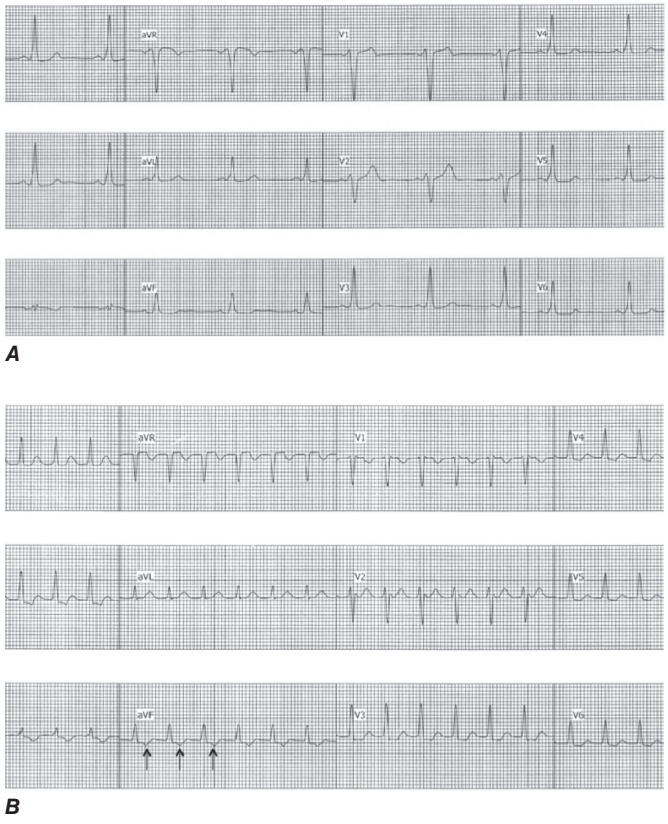

FIGURE 256-3 Wolff-Parkinson-White (WPW) syndrome. ***A.*** A 12-lead electrocardiogram in sinus rhythm (SR) of a patient with WPW demonstrating short P-R interval, delta waves, and widened QRS complex. This patient had an anteroseptal location of the accessory pathway (AP). ***B.*** Orthodromic atrioventricular (AV) reentry in a patient with WPW syndrome using a posteroseptal AP. Note the P waves in the ST segment (*arrows*) seen in lead III and normal appearance of QRS complex. ***C.*** Three most common rhythms associated with WPW syndrome: sinus rhythm demonstrating antegrade conduction over the AP and AV node; orthodromic AV reentry tachycardia (AVRT) using retrograde conduction over the AP and antegrade conduction over the AV node; and antidromic AVRT using retrograde conduction over the AV node and antegrade conduction over the AP.

mimicking the Q waves of inferior wall infarction (Fig. 256-4). Preexcitation can be intermittent and disappear during exercise as conduction over the AV node accelerates and may take over ventricular activation completely.

Wolff-Parkinson-White (WPW) syndrome is defined as a preexcited QRS during sinus rhythm and episodes of PSVT. There are a number of variations of APs that may not cause preexcitation and/or arrhythmias. Concealed APs allow only retrograde conduction, from ventricle to atrium, so no preexcitation is present during sinus rhythm, but SVT

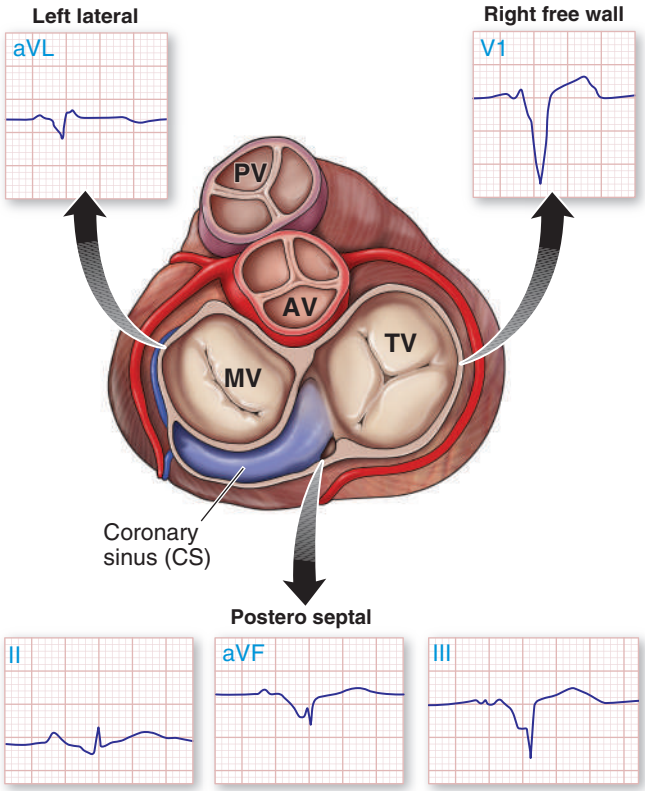

FIGURE 256-4 Potential locations for accessory pathways in patients with Wolff-Parkinson-White syndrome and typical QRS appearance of delta waves that can mimic underlying structural heart disease such as myocardial infraction of bundle branch block. AV, aortic valve; MV, mitral valve; PV, pulmonary valve; TV, tricuspid valve.

can occur. Other unusual forms of APs exist. Fasciculoventricular connections between the His bundle and ventricular septum produce preexcitation but do not cause arrhythmia, probably because the circuit is too short to promote reentry. Atriofascicular pathways, also known as Mahaim fibers, probably represent a duplicate AV node and His-Purkinje system that connect the right atrium to fascicles of the right bundle branch and produce a wide-complex tachycardia having a left bundle branch block configuration.

ATRIOVENTRICULAR RECIPROCATING TACHYCARDIA

The most common tachycardia caused by an AP is the PSVT designated *orthodromic AV reciprocating tachycardia*. The circulating reentry wavefront propagates from the atrium anterogradely over the AV node and His-Purkinje system to the ventricles and then reenters the atria via retrograde conduction over the AP. The QRS is narrow or may have typical right or left bundle branch block, but without preexcitation during tachycardia. Because excitation through the AV node and AP are necessary, AV or VA block results in tachycardia termination. During sinus rhythm, preexcitation is seen if the pathway also allows anterograde conduction. Most commonly, during tachycardia, the R-P interval is shorter than the P-R interval and can resemble AVNRT. Unlike typical AVNRT, P waves always follow the QRS and are never simultaneous with a narrow QRS complex because the ventricles must be activated before the reentry wavefront reaches the AP and conducts back to the atrium. The morphology of the P wave during tachycardia is determined by the pathway location, but it can be difficult to assess because it is usually inscribed during the ST segment. The P wave in posteroseptal APs is negative in leads II, III, and aVF, similar to that in AV nodal reentry, but P-wave morphology will differ from AV nodal reentry for pathways in other locations. Occasionally, an AP conducts extremely slowly in the retrograde direction, resulting in tachycardia with a long R-P interval, similar to most ATs. These pathways are usually located in the septal region and have negative P waves in leads II, III, and aVF. Slow AP conduction facilitates reentry, often leading to nearly incessant tachycardia, known as *permanent junctional reciprocating tachycardia* (PJRT). Tachycardia-induced cardiomyopathy can occur. Without an invasive electrophysiology study, it may be difficult to distinguish this form of orthodromic AV reentry from atypical AV nodal reentry or AT.

PREEXCITED TACHYCARDIAS

Preexcited tachycardia occurs when the ventricles are activated by antegrade conduction over the AP. The most common mechanism is *antidromic AV reciprocating tachycardia* in which activation propagates from atrium to ventricle via the AP and then conducts retrogradely to the atria via the His-Purkinje system and the AV node (or rarely a second AP). The wide QRS complex is produced entirely via ventricular excitation over the AP because there is no contribution of ventricular activation over more rapidly conducting specialized His-Purkinje fibers. This tachycardia is often indistinguishable from monomorphic ventricular tachycardia. The presence of preexcitation in sinus rhythm suggests the diagnosis.

Preexcited tachycardia also occurs if an AP allows antegrade conduction to the ventricles during AT, atrial flutter, atrial fibrillation (AF), or AV nodal reentry, otherwise known as bystander AP conduction. AF and atrial flutter are potentially life-threatening if the AP allows very rapid repetitive conduction **(Fig. 256-5)**.

Approximately 25% of APs causing preexcitation allow minimum R-to-R intervals of <250 ms during AF and are associated with a higher risk of inducing ventricular fibrillation and sudden death. Preexcited AF presents as a wide-complex, very irregular rhythm. During AF, the ventricular rate is determined by the conduction properties of the AP and AV node. The QRS complex can appear quite bizarre and change on a beat-to-beat basis due to the variability in the degree of fusion from activation over the AV node and AP, or all beats may be due to conduction over the AP. Ventricular activation from the Purkinje system may depolarize the ventricular aspect of the AP and prevent atrial wavefront conduction over the AP. Slowing AV nodal conduction without slowing AP conduction can thereby facilitate AP conduction and dangerously accelerate the ventricular rate. Administration of AV nodal–blocking agents, including oral or intravenous verapamil, diltiazem, beta blockers, intravenous adenosine, and intravenous amiodarone, is contraindicated during preexcited AF. Rapid preexcited tachycardia should be treated with electrical cardioversion or intravenous procainamide or ibutilide, which may terminate the arrhythmia or slow the ventricular rate.

MANAGEMENT OF PATIENTS WITH ACCESSORY PATHWAYS

Acute management of orthodromic AV reentry is discussed below for PSVT. Patients with WPW syndrome may have wide-complex tachycardia due to antidromic AV reentry, orthodromic AV with bundle branch block, or a preexcited tachycardia, and treatment depends on the underlying rhythm. Initial patient evaluation should include assessment for aggravating factors, including intercurrent illness and factors that increase sympathetic tone. Examination should focus on excluding underlying heart disease. An echocardiogram is reasonable to exclude Ebstein's anomaly, forms of hypertrophic cardiomyopathy that can be associated with APs, or tachycardia-mediated cardiomyopathy.

Patients with preexcitation who have symptoms of arrhythmia are at risk for developing AF and sudden death if they have an AP that allows rapid antegrade conduction. The risk of cardiac arrest is in the range of 2 per 1000 patients in adults but is likely greater in children. An invasive electrophysiology study is recommended to assess whether the pathway can support dangerously rapid heart rates if AF were to occur, and it is usually combined with potentially curative catheter ablation. Catheter ablation is warranted for recurrent arrhythmias when drugs are ineffective, not tolerated, or not desired by the patient. Efficacy is in the range of 95% depending on the location of the AP. Serious complications occur in <3% of patients but can include AV

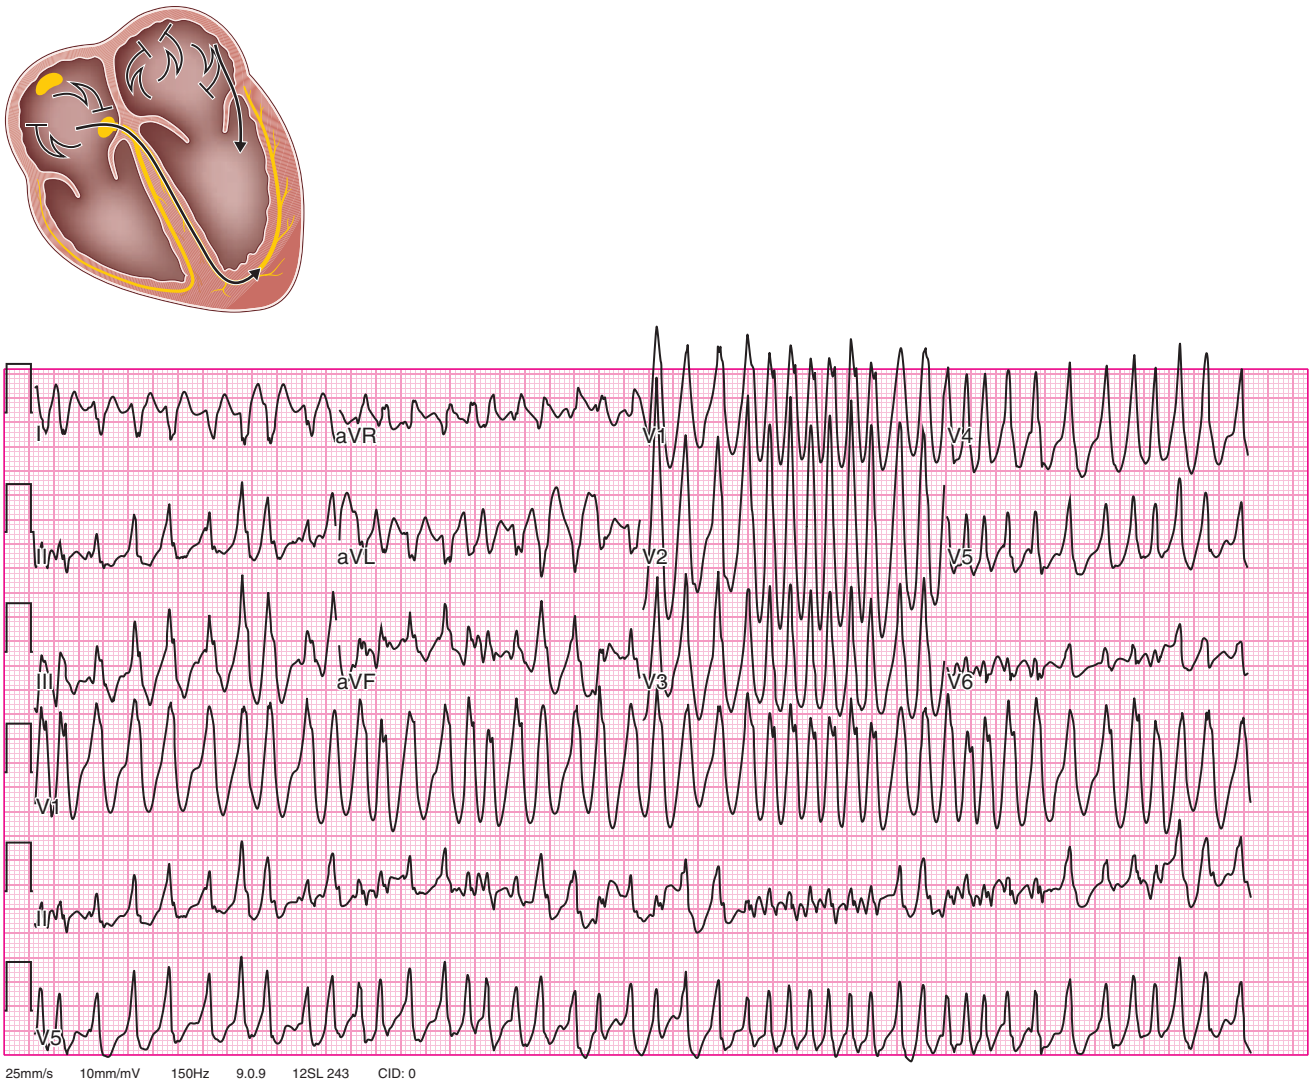

FIGURE 256-5 Preexcited atrial fibrillation (AF) due to conduction over a left free wall accessory pathway (AP). The electrocardiogram shows rapid irregular QRS complexes that represent fusion between conduction over the atrioventricular node and left free wall AP. Shortest R-R intervals between preexcited QRS complexes of <250 ms, as in this case, indicate a risk of sudden death with this arrhythmia.

block, cardiac tamponade, thromboembolism, coronary artery injury, and vascular access complications. The risk of AV block is higher when the AP is located near the AV node and/or His bundle, in the so-called anteroseptal or mid-septal locations. Procedure mortality is <1 in 1000 patients. Ambulatory monitoring or exercise testing is often used to gain reassurance that the AP is not high risk, evaluating for abrupt loss of conduction (preexcitation) at physiologic heart rates consistent with a low-risk pathway, but this is not completely reliable. Gradual loss of AP conduction with increased sympathetic tone does not reliably indicate low risk since this can occur as AV nodal conduction time shortens, and therefore, the possibility of rapid antegrade AP conduction is not excluded definitively.

For patients with concealed APs or known low-risk APs causing orthodromic AVRT, chronic therapy is guided by symptoms and frequency of events. Vagal maneuvers may terminate episodes, as may a dose of beta blocker, verapamil, or diltiazem taken at the onset of an episode. Chronic therapy with these agents or flecainide can reduce the frequency of episodes in some patients.

Adults who have preexcitation but no arrhythmia symptoms have a risk of sudden death estimated to be 1 per 1000 patient-years. Electrophysiology study is usually advised for people in occupations for which an arrhythmia occurrence would place them or others at risk, such as police, military, and pilots, or for individuals who desire evaluation for risk. Routine follow-up without therapy is reasonable in others. Children are at greater risk of sudden death, ~2 per 1000 patient-years.

TREATMENT

Paroxysmal Supraventricular Tachycardia

Acute management of narrow QRS PSVT is guided by the clinical presentation. Continuous ECG monitoring should be implemented, and a 12-lead ECG should always be obtained when possible, since this may be useful in determining the mechanism. In the presence of hypotension with unconsciousness or respiratory distress, QRS-synchronous direct current cardioversion is warranted, but this is rarely needed, because intravenous adenosine works promptly in most situations (see below). For stable individuals, initial therapy takes advantage of the fact that most PSVTs are dependent on AV nodal conduction (AV nodal reentry or orthodromic AV reentry) and, therefore, likely to respond to sympatholytic and vagotonic maneuvers and drugs. As these are administered, the ECG should be continuously recorded because the response can establish the diagnosis. AV block with only transient slowing of tachycardia may expose ongoing P waves, indicating AT or atrial flutter as the mechanism **(Fig. 256-6)**.

Carotid sinus massage is reasonable provided the risk of carotid vascular disease is low, as indicated by absence of carotid bruits and no prior history of stroke. A Valsalva maneuver should be attempted in cooperative individuals, and if effective, the patient can be taught to perform this maneuver as needed. If vagal maneuvers fail or

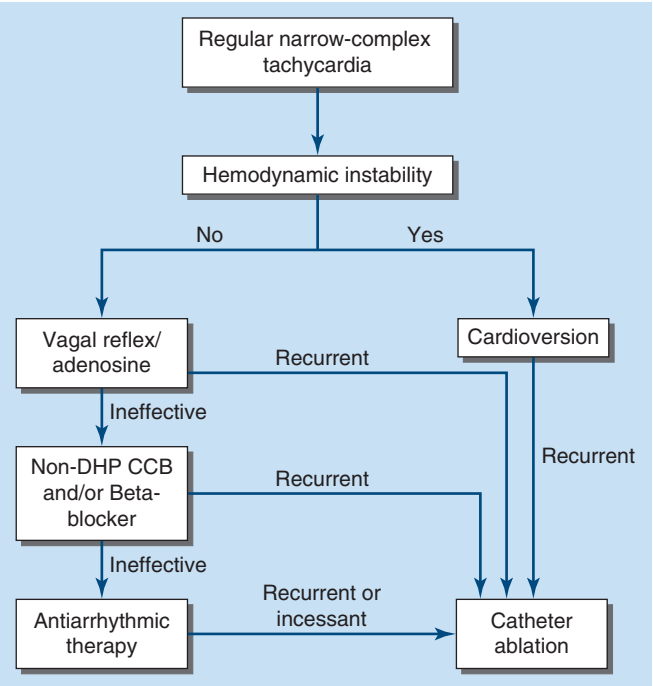

FIGURE 256-6 Treatment algorithm for patients presenting with hemodynamically stable paroxysmal supraventricular tachycardia. CCB, calcium channel blocker; DHP, dihydropyridine.

cannot be performed, intravenous adenosine will terminate the vast majority of PSVT episodes by transiently blocking conduction in the AV node. Adenosine may produce transient chest pain, dyspnea, and anxiety. It is contraindicated in patients with prior cardiac transplantation due to potential hypersensitivity due to surgical sympathetic denervation. It can theoretically aggravate bronchospasm. Adenosine precipitates AF, which is usually brief, in up to 15% of patients, so it should be used cautiously in patients with WPW syndrome in whom AF may produce hemodynamic instability. Intravenous beta blockers and calcium channel blockers (verapamil or diltiazem) are also effective but may cause hypotension before and after arrhythmia termination and have a longer duration of action. These agents can also be given orally and can be taken by the patient on an as-needed basis to slow ventricular rate and facilitate termination by Valsalva maneuver.

The differential diagnosis of wide-complex tachycardia includes ventricular tachycardia, PSVT with bundle branch block aberrancy, and preexcited tachycardia (see above). In general, these should be managed as ventricular tachycardia until proven otherwise. If the tachycardia is regular and the patient is stable, a trial of intravenous adenosine is reasonable. Very irregular wide-complex tachycardia is most likely preexcited AF or flutter (see above) and should be managed with cardioversion, intravenous procainamide, or ibutilide. If the diagnosis of PSVT with aberrancy is unequivocal, as may be the case in patients with prior episodes, treatment for PSVT with vagal maneuvers and adenosine is reasonable. In all cases, continuous ECG monitoring should be implemented, and emergency cardioversion and defibrillation should be available.

For management of PSVT outside of the acute setting, most patients with recurrent episodes are candidates for catheter ablation (see above).

257 Common Atrial Flutter and Macroreentrant and Multifocal Atrial Tachycardias

William H. Sauer, Jorge E. Romero, Paul C. Zei

Macroreentrant atrial tachycardia is characterized by a large anatomic reentry circuit, often associated with areas of atrial scar tissue with slow conduction. *Common or typical right atrial flutter* is attributed to a wavefront of electrical propagation encircling the tricuspid valve annulus, bounded anteriorly by the annulus and posteriorly by the inferior vena cava and the Eustachian ridge. The wavefront passes between the inferior vena cava and the tricuspid valve annulus, known as the sub-Eustachian or cavotricuspid isthmus, where it is susceptible to interruption by catheter ablation. Thus, common atrial flutter is also known as *cavotricuspid isthmus-dependent atrial flutter*. This circuit most commonly revolves in a counterclockwise direction (as viewed looking toward the tricuspid annulus from the ventricular apex), which produces the characteristic negative sawtooth flutter waves in leads II, III, and aVF and positive P waves in lead V_1. When the direction is reversed, clockwise rotation produces the opposite P-wave vector in those leads and is called "reverse typical atrial flutter." The atrial rate is typically 240–300 beats/min but may be slower in the presence of atrial disease or antiarrhythmic drugs. It often conducts to the ventricles with 2:1 atrioventricular (AV) block, creating a regular tachycardia at 140–150 beats/min, with flutter waves that may be difficult to discern from the T wave. Maneuvers that increase AV nodal block will typically expose flutter waves, allowing diagnosis. AV nodal disease or AV nodal–blocking agents may render the conduction ratio between atrium and ventricle higher, resulting in more obvious flutter waves **(Fig. 257-1)**. However, controlling ventricular rates during atrial flutter with AV nodal–blocking agents is frequently challenging.

Common or typical right atrial flutter often occurs alongside atrial fibrillation and is frequently associated with atrial scarring from senescence or prior cardiac surgery. Nonetheless, the onset of typical atrial flutter has been proposed to be preceded by atrial fibrillation, indicating a potential transition from atrial fibrillation to atrial flutter due to a line of functional block or the coalescence of fibrillatory wavelets surrounding anatomic barriers such as the crista terminalis and eustachian valve. Interestingly, some patients with atrial fibrillation treated with antiarrhythmic drugs, particularly flecainide, propafenone, or amiodarone, may present with atrial flutter rather than atrial fibrillation, because these agents slow atrial conduction velocity and can promote reentry, in addition to suppressing ectopic atrial triggers. This mechanism highlights the complex interplay between atrial fibrillation and atrial flutter, as well as the influence of antiarrhythmic medications on arrhythmia presentation.

Macroreentrant atrial tachycardias (ATs) that are not dependent on conduction through the cavotricuspid isthmus are referred to as *atypical atrial flutters*, also known as "non-cavotricuspid isthmus–dependent" atrial flutters. They can occur in either atrium and are almost universally associated with areas of atrial scar. Right atrial atypical flutter often occurs after cardiac surgery if an atriotomy is performed in the right atrium as part of the surgery. Left atrial flutter and perimitral left

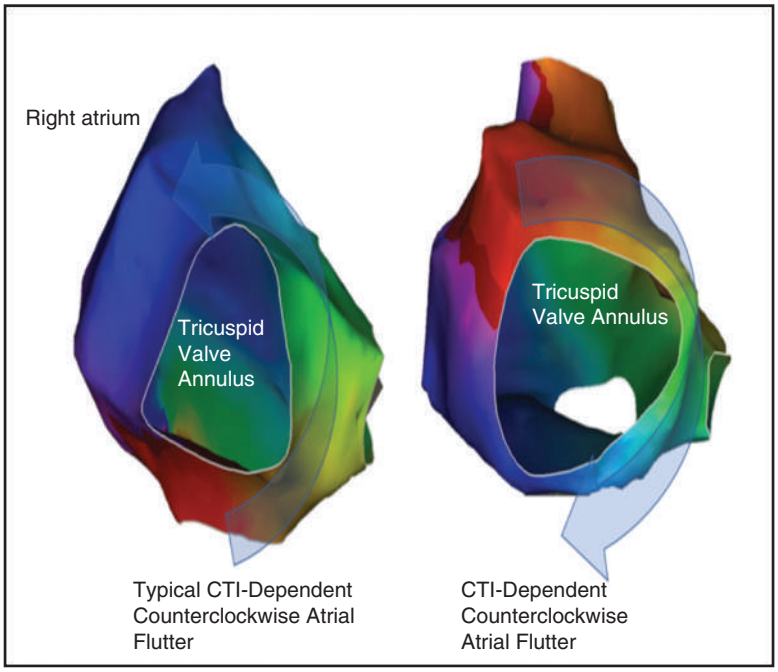

FIGURE 257-1 A 12-lead electrocardiogram (ECG) of typical or common atrial flutter (counterclockwise activation) is shown. Note the sawtooth pattern of atrial activation, with negative flutter (F) waves in inferior limb lead and positive flutter waves in lead V_1, as well as 4:1 atrioventricular (AV) conduction during flutter. CTI, cavotricuspid isthmus.

atrial flutter are commonly seen after extensive left atrial ablation for atrial fibrillation or mitral valve surgery **(Fig. 257-2)**. While the clinical presentation resembles common atrial flutter, it exhibits different P-wave morphologies. They can be difficult to distinguish from focal AT, and in most cases, the underlying mechanism can only be confirmed by an electrophysiology study **(Fig. 257-3)**.

ATRIAL FLUTTER

Initial management of atrial flutter is similar to that for atrial fibrillation, discussed in more detail in **Chap. 258**. Anticoagulation therapy plays a pivotal role in preventing thromboembolic events in this population and should be determined based on individual thromboembolic risk profiles with the CHA_2DS_2-VASc scoring system and bleeding risk assessment. Nonetheless, anticoagulation is crucial before considering conversion to sinus rhythm, unless electrical cardioversion is warranted for hemodynamic instability or severe symptoms.

Rate control can be achieved with administration of AV nodal–blocking agents. However, achieving optimal rate control in atrial flutter may be more challenging compared to atrial fibrillation. Once rate control is achieved or the patient is hemodynamically stable, consideration is given to rhythm control strategies for restoring and maintaining sinus rhythm. Antiarrhythmic drug therapy such as sotalol, dofetilide, disopyramide, ibutilide, and amiodarone may be considered, but >70% of patients experience recurrences. Therefore, catheter ablation is recognized as first-line therapy due to its high success rate (i.e., >95%), low risk of complications, and low recurrence rates. However, up to half of the patients undergoing cavotricuspid isthmus ablation go on to develop atrial arrhythmias, with atrial fibrillation being the most

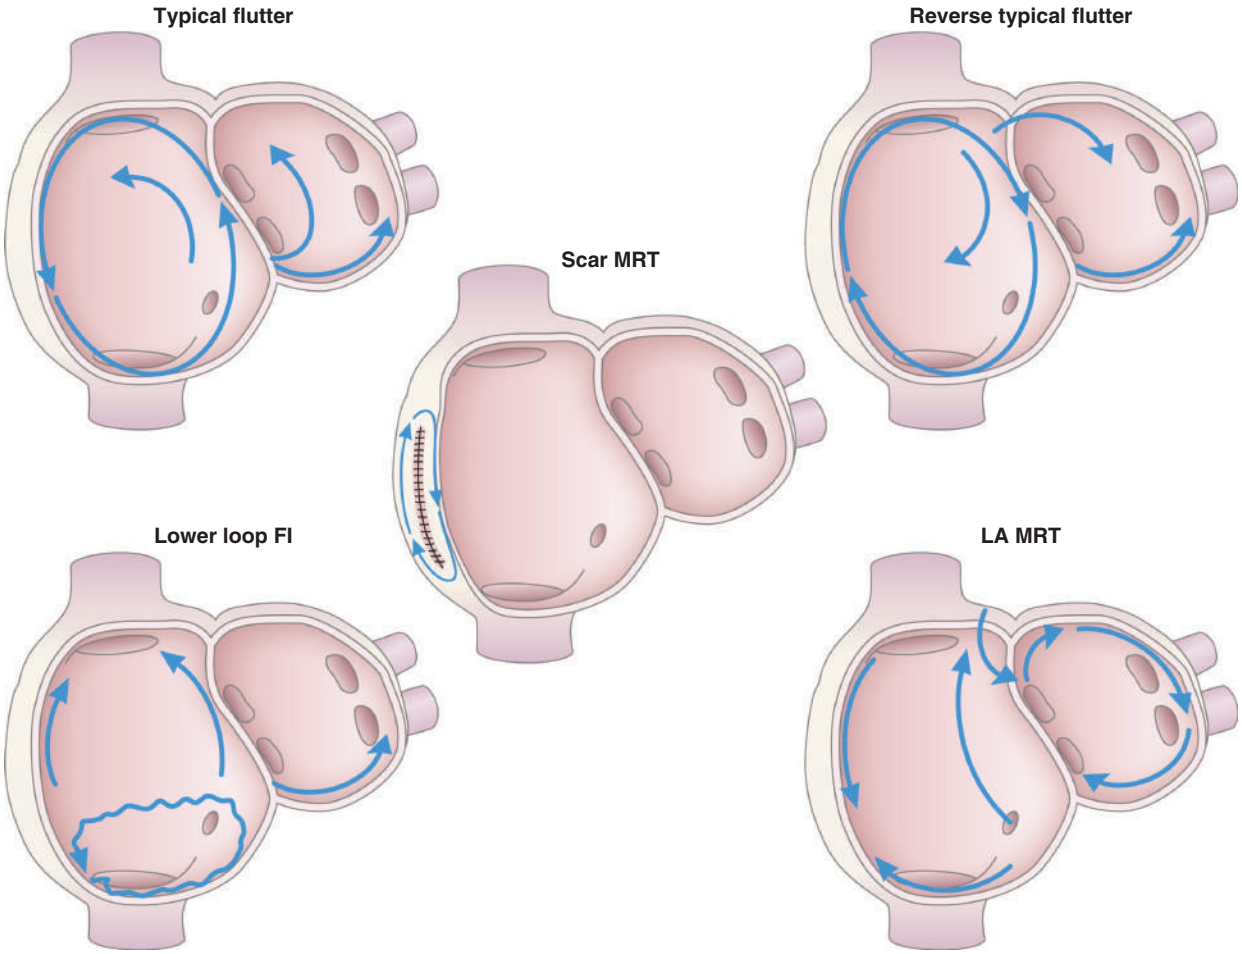

FIGURE 257-2 Types of atrial flutter and macroreentrant atrial tachycardia. The typical, reverse typical, and lower-loop flutter circuits all involve the low right atrial isthmus. Additionally, other forms of macroreentrant flutters encompass scar-mediated reentrant tachycardia and left atrial mitral isthmus flutter. Circulation. 149:e1, 2024.)*

common among them. While prophylactic cavotricuspid isthmus ablation may not be beneficial in patients with atrial fibrillation, a recent study suggested that treating atrial flutter with pulmonary vein isolation as first-line therapy can prevent recurrent atrial flutter, in addition to reducing the risk of new-onset atrial fibrillation.

In summary, the management of atrial flutter involves a stepwise approach beginning with anticoagulation for thromboembolic prevention, followed by rate control to manage symptoms and hemodynamic stability and, more importantly, rhythm control to maintain sinus rhythm. Catheter ablation is increasingly favored as the first-line therapy for achieving long-term rhythm control and improving quality of life in these patients. More importantly, additional studies are needed to substantiate a more effective ablation strategy aimed at preventing the recurrence of atrial flutter and reducing the incidence of new-onset atrial fibrillation episodes. Lastly, postablation anticoagulation remains a subject of controversy, contingent upon the likelihood of developing atrial fibrillation **(Fig. 257-4)**.

MULTIFOCAL ATRIAL TACHYCARDIA

Multifocal AT (MAT) is characterized by a rhythm with at least three distinct P-wave morphologies, with rates typically from 100 to 150 beats/min. Unlike atrial fibrillation, MAT exhibits clear isoelectric intervals between P waves, and the atrial rate tends to be slower. The underlying mechanism is often attributed to triggered automaticity originating from multiple atrial foci. This condition is commonly observed in patients with chronic pulmonary disease and acute illnesses **(Fig. 257-5)**.

Therapy for MAT is directed at treating the underlying disease and correcting any metabolic abnormalities. Electrical cardioversion is ineffective. Calcium channel blockers such as verapamil or diltiazem may be used to slow the atrial and ventricular rate. Patients with severe pulmonary disease often do not tolerate beta-blocker therapy well. MAT may respond to amiodarone, but long-term therapy with this agent is usually avoided due to its potential toxicities, particularly pulmonary fibrosis. The associated risk of thromboembolism in MAT remains unclear but is not considered to be the same as atrial fibrillation or atrial flutter.

FIGURE 257-5 Multifocal atrial tachycardia. Rhythm strip obtained from a patient with severe pulmonary disease during an acute illness. Note the irregularity of the rhythm but with distinct P waves. *Arrows* note three distinct P-wave morphologies.

258 Atrial Fibrillation

William H. Sauer, Jorge E. Romero, Paul C. Zei

PATHOPHYSIOLOGY AND EPIDEMIOLOGY

Atrial fibrillation (AF) is a cardiac arrhythmia characterized by seemingly disorganized, rapid, and irregular atrial electrical activation, resulting in loss of organized atrial mechanical contraction. These rapid and irregular electrical signals input into the atrioventricular (AV) node, which determines ventricular activation and rate. The conducted ventricular rate is variable, resulting in an irregular, usually rapid ventricular rate, ranging typically between 110 and 160 beats/min in most. In some patients, the sustained ventricular rate can exceed 200 beats/min, whereas in others with either high vagal tone or AV nodal conduction disease, the ventricular rate may be excessively slow **(Fig. 258-1)**.

The disorganized atrial activation is best appreciated in lead V_1 for this patient. AF is the most common sustained arrhythmia; as a result, it is a major public health issue. Prevalence increases with age, with >95% of AF patients >60 years of age. The prevalence in humans over age 80 is ~20%. The lifetime risk of developing AF for men aged 40 years old is ~25%. AF is slightly more common in men than women and more common in whites than blacks. Risk factors for developing AF in addition to age and underlying cardiac disease include hypertension, diabetes mellitus, cardiac disease, family history of AF, obesity, thyroid disease, and sleep-disordered breathing. AF is not a benign condition, with a 1.5- to 1.9-fold increased risk of mortality after controlling for underlying cardiac disease. Perhaps the most important consequence of AF is a significantly increased risk of stroke compared to the general population, causing ~25% of all strokes. AF has been detected up to 8.9% of patients within 6 months following cryptogenic stroke using insertable cardiac monitors.

The risk of dementia is increased in patients with AF, as is the risk of magnetic resonance imaging (MRI)-detected asymptomatic embolic infarct. AF, most often when ventricular rate remains uncontrolled for prolonged periods, increases the risk of developing congestive heart failure and cardiomyopathy. Moreover, as a corollary, patients with underlying heart disease, in particular cardiomyopathy and congestive heart failure, are at higher risk for developing AF. AF is a marker for worsened morbidity and mortality in patients with existing heart disease, although the precise extent of the independent risk increase associated with AF in heart disease is unclear. AF may, on occasion, be associated with an identifiable precipitating factor, such as hyperthyroidism, acute alcohol intoxication, myocardial infarction, pulmonary embolism, pericarditis, and cardiac surgery, where AF occurs in up to 50% of patients postoperatively.

AF is clinically most typically defined by the pattern of episodes. Paroxysmal AF is defined as a pattern of AF episodes that occur and terminate with a relatively short duration either spontaneously or by pharmacologic or electrical cardioversion, most commonly defined as 7 days or less. Persistent AF refers to AF that occurs continuously for >7 days but <1 year, whereas long-standing persistent AF refers to AF that has been persistent for >1 year. These descriptors for AF correlate somewhat with the underlying pathophysiology of AF. AF tends to be a progressive condition, with, at this point, no definitive "cure" that will completely eliminate AF durably in a predictable fashion. The pathophysiology of AF, however, remains incompletely understood. Most data support a multifactorial process that leads to the development of manifest AF. Clinical and epidemiologic studies have demonstrated that, in addition to cardiovascular disease, age, alcohol use, obesity, hypertension, diabetes mellitus, and sleep-disordered breathing are associated with higher risk of developing AF. The proposed pathophysiology suggests a "final common pathway" of these risk factors leading to electrophysiologic changes in atrial tissues. Alterations in regulation of membrane channels and other proteins result in abnormal electrical excitability. Atrial tissues, in particular pulmonary vein musculature, exhibit enhanced automaticity, resulting in ectopic beats (premature atrial contractions), as shown in **Fig. 258-2**. Bouts of rapid atrial ectopy may then initiate either atrial tachycardia or frank AF. Additional cellular and, eventually, tissue remodeling results in abnormal conduction properties throughout the atria, including, in particular, shortening of atrial tissue refractory periods. This enables sustained AF through a combination of rapid automaticity-based "drivers" and areas of functional reentry. Further remodeling leads to the development of fibrosis and left atrial enlargement **(Table 258-1)**.

These functional and anatomic changes in atrial tissues appear to correlate with the progression of clinical AF. AF tends to be a progressive disease in most, although exceptions occur. Typically, for a period of time, patients experience sporadic ectopic beats and short runs of atrial tachycardia, likely originating from the pulmonary veins, preceding the onset of frank AF.

Other regions of the atria have been demonstrated to produce ectopic depolarizations that may trigger AF; these include the posterior wall of the left atrium and muscular tissue sleeves within the superior vena cava, coronary sinus, or the remnant of the vein of Marshall. When enough frequent bursts of ectopic beats/tachycardia and/or changes in underlying substrate support the maintenance of AF for short periods, the patient develops episodes of paroxysmal AF. In the untreated patient, over time, as the electrical, contractile, and structural remodeling continues to progress, episodes of paroxysmal AF may be prolonged to the point of not terminating spontaneously, the hallmark of persistent AF. After further remodeling, not only do patients continue to long-standing persistent AF but also the efficacy of therapeutic interventions to restore sinus rhythm diminishes.

CLINICAL PRESENTATION AND MANIFESTATIONS

The clinical manifestations of AF result from (1) symptoms related to the irregular, often rapid but sometimes slow ventricular rates that result; (2) the hemodynamic consequences of altered cardiac function; (3) the consequences of cardioembolic phenomena; and/or (4) the impact of AF on cardiovascular function over time. AF is diagnosed by electrocardiogram (ECG), either by 12-lead standard ECG, limited lead ambulatory monitor ECG and implantable loop recorders, with findings of lack of organized atrial activity (no P wave), with an irregular ventricular response. The role of screening populations for AF is evolving with the use of wearable monitors and home ECG capabilities.

With irregular, rapid ventricular rates, there is variable cardiac displacement and contraction, resulting in the sensation of palpitations and awareness of the heartbeat, when of course, in a normal rhythm, most humans do not sense each heartbeat. Interestingly, many patients are, for the most part, unaware of the irregular ventricular beating for unknown reasons.

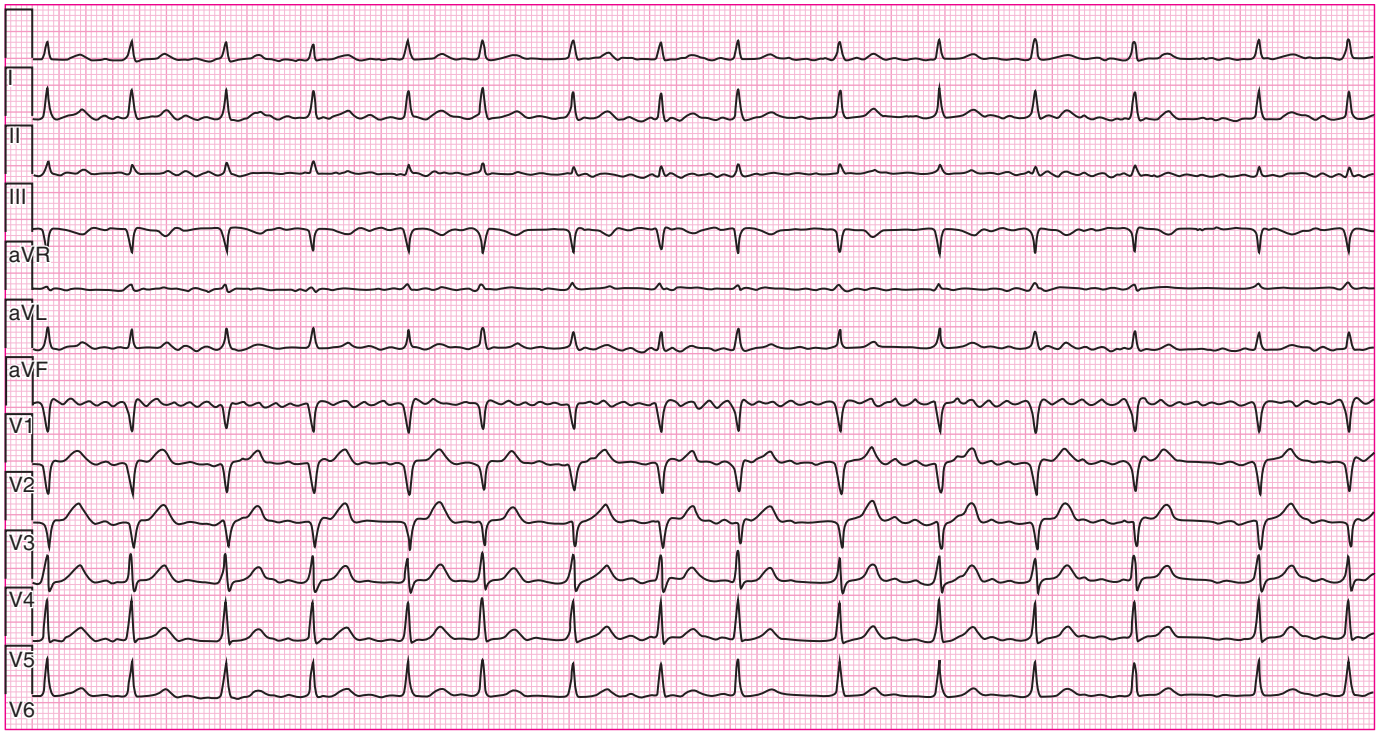

FIGURE 258-1 Electrocardiogram of an irregularly irregular heart rhythm without discernable P waves. The disorganized atrial activation is best appreciated in lead V_1 for this patient.

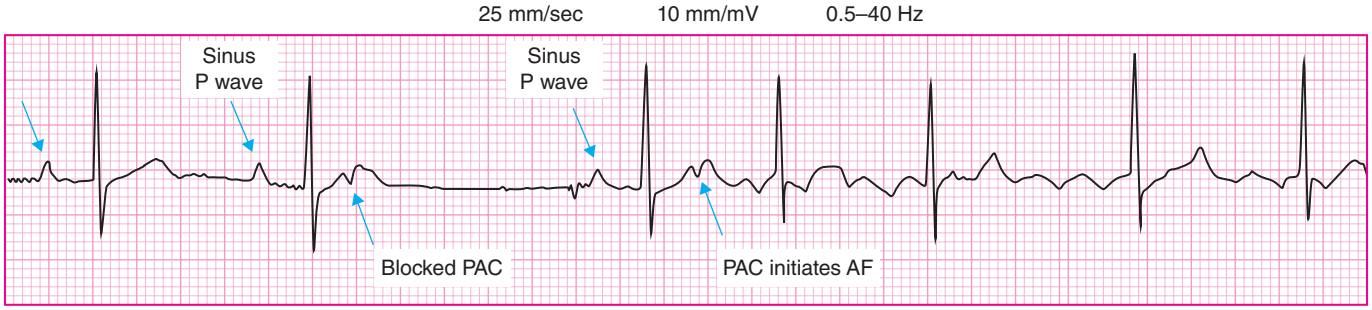

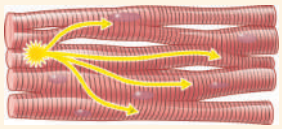

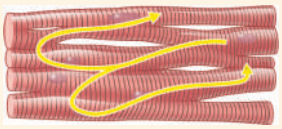

FIGURE 258-2 Surface electrocardiogram (ECG) of atrial ectopy initiating atrial fibrillation (AF). In this single-lead surface ECG recording, the tracing begins with two conducted sinus beats. A nonconducted premature atrial contraction (PAC) (labeled "blocked PAC") is shown after the second QRS complex. After the next sinus P wave and QRS, an ectopic beat (PAC) initiates atrial fibrillation, as demonstrated by (somewhat organized) erratic atrial activity and an irregular ventricular response.

TABLE 258-1 Categorization of Atrial Fibrillation (AF) by Clinical Temporal Characteristics and Associated Features

	PAROXYSMAL AF	PERSISTENT AF	LONG-STANDING PERSISTENT AF
Definition	Episodes self-terminate or via pharmacologic or electrical CV in <7 days	Episodes lasting >7 days and <1 year	Persistent AF >1 year
LA size	Normal to mildly enlarged	Mild to severely enlarged	Typically, severely enlarged
LA scar burden	Low	Moderate	High
Efficacy of AAD	Often effective	Not as effective	Usually refractory
When to offer ablation?	First-line therapy reasonable	First-line appropriate but usually offered after AAD failure	After AAD failure, not always a good option
Ablation technique	PV isolation alone usually effective	PV isolation and any identified non-PV AF source	PV isolation; additional ablation for substrate modification likely needed

Note: With paroxysmal, persistent, and long-standing persistent AF, definitions are based on duration of events and diagnosis overall. These categorizations correlate with LA size, LA scar burden, and resultant efficacy of medical and ablative therapies.

Abbreviations: AAD, antiarrhythmic drugs; CV, cardioversion; LA, left atrium; PV, pulmonary vein.

During AF, there is loss of the contribution of atrial systole to overall cardiac output and, with irregular ventricular rates, variable ventricular filling and, consequently, variable stroke volume. The resultant impact on overall cardiac output may result in exercise intolerance, fatigue, weakness, presyncope, or dyspnea. In patients with underlying cardiac disease, the additional hemodynamic compromise resulting from AF may result in exacerbation of the disease and/or heart failure symptoms. Patients with hypertrophic cardiomyopathy, coronary artery disease, valvular disease, heart failure with either depressed or preserved ejection fraction, or amyloidosis are particularly susceptible. In patients with concomitant AV nodal conduction disease, bradycardia during AF may result in presyncope or syncope. Pauses at the time of spontaneous conversion from AF to sinus rhythm, a manifestation of sinus node dysfunction that commonly occurs in patients with AF, may result in presyncope or syncope as well.

With the loss of atrial mechanical contraction, blood stasis may promote in situ thrombosis, which, when embolized, may result in a range of clinical consequences, most importantly, ischemic stroke. Thrombus formation occurs primarily in the left atrial appendage. Over time, recurrent thromboembolism to the brain, even if asymptomatic, may result in debilitating neurologic sequelae, including cognitive impairment. An increased risk of dementia in patients with AF may be the consequence of this phenomenon, although the contribution of chronic hypoperfusion in patients with long-standing persistent atrial fibrillation is unclear.

In patients with prolonged periods of rapid ventricular rates resulting from AF, there is risk of developing a tachycardia-induced cardiomyopathy, with associated depressed left ventricular function. Tachycardia-induced myopathy appears generally to be reversible once ventricular rates are controlled. In patients with long-standing persistent AF, the atria, especially the left atrium, tend to be more dilated and to contain a higher burden of fibrotic, noncontractile atrial tissue. The hemodynamic consequences of a noncompliant, fibrotic left atrium, including elevated left atrial filling pressures, volume overload, and congestive heart failure, have been described as "stiff left atrial syndrome."

TREATMENT

Atrial Fibrillation

The treatment and management of the patient with AF centers on three aims: (1) control of patient symptoms through a strategy of rate control and/or rhythm control; (2) appropriate mitigation of thromboembolism risk; and (3) addressing modifiable risk factors for progression of AF. In the acute onset of AF, if significant hemodynamic compromise, pulmonary edema, or evidence of coronary ischemia is present, emergent cardioversion is recommended. Electrical cardioversion can be achieved with a QRS synchronous shock, preferably in a sedated patient, or via pharmacologic cardioversion, most typically with the intravenous administration of the class III antiarrhythmic ibutilide. Ibutilide should be avoided in patients with baseline prolonged QT interval or severe left ventricular dysfunction, given the risk of torsades des pointes. In the hemodynamically stable patient with new-onset AF, therapy should focus on control of ventricular rate to prevent hemodynamic sequelae, consideration of anticoagulation to mitigate thromboembolic risk, and consideration of restoration and maintenance of sinus rhythm—a so-called rhythm control strategy. If restoration of sinus rhythm is being considered, a more immediate risk of thromboembolism must be factored into the management strategy. Although there is a lack of definitive data, it is presumed that if the presenting episode of AF is >48 h or if the episode duration is unknown, there is risk for precipitating a thromboembolic complication through cardioversion, whether electrically or pharmacologically achieved. Therefore, in this circumstance, the patient should be either initiated on anticoagulation, with cardioversion deferred for at least 3 weeks after uninterrupted anticoagulation, or evaluated to exclude the presence of left atrial appendage thrombus. Most commonly, transesophageal echocardiography (TEE) is used to evaluate for left atrial appendage thrombus, although cardiac computed tomography (CT) angiography using delayed acquisition imaging has been demonstrated to have excellent sensitivity and specificity as well.

CARDIOVERSION AND ANTICOAGULATION

The major source of thromboembolism and stroke in nonvalvular AF is formation of thrombus in the left atrial appendage where flow is relatively stagnant, although thrombus occasionally forms in other locations as well, particularly in patients with mitral valvular disease and severely dilated left atrium. Following conversion from prolonged AF to sinus rhythm, atrial mechanical function can be delayed for weeks (i.e., atrial stunning), such that thrombi can form even during sinus rhythm. When AF has been present for >48 h and in patients at high risk for thromboembolism, such as those with mitral stenosis or hypertrophic cardiomyopathy, conversion to sinus rhythm is associated with an increased risk of thromboembolism. Thromboembolism can occur soon or several days after restoration of sinus rhythm if appropriate anticoagulation measures are not taken. In patients with AF and left atrial appendage closure devices (e.g., Watchman device), electrical cardioversion is feasible without the need for oral anticoagulation if preprocedural transesophageal echocardiography shows good device position, absence of device-related thrombus, and peri-device leak of ≤5 mm.

Cardioversion *within 48 h of the onset of AF* without TEE or cardiac CT is common practice in patients who have not been anticoagulated, provided that they are not at high risk for stroke due to a prior history of embolic events, rheumatic mitral stenosis, or hypertrophic cardiomyopathy with marked left atrial enlargement. These low-risk patients with occasional episodes of AF can be instructed to notify their physician when AF occurs to arrange for cardioversion to be done within 48 h.

If the duration of AF exceeds 48 h or is unknown, there is greater concern for thromboembolism after cardioversion, even in patients considered low risk (CHA_2DS_2-VASc of 0 or 1 [see below]) for stroke. There are two approaches to mitigate the risk related to cardioversion. One option is to anticoagulate continuously for 3 weeks before and a minimum of 4 weeks after cardioversion. A second more frequently used approach is to start anticoagulation and perform a TEE or high-resolution cardiac CT scan to detect the presence of thrombus in the left atrial appendage. If thrombus is absent, electrical or pharmacologic cardioversion can be performed and anticoagulation continued for a minimum of 4 weeks to allow time for recovery of atrial mechanical function. In either case, cardioversion of AF is associated with a substantial risk of recurrence, which may not be symptomatic. It should be noted that these recommendations for short-term anticoagulation and thrombus exclusion at the time of cardioversion lack contemporary robust data to support these strategies. Longer-term maintenance of anticoagulation is considered based on the patient's individual risk for stroke, commonly assessed using the CHA_2DS_2-VASc score.

ACUTE RATE CONTROL

The goal of rate control in AF is to allow more diastolic filling time, improving cardiac output and reducing patient symptoms. In the longer term, adequate rate control will minimize the risk of congestive heart failure and tachycardia-induced cardiomyopathy. Acute rate control can be achieved with beta blockers and/or the calcium channel blockers verapamil and diltiazem administered either intravenously or orally, as warranted by the urgency of the clinical situation. Digoxin has been used for several years for rate control, particularly in patients with labile blood pressure and in patients with cardiomyopathy susceptible to congestive heart failure, because it lacks the negative inotropic effect seen in calcium channel blockers and beta blockers. It acts synergistically with beta blockers and calcium channel blockers and, therefore, may be useful as an added agent when rate control is inadequate. However, recent evidence suggests increased mortality with its chronic use, and so its utilization has declined.

CHRONIC RATE CONTROL

For patients who remain in AF chronically, the goal of rate control is to both alleviate symptoms and prevent deterioration of ventricular function from excessive rates. β-Adrenergic blockers and calcium channel blockers are often used either alone or in combination. Exertion-related symptoms are often an indication of inadequate rate control. Rate should be assessed with exertion and medications adjusted accordingly. Adequate rate control is defined as a resting heart rate of <80 beats/min that increases to <100 beats/min with light exertion, such as walking. If it is difficult to slow the ventricular rate to that degree, allowing a resting rate of up to 110 beats/min is acceptable provided it does not cause symptoms and ventricular function is normal; however, periodic assessment of ventricular function is warranted because some patients develop tachycardia-induced cardiomyopathy. In patients with permanent atrial fibrillation, a lenient rate-control strategy (resting heart rate <110 beats/min) is as effective as strict rate-control strategy (resting heart rate <80 beats/min and heart rate during moderate exercise <110 beats/min) in terms of death from cardiovascular causes, hospitalization for heart failure and stroke, systemic embolism, bleeding, and life-threatening arrhythmic events, and this strategy is easier to achieve.

If adequate rate control in AF is difficult to achieve, further consideration should be given to restoring sinus rhythm (see below). Catheter ablation of the AV junction to create permanent AV block and implantation of a permanent pacemaker reliably achieve rate control without the need for AV nodal–blocking agents, a so-called "ablate and pace" strategy. These patients not only remain in AF but also become dependent on the pacemaker to support ventricular rate. The typical pacing configuration with placement of a ventricular lead in the right ventricular apex may induce dyssynchronous ventricular activation that can depress ventricular function in some patients. Biventricular pacing or direct pacing of the left bundle branch area may be used to minimize the degree of ventricular dyssynchrony. AV nodal ablation and cardiac resynchronization therapy have been demonstrated to be superior to pharmacologic therapy in improving quality of life and in reducing the development of heart failure, heart failure hospitalizations, and all-cause mortality in patients with permanent AF and a narrow QRS, irrespective of their baseline left ventricular ejection fraction.

STROKE PREVENTION IN ATRIAL FIBRILLATION

Thromboembolic complications, in particular, stroke, are the most significant and potentially life-threatening sequelae of AF. Therefore, appropriate stroke prevention strategies are a key aspect of AF management. The mainstay of stroke prevention is continuous anticoagulation therapy, most commonly using an oral medication. Specific patient populations have a high risk of stroke, including patients with hypertrophic cardiomyopathy, mitral stenosis, and prior stroke history, and therefore, anticoagulation is recommended, barring contraindications. AF in patients without mitral stenosis is commonly referred to as nonvalvular AF. In most patients with AF, the decision about whether a stroke prevention regimen is indicated is largely based on an assessment of stroke risk, balanced by the risk of the preventative therapy. The risk of stroke appears to be most accurately predicted by the presence of underlying risk factors known to increase stroke risk. The CHA_2DS_2-VASc scoring system **(Fig. 258-3)** is a widely used tool to estimate stroke risk. Anticoagulation is currently recommended in the United States and Europe for patients with a score of ≥1 unless the lone risk factor is female gender. Stroke risk increases with increasing CHA_2DS_2-VASc score, such that annual stroke risk may be as high as nearly 20% without anticoagulation. On the other hand, anticoagulation carries a risk of serious and potentially life-threatening bleeding complications, in particular, intracranial hemorrhage and gastrointestinal bleed. Bleeding risk is often assessed using the HAS-BLED scoring system (Fig. 258-3). If bleeding risk is deemed to be outweighed by stroke risk, anticoagulation is recommended. It is important to note the conventional wisdom that the *perceived* burden of AF has not been shown to predict stroke risk. The approach to patients with paroxysmal AF is therefore the same as for persistent AF. It is recognized that many patients who appear to have infrequent AF episodes based on office visits often have asymptomatic episodes that put them at risk. Absence of AF during periodic monitoring is not sufficient to indicate low risk. The role of continuous monitoring with implanted recorders or pacemakers as a guide for anticoagulation in patients with a borderline risk profile is not clear. Subclinical AF is short-lasting and asymptomatic and can usually be detected only by long-term continuous monitoring with implantable loop recorders, pacemakers, or defibrillators. Subclinical AF is associated with an increased risk of stroke by a factor of 2.5. In patients with subclinical AF lasting 6 min to 24 h, apixaban has been shown to decrease the risk of stroke or systemic embolism but increases the risk of major bleeding. Therefore, a more accurate accounting for the impact of AF burden on stroke risk remains to be clarified.

Antiplatelet agents alone are generally not sufficient. In nonvalvular AF, warfarin reduces the annual risk of stroke by 64% compared to placebo and by 37% compared to antiplatelet therapy. Patients with AF with an increased risk of stroke also have an increased risk of venous thromboembolism, which appears to be lower with oral anticoagulation. The direct-acting anticoagulants dabigatran, rivaroxaban, apixaban, and edoxaban were noninferior to warfarin in individual trials of nonvalvular AF patients, and intent-to-treat analysis of pooled data suggests superiority to warfarin by small absolute margins of 0.4–0.7% in reduction of mortality, stroke, major bleeding, and intracranial hemorrhage. Warfarin is required for patients with rheumatic mitral stenosis or mechanical heart valves. Among patients with rheumatic heart disease–associated AF, warfarin therapy has led to a lower rate of a composite of cardiovascular events or death than rivaroxaban therapy, without

CHA_2DS_2-VASc			HAS-BLED

Congestive heart failure	1		Hypertension	1
Age >75	2		Abnormal renal or liver function	1 each
Hypertension	1		Stroke history	1
			Bleeding diasthesis	1
Diabetes mellitus	1		Labile INR (on warfarin)	1
Prior stroke or TIA	2		Elderly (Age >65)	1
Vascular disease	1		Drugs that predispose to bleeding or alcohol	1 each
Age >65	1			
Sex category (F)	1			

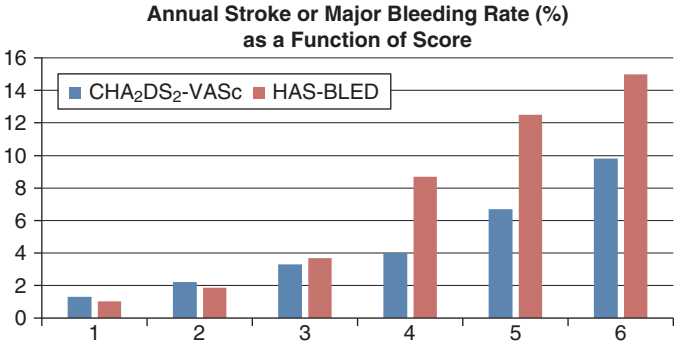

FIGURE 258-3 CHA_2DS_2-VASc and HAS-BLED systems. The CHA_2DS_2-VASc scoring system gives a point for each outlined stroke risk factor, whereas the HAS-BLED scoring system gives a point for each bleeding risk factor, as outlined in the table. In the chart below the table, the corresponding risk of stroke (CHA_2DS_2-VASC) or major bleed event (HAS-BLED) is plotted as a percent risk per annum as a function of score. F, female; INR, international normalized ratio; TIA, transient ischemic attack.

a higher rate of bleeding. Similarly, apixaban and dabigatran have failed to demonstrate noninferiority to warfarin and are less effective than warfarin for the prevention of valve thrombosis or thromboembolism in patients with mechanical heart valves.

Warfarin can be an inconvenient agent that requires several days to achieve a therapeutic effect (prothrombin time [PT]/international normalized ratio [INR] >2), requires monitoring of PT/INR to adjust dose, and has many drug and food interactions that can hinder patient compliance and render maintaining a therapeutic effect challenging. The direct-acting agents are easier to use and achieve reliable anticoagulation promptly without requiring dosage adjustment based on blood tests. Dabigatran, rivaroxaban, and apixaban have renal excretion and require dose adjustment for modest renal impairment, which is of particular concern in the elderly, who are at increased bleeding risk. Limited experience with apixaban and rivaroxaban demonstrates safety and efficacy in patients undergoing chronic hemodialysis for end-stage kidney disease. Excretion can also be influenced by P-glycoprotein inducers and inhibitors. Warfarin anticoagulation can be reversed by administration of fresh frozen plasma, prothrombin complex concentrate, and vitamin K. Reversal agents are available for dabigatran (idarucizumab), and Xa inhibitors are available (andexanet alfa), and both are administered intravenously. These agents may be prothrombotic, and administration must be judicious. The antiplatelet agents aspirin and clopidogrel are inferior to warfarin for stroke prevention in AF and do not have less risk of bleeding. Clopidogrel combined with aspirin is better than aspirin alone for stroke prevention, but this combination is inferior to warfarin and has a greater bleeding risk than aspirin alone.

Bleeding is the major risk of anticoagulation. Major bleeding requiring transfusion and intracranial bleeding occur in ~1% of patients per year with warfarin. Direct-acting anticoagulants appear to have a lower risk of intracranial bleeding compared with warfarin without sacrificing protective effects against thromboembolism. Risk factors for bleeding include age >65–75 years, heart failure, renal insufficiency, prior bleeding, and excessive alcohol or nonsteroidal anti-inflammatory drug use. In patients who require dual antiplatelet therapy (e.g., aspirin and clopidogrel) after coronary or peripheral arterial stenting, there is a substantially increased bleeding risk when standard oral anticoagulation with warfarin or a direct-acting anticoagulant is added. In AF patients undergoing percutaneous coronary intervention, the combination of oral platelet inhibition with a $P2Y_{12}$ inhibitor (preferably clopidogrel) is recommended. Triple antithrombotic therapy, preferably including a direct-acting anticoagulant, should be considered in patients with high ischemic risk (e.g., acute coronary syndrome) and for up to 30 days.

Chronic anticoagulation is contraindicated in some patients due to bleeding risks. Because most atrial thrombi likely originate in the left atrial appendage, surgical removal of the appendage, combined with atrial maze surgery, may be considered for patients undergoing surgery, although removal of the appendage has not been unequivocally shown to reduce the risk of thromboembolism. Percutaneously deployed devices that occlude or ligate the left atrial appendage are also available, appear to be noninferior to warfarin in reducing stroke risk, and are considered in patients who have a high risk of thromboembolism but serious bleeding risk from chronic oral anticoagulation **(Table 258-2)**. Importantly, left atrial appendage closure devices (i.e., Watchman) provide stroke prevention comparable to warfarin, with additional significant reductions in major bleeding, particularly hemorrhagic stroke, and all-cause mortality. Furthermore, left atrial appendage closure devices appear to be noninferior to direct-acting anticoagulants in preventing major AF-related cardiovascular, neurologic, and bleeding events.

RHYTHM CONTROL

The decision to administer antiarrhythmic drugs or perform catheter ablation to attempt maintenance of sinus rhythm (commonly referred to as the *rhythm control strategy*) is mainly guided by patient symptoms and preferences regarding the benefits and risks of therapies. In general, patients who maintain sinus rhythm have better survival than those who continue to have AF. This may be because continued AF is a marker of disease severity or that AF promotes deterioration in cardiac function. In older randomized trials, administration of antiarrhythmic medications to maintain sinus rhythm did not improve survival or symptoms compared to a rate control strategy, and the drug therapy group had more hospitalizations. Disappointing efficacy and toxicities of available antiarrhythmic drugs, in retrospect inappropriate discontinuation of anticoagulation in the rhythm control arms, and patient selection bias may be factors that influenced the results of these trials. Recently, a randomized trial evaluating an early rhythm control strategy (within 1 year of initial presentation) compared to standard rate control demonstrated a reduction in cardiovascular events, including death from cardiovascular causes and stroke. Differences between this study and earlier randomized trials that failed to show a significant difference in outcomes in rate versus rhythm control included the use of catheter ablation and a high adherence rate to anticoagulation despite apparent rhythm control. In patients with heart failure due to depressed left ventricular function, a catheter ablation–based strategy to maintain sinus rhythm appears to provide all-cause mortality benefit compared with a medical rhythm control strategy. Furthermore, the combination of catheter ablation and guideline-directed medical therapy in patients with symptomatic AF and end-stage heart failure who are referred for heart transplantation evaluation is associated with a lower likelihood of a composite of death from any cause, implantation of a left ventricular assist device, or urgent heart transplantation than medical therapy alone.

A rhythm control strategy is usually selected for patients with symptomatic paroxysmal AF, recurrent episodes of symptomatic persistent AF, AF with difficult rate control, and AF that has resulted in depressed ventricular function or that aggravates heart failure. A rhythm control strategy is more likely to be favored in younger patients than in sedentary or elderly patients in whom rate control is more easily achieved. Even if sinus rhythm is apparently maintained, anticoagulation is recommended according to the CHA_2DS_2-VASc stroke risk profile because asymptomatic episodes of AF are common. Following a first episode of persistent AF, a strategy using AV nodal–blocking agents, cardioversion, and anticoagulation is reasonable, in addition to addressing possible aggravating factors. If recurrences are infrequent, periodic cardioversion is reasonable. However, if a patient has frequent symptomatic AF despite rate control, then a rhythm control strategy incorporating

TABLE 258-2 Novel Oral Anticoagulant Dosing

	DABIGATRAN	RIVAROXABAN	APIXABAN	EDOXABAN
Standard dose	150 mg bid	20 mg qd	5 mg bid	60 mg qd
Reduced dose	110 mg bid	15 mg qd	2.5 mg bid	30 mg qd
Dose reduction criteria	Dabigatran 110 mg bid in patients with: age ≥80 years, concomitant use of verapamil, or increased bleeding risk	Creatine clearance 15–49 mL/min	At least 2 of 3 criteria: age ≥80 years, body weight ≤60 kg, or serum creatinine ≥1.5 mg/dL (133 mol/L)	If any of the following: creatinine clearance 30–50 mL/min, body weight ≤60 kg, or concomitant use of dronedarone, cyclosporine, erythromycin, or ketoconazole

Note: As of publication, four novel or direct oral anticoagulants are available and indicated for stroke prevention for atrial fibrillation. The standard dosing, reduced dosing, and criteria for reduced dosing are shown for each agent.

catheter ablation and/or antiarrhythmic medications is indicated. Based on recent randomized trial data demonstrating superiority of ablation over medications for maintenance of sinus rhythm and benefits of an early rhythm control strategy, catheter ablation is considered first-line therapy, especially for individuals with paroxysmal AF.

Pharmacologic Therapy for Maintaining Sinus Rhythm The goal of pharmacologic therapy is to maintain sinus rhythm or reduce episodes of AF. Risks and side effects of antiarrhythmic drugs are a major consideration in selecting therapy. Drug therapy can be instituted once sinus rhythm has been established or in anticipation of cardioversion. However, antiarrhythmic medications may in some instances pharmacologically cardiovert the patient into sinus rhythm. Therefore, an appropriate anticoagulation strategy approach similar to electrical cardioversion is recommended, particularly at the time of initiation of therapy. β-Adrenergic blockers and calcium channel blockers help control ventricular rate, improve symptoms, and possess a low-risk profile, but have low efficacy for preventing or terminating AF episodes. Class I sodium channel–blocking agents (e.g., flecainide, propafenone, disopyramide) are options for patients without significant structural heart disease, but negative inotropic and proarrhythmic effects warrant avoidance in patients with coronary artery disease or heart failure. The class III agents sotalol and dofetilide can be administered to patients with coronary artery disease or structural heart disease but have ~3% risk of inducing excessive QT prolongation and torsades des pointes. Dofetilide should be initiated only in a hospital with ECG monitoring, and many physicians take this approach with sotalol as well. Dronedarone increases mortality in patients with heart failure or long-standing persistent AF. All these agents have modest efficacy in patients with paroxysmal AF, of whom ~30–50% will benefit. Amiodarone is more effective, maintaining sinus rhythm in approximately two-thirds of patients. It can be administered to patients with heart failure and coronary artery disease. However, >40% of patients experience amiodarone-related toxicities during long-term therapy, and thus, careful monitoring of potential toxicities, including skin, liver, lung, and thyroid abnormalities, must be accompanied with this therapy.

Catheter and Surgical Ablation for Maintaining Sinus Rhythm Successful catheter ablation avoids antiarrhythmic drug toxicities, but procedural risks and efficacy depend on operator experience. For patients with previously untreated but recurrent paroxysmal AF, catheter ablation has superior efficacy compared to antiarrhythmic drug therapy, and ablation is even more clearly superior to antiarrhythmic drugs for patients who have recurrent AF despite drug treatment. Long-term control of AF is more difficult to achieve in patients with persistent and long-standing persistent AF, likely because of more extensive atrial abnormalities and associated greater comorbidities in these patients that may promote ongoing progression of atrial abnormalities that in turn promote AF recurrence.

Catheter ablation involves percutaneous venous access (typically via the femoral veins), trans (atrial) septal puncture, and radiofrequency ablation or cryoablation to electrically isolate the left atrial regions around the pulmonary vein antra, abolishing the ability of triggering foci in these regions to initiate AF and also likely impacting the substrate for reentry in the left atrium **(Fig. 258-4)**. Gaps in healed ablation areas or emergence of new trigger sites outside the pulmonary veins necessitate a repeat procedure in 10–30% of patients. Several alternative energy sources to create ablative lesions are being evaluated for ablation of AF and other arrhythmias, including laser, external beam radiation, and pulsed field electroporation.

Pulsed-field ablation uses electric fields generated by short pulses of high energy and has shown promise by specifically targeting myocardium without generating heat or damaging adjacent tissue **(Fig. 258-5)**. Myocardial cells are uniquely sensitive to high-voltage, short-duration electric fields with electroporation thresholds of 268–375 V/cm compared to other tissue types including nerves, endothelium, vascular smooth muscle, and blood cells, all of which have electroporation thresholds >1600 V/cm. The pulse waveforms used to generate an electric field can have many different characteristics including voltage amplitude, pulse width, cycle period, voltage polarity (monophasic vs. biphasic), electrode polarity (unipolar vs. bipolar), and the number of pulses delivered in a train. There are limited data evaluating the impact of how each of these variables affect lesion safety and efficacy (Fig. 258-5). Therefore, unlike radiofrequency ablation, pulsed-field ablation in its current clinical iteration lacks the ability to titrate and tailor energy delivery during ablation.

In patients with paroxysmal AF, sinus rhythm is maintained for >1 year after a single ablation procedure in ~80% of patients and is achieved in >90% of patients after multiple procedures in some studies. Among patients with paroxysmal AF receiving a catheter-based therapy, pulsed-field ablation has demonstrated to be noninferior to conventional thermal ablation (i.e., radiofrequency ablation and cryoablation) with respect to freedom from a composite of initial procedural failure, documented atrial tachyarrhythmia after a 3-month blanking period, antiarrhythmic drug use, cardioversion, or repeat ablation and with respect to device- and procedure-related serious adverse events at 1 year.

Many patients become more responsive to antiarrhythmic drugs or become less symptomatic with a reduced AF burden after a pulmonary vein isolation procedure, and thus, repeat ablation may not be required for symptom control in some. Ablation is less effective in patients with persistent AF, particularly long-standing persistent AF, especially when associated with more extensive cardiac disease, comorbidities, and evidence of moderate and severe left atrial enlargement. More extensive ablation is often required, targeting areas that likely support reentry and/or AF maintenance and regions outside but adjacent to the pulmonary venous antra.

Most ablation targets and strategies beyond pulmonary vein isolation have failed to show systematic outcome improvement in randomized controlled clinical trials. However, individualized

ablation of atrial low-voltage myocardium in addition to pulmonary vein isolation significantly improved outcomes in patients with persistent AF in one study. Similarly, in patients with persistent AF, treatment with combined catheter ablation and vein of Marshall ethanol infusion had better outcomes compared with catheter ablation alone. Ablation of areas of rapid activity during AF and creation of empiric ablation lines to block conduction across regions of the atria have not been proven to improve outcomes in unselected patients. Other ablation targets include non–pulmonary vein foci that fire in response to high-dose isoproterenol and regions with repetitive rotational or focal activation during AF. More than one ablation procedure is often required to maintain sinus rhythm in patients with persistent and long-standing persistent AF because of lack of lesion durability and complex atrial substrate with non–pulmonary vein sources that may be incompletely treated at the initial ablation session **(Table 258-3)**.

Catheter ablation has a 2–7% risk of major procedure-related complications, with the long-term trend suggesting steady improvement in complication rates. Complication rates are clearly lowest with high-volume operators and centers. Complications include stroke (0.5–1%), cardiac tamponade (1%), phrenic nerve paralysis, bleeding from femoral access sites, and fluid overload with heart failure, which can emerge 1–3 days after the procedure. It is important to recognize the potential for delayed presentation of some complications. Ablation within the pulmonary vein can lead to pulmonary vein stenosis, presenting weeks to months after the procedure with dyspnea or hemoptysis. The esophagus abuts the posterior wall of the left atrium where it is subject to injury, and esophageal ulcers can form immediately after the procedure and may rarely lead to a fistula between the left atrium and esophagus (estimated incidence of <0.1%) that presents as endocarditis and stroke 10 days to 3 weeks after the procedure. Early diagnosis

TABLE 258-3 Recommendations for Catheter Ablation in Patients with Atrial Fibrillation (AF)

CLASS	LEVEL OF EVIDENCE	RECOMMENDATIONS
1	A	In patients with symptomatic AF in whom antiarrhythmic drugs have been ineffective, contraindicated, not tolerated or not preferred, and continued rhythm control is desired, catheter ablation is useful to improve symptoms.
1	A	In selected patients (generally younger with few comorbidities) with symptomatic paroxysmal AF in whom rhythm control is desired, catheter ablation is useful as first-line therapy to improve symptoms and reduce progression to persistent AF.
1	A	In patients with symptomatic or clinically significant atrial flutter, catheter ablation is useful for improving symptoms.
2a	B	In patients who are undergoing ablation for AF, ablation of additional clinically significant supraventricular arrhythmias can be useful to reduce the likelihood of future arrhythmia.
2a	B	In patients (other than younger with few comorbidities) with symptomatic paroxysmal or persistent AF who are being managed with a rhythm-control strategy, catheter ablation as first-line therapy can be useful to improve symptoms.

of atrioesophageal fistula is important because delayed diagnosis leads to likely death. Diagnosis is made by chest CT scan with water-soluble oral and IV contrast. Endoscopy should be avoided in patients with a suspected fistula because of the risk of air/esophageal fluid embolus. Definitive repair of the atrioesophageal fistula with emergent surgery is required. Pulsed-field ablation is associated with a significantly reduced risk of pulmonary vein stenosis, phrenic nerve injury, and left atrial esophageal fistula.

Surgical ablation of AF is most frequently performed concomitant with cardiac valve or coronary artery surgery and less commonly as a stand-alone procedure. There is no significant difference in the rate of freedom from AF between patients who undergo pulmonary vein isolation and those who undergo the biatrial maze procedure.

However, for patients with persistent AF, surgical or hybrid procedures (a combination of a surgical and catheter-based approach, most often in separate procedures) appear to have comparable efficacy to catheter ablation. Risks include sinus node injury requiring pacemaker implantation and higher morbidity with surgical ablation. Surgical removal of the left atrial appendage may reduce stroke risk, although thrombus can form in the remnant of the appendage or if the appendage is not completely ligated.

RISK FACTORS FOR AND LIFESTYLE IMPACT ON ATRIAL FIBRILLATION

There is strong evidence that AF is associated with a sedentary lifestyle, obesity, hypertension, smoking, alcohol use, and sleep apnea. Aggressive treatment of these risk factors can substantially reduce AF episodes in some patients and is warranted in all patients, as additional benefits to the patient are likely beyond AF improvement. The amount of exercise appears to have a complex relationship with the risk of AF development. In males, a U-shaped curve exists, where AF risk is high among those with sedentary lifestyles and those who participate extensively in endurance athletics such as long-distance running or cycling. Moderate exercise appears to confer a lower risk of AF. On the other hand, in females, a linear relationship exists between exercise and AF risk, with risk of AF decreasing continuously with increasing exercise activity. Although caffeine intake is often invoked as a risk for AF development or as a trigger for AF episodes in patients with a known AF diagnosis, large cohort studies have demonstrated, in contrast, a modest decrease in AF risk with modest caffeine intake. Other proposed risk factors are being evaluated, including psychological stress. Genetic predisposition to AF is seen in those with first-degree relatives with AF, and a small subset of AF patients can be determined have a familial form of AF.

There is emerging emphasis on an integrated approach to management of AF patients, with coordinated management of risk factor modification, stroke prevention, rate control, rhythm control, and management of associated comorbidities of critical importance. The previous classification of AF, which was based only on arrhythmia duration (i.e., paroxysmal, persistent, and long-standing persistent), although useful, tended to emphasize therapeutic interventions. A more recent classification using four stages (i.e., at risk of AF, pre-AF, AF, and permanent AF) has been proposed and recognizes AF as a disease continuum that requires a variety of strategies at the different stages, including prevention, lifestyle and risk factor modification, screening, and therapy.

259 Approach to Ventricular Arrhythmias

William H. Sauer, Usha B. Tedrow

There are myriad types of ventricular arrhythmias (VAs), ranging from benign to life-threatening, occurring both in patients with normal hearts and in those with structural heart disease. An understanding of an approach to these arrhythmias is critical to being appropriately parsimonious with benign forms, while understanding timely workup and management of the malignant forms.

TYPES OF VAs

VAs can arise from focal sites of origin or from reentrant circuits. Focal VAs can originate from myocardial or specialized Purkinje cells capable of automaticity or triggered activity. Reentrant VAs often involve areas of scar such as old myocardial infarction or a cardiomyopathic process. Less commonly, diseased Purkinje conduction pathways can also result in reentrant circuits. VAs are characterized by their electrocardiographic appearance and duration. Conduction away from the ventricular focus or reentrant circuit exit, propagating through the ventricular myocardium, is slower than activation of the ventricles over the normal Purkinje system. For this reason, the QRS complex duration during VAs will be wide, typically >0.12 s, though there are unusual situations that can arise with narrow QRS duration as well.

Premature ventricular beats (also referred to as a *premature ventricular contractions* or *premature ventricular complexes* [PVCs]) are single ventricular beats that occur earlier than the next anticipated supraventricular beat **(Fig. 259-1)**. PVCs that originate from the same focus will have the same QRS morphology and are referred to as unifocal **(Fig. 259-1*A*)**. PVCs that originate from different ventricular sites have different QRS morphologies and are referred to as multifocal **(Fig. 259-1*B*)**. Two consecutive ventricular beats are ventricular couplets.

Ventricular tachycardia (*VT*) is three or more consecutive beats at a rate faster than 100 beats/min. Three or more consecutive beats at

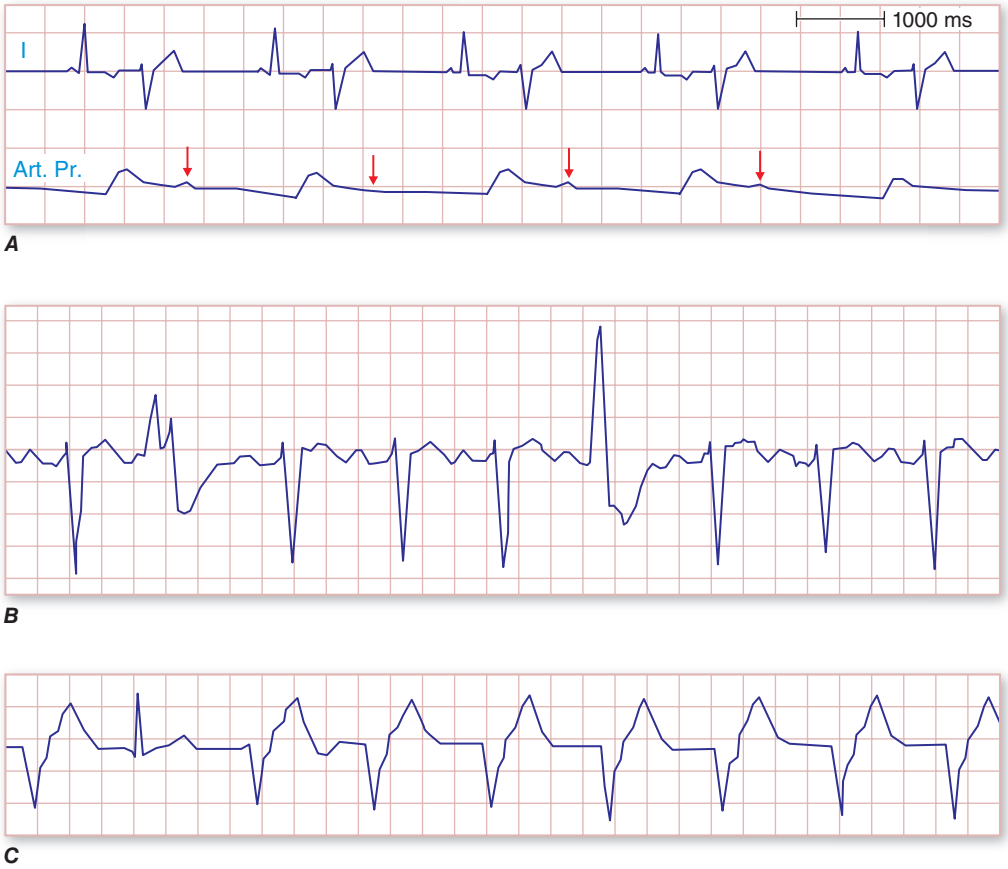

FIGURE 259-1 ***A.*** Unifocal premature ventricular contractions (PVCs) at bigeminal frequency. Trace shows electrocardiogram lead 1 and arterial pressure (Art. Pr.). Sinus rhythm beats are followed by normal arterial waveform. The arterial pressure following premature beats is attenuated (*arrows*) and imperceptible to palpation. The pulse in this patient is registered at half the heart rate. ***B.*** Multifocal PVCs. The two PVCs shown have different morphologies. ***C.*** Example of accelerated idioventricular rhythm. (See text for details.)

slower rates are designated an idioventricular rhythm. VT that terminates spontaneously within 30 s is designated *nonsustained*, whereas sustained VT persists for >30 s or is terminated by an active intervention, such as administration of an intravenous medication, external cardioversion, antitachycardia pacing, or a shock from an implanted cardioverter-defibrillator **(Fig. 259-2)**.

Monomorphic VT has the same QRS complex from beat to beat, indicating that the activation sequence is the same from beat to beat

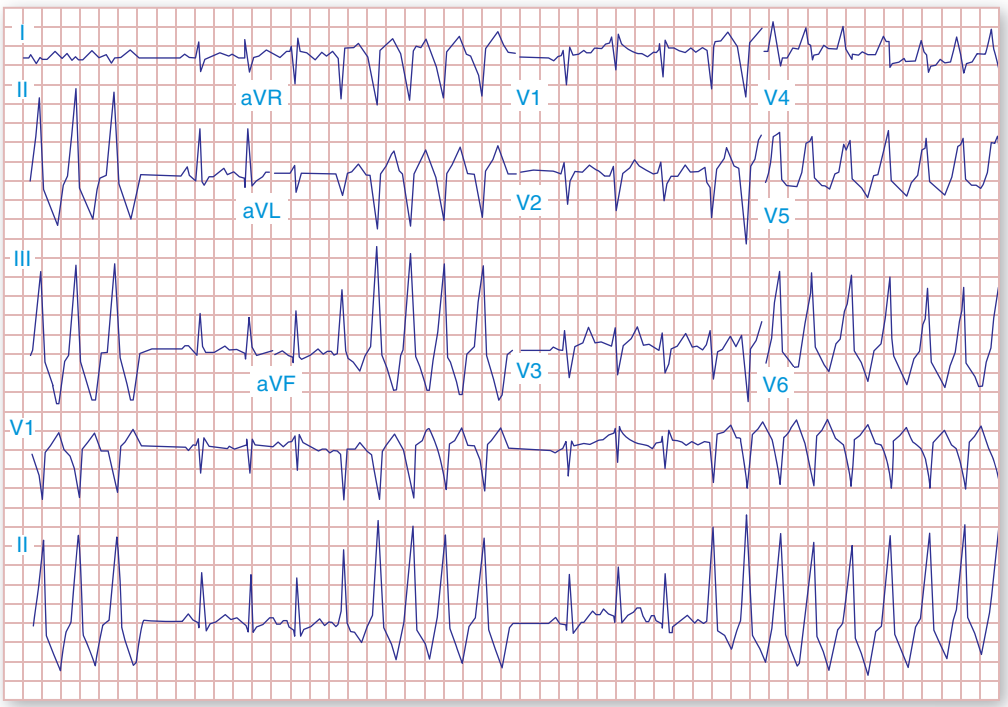

FIGURE 259-2 Repetitive monomorphic nonsustained ventricular tachycardia (VT) of right ventricular outflow tract origin. The VT has a left bundle branch block pattern with inferior axis with tall QRS complexes in the inferior leads.

and that each beat likely originates from the same source **(Fig. 259-3*A*)**. The initial site of ventricular activation largely determines the sequence of ventricular activation. Therefore, the QRS morphology of PVCs and monomorphic VT provides an indication of the site of origin within the ventricles **(Fig. 259-4)**. The likely origin often suggests whether an arrhythmia is idiopathic or associated with structural disease. Arrhythmias that originate from the right ventricle or septum result in late activation of much of the left ventricle, thereby producing a prominent S wave in V_1 referred to as a left bundle branch block–like configuration. Arrhythmias that originate from the free wall of the left ventricle have a prominent positive deflection in V_1, thereby producing a right bundle branch block–like morphology in V_1. The frontal plane axis of the QRS is also useful. An axis that is directed inferiorly, as indicated by dominant R waves in leads II, III, and AVF, suggests initial activation of the cranial portion of the ventricle, whereas a frontal plane axis that is directed superiorly (dominant S waves in II, III, and AVF) suggests initial activation at the inferior wall.

Very rapid monomorphic VT has a sinusoidal appearance, also called *ventricular flutter*, because it is not possible to distinguish the QRS complex from the T wave **(Fig. 259-3*B*)**. Relatively slow *sinusoidal* VTs have a wide QRS indicative of slowed ventricular conduction **(Fig. 259-3*C*)**. Hyperkalemia, toxicity from excessive effects of drugs that block sodium channels (e.g., flecainide, propafenone, or tricyclic antidepressants), and severe global myocardial ischemia are possible causes.

Polymorphic VT has a continually changing QRS morphology indicating a changing ventricular activation sequence. Polymorphic VT that occurs in the context of congenital or acquired prolongation of the QT interval often has a waxing and waning QRS amplitude, creating a characteristic shifting axis referred to as torsades des pointes after the classic ballet sequence **(Fig. 259-3*D*)**.

Ventricular fibrillation (VF) has continuous irregular activation with no discrete QRS complexes. Monomorphic or polymorphic VT may transition to VF in susceptible patients. Cardiac ischemia is the most common cause of VF **(Fig. 259-3*E*)**.

The term *idiopathic ventricular arrhythmia* generally refers to PVCs or VT that occurs in patients with a normal electrocardiogram (ECG), without structural heart disease, and not associated with an underlying genetic syndrome or risk of sudden death.

CLINICAL MANIFESTATIONS

Common symptoms of VAs include palpitations, dizziness, exercise intolerance, episodes of lightheadedness, syncope, or sudden cardiac arrest leading to sudden death if not resuscitated. VAs can also be asymptomatic and encountered unexpectedly as an irregular pulse or heart sounds on examination or may be seen on a routine ECG, exercise test, or cardiac ECG monitoring. Occasionally when every other beat is a PVC (*bigeminy*), pulse measurements for heart rate can be erroneously low (*pseudobradycardia*) because the PVCs may not generate a separate pulse wave.

Syncope is a concerning symptom, particularly when occurring without prodrome, during exercise, or in the setting of abnormal ECG or structural heart disease. Such episodes can be due to VT that produces severe hypotension, warranting concern for risk of cardiac arrest and sudden death with arrhythmia recurrence. Although benign processes such as reflex-mediated neurocardiogenic (vasovagal) episodes and orthostatic hypotension are the most common causes of syncope, it is important to consider the possibility of underlying heart disease or a genetic syndrome causing VT. When these are suspected, hospitalization for further evaluation and monitoring is often appropriate.

Sustained VT may present as a wide QRS complex tachycardia that must be distinguished from supraventricular tachycardia with aberrancy **(Chap. 253)**. Symptoms can be minor but more commonly include hypotension with syncope and even imminent cardiac arrest, particularly in patients with structural heart disease. Sustained VT may degenerate to VF, most commonly if it is rapid and polymorphic. Many patients who are at risk for VT have known heart disease, and many have an implantable cardioverter-defibrillator (ICD). In patients with an ICD, VT episodes may cause transient lightheadedness, palpitations, or syncope followed by a shock from the ICD (see below).

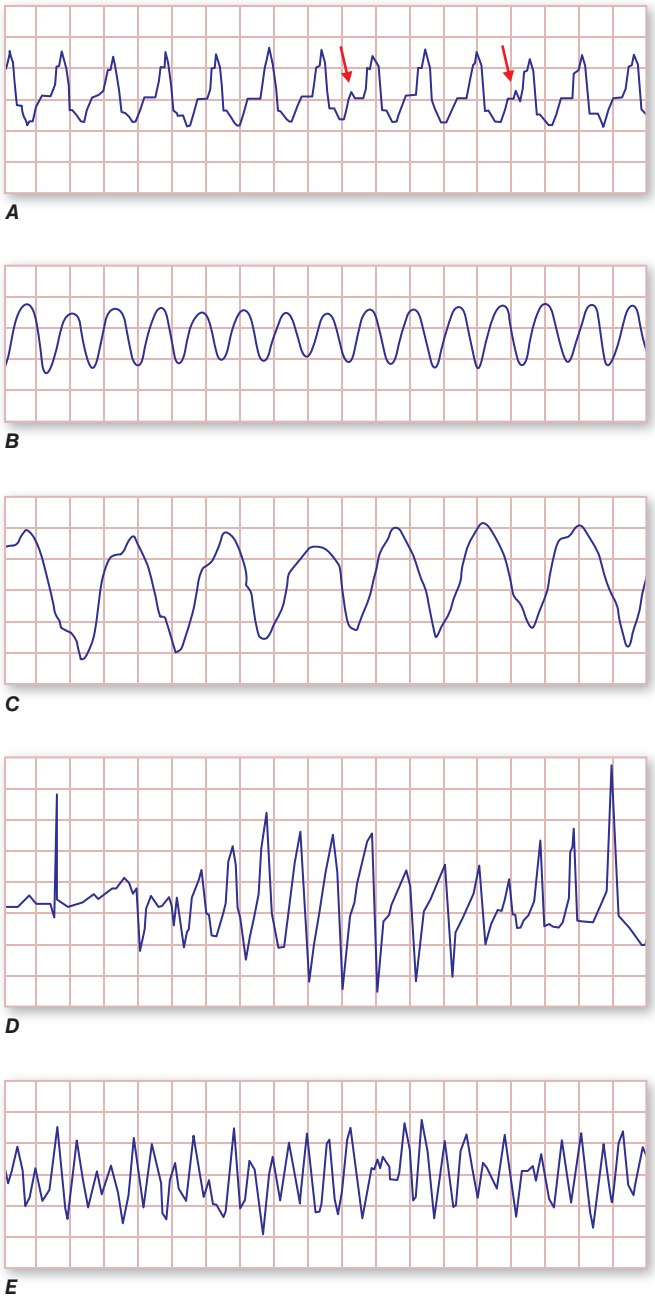

FIGURE 259-3 ***A.*** Monomorphic ventricular tachycardia (VT) with dissociated P waves (*short arrows*). ***B.*** Ventricular flutter. ***C.*** Sinusoidal VT due to electrolyte disturbance or drug effects. ***D.*** Polymorphic VT resulting from prolongation of QT interval (torsade de pointe VT). ***E.*** Ventricular fibrillation. EVALUATION OF PATIENTS WITH DOCUMENTED OR SUSPECTED VENTRICULAR ARRHYTHMIAS

There are several important considerations that guide evaluation of patients with documented or suspected cardiac arrhythmias. First, establish whether a VA is the cause of the symptoms or clinical presentation. Second, determine whether the arrhythmia is associated with a cardiac disease, and establish the prognostic significance of that disease and, in particular, whether it is associated with a risk of sudden cardiac death. Finally, define the likelihood of arrhythmia recurrence and the symptoms and risk imposed by the recurrence. The risks of cardiac arrest and sudden cardiac death are largely determined by the cause of the arrhythmia and the associated underlying heart disease.

The diagnosis of VAs can be established by recording the arrhythmia on an ECG, by an ambulatory or implanted cardiac monitor, by an implanted rhythm management device such as a pacemaker or ICD, or in some cases, initiation of the arrhythmia during an electrophysiologic

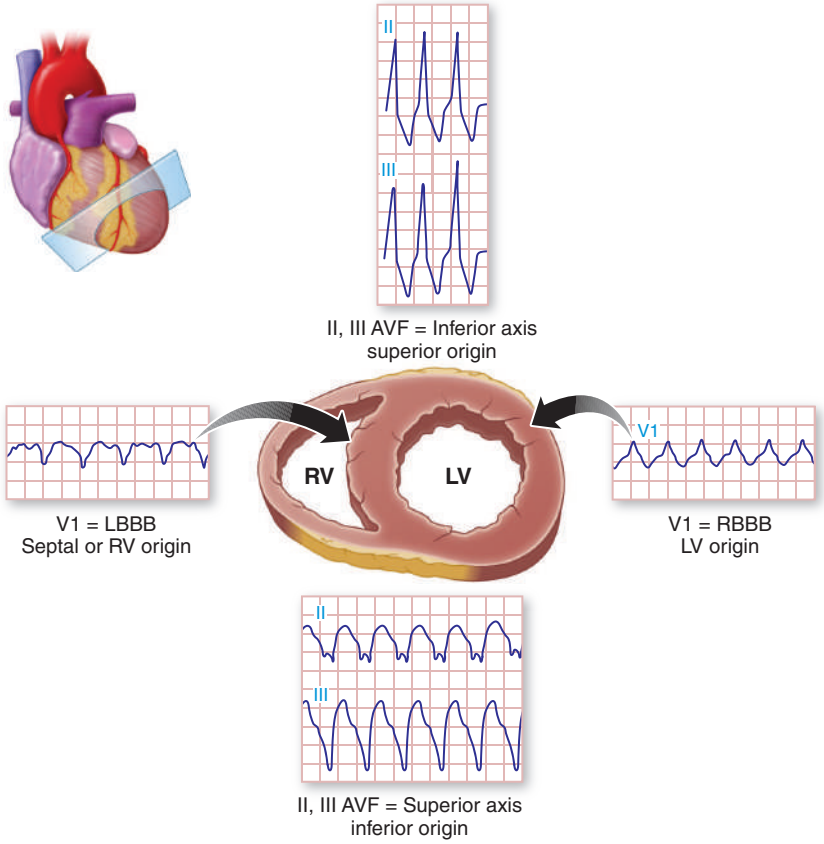

FIGURE 259-4 Site of ventricular tachycardia origin based on QRS morphology. (See text for details.) LBBB, left bundle branch block; LV, left ventricle; RBBB, right bundle branch block; RV, right ventricle.

study. A 12-lead ECG of the arrhythmia should be obtained when possible and often provides clues to the potential site of origin and possible presence of underlying heart disease (see above) (Fig. 259-4).

For patients with sustained wide-complex tachycardia, initial management is guided by the patient's hemodynamic stability. The approach to sustained wide-complex tachycardia is discussed in **Chap. 261**. The management of VT that causes cardiac arrest is discussed in **Chap. 317**. Once hemodynamic stability is restored, further management is guided by the possibility of a recurrence and the risk imposed by a recurrence.

EVALUATION OF THE PATIENT WITH ARRHYTHMIA SYMPTOMS

When symptoms are intermittent, initial evaluation aims to establish symptom severity, provocative factors, and presence of underlying heart disease. Syncope or near syncope raises concern that an arrhythmia is causing episodes of hypotension and that there may be a risk of cardiac arrest. Symptoms that occur with exertion suggest arrhythmias that are provoked by sympathetic stimulation but can also be related to exertional ischemia in patients with coronary artery disease, although nonarrhythmia causes must also be considered. A past history of any cardiac disease is important. A review of all medications is relevant. Medications that prolong the QT interval predispose to polymorphic VT **(Chap. 262)**. Adrenergic stimulants can provoke PVCs.

Family history should determine the presence of premature coronary artery disease, cardiomyopathy, or cardiac arrhythmias, particularly a history of sudden death. Family history may also suggest that the possibility of a genetic cause of an arrhythmia warrants careful consideration. Details of premature deaths are relevant. Sudden death victims are often said to have died of a "massive heart attack" despite absence of definite confirmation of thrombotic myocardial infarction and when other causes such as arrhythmia may have been possible.

The physical examination focuses on evidence of structural heart disease with assessment of pulse, jugular venous pressure lung fields, and cardiac auscultation. Stigmata of neuromuscular disease or dysmorphic features may suggest a genetic arrhythmia syndrome.

A 12-lead ECG should be obtained even if the patient is not having symptoms at the time of evaluation. Occasionally, premature ventricular contractions will be detected. Patients with benign idiopathic arrhythmias usually have a completely normal ECG during sinus rhythm. Any ECG abnormality warrants further evaluation. Particularly relevant findings include Q waves that indicate prior myocardial infarction, which may have been silent, and ventricular hypertrophy, which may indicate hypertrophic cardiomyopathy or other ventricular disease. An ECG finding is the major diagnostic manifestation of several genetic arrhythmia syndromes in patients without structural heart disease, including the long QT syndrome, Brugada syndrome, and short QT syndrome.

If there is suspicion of structural heart disease, cardiac imaging is warranted to assess ventricular function and structure. Transthoracic echocardiography is most frequently employed for initial evaluation. Depressed ventricular function increases concern for a risk of sudden death and warrants further evaluation to establish the cause, which may be cardiomyopathy, coronary artery disease, or valvular heart disease. Ventricular thickening may indicate hypertrophic cardiomyopathy or infiltrative diseases such as amyloidosis. Cardiac magnetic resonance imaging with gadolinium contrast imaging provides similar assessment but also can detect areas of ventricular scar, evident as regions of delayed hyperenhancement, which are usually present in patients who have sustained monomorphic VT **(Fig. 259-5)**. The nature and location of abnormalities are helpful in assessing the type of heart disease. Evaluation to exclude atherosclerotic coronary artery disease should be performed in patients at risk, guided by age and other risk factors.

TREATMENT OPTIONS FOR VENTRICULAR ARRHYTHMIAS

Treatment of VAs is guided by the severity and frequency of symptoms. For those with structurally normal hearts and normal ECGs, reassurance and removal of aggravating factors (e.g., caffeine or alcohol) may be all that is needed. For arrhythmias associated with a sudden death risk, ICD implantation is usually indicated and will provide a "safety net" to terminate life-threatening VT or VF, preventing sudden death but without preventing the arrhythmia. When suppression of the arrhythmia is required, antiarrhythmic drug therapy or catheter ablation is a major consideration.

ANTIARRHYTHMIC DRUGS

Use of antiarrhythmic drugs is based on consideration of the risks and potential benefit for the individual patient. Efficacy and side effects for the individual patient are not always predictable and are assessed by individual therapeutic trial. Causes of drug intolerance are mostly noncardiac and minor but can sometimes be severe enough to limit their use. Cardiac adverse events, however, include the potential for "proarrhythmia," whereby a drug can increase the frequency of arrhythmia or cause a new arrhythmia. Aggravation of bradyarrhythmias is also a common concern. Although antiarrhythmic drugs are classified based on their actions on receptors or ion channels, most have multiple effects, affecting more than one channel.

β-ADRENERGIC BLOCKERS

Many VAs are sensitive to sympathetic stimulation, and β-adrenergic stimulation may also interact with the electrophysiologic effects of many membrane-active antiarrhythmic drugs. The safety of β-blocking agents makes them the first choice of therapy for most VAs. β-Blockers are particularly useful for exercise-induced arrhythmias and idiopathic arrhythmias but have limited efficacy for most arrhythmias associated

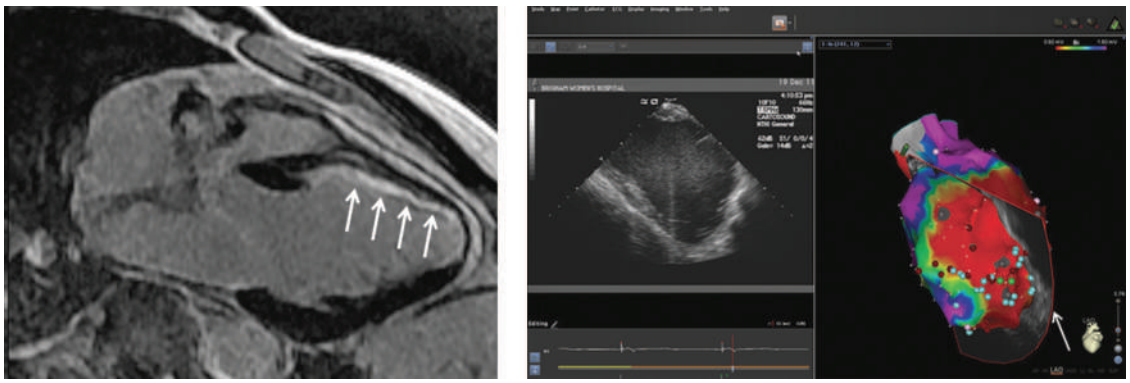

FIGURE 259-5 Imaging studies of the left ventricle (LV) used to assist ablation for ventricular tachycardia (VT). *Left panel* is a magnetic resonance image of a longitudinal section demonstrating thinning of the anterior wall and late gadolinium enhancement in a subendocardial scar (*white arrows*). The *middle panel* shows a two-dimensional image of the LV in long axis corresponding to the sector through the mid-LV (*arrow in figure on right panel*) obtained by an intracardiac echocardiography probe positioned in the right ventricle. An electroanatomic three-dimensional map of the LV in the left anterior oblique projection is displayed in the *right panel*. The purple areas depict areas of normal voltage (>1.5 mV). Blue, green, and yellow represent progressively lower voltages, with the red areas indicating scar (<0.5 mV). Channels of viable myocardium with slow conduction within the scar are identified with the light blue dots. Areas of ablation delivered to regions involved in reentrant VT are indicated by maroon dots.

with heart disease. Bradyarrhythmias and negative inotropic effects are the major cardiac adverse effects.

CALCIUM CHANNEL BLOCKERS

The nondihydropyridine calcium channel blockers diltiazem and verapamil can be effective for some idiopathic VTs. The risk of proarrhythmia is low, but they have negative inotropic and vasodilatory effects that can aggravate hypotension.

SODIUM CHANNEL–BLOCKING AGENTS

Drugs whose major effect is mediated through sodium channel blockade include mexiletine, quinidine, disopyramide, flecainide, and propafenone, which are available for chronic oral therapy. Blockade of the fast inward sodium current has been referred to as a class I antiarrhythmic drug effect. Antiarrhythmic actions are the result of depressing cardiac conduction and membrane excitability. Conduction slowing can be manifest as a prolongation of QRS duration. Lidocaine, quinidine, and procainamide are available as intravenous formulations. Quinidine, disopyramide, and procainamide also have potassium channel–blocking effects that may prolong the QT interval (class III antiarrhythmic drug action), contributing to their antiarrhythmic effect. Quinidine also blocks a particular potassium current, I_{to}, the blockade of which can be important in Brugada syndrome. These agents have potential proarrhythmic effects and, with the possible exception of quinidine, also have negative inotropic effects that may have contributed to the increased mortality observed when some were administered chronically to patients with prior myocardial infarction. Long-term therapy is generally avoided in patients with structural heart disease but may be used to reduce symptomatic arrhythmias in patients with ICDs.

POTASSIUM CHANNEL BLOCKING AGENTS

Sotalol and dofetilide block the delayed rectifier potassium channel I_{Kr}, thereby prolonging action potential duration (QT interval) and the cardiac refractory period, known as the class III antiarrhythmic drug effect. Sotalol also has nonselective β-adrenergic–blocking activity. It has been shown to have a modest effect on reducing ICD shocks due to ventricular and atrial arrhythmias. Proarrhythmia due to the polymorphic VT torsade de pointe that is associated with QT prolongation occurs in 3–5% of patients. Both sotalol and dofetilide are excreted via the kidneys, necessitating dose adjustment or avoidance in renal insufficiency. These drugs must be avoided in patients with other risk factors for torsades de pointes, including QT prolongation, other administered medications that prolong the QT interval, hypokalemia, and significant bradycardia.

AMIODARONE

Amiodarone blocks multiple cardiac ionic currents and has sympatholytic activity. It is the most effective antiarrhythmic drug for suppressing VAs. It is administered intravenously for life-threatening arrhythmias. During chronic oral therapy, electrophysiologic effects develop over several days. It is more effective than sotalol in reducing ICD shocks and is often used for VAs in patients with heart disease. Bradyarrhythmias are the major cardiac adverse effect. Ventricular proarrhythmia can occur, but torsades de pointes VT is rare. Noncardiac toxicities are a major problem and contribute to drug discontinuation in at least a third of patients during long-term therapy. Hyper- and hypothyroidism are related to the iodine content of the drug. Pneumonitis or pulmonary fibrosis occurs in ~1% of patients. Photosensitivity is common, and neuropathy and ocular toxicity can occur. Systematic monitoring is recommended during chronic therapy including assessment for thyroid, liver, and pulmonary toxicity. Intravenous administration of amiodarone via a peripheral vein for >24 h can cause severe peripheral thrombophlebitis. Dronedarone has structural similarities to amiodarone but without the iodine moiety. Efficacy for VAs is poor, and dronedarone increases mortality in patients with heart failure, so dronedarone is not typically used for treatment of VAs.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

ICDs detect sustained VT, largely based on heart rate, and then terminate the arrhythmia. In transvenous devices, VF is terminated by a shock applied between a lead in the right ventricle and the ICD pulse generator. The lead can provide pacing for bradycardia if needed. This transvenous form of ICD has the disadvantages of vascular occlusion, risk of lead fracture, endocarditis in the event of infection, and difficulty with removal. Monomorphic VT can also be terminated by a burst of rapid pacing faster than the VT, known as antitachycardia pacing (ATP) **(Fig. 259-6*A*)**. If ATP fails or is not a programmed treatment, as is often the case for rapid VT or VF, a shock is delivered **(Fig. 259-6*B*)**. ICDs can also be subcutaneous or extravascular, without a transvenous lead. The rhythm is also sensed by this lead, in a manner similar to a surface ECG. The lead is placed overlying the left chest with a coil parallel and next to or underneath the sternum. No matter the type of ICD, shocks are uncomfortable and distressing if the patient is conscious, sometimes leading to a posttraumatic stress disorder (PTSD). The most common ICD complication is the delivery of unnecessary therapy (either ATP or shocks) in response to an inappropriately detected rapid supraventricular tachycardia or electrical noise as a result of an ICD lead fracture or electromagnetic interference from an external source. ICDs record and store electrograms from arrhythmia episodes that can be retrieved by interrogation of the ICD, which can be performed remotely and communicated via the internet. This assessment is critical after an ICD shock to determine the arrhythmia diagnosis and exclude unnecessary therapy. Device infection is an important problem long term and occurs in ~1% of patients. This risk may be less for subcutaneous or extravascular implants.

ICDs decrease mortality in patients at risk for sudden death due to structural heart diseases. In all cases, ICDs are recommended only if there is also an expectation for survival of at least a year with acceptable

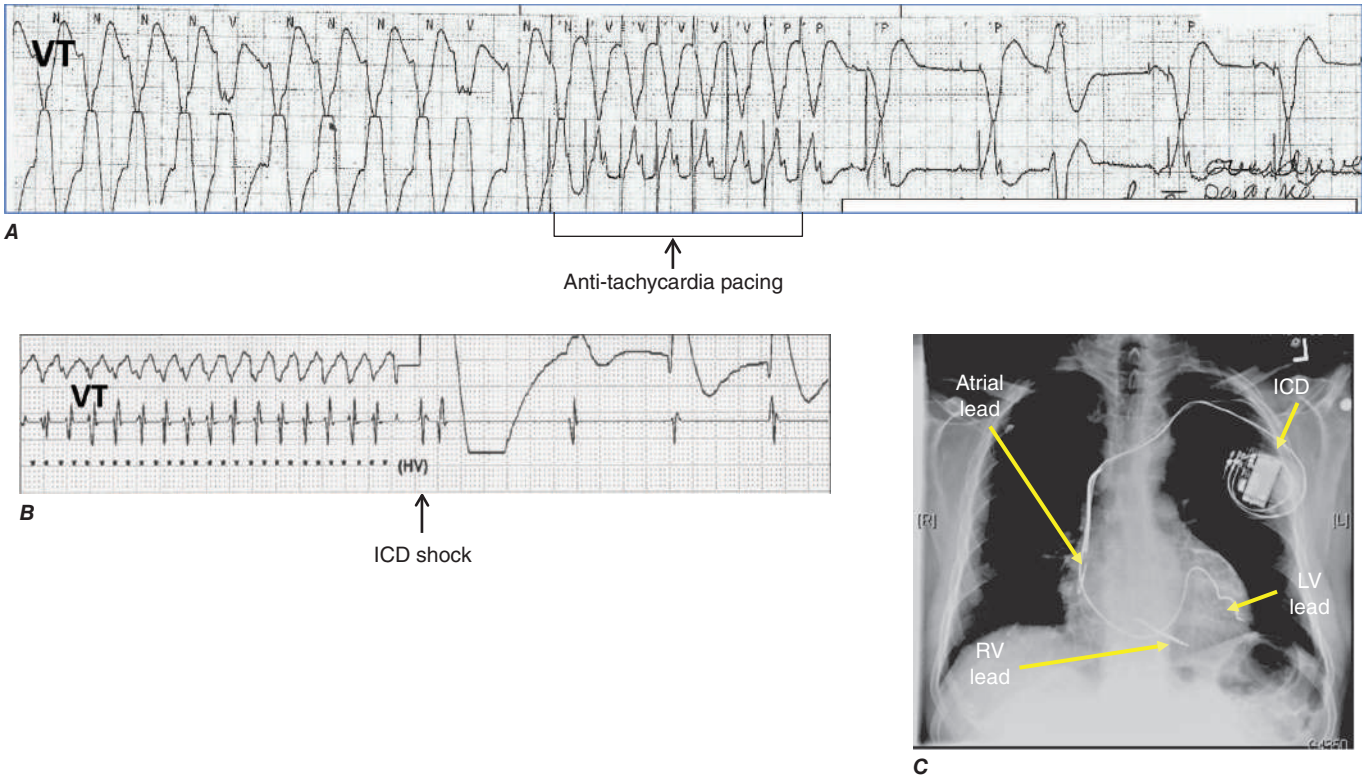

FIGURE 259-6 Implantable cardioverter-defibrillator (ICD) and therapies for ventricular arrhythmias. ***A.*** A monomorphic ventricular tachycardia (VT) is terminated by a burst of pacing impulses at a rate faster than VT (antitachycardia pacing). ***B.*** A rapid VT is converted with a high-voltage shock (*arrow*). The chest x-ray in the panel ***C*** shows the components of an ICD capable of biventricular pacing (*yellow arrows*). ICD generator in the subcutaneous tissue of the left upper chest, pacing leads in the right atrium and the left ventricular (LV) branch of the coronary sinus (LV lead), and a pacing/defibrillating lead in the right ventricle (RV lead) are shown.

functional capacity. The exception is in cases of patients with end-stage heart disease who are awaiting cardiac transplantation outside the hospital or who have left bundle branch block QRS prolongation such that they are likely to have improvement in ventricular function with cardiac resynchronization therapy from a biventricular ICD or conduction system pacing (Fig. 259-6*C*). In these cases, an ICD may be warranted despite a guarded prognosis. A wearable ICD system with electrodes incorporated into a vest and an external battery pack is also available for short-term use in patients pending a decision regarding a permanent implanted system, or when a permanent system cannot be implanted for other reasons such as an ongoing infection.

Despite prompt termination of VT or VF by an ICD, the occurrence of these arrhythmias predicts subsequent increased mortality and risk of heart failure. Occurrence of VT or VF should therefore prompt assessment for potential causes including worsening heart failure, electrolyte abnormalities, and ischemia. Repeated shocks, even if appropriate, often induce posttraumatic stress disorder. Antiarrhythmic drug therapy, most commonly amiodarone, or catheter ablation is often required for suppression of recurrent arrhythmias. Antiarrhythmic drug therapy can alter the VT rate and the energy required for defibrillation, thereby necessitating programming changes in the ICD's algorithms for detection and therapy.

CATHETER ABLATION FOR VT

Catheter ablation is usually performed by applying radiofrequency (RF) current to cause thermal injury by resistive heating of cardiac tissue responsible for the arrhythmia. An electrode catheter with an electroanatomic mapping system is used to map local electrical activity to identify the ventricular myocardium that is causing the arrhythmia, referred to as the arrhythmia substrate. The size and location of the arrhythmia substrate determine the ease and likely effectiveness of the procedure, as well as the potential complications. When the arrhythmia originates from the endocardium, as is most commonly the case, it can be reached from an endovascular approach via a femoral vein or artery. Less commonly, arrhythmias originate from the subepicardium, and percutaneous pericardial puncture, similar to pericardiocentesis, is required to insert a catheter into the pericardial space for mapping and ablation. In patients with scar-related VT due to prior infarction or cardiomyopathy, ablation typically targets abnormal regions in the scar or region of fibrosis. Because these scars often contain multiple reentry circuits over relatively large regions, extensive areas of ablation can be required, and these areas are often identified as regions of low voltage displayed on electroanatomic reconstructions of the ventricle (Fig. 259-5).

Catheter ablation is often performed in patients with recurrent VAs associated with poor cardiac function, and the procedure-related mortality in this situation is 0.5–3%. Outcomes are better for patients with prior infarction and VT than for patients with nonischemic cardiomyopathies in which the scar locations are more variable and often intramural or subepicardial. Ablation can be lifesaving for patients with very frequent or incessant VT. Methods of delivering ablative energy to intramural areas or areas requiring very extensive ablation are under development. These include needle catheters capable of delivering ablative energy into intramural sources, and bipolar ablation where radiofrequency energy is delivered across two ablation catheters. Stereotactic body radiation therapy (SBRT), classically used for treating thoracic tumors, has been used to direct radiation therapy to a specific portion of the scar substrate to noninvasively ablate VT with encouraging early studies.

Idiopathic VTs and PVCs that occur in the absence of structural heart disease usually originate from a small focus, for which catheter ablation typically has a higher success rate for preventing recurrent arrhythmia. Long-term arrhythmia-free survival in these patients is excellent.

ARRHYTHMIA SURGERY

When antiarrhythmic drug therapy and catheter ablation fail or are not an option, surgical cryoablation, often combined with aneurysmectomy, can be effective therapy for recurrent VT due to prior myocardial infarction and has also been used successfully in a few patients with nonischemic heart disease. Few centers now maintain the expertise for this therapy, though some use this therapy as an adjunct to ventricular assist device implantation.

260 Premature Ventricular Contractions, Nonsustained Ventricular Tachycardia, and Accelerated Idioventricular Rhythm

William H. Sauer, Usha B. Tedrow

Ventricular ectopic beats are very common and may be identified during outpatient or inpatient telemetry monitoring either due to symptoms of palpitations or as an incidental finding. In most cases, ventricular ectopy, presenting as premature ventricular contractions (PVCs), nonsustained ventricular tachycardia (NSVT), and accelerated idioventricular rhythm (AIVR), is asymptomatic and does not require specific treatment. While most commonly benign when presenting in patients with structurally normal hearts and normal electrocardiograms (ECGs), these ventricular arrhythmias can rarely be associated with structural heart disease and a risk of sudden death.

PREMATURE VENTRICULAR CONTRACTIONS AND NONSUSTAINED VENTRICULAR TACHYCARDIA

PVCs are very common and can be due to enhanced automaticity, triggered automaticity, or localized reentry. PVCs are often sensitive to sympathetic stimulation and can be a sign of increased sympathetic tone, myocardial ischemia, hypoxia, electrolyte abnormalities, or underlying heart disease. During myocardial ischemia or in association with other structural heart disease, PVCs can be a harbinger of sustained ventricular tachycardia (VT) or ventricular fibrillation (VF).

The ECG characteristics of the arrhythmia are often suggestive of whether structural heart disease is present. PVCs with smooth uninterrupted contours and sharp QRS deflections may suggest an ectopic focus in relatively normal myocardium, whereas broad notching and slurred QRS deflections may suggest a diseased myocardial substrate. The QRS morphology also suggests the likely site of origin within the ventricle. PVCs that have a dominant S wave in V_1, referred to as a left bundle branch block–like configuration, originate from the right ventricle or interventricular septum. Those with a dominant R wave in V_1 originate from the left ventricle. A superior frontal plane axis (negative in II, III, aVF) indicates initial depolarization of the inferior wall (diaphragmatic aspect of the heart), whereas an inferior frontal plane axis (positive in II, III, aVF) indicates an origin in the cranial aspect of the heart. The location of arrhythmia origin often suggests the nature of underlying heart disease. Most common ventricular arrhythmias that are not associated with structural heart disease have a left bundle branch block–like configuration. PVCs with a right bundle branch block configuration are more likely to be associated with structural heart disease. Multiple morphologies of PVCs (multifocal PVCs) are also more likely to indicate structural heart disease or a myopathic disease process. In patients with heart disease, greater frequency and complexity (couplets and NSVT) of these arrhythmias are associated with more severe disease.

PVCs AND NSVT DURING ACUTE ILLNESS

These arrhythmias are often encountered in patients who are being evaluated in the emergency department or who have been hospitalized and are on an ambulatory cardiac monitor. When encountered during acute illness or as a new finding, evaluation should focus on detection and correction of potential aggravating factors and causes, specifically myocardial ischemia, ventricular dysfunction, and electrolyte abnormalities, most commonly hypokalemia. If there is a suspicion of underlying heart disease, then this should be evaluated. Otherwise, asymptomatic PVCs and NSVT in the hospitalized patient do not indicate any specific treatment outside the patient's presenting illness.

PVCs AND NSVT IN PATIENTS WITHOUT HEART DISEASE

Idiopathic ventricular arrhythmias frequently originate from the left or right ventricular outflow tracts near the valve annuli, giving rise to PVCs or VT that have a left bundle branch block–like configuration, with an inferiorly directed frontal plane axis, as discussed below. Other regions that give rise to PVCs in normal hearts include the papillary muscles and fascicular tissue. NSVT from a benign idiopathic source is usually monomorphic, with rates <200 beats/min. NSVT that is very rapid, polymorphic, or with a first beat that occurs prior to the peak of the T wave ("short-coupled") is uncommon and should prompt concern and careful evaluation for underlying disease or genetic syndromes associated with sudden death.

A family history of sudden death should prompt evaluation for genetic syndromes associated with sudden death, including cardiomyopathy, long QT syndrome, and arrhythmogenic right ventricular cardiomyopathy (ARVC) (see below). Any abnormality on the 12-lead ECG warrants further evaluation. Repolarization abnormalities are seen in a number of genetically determined syndromes associated with sudden death, including the long QT syndrome, Brugada syndrome, ARVC, and hypertrophic cardiomyopathy **(Fig. 260-1)**. Structural abnormalities such as mitral valve prolapse and mitral annular disjunction can be associated with papillary muscle PVCs and sudden death. An echocardiogram is often necessary to assess ventricular function, wall motion abnormalities, and valvular heart disease. Contrast-enhanced cardiac magnetic resonance imaging (MRI) is also useful for this purpose and for the detection of ventricular scarring that is the substrate for sustained VT. Exercise stress testing should be performed in patients with effort-related symptoms and for those at risk for coronary artery disease.

TREATMENT OF IDIOPATHIC ARRHYTHMIAS

For PVCs and NSVT in the absence of structural heart disease or a genetic sudden death syndrome, no specific therapy is needed unless the patient has significant symptoms or evidence that frequent PVCs are depressing ventricular function (see below). Reassurance that the arrhythmia is benign is often sufficient to allow the patient to cope with the symptoms, which will often wax and wane in frequency over years. Avoiding stimulants, such as caffeine and alcohol, is helpful in some patients. If symptoms require treatment, β-adrenergic blockers and nondihydropyridine calcium channel blockers (verapamil and

diltiazem) are sometimes helpful. If these fail, more membrane active antiarrhythmic drugs and catheter ablation are options. The antiarrhythmic agents flecainide, propafenone, mexiletine, and amiodarone can be effective, but the potential for side effects warrants careful consideration prior to prescribing these agents for long-term use. Catheter ablation is effective at suppressing this arrhythmia in ~90% of patients. Failure of ablation is usually due to inability to provoke the arrhythmia for mapping in the electrophysiology laboratory or if the site of origin is near a vital structure, such as the coronary arteries or His-Purkinje system, or is not accessible due to a site of origin deep within the myocardium.

PVCs AND NSVT ASSOCIATED WITH ACUTE CORONARY SYNDROMES

In the peri-infarct period, PVCs and NSVT are common and can be an early manifestation of ischemia and a harbinger of subsequent VF. Treatment with β-adrenergic blockers and correction of hypokalemia and hypomagnesemia reduce the risk of VF. Routine administration of antiarrhythmic drugs such as lidocaine or amiodarone does not reduce mortality and is not indicated for suppression of PVCs or asymptomatic NSVT but may be implemented transiently if an episode of sustained VT or VF occurs, with the goal of reducing the likelihood of a subsequent episode.

Following recovery from acute myocardial infarction (MI), frequent PVCs (typically >10 PVCs/h), repetitive PVCs with couplets, and NSVT are markers for depressed ventricular function and increased mortality, but routine antiarrhythmic drug therapy to suppress these arrhythmias has not been shown to improve mortality. Therefore, amiodarone is an option for treatment of symptomatic arrhythmias in this population when the potential benefit outweighs its potential toxicities. β-Adrenergic blockers reduce sudden death but have limited effect on spontaneous arrhythmias.

For survivors of an acute MI, an implantable cardioverter-defibrillator (ICD) reduces mortality in certain high-risk groups: patients who have survived >40 days after the acute MI and have a left ventricular ejection fraction of <30%, or who have an ejection fraction <35% and have symptomatic heart failure (functional class II or III); and patients >5 days after MI who have a reduced left ventricular ejection fraction, NSVT, and inducible sustained VT or VF on electrophysiologic testing. ICDs do not reduce total mortality when routinely implanted early after MI and have not been demonstrated to improve mortality when implanted early after coronary artery revascularization.

PVCs AND NSVT ASSOCIATED WITH DEPRESSED VENTRICULAR FUNCTION AND HEART FAILURE

PVCs and NSVT are common in patients with depressed ventricular function and heart failure and are markers for disease severity and increased mortality, but antiarrhythmic drug therapy to suppress these arrhythmias has not been shown to improve survival. The use of antiarrhythmic drugs whose major action is blockade of the cardiac sodium channel (flecainide, propafenone, mexiletine, quinidine, and disopyramide) is avoided in patients with structural heart disease because of a risk of proarrhythmia and negative inotropic effects. Amiodarone suppresses ventricular ectopy and reduces sudden death but does not improve overall survival. ICDs are the major therapy to protect against sudden death in patients at high risk and are recommended for those with a left ventricular ejection fraction <35% and New York Heart Association class II or III heart failure, in whom they reduce mortality from 36 to 29% over 5 years.

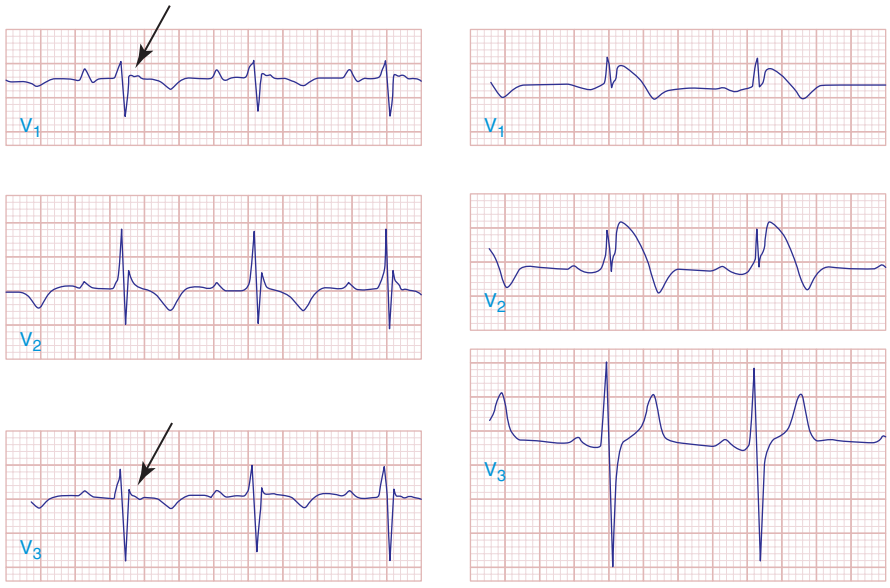

FIGURE 260-1 Electrocardiogram leads depicting Brugada syndrome. Precordial chest leads V_1–V_3 showing typical abnormalities of arrhythmogenic right ventricular cardiomyopathy (ARVC) (***A***) and Brugada syndrome (**B**). In ARVC, there is T inversion and delayed ventricular activation manifest as epsilon waves (*arrows*). Panel ***B*** shows ST elevation in V_1 and V_2 typical of the Brugada syndrome.

PVC AND NSVT ASSOCIATED WITH OTHER CARDIAC DISEASES

Ventricular ectopy is associated with increased mortality in patients with hypertrophic cardiomyopathy or with congenital heart disease associated with right or left ventricular dysfunction. In these patients, management is similar to that for patients with ventricular dysfunction. Pharmacologic suppression of the arrhythmia has not been shown to improve mortality. ICDs are indicated for patients considered at high risk for sudden cardiac death.

PVC-INDUCED VENTRICULAR DYSFUNCTION

Very frequent ventricular ectopy and repetitive NSVT can depress ventricular function, possibly through an effect similar to chronic tachycardia or by inducing ventricular dyssynchrony. Depression of ventricular function rarely occurs unless PVCs account for at least 10–20% of total beats over a 24-h period, and only a minority of patients with PVCs will have a reversible cardiomyopathy. Often the PVCs are idiopathic and unifocal, most commonly originating from the outflow tract regions or left ventricular papillary muscles **(Fig. 260-2)**, where they can be targeted for ablation.

Other sites of origin such as the mitral and tricuspid valve annuli, right ventricular moderator band, and even the epicardial surface of the heart also occur **(Fig. 260-3)**. The factors that can potentially predict development of heart failure and increased risk of adverse outcomes include PVC frequency, characteristics of the PVC morphology, and timing of the PVC coupling interval. In addition, the presence of late gadolinium enhancement on cardiac MRI may suggest the presence of an additional underlying cardiomyopathic process. The degree of expected recovery of ventricular function with PVC suppression is difficult to predict. Even in the setting of known underlying cardiomyopathy, controlling frequent ventricular ectopy can be helpful to improve ejection fraction and improve other factors such as delivery of resynchronization pacing.

ACCELERATED IDIOVENTRICULAR RHYTHMS

Three or more ventricular beats at a rate slower than 100 beats/min are termed an AIVR **(Fig. 260-4)**. Automaticity is the likely mechanism, although in some rare cases, a reentrant circuit utilizing diseased

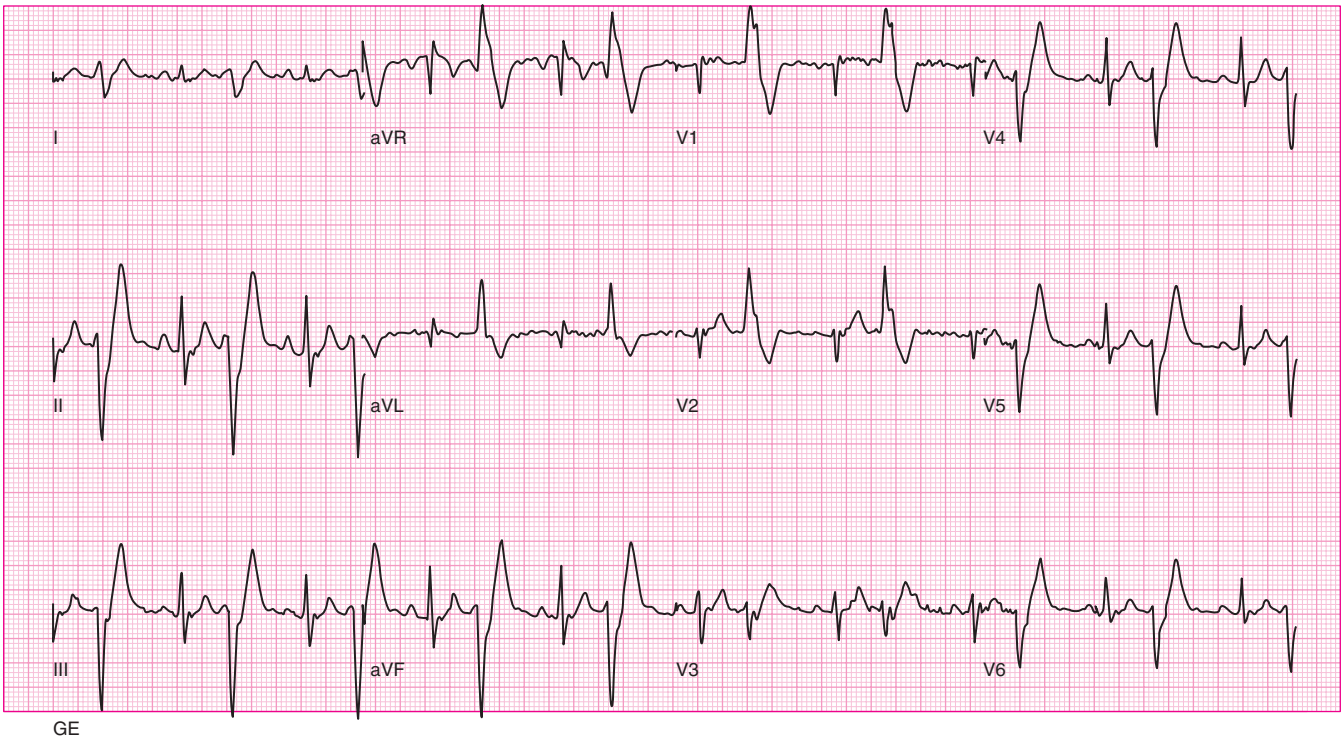

FIGURE 260-2 Ventricular bigeminy with premature ventricular contractions (PVCs) originating from the posteromedial papillary muscle. Twelve-lead electrocardiogram showing normal sinus rhythm with ventricular bigeminy. The PVCs have a right bundle branch block configuration in V_1 with superiorly directed axis. The leads V_4–V_6 are negative. The configuration is consistent with a PVC origin in the posteromedial papillary muscle of the left ventricle.

FIGURE 260-3 Catheter ablation of premature ventricular contractions (PVCs) from the left ventricular outflow tract. Shown is an electroanatomic map on the left and PVC morphology with superimposed pacing morphology on the right. The left ventricle is seen from the atrial side (posteriorly), and an ablation catheter is seen passing through the aortic valve at the top of the electroanatomic map and contacting the anterolateral portion of the left ventricular outflow tract. Maroon dots are ablation lesions that have been delivered at the site of interest. Pacing from the site of interest generates a QRS complex very similar to the clinical PVC as seen on the right.

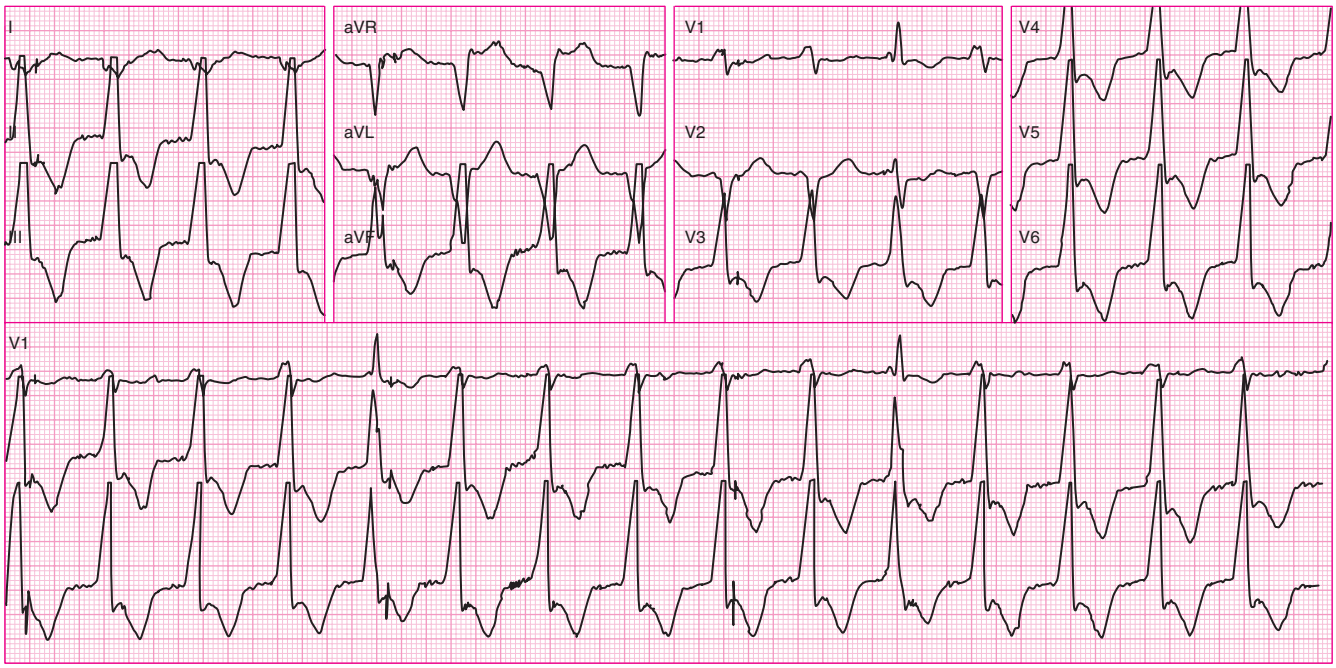

FIGURE 260-4 Accelerated idioventricular rhythm. Shown is an example of a slow regular wide-complex rhythm. Fusion beats are seen on complexes 4 and 10, which are more positive in lead V_1 and narrower than the rest of the beats. These features are consistent with an accelerated idioventricular rhythm.

myocardium can cause AIVR. Idioventricular rhythms are common during acute MI and may emerge during sinus bradycardia. Often, they are not symptomatic, but hemodynamic compromise may occur with the loss of atrioventricular synchrony in susceptible patients. Atropine may be administered to increase the sinus rates if this is a concern. This rhythm is also common in patients with cardiomyopathies or sleep apnea. It can also be idiopathic, often emerging when the sinus rate slows during sleep. Therapy should target any underlying cause and correction of bradycardia. Specific antiarrhythmic therapy for asymptomatic idioventricular rhythm is not necessary.

FUTURE DIRECTIONS

Recently, it has been appreciated that inflammation plays a role in the genesis of PVCs in specific patients with inflammatory cardiomyopathies and even in inherited cardiomyopathies. The roles of early identification of this process and targeted treatment are areas of active research.

261 Sustained Ventricular Tachycardia

William H. Sauer, Usha B. Tedrow

Sustained monomorphic ventricular tachycardia (VT) is a ventricular arrhythmia with a wide QRS lasting for at least 30 s or requiring an intervention such as antitachycardia pacing from a defibrillator or a cardioversion for termination. Each QRS complex resembles the others, indicating either a focal site of origin or a repetitive exit from a fixed arrhythmia reentry circuit. In structural heart disease, the arrhythmia substrate is most often an area of patchy replacement fibrosis due to infarction, fibrosis, inflammation, or prior cardiac surgery that creates anatomic or functional reentrant pathways. Less commonly, VT is related to reentry or automaticity in diseased conduction pathways in the Purkinje system. While scar-related reentrant VTs are associated with risk of sudden death, idiopathic VT is a more benign form of VT that occurs in structurally normal hearts and can be due to a focal region of automaticity in the myocardium or reentry involving a portion of the Purkinje system.

The clinical presentation varies depending on the rate of the arrhythmia, underlying cardiac function, and autonomic adaptation in response to the arrhythmia. Rapid VT can produce hypotension that may present as syncope, particularly in patients with significant ventricular dysfunction. In contrast, patients with normal cardiac function might tolerate sustained VT, even presenting with simple palpitations, despite rapid rates. Monomorphic VT that is rapid or associated with structural heart disease may eventually deteriorate to ventricular fibrillation (VF), which may be the initial cardiac rhythm recorded at the time of resuscitation of an out-of-hospital cardiac arrest.

DIAGNOSIS

Sustained monomorphic VT **(Table 261-1)** has to be distinguished from other causes of uniform wide QRS tachycardia. These include supraventricular tachycardia with left or right bundle branch block

TABLE 261-1 Sustained Ventricular Arrhythmias

1. **Idiopathic ventricular tachycardia (VT) without structural heart disease**
   - A. Outflow tract origin
     - Right ventricular (RV) outflow tract: left bundle branch block pattern in V_1 with inferior axis (tall QRS in inferior leads) and late transition in the precordial leads
     - Left ventricular (LV) outflow tract: similar inferiorly directed axis but with early precordial transition with prominent R wave in V_2–V_3
   - B. LV fascicular VT: Typical right bundle branch block pattern in V_1 with sharp intrinsicoid deflection and left axis deviation (arising from left posterior fascicle in its most common form)
   - C. Papillary muscle VT
     - Posteromedial: atypical right bundle branch block pattern in V_1 with monophasic R wave and left axis deviation
     - Anterolateral: atypical right bundle branch block pattern in V_1 with positive deflection in lead III and negative deflection in lead I
2. **Ischemic cardiomyopathy**
   - Monomorphic VT is common with prior large myocardial infarction
   - Polymorphic VT and ventricular fibrillation (VF) should prompt ischemia evaluation
3. **Nonischemic cardiomyopathy**
   - Fibrotic scars can cause monomorphic VT, especially with sarcoidosis or other inflammatory cardiomyopathies, Chagas' disease, and familial arrhythmogenic cardiomyopathies such as Lamin A/C genetic cardiomyopathy
   - Polymorphic VT and VF can also occur independently or related to degeneration of monomorphic VT
4. **Arrhythmogenic RV cardiomyopathy**
   - Monomorphic VT usually of RV origin (left bundle branch morphology in V_1)
   - Polymorphic VT and VF can occur independently or related to degeneration of monomorphic VT
5. **Repaired tetralogy of Fallot**
   - Monomorphic VT of RV origin (usually left bundle branch morphology in V_1)
6. **Hypertrophic cardiomyopathy**
   - Polymorphic VT or ventricular fibrillation
   - Less commonly, monomorphic VT associated with myocardial scars, particularly apical aneurysms
7. **Genetic arrhythmia syndromes**
   - A. Long QT syndrome
     - Torsades des pointes VT
   - B. Brugada syndrome
     - Ventricular fibrillation episodes, often nocturnal
   - C. Catecholaminergic polymorphic VT
     - Polymorphic VT or bidirectional VT
   - D. Short QT and early repolarization syndromes
     - Ventricular fibrillation
8. **Idiopathic polymorphic VT or ventricular fibrillation**
   - Usually triggered by recurrent premature ventricular contractions; the most common site of origin is the left posterior fascicle (right bundle branch block/left anterior fascicular block pattern)

aberrant conduction, supraventricular tachycardias conducted to the ventricles over an accessory pathway, and rapid cardiac pacing, appropriate or inappropriate, in a patient with a ventricular pacemaker or defibrillator. In the presence of known heart disease, VT is the most likely diagnosis of a wide QRS tachycardia, independent of QRS morphology. When left ventricular (LV) function is depressed or there is evidence of structural myocardial disease, scar-related reentry is the most likely cause of sustained monomorphic VT. Scars are suggested by pathologic Q waves on the electrocardiogram (ECG), segmental LV or right ventricular wall motion abnormalities on echocardiogram or nuclear imaging, and areas of delayed gadolinium enhancement during magnetic resonance imaging (MRI).

Hemodynamic stability during the arrhythmia does not help distinguish between VT and other mechanisms of wide-complex tachycardia. A number of ECG criteria have been evaluated to distinguish supraventricular tachycardia with aberrancy from VT. The presence of

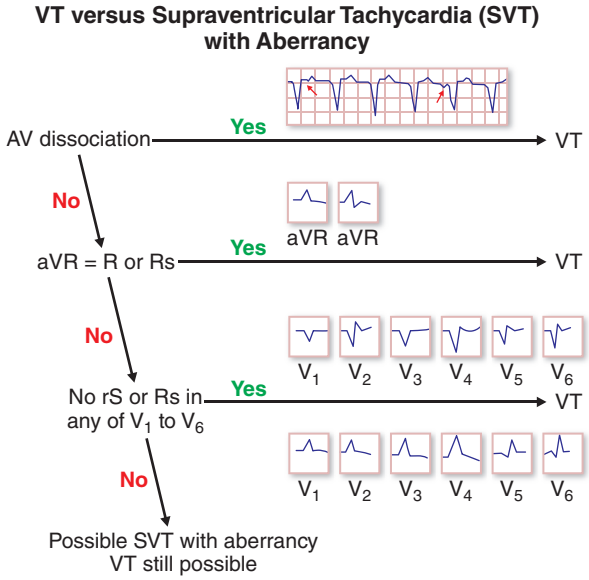

FIGURE 261-1 Algorithm for differentiation of ventricular tachycardia (VT) from supraventricular tachycardia with aberration. AV, atrioventricular.

ventriculoatrial (VA) dissociation is a reliable marker for VT, provided the atrial rate is slower than the ventricular rate. Sometimes, P waves can be difficult to define, and the VA relationship cannot be assessed in a patient with an ongoing atrial arrhythmia such as atrial fibrillation. A P wave following each QRS does not exclude VT because 1:1 conduction from ventricle to atrium can occur. A monophasic R wave or Rs complex in aVR or concordance from V_1 to V_6 of monophasic R or S waves is also relatively specific for VT (Fig. 261-1). A number of other QRS morphology criteria have also been described, but all have limitations and are not very reliable in patients with severe heart disease. In patients with known bundle branch block, the same QRS morphology during tachycardia as during sinus rhythm suggests supraventricular tachycardia rather than VT, but even this is not absolutely reliable. Patients with reentry involving the bundle branches of the Purkinje system can have a VT morphology that resembles their native QRS in sinus rhythm. An electrophysiologic study is sometimes required for definitive diagnosis. Occasionally, noise and movement artifacts on telemetry recordings can simulate VT, and prompt recognition of this can avoid unnecessary tests and interventions.

TREATMENT AND PROGNOSIS

Initial management follows Advanced Cardiac Life Support (ACLS) guidelines. If hypotension, impaired consciousness, or pulmonary edema is present, QRS synchronous electrical cardioversion should be performed, ideally after sedation if the patient is conscious. For stable tachycardia, a trial of adenosine is reasonable as this may clarify a supraventricular tachycardia with aberrancy. Adenosine should not be used if the patient has a heart transplant or if the wide-complex rhythm is irregular or unstable. Intravenous amiodarone is the drug of choice if heart disease is present. Following restoration of sinus rhythm, hospitalization and evaluation to define underlying heart disease are required. Assessment of cardiac biomarkers for evidence of myocardial infarction (MI) is appropriate, but acute MI is rarely a cause of sustained monomorphic VT. Elevations in troponin or creatine kinase (CK)-MB are more likely to indicate myocardial injury that is secondary to hypotension and ischemia from fixed coronary lesions during the VT rather than an acute coronary event. Subsequent management is determined by the underlying heart disease and frequency of VT. If VT recurs frequently or is incessant, administration of antiarrhythmic medications or catheter ablation may be required to restore stability. More commonly, sustained monomorphic VT occurs as a single episode but with a high risk of recurrence. Implantable cardioverter-defibrillators (ICDs) are warranted for secondary prevention of sudden death in patients who present with sustained VT associated with structural heart disease (Fig. 261-2).

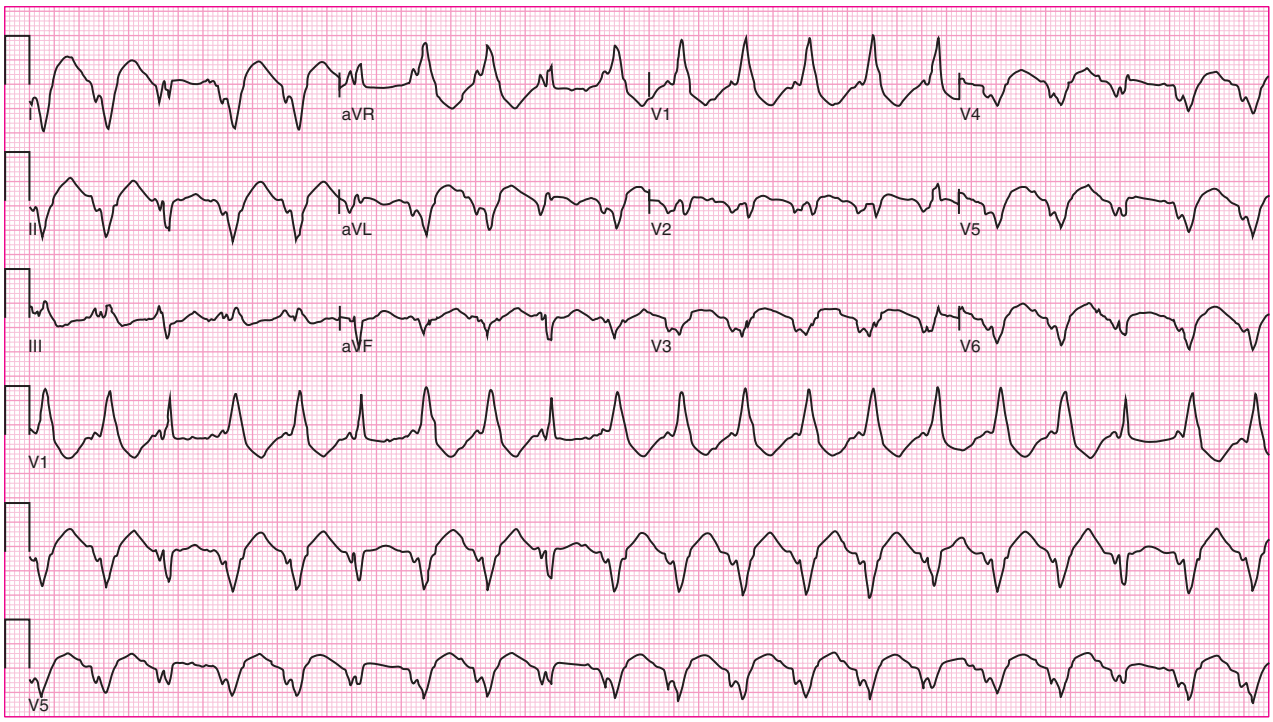

FIGURE 261-2 Monomorphic ventricular tachycardia in a patient with prior myocardial infarction. Shown is a wide-complex tachycardia. Complexes 3, 6, 9, and 18 are narrower and are examples of fusion beats, proving ventriculoatrial (VA) dissociation and proving that this rhythm is in fact ventricular tachycardia.

SUSTAINED MONOMORPHIC VT IN SPECIFIC DISEASES

CORONARY ARTERY DISEASE

Patients who present with sustained monomorphic VT associated with coronary artery disease typically have a history of a remote prior large MI. Patients typically present years after the acute infarct with a remodeled ventricle and markedly depressed LV function. Even when there is biomarker evidence of acute MI, a preexisting scar from previous MI should be suspected as the cause of the VT. Infarct scars provide a durable substrate for sustained VT, and up to 70% of patients have a recurrence of the arrhythmia within 2 years. Scar-related reentry is not usually dependent on recurrent acute myocardial ischemia, so coronary revascularization is unlikely to prevent recurrent VT, although it may be appropriate for treatment of angina or other indications. Depressed ventricular function, which is a risk factor for sudden death, is usually present. Implantation of an ICD is clearly indicated for secondary prevention provided that there is a reasonable expectation of survival for 1 year with acceptable functional status. Compared with antiarrhythmic drug therapy, ICDs reduce annual mortality from 12.3 to 8.8% and lower arrhythmic deaths by 50% in patients with hemodynamically significant sustained VT or a history of cardiac arrest. Antiarrhythmic drugs may have some utility for palliation of VT symptoms and prevention of ICD therapies, such as shocks and antitachycardia pacing; however, without an ICD, these drugs do not improve survival.

Following ICD implantation, patients with depressed ejection fraction remain at risk for clinical heart failure, recurrent ischemic events, and recurrent VT, with a 5-year mortality that exceeds 30%. Attention to guideline-directed medical therapy for patients with heart failure and coronary artery disease, including β-adrenergic blocking agents and angiotensin-converting enzyme inhibitors, is important.

ICD therapies, whether shocks or antitachycardia pacing, constitute an adverse event for the patient and are associated with increased rates of heart failure, mortality, and psychological stress. For this reason, recurrent VT episodes in patients with an ICD warrant treatment with medications or catheter ablation. In a randomized study of catheter ablation versus escalated medical therapy (Ventricular Tachycardia Ablation versus Escalation of Antiarrhythmic Drugs [VANISH]), patients receiving catheter ablation fared better than those receiving increasing doses of antiarrhythmic drugs, in particular, amiodarone. Another randomized trial (BERLIN VT) examined a preventative versus deferred ablation strategy in patients who had not yet failed an antiarrhythmic drug. This trial was stopped early for futility, with more procedural complications but fewer VT episodes in the catheter ablation group. For this reason, the most recent consensus statement most strongly recommends catheter ablation for patients with ischemic cardiomyopathy failing or intolerant of antiarrhythmic drugs but also allows for consideration of catheter ablation when long-term therapy with an antiarrhythmic drug (such as amiodarone, which has significant long-term toxicities) is not desired **(Table 261-2)**.

NONISCHEMIC DILATED CARDIOMYOPATHY

Sustained monomorphic VT associated with nonischemic cardiomyopathy is usually due to scar-related reentry. The etiology of scar is often unclear, but progressive replacement fibrosis is the likely cause. Patients with nonischemic cardiomyopathy (NICM) have historically been presumed to have a postviral etiology, although increasingly, genetic causes are found in many. Inflammatory etiologies (myocarditis, sarcoidosis) are also increasingly appreciated. On cardiac MRI, scars are detectable as areas of delayed gadolinium enhancement and are more often intramural **(Fig. 261-3)** or subepicardial in location as compared with patients with prior MI. Scars that cause VT are often located adjacent to a valve annulus and can occur in either ventricle. Any cardiomyopathic process can cause scars and VT, but cardiac sarcoidosis, Chagas' disease, and cardiomyopathy due to Lamin A/C mutations are particularly associated with monomorphic VT. An ICD is indicated for patients with a history of sustained VT, syncope, or New York Heart Association class II or III heart failure symptoms, with additional drugs or catheter ablation for control of recurrent VT. In addition, for patients with malignant familial arrhythmogenic cardiomyopathies, an ICD may be considered earlier in the clinical course.

Overall, there are fewer studies of catheter ablation for VT in NICM. Reported success rates are lower than VT ablation in ischemic cardiomyopathy in most observational series. Additionally, inability to reproduce the clinical VT at ablation attempts and epicardial and intramural reentry circuits are important causes of failure of endocardial VT ablation in NICM. Imaging with MRI or computed tomography (CT) scans with late contrast administration to define areas of fibrosis can be useful to guide ablation (Table 261-2).

TABLE 261-2 Summary of Randomized Controlled Studies Assessing Catheter Ablation of Ventricular Tachycardia in Patients with Structural Heart Disease

STUDY, YEAR	STUDY PERIOD	SAMPLE SIZE		INCLUSION CRITERIA	CONTROL ARM	AGE (years)	MALE (%)	ICM (%)	BASELINE LVEF (%)	FOLLOW-UP (months)
		CA	OC

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a rare genetic disorder most commonly due to mutations in genes encoding for cardiac desmosomal proteins; however, it is increasingly appreciated that other cardiomyopathic processes may produce a similar phenotype. Approximately 50% of patients have a familial transmission with autosomal dominant inheritance. A less common, autosomal recessive form is classically associated with cardiocutaneous syndromes that include Naxos disease and Carvajal syndrome. The former is most commonly related to mutations in plakophilin-2 and plakoglobin, while the latter is most commonly due to a mutation in desmoplakin. Patients are typically diagnosed between the second and fifth decades with palpitations, syncope, or cardiac arrest owing to sustained monomorphic VT, although polymorphic VT can also occur. Fibrosis and fibrofatty replacement most commonly involve the right ventricular myocardium and provide the substrate for reentrant VT that usually has a left bundle branch block–like configuration in ECG lead V_1, consistent with the right ventricular origin, and can resemble idiopathic VT. The sinus rhythm ECG suggests the disease in >85% of patients, most often showing T-wave inversions in V_1–V_3. Delayed activation of the right ventricle may cause a widened QRS (>110 ms) in the right precordial leads (V_1–V_3) and a prolonged S-wave upstroke in those leads and, occasionally, a notched deflection at the end of the QRS known as an epsilon wave. Cardiac imaging may show right ventricular enlargement or areas of abnormal motion or reveal areas of scar on contrast-enhanced MRI.

LV involvement can occur and can occasionally precede manifest right ventricular disease. Clinical heart failure is rare except in late stages, and survival to advanced age can be anticipated provided that VT can be controlled. An ICD is recommended. When VT is exercise induced, it may respond to β-adrenergic blockers and limiting exercise. Sotalol, flecainide, and amiodarone have been used to reduce ventricular arrhythmias. Catheter ablation prevents or reduces VT episodes in 70% of patients, but epicardial mapping and ablation are often required.

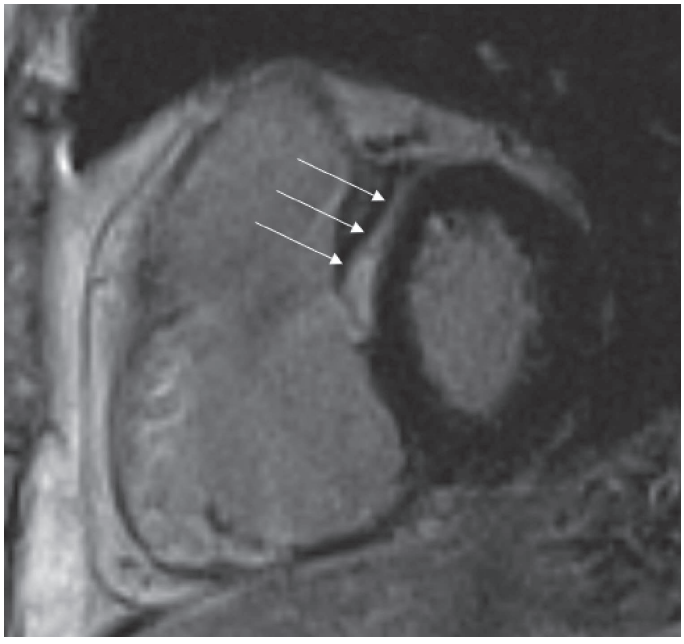

FIGURE 261-3 Cardiac magnetic resonance image (MRI). Shown is an MRI of the heart with the right ventricle on the left and the left ventricle on the right. Between the ventricles (*arrows*) is a stripe of late gadolinium enhancement, indicating midmyocardial fibrosis in the interventricular septum. This type of scar pattern is often seen in patients with nonischemic cardiomyopathies and ventricular tachycardia.

ADULT CONGENITAL HEART DISEASE

Among all patients with adult congenital heart disease (ACHD), sustained monomorphic VT is quite rare. However, the most common substrate for sustained VT is seen in those with repairs of a ventricular

septal defect, in particular tetralogy of Fallot (TOF). The prevalence of VT after TOF repair is estimated to be 3–14%, and risk of sudden cardiac death may reach as high as 1% per year in adulthood by the fourth or fifth decade of life. The greatest risk for ventricular arrhythmias is posed via two potential mechanisms: (1) those who have undergone repair involving a ventriculotomy and (2) those with long-standing hemodynamic overload causing ventricular dysfunction and/or hypertrophy independent of surgical incisions.

Monomorphic VT in TOF most commonly occurs in stereotyped circuits due to reentry around areas of surgically created scar in the right ventricle. Factors associated with VT risk include age >5 years at the time of repair, high-grade ventricular ectopy, inducible VT on an electrophysiologic study, abnormal right ventricular hemodynamics, and sinus rhythm QRS duration >180 ms. An ICD is usually warranted for patients who have a spontaneous episode of VT, but ICDs are also considered for patients with multiple risk factors. Catheter ablation or antiarrhythmic drug therapy is used to control recurrent episodes.

BUNDLE BRANCH REENTRY VT

Reentry through the Purkinje system occurs in ~5% of patients with monomorphic VT in the presence of structural heart disease. The reentry circuit typically revolves retrograde via the left bundle and anterograde down the right bundle, thereby producing VT that has a left bundle branch block configuration. The VT QRS morphology may closely resemble the QRS morphology in sinus rhythm. Catheter ablation of the right bundle branch abolishes this VT. Bundle branch reentry is usually associated with severe underlying heart disease. Other scar-related VTs are often present and often require additional therapy.

IDIOPATHIC MONOMORPHIC VT

Idiopathic VT in patients without structural heart disease usually presents with palpitations, lightheadedness, and, rarely, syncope. Episodes can be provoked either by sympathetic stimulation or acute withdrawal of sympathetic tone, as in the immediate postexercise period. The QRS morphology of the arrhythmia suggests the diagnosis (see below). The sinus rhythm ECG is normal. Family history suggests no familial cardiomyopathy or sudden death. Cardiac imaging, including echocardiography and cardiac MRI, shows normal ventricular function and no evidence of ventricular scar. Occasionally, a patient with structural heart disease is found to have concomitant idiopathic VT unrelated to the structural disease, in which case, the underlying disease should be treated as per the guidelines, separate from the VT. Repeated bursts of nonsustained VT, which may occur incessantly, are known as repetitive monomorphic VT and can cause a tachycardia-induced cardiomyopathy with depressed ventricular function that recovers after suppression of the arrhythmia. Sudden death in isolated idiopathic VT is rare, and an ICD is not recommended.

Outflow tract VTs originate from a focus near the pulmonic or aortic valve annuli, usually with features consistent with triggered automaticity. The arrhythmia may present with sustained VT, nonsustained VT, or premature ventricular contractions (PVCs). Most originate in the right ventricular outflow tract, which gives rise to VT that has a left bundle branch block configuration in V_1 and an axis that is directed inferiorly, with tall R waves in II, III, and aVF. Idiopathic VT can also arise in the LV outflow tract or in sleeves of myocardium that extend along the aortic root. LV origin is suspected when lead V_1 or V_2 has prominent R waves. Although this typical outflow tract QRS morphology favors idiopathic VT, some cardiomyopathies, notably ARVC, can cause PVCs or VT from this region. Excluding these diseases is an initial focus of evaluation **(Fig. 261-4)**.

LV fascicular VT, sometimes referred to as Belhassen's VT or verapamil-sensitive VT, is the second most common form of idiopathic VT after outflow tract VTs. It often presents with sustained VT that has a right bundle branch block–like configuration and is negative in the inferior leads. It is often exercise induced and occurs more often in men than women. The mechanism was originally thought to be focal but has been demonstrated to be due to a small reentry circuit in or near the septal ramifications of the LV Purkinje system. There can be an LV false tendon associated with this rhythm. Despite its reentrant nature, the course of this type of VT is typically benign.

Other sites of origin for idiopathic VT exist, including papillary muscles, mitral and tricuspid valve annuli, and the moderator band in the right ventricle. Even focal sites from the epicardial surface have been described. The presence of VT from these more unusual sites should prompt even more careful assessment for structural heart disease.

MANAGEMENT OF IDIOPATHIC VT

Treatment is required for symptoms or when frequent or incessant arrhythmias depress ventricular function. Symptoms can be controlled with medications including beta blockers, calcium channel blockers,

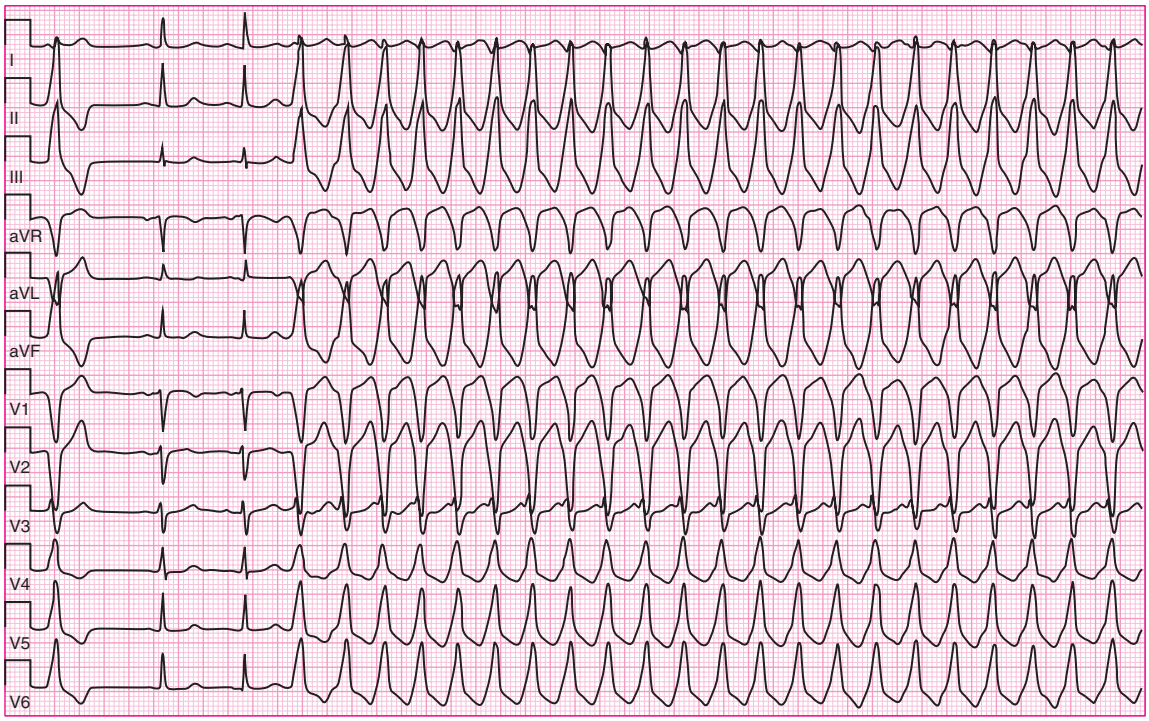

FIGURE 261-4 Idiopathic monomorphic ventricular tachycardia (VT). This is a 12-lead electrocardiogram showing the onset of idiopathic VT in a young patient without structural heart disease. The VT has a left bundle branch block configuration in V_1 and an inferiorly directed axis consistent with an outflow tract origin. Note that the narrow (normal sinus) beats have a normal QRS configuration, consistent with the patient's lack of structural heart disease.

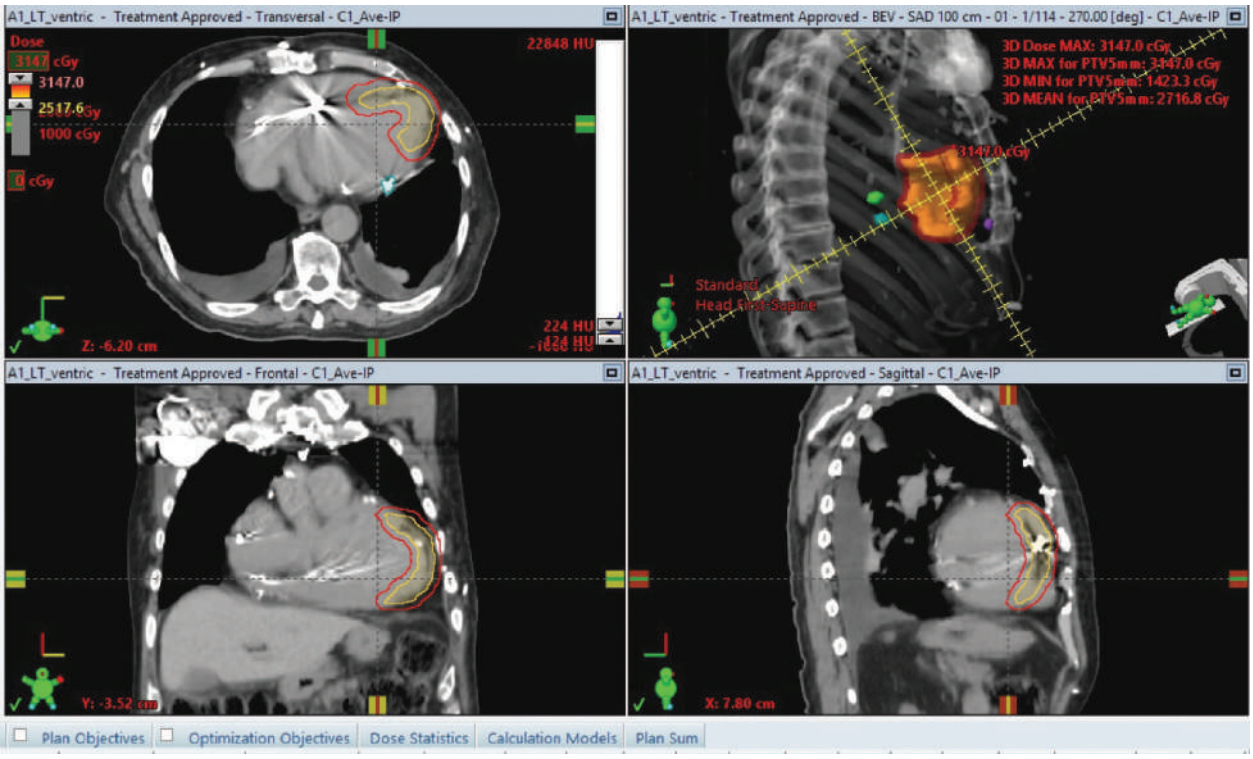

FIGURE 261-5 Stereotactic body radiation therapy. Shown is a planning computed tomography scan for noninvasive cardiac ablation delivered with stereotactic radiation. The region of interest is determined by analysis of presenting arrhythmias, underlying structural heart disease, and proximity to adjacent structures such as coronary arteries, the phrenic nerve, and the gastrointestinal tract. Radiation is delivered to the chosen treatment volume in order to create conduction block in the culprit scar region.

and sodium channel blockers such as flecainide. Although flecainide is not typically recommended in patients with structural heart disease, it has been used successfully to resolve tachycardia-induced cardiomyopathy in the setting of idiopathic PVCs and VT in patients with a normal underlying ECG and no fibrosis evident on cardiac MRI. Catheter ablation is also indicated for control of symptoms, has an overall success rate of 80%, and is recommended for those with symptomatic VT in whom medications are ineffective or not preferred by the patient. Efficacy and risks of catheter ablation vary with the specific site of origin of the VT, being most favorable for arrhythmias originating in the right ventricular outflow tract. Failure of ablation is most often due to inability to initiate the arrhythmia for mapping in the electrophysiology laboratory.

LV interfascicular VT can be terminated by intravenous administration of verapamil, although chronic therapy with oral verapamil is not always effective. Catheter ablation is recommended if β-adrenergic blockers or calcium channel blockers are ineffective or not desired.

FUTURE DIRECTIONS

Treatment of monomorphic VT, especially in the setting of structural heart disease, is an important cause of morbidity and mortality. Limitations of current therapies include toxicities of antiarrhythmic drugs and inability to successfully perform catheter ablation of the substrate for arrhythmias. Advances in imaging and intracardiac mapping techniques are likely to improve success rates over time. In addition, the inability of ablative energy to reach deep intramural substrates is a current limitation. Innovations in delivery of ablative energy, including bipolar ablation, needle catheter ablation, and electroporation, are ongoing. In addition, noninvasive ablation is a promising area of investigation. Proton beam or stereotactic radiation can be used to target VTs identified by advanced cardiac imaging or by a multielectrode ECG vest. Early multicenter studies suggest durable control of VT with noninvasive ablation **(Fig. 261-5)**.

262 Polymorphic Ventricular Tachycardia and Ventricular Fibrillation

William H. Sauer, Usha B. Tedrow

POLYMORPHIC VENTRICULAR TACHYCARDIA

Sustained polymorphic ventricular tachycardia (VT) has a continuously changing QRS configuration from beat to beat, indicating a continually changing ventricular activation sequence. However, unlike sustained monomorphic VT, polymorphic VT does not necessarily indicate a fixed structural abnormality or focus of automaticity. Reentry can occur with variable reentrant paths, spiral wave reentry, and multiple automatic foci as potential mechanisms. This type of reentry can occur

near fibrotic areas of myocardium, potentiated by proximity to damaged Purkinje cells or ventricular hypertrophy. Abnormal transmural dispersion of repolarization can occur in the setting of channelopathies or antiarrhythmic drugs in the absence of structural heart disease. Sustained polymorphic VT usually degenerates into ventricular fibrillation (VF). Polymorphic VT is typically seen in association with acute myocardial infarction or ischemia (MI), ventricular hypertrophy, and a number of genetic mutations that affect cardiac ion channels.

POLYMORPHIC VT ASSOCIATED WITH ACUTE MYOCARDIAL INFARCTION/ ISCHEMIA

Acute MI or ischemia is a common cause of polymorphic VT and should be the initial consideration in management. Approximately 10% of patients with acute MI develop VT that degenerates to VF, likely related to reentry through the infarct border zone. The risk is greatest in the first hour of acute MI. More rarely, surviving Purkinje cells with automaticity can initiate polymorphic VT. Following defibrillation as per the Advanced Cardiac Life Support (ACLS) guidelines, management is as for acute MI. β-Adrenergic blockers, correction of electrolyte abnormalities, and prompt myocardial reperfusion are required. Repeated episodes of polymorphic VT may suggest ongoing MI and warrant assessment of adequacy of myocardial reperfusion. Polymorphic VT and VF that occur within the first 48 h of acute MI are associated with greater in-hospital mortality, but patients who survive past hospital discharge are not at increased risk for arrhythmic sudden death. Long-term therapy for postinfarct ventricular arrhythmia is determined by residual left ventricular (LV) function, with an implantable cardioverter defibrillator (ICD) indicated for persistent severe LV dysfunction (LV ejection fraction <35%).

REPOLARIZATION ABNORMALITIES AND GENETIC ARRHYTHMIA SYNDROMES

■ ACQUIRED LONG QT SYNDROME

Abnormal prolongation of the QT interval is associated with the polymorphic VT torsades des pointes. The VT often has a characteristic initiation sequence of a premature ventricular beat that induces a pause, followed by a sinus beat that has a longer QT interval and interruption of the T wave by the premature ventricular contraction (PVC) that is the first beat of the polymorphic VT **(Fig. 262-1)**. This characteristic initiation is termed *pause-dependent*. Causes of QT prolongation include electrolyte abnormalities, bradycardia, and a number of medications that block repolarizing potassium currents, notably the antiarrhythmic drugs sotalol, dofetilide, and ibutilide, but also a number of other medications used for noncardiac diseases, including erythromycin, pentamidine, haloperidol, phenothiazines, and methadone. Individual susceptibility may be related to genetic polymorphisms or mutations that influence repolarization. The website *crediblemeds.org* is an excellent resource for the clinician to determine whether a given medication has been reported to prolong the QT interval.

Patients typically present with near-syncope, syncope, or cardiac arrest. Sustained episodes degenerate to VF requiring defibrillation. PVCs and nonsustained VT often precede episodes of sustained VT. Intravenous administration of 1–2 g of magnesium sulphate usually suppresses recurrent episodes. If magnesium alone is ineffective, increasing heart rate with isoproterenol infusion or pacing, to a rate of 100–120 depolarizations/min as required to suppress PVCs, usually suppresses VT recurrences. These maneuvers allow time for correction of associated electrolyte disturbance (hypokalemia and hypocalcemia) and bradycardia and removal of any causative drugs **(Table 262-1)**. Drug interactions that elevate levels of the offending agent are often a precipitating factor. Patients who experience a polymorphic VT induced by QT prolongation should be considered to have a susceptibility to the arrhythmia and should avoid all future exposure to medications known to prolong the QT interval.

■ CONGENITAL LONG QT SYNDROME

The congenital long QT syndrome (LQTS) is caused by mutations in genes coding for cardiac ion channels responsible for ventricular repolarization. The corrected QT (QTc) is typically prolonged to >440 ms in men and 460 ms in women. Symptoms are due to torsades des pointes VT. Several forms of congenital LQTS have been identified, but three groups of mutations that lead to LQTS-1, LQTS-2, and LQTS-3

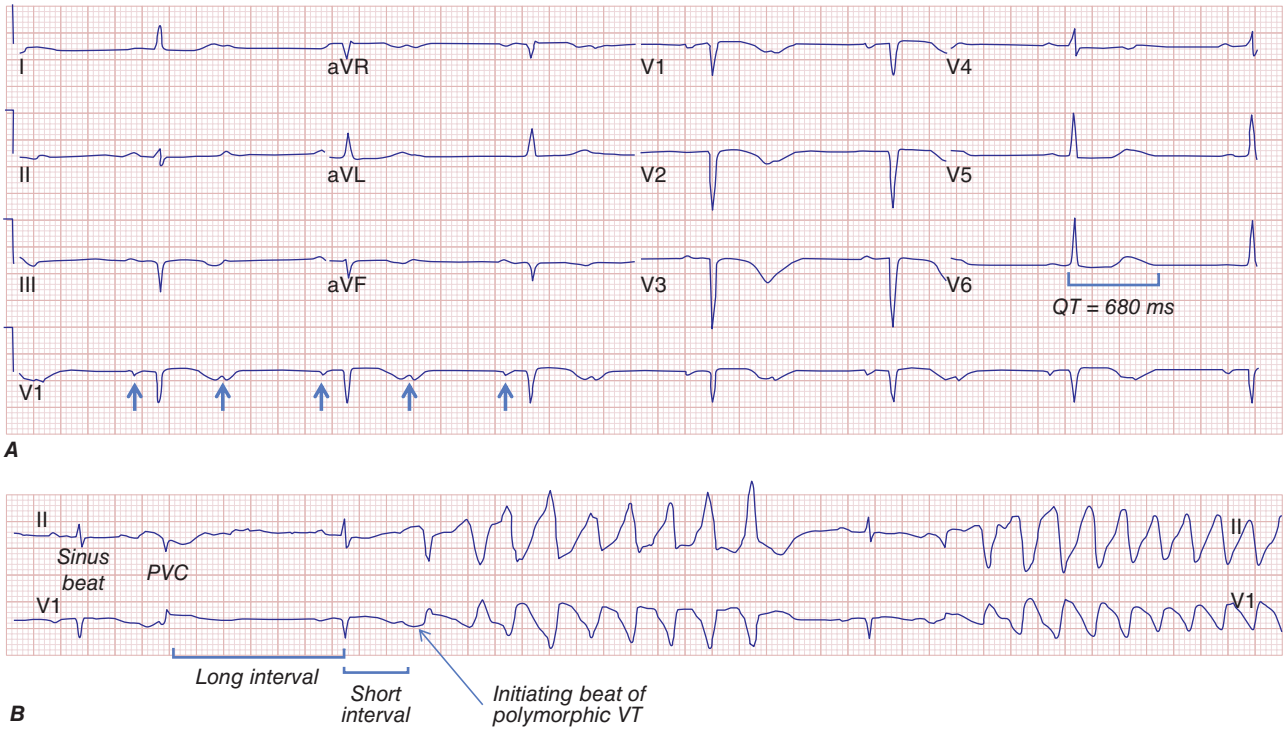

FIGURE 262-1 Torsades des pointes ventricular tachycardia (VT) in a patient with bradycardia and marked QT prolongation. ***A.*** Twelve-lead electrocardiogram showing 2:1 atrioventricular block (P waves marked by *blue arrows*) with a heart rate of 40 beats/min and QT interval of 680 ms and corrected QT of 550 ms. ***B.*** The bottom panel shows a telemetry rhythm strip with periods of self-limiting torsades des pointes polymorphic VT. Following a normally conducted sinus beat, a premature ventricular contraction (PVC) causes a compensatory pause, leading to a long RR interval. A PVC after the next sinus beat initiates VT. This is the classic pause-dependent mode of initiation of torsades des pointes VT with long–short intervals.

TABLE 262-1 Causes of QT Prolongation and Torsades des Pointes

1. Congenital long QT syndromes
   - Long QT syndrome type 1: Reduced repolarizing current I_{Ks} due to mutation in *KCNQ1* gene
   - Long QT syndrome type 2: Reduced repolarizing current I_{Kr} due to mutation in *KCNH2* gene
   - Long QT syndrome type 3: Delayed inactivation of the I_{Na} due to mutations in *SCN5A* gene
   - Others: Several other types of long QT syndromes have been described; long QT syndrome types 1, 2, and 3 account for 80–90% of cases
2. Electrolyte abnormalities: Hypokalemia, hypomagnesemia, hypocalcemia
3. Drug-induced acquired prolongation of QT interval
   - Antiarrhythmic drugs
     - Class IA: Quinidine, disopyramide, procainamide
     - Class III: Sotalol, dronedarone, ranolazine, amiodarone, ibutilide, dofetilide
   - Antibiotics
     - Macrolides: Erythromycin, clarithromycin, azithromycin
     - Fluroquinolones: Levofloxacin, moxifloxacin
     - Trimethoprim-sulfamethoxazole
     - Clindamycin
     - Pentamidine
     - Chloroquine
     - Antifungals: Ketoconazole, itraconazole
     - Antivirals: Amantadine
   - Antipsychotics
     - Haloperidol, phenothiazines, thioridazine, trifluoperazine, sertindole, zimelidine, ziprasidone
     - Tricyclic and tetracyclic antidepressants
   - Antihistamines (histamine 1-receptor antagonists)
     - Astemizole, diphenhydramine, hydroxyzine
   - Other drugs
     - Citrate (massive blood transfusions)
     - Cocaine
     - Methadone
     - Hydroxychloroquine
4. Cardiac conditions
   - Myocardial ischemia and infarction
   - Myocarditis
   - Marked bradycardia
   - Stress cardiomyopathy
5. Endocrine disorders
   - Hypothyroidism
   - Hyperparathyroidism
   - Pheochromocytoma
   - Hyperaldosteronism
6. Intracranial disorders
   - Subarachnoid hemorrhage
   - Thalamic hematoma
   - Cerebrovascular accident
   - Encephalitis
   - Head injury
7. Nutritional disorders
   - Anorexia nervosa
   - Starvation
   - Liquid protein diets
   - Gastroplasty and ileojejunal bypass
   - Celiac disease

syndromes account for 90% of cases. The most frequently encountered mutations (LQTS-1 and LQTS-2) are due to abnormalities of potassium channels, but mutations affecting the sodium channel (LQTS-3) and calcium channels have also been described.

Typical presentation is with syncope or cardiac arrest, usually during childhood. In LQTS-1, episodes tend to occur during exertion, particularly swimming. In LQTS-2, sudden auditory stimuli or emotional upset predisposes to events. In LQTS-3, sudden death tends to occur during sleep. Asymptomatic patients may be discovered in the course of family screening or on a routine electrocardiogram (ECG). Genotyping can be helpful for family screening and to provide reassurance regarding the diagnosis. Correlations of genotype with risk and response to therapy are beginning to emerge. In most patients with LQTS-1 or LQTS-2, adequate doses of beta-blocker therapy (the nonselective agents nadolol and propranolol are favored) are sufficient protection from arrhythmia episodes. Markers of increased risk include QTc interval exceeding 500 ms, female gender, and a history of syncope or cardiac arrest. Recurrent syncope despite beta-blocker therapy or a high-risk profile merits consideration of an ICD. Avoidance of QT-prolonging drugs is critical for all patients with LQTS, including those who are genotype positive but have normal QT intervals.

SHORT QT SYNDROME

Short QT syndrome is very rare compared to LQTS. The QTc is <360 ms and usually <300 ms. The genetic abnormality causes a gain of function of the potassium channel (I_{Kr}) or reduced inward depolarizing currents. The abnormality is associated with atrial fibrillation, polymorphic VT, and sudden death.

BRUGADA SYNDROME

Brugada syndrome is a rare syndrome characterized by >0.2 mV of ST-segment elevation with a coved ST segment and negative T wave in more than one anterior precordial lead (V_1–V_3) **(see Fig. 260-1)** and episodes of syncope or cardiac arrest due to polymorphic VT in the absence of structural heart disease. The term *Brugada syndrome* is distinguished from *Brugada pattern* observed in asymptomatic individuals with the characteristic ECG findings, similar to how Wolff-Parkinson-White syndrome is distinguished from the Wolff-Parkinson-White pattern. Cardiac arrest may occur during sleep or be provoked by febrile illness. The mechanism of the ventricular arrhythmias associated with Brugada syndrome are related to the dispersion of repolarization across the ventricular wall with epicardial and M cells that are more affected than endocardial cells. The characteristic coved ST segment in the anterior precordial leads is a consequence of this difference in transmembrane action potentials localized to the right ventricular outflow tract. This regionalized substrate is apparent with epicardial mapping and allows for ablation as a potential treatment option for patients with recurrent VT/VF despite pharmacologic therapy.

Males are more commonly affected than females and men are much more likely to have Brugada pattern on ECG compared to women. In cases where there is a family history, Brugada syndrome demonstrates an autosomal dominant inheritance pattern with variable penetrance. Mutations involving cardiac sodium channels (*SCN5A*, *SCN1B*, and *SCN10A*) are identified in ~25% of cases. There are non–sodium channel genes that have also been described including loss-of-function mutations in calcium and gain-of-function mutations in potassium channel component genes affecting the transient outward current (I_{to}). Structural and trafficking proteins have also been implicated in Brugada syndrome, revealing a higher level of complexity compared to other monogenetic arrhythmia substrates.

Distinction from patients with similar ST elevation owing to LV hypertrophy, pericarditis, myocardial ischemia or MI hyperkalemia, hypothermia, right bundle branch block, and arrhythmogenic right ventricular cardiomyopathy is often difficult. Furthermore, the characteristic ST-segment elevation can wax and wane over time and may become pronounced during acute illness and fever or with changes in autonomic tone. Administration of the sodium channel–blocking drugs flecainide, ajmaline, or procainamide can augment or unmask ST elevation in affected individuals. An ICD is indicated for individuals who have had unexplained syncope or have been resuscitated from cardiac arrest. Patients with Brugada syndrome must avoid drugs known to affect sodium channels including cocaine, cannabis, some sodium channel antiepileptic agents, and other psychotropic medications. Quinidine and catheter ablation of abnormal regions in the epicardial right ventricular outflow tract have been used successfully to suppress frequent episodes of VT.

EARLY REPOLARIZATION SYNDROME

Patients resuscitated from VF who have no structural heart disease or other identified abnormality have a higher prevalence of J-point elevation with notching in the terminal QRS. A family history of sudden death is present in some patients, suggesting a potential genetic basis. J-point elevation is also seen in some patients with the Brugada syndrome and is associated with a higher risk of arrhythmias. An ICD is recommended for those who have had prior cardiac arrest. It should be noted that J-point elevation is commonly seen as a normal variant in patients without arrhythmias, and in the absence of specific symptoms, the clinical relevance is not known.

CATECHOLAMINERGIC POLYMORPHIC VT

This rare familial syndrome is due to mutations in the cardiac ryanodine receptor and, less commonly, the sarcoplasmic calcium binding protein calsequestrin 2. These mutations result in abnormal sarcoplasmic calcium handling and polymorphic ventricular arrhythmias that resemble those seen with digitalis toxicity. The VT is polymorphic or has a characteristic alternating QRS morphology termed bidirectional VT. Patients usually present during childhood with exercise or emotion-induced palpitations, syncope, or cardiac arrest. β-Adrenergic blockers (e.g., nadolol and propranolol) and an ICD are usually recommended. Verapamil, flecainide, or surgical left cardiac sympathetic denervation reduces or prevents recurrent VT in some patients. The use of ICDs is controversial because of the fear that an ICD shock could initiate a vicious cycle of adrenergic output and escalated ventricular arrhythmias, leading to death.

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy (HCM) is the most common genetic cardiovascular disorder, occurring in 1 in 500 individuals, and is a prominent cause of sudden death before the age of 35 years. Sudden death can be due to polymorphic VT/VF. Rarely, sustained monomorphic VT occurs related to areas of ventricular scar, most commonly in patients who develop an apical aneurysm. Risk factors for sudden death in this disease include young age, nonsustained VT, failure of blood pressure to increase during exercise, recent (within 6 months) syncope, ventricular wall thickness >3 cm, and possibly the severity of LV outflow obstruction. An ICD is generally indicated for high-risk subjects, but the specific risk profile warranting an ICD continues to be debated. Surgical myectomy, performed to relieve outflow obstruction, has been associated with a sudden death rate of <1% per year. The reported annual rate of sustained VT or sudden death after transcoronary ethanol septal ablation done to relieve outflow obstruction has been reported to range between 1 and 5%.

GENETIC DILATED CARDIOMYOPATHIES

Genetic dilated cardiomyopathies account for 30–40% of cases of nonischemic dilated cardiomyopathies. Some are associated with muscular dystrophy. Autosomal dominant, recessive, X-linked, and mitochondrial inheritance patterns are recognized. Mutations in genes coding for structural proteins of the nuclear lamina (Lamin A/C) and the *SCN5A* gene are particularly associated with conduction system disease and ventricular arrhythmias. Patients can experience polymorphic VT and cardiac arrest or develop areas of scar causing sustained monomorphic VT. ICDs are recommended for those who have had a sustained VT, are at high risk due to significantly depressed ventricular function (LV ejection fraction <35% and associated with heart failure), or have a malignant family history of sudden death.

VENTRICULAR FIBRILLATION

VF is characterized by disordered electrical ventricular activation without identifiable QRS complexes **(Fig. 262-2)**. Spiral wave reentry and multiple circulating reentry wavefronts are possible mechanisms. Sustained polymorphic or monomorphic VT that degenerates to VF is a common cause of out-of-hospital cardiac arrest. Treatment follows ACLS guidelines with defibrillation to restore sinus rhythm. If resuscitation is successful, further evaluation is performed to identify and treat underlying heart disease and potential causes of the arrhythmia, including the possibility that monomorphic or polymorphic VT could have initiated VF. If a transient reversible cause such as acute MI is not identified, therapy to reduce the risk of sudden death with an ICD is often warranted.

FUTURE DIRECTIONS

The role for catheter ablation in polymorphic VT and VF is rapidly evolving, with some investigators making use of simultaneous electrical recordings from basket catheters to define critical sites for the arrhythmia and correlating these with detailed cardiac imaging to identify typical vulnerable sites for ablation.

FIGURE 262-2 Fascicular ectopy triggering ventricular fibrillation. Shown is a multilead monitor from a patient with recent inferoposterior myocardial infarction and surgical revascularization. Purkinje fibers can often survive acute infarction due to greater cellular glycogen stores and oxygenation from the left ventricular cavity. Upon revascularization, these now surviving but poorly coupled Purkinje fibers can trigger premature ventricular contractions and ventricular fibrillation as shown in this strip.

Eur Heart J 43:3997, 2022.

263 Electrical Storm and Incessant Ventricular Tachycardia

William H. Sauer, Usha B. Tedrow

ELECTRICAL STORM

Electrical storm or ventricular tachycardia (VT) storm refers to the occurrence of three or more episodes of VT or ventricular fibrillation (VF) within 24 h requiring intervention for termination. Although this disorder is uncommon in the general population, it is of great concern to internists because of its rapid course leading to patient death in the absence of treatment. Therefore, prompt recognition and therapeutic intervention are required. Electrical storms occur in 4% of patients with a primary prevention implantable cardioverter-defibrillator (ICD) but in as many as 20% of patients with a history of known VT or resuscitated sudden death. Catheter ablation, antiarrhythmic drug therapy, and other adjunctive therapies in electrical storms can be life-saving.

INCESSANT VT

VT is designated incessant when VT continues to recur shortly after electrical, pharmacologic, or spontaneous conversion to sinus rhythm **(Fig. 263-1)**. Typically, VT is monomorphic. Rarely, a slow incessant monomorphic VT will fail detection by an ICD because it falls outside of the programmed detection parameters. If the arrhythmia is hemodynamically stable acutely, patients can present with symptoms of gradual cardiac decompensation. VT may become incessant due to the proarrhythmic effect of an antiarrhythmic drug such as amiodarone or a sodium channel blocker such as flecainide. Hemodynamic support may be required acutely until the precipitating factors can be corrected. Urgent catheter ablation is often warranted.

MANAGEMENT OF PATIENTS PRESENTING WITH ICD SHOCKS

A substantial number of patients who receive an ICD can be expected to have an arrhythmia that is terminated by the ICD, either by a shock or antitachycardia pacing. Although this is an expected event, it can be a sign of impending instability, deterioration of cardiac function, or emergence of a new arrhythmia and therefore requires evaluation. Interrogation of the ICD is crucial after a patient reports a shock or symptoms of arrhythmia to confirm that the therapy was indeed delivered for a ventricular arrhythmia and not for lead malfunction or an atrial arrhythmia. After a shock and in the absence of other symptoms to suggest arrhythmia or ischemia, patients have the option of waiting until the next working day or using remote monitoring to transmit device interrogation data to their physician. However, occurrence of multiple ICD shocks constitutes a medical emergency and warrants immediate medical attention by activating the emergency medical system. Patients should never drive to the hospital themselves after receiving a shock from their ICD.

Spontaneous arrhythmias, particularly those that are converted with a shock, are associated with a subsequent increased risk of death and hospitalization in patients with depressed ventricular function. The occurrence of an arrhythmia, therefore, warrants a reevaluation for possible decline in cardiac function, emergence of ischemia, or intercurrent illness.

If the ICD therapy is appropriate for VT or VF, consideration is given to whether therapy is warranted to reduce further episodes with either antiarrhythmic drug therapy or catheter ablation. Patients who have a rare episode of VT that is appropriately terminated and who have no other evidence of instability may not need any additional therapy, particularly if the VT is terminated by antitachycardia pacing rather than a shock. Shocks reduce quality of life and can lead to posttraumatic stress disorder. In many patients, the possibility of a shock can be reduced with appropriate ICD programming. Studies have shown that antitachycardia pacing effectively terminates >70% of VT episodes, even when VT is very rapid. Most ICDs can be programmed to attempt overdrive pace termination during capacitor charge. If the arrhythmia then terminates, the shock is aborted. Appropriate programming of antitachycardia pacing is therefore critical for reducing shocks. For patients implanted with ICDs as primary prevention, programming of VF detection zones >220 beats/min significantly reduces unnecessary and inappropriate shocks. Long detection times will also help avoid unnecessary therapies for VT episodes liable to terminate spontaneously.

Recurrent symptomatic episodes of VT or VF **(Fig. 263-2)** warrant specific therapy with antiarrhythmic drugs or ablation as discussed for the specific arrhythmia. The beta blockers sotalol and amiodarone are the most common pharmacologic options. Amiodarone combined with beta blockers is more effective than sotalol or beta blockers alone. It is important to recognize that although VT/VF episodes may represent a deterioration of clinical status in these patients, interventions to control the arrhythmia itself may have adverse effects on outcome. Most antiarrhythmic drugs have the potential to induce bradycardia to the point of requiring pacing from the ICD that, in itself, may have deleterious effects on ventricular function. Catheter ablation is an important option for patients with monomorphic VT.

MANAGEMENT OF THE PATIENT WITH ELECTRICAL STORM

Patients should be adequately sedated to allay anxiety and provide pain relief. Recurrent VT/VF is treated using standard Advanced Cardiac Life Support guidelines; treatment includes the use of medications such as beta blockers, amiodarone, and lidocaine with correction of any metabolic abnormalities. Recordings from electrocardiogram (ECG) monitoring or an implanted ICD are important to assess whether VT

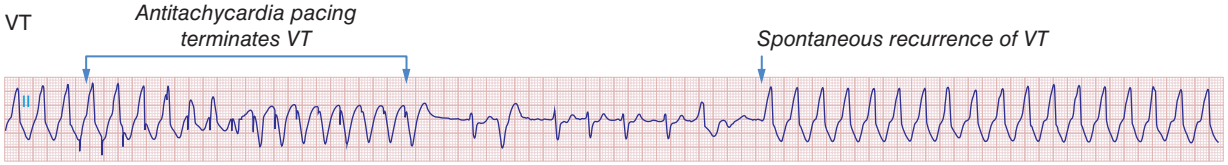

FIGURE 263-1 Example of incessant monomorphic ventricular tachycardia (VT). In the initial portion of this electrocardiogram tracing, monomorphic VT is present. A train of antitachycardia pacing (area bracketed by *arrows*) that is initiated at the fourth VT complex results in ventricular capture with fusion by the eighth beat and termination of VT at cessation of pacing. The patient has underlying atrial fibrillation. Multifocal premature ventricular contractions are present. VT similar in morphology to the initial VT restarts spontaneously toward the latter part of the trace (*arrow*).

FIGURE 263-2 Multiple implantable cardioverter-defibrillator (ICD) shocks from a subcutaneous ICD. Shown is a tracing from a patient with a subcutaneous ICD with recurrent episodes of ventricular fibrillation. The first five lines show gradually increasing amounts of ventricular ectopy and then ventricular fibrillation on the sixth line, which is terminated by a shock (*thunderbolt*) on the ninth line. The sequence repeats itself, and the patient receives a second shock that successfully terminates the arrhythmia.

Electrical storm treatments

Speed of Deployment	Stabilize rhythm	Relieve triggers	Reduce sympathetic drive
Rapid	• Defibrillation • Amiodarone • Lidocaine	• Electrolyte management • Volume removal • Coronary revascularization	• Beta blockers • Sedation and intubation • Anxiolytics
	• Quinidine • Ranolazine • Procainamide • Catheter ablation	• Overdrive pacing • Mechanical support (ECMO/IABP)	• Stellate ganglion block (SGB)
Delayed		• Consideration of biopsy/anti-inflammatory therapies	• Cardiac surgical sympathetic denervation

FIGURE 263-3 Global strategy for managing electrical storm. Shown are considerations for stabilization of electrical storm with medication strategies and procedures. ECMO, extracorporeal membrane oxygenation; IABP, intra-aortic balloon pump.

is monomorphic or polymorphic. The initiation and termination of tachycardia in the stored ICD electrograms may also suggest possible precipitating or aggravating factors. Sedation or general anesthesia should be considered for suppression of recurrent hemodynamically unstable ventricular arrhythmia. Percutaneous stellate ganglion block and upper thoracic epidural anesthesia may reduce cardiac sympathetic outflow and have been used to restore stability in some patients. Rarely, mechanical ventricular support with extracorporeal membrane oxygenation, percutaneous left ventricular assist device, or intra-aortic balloon pump may be considered **(Fig. 263-3)**.

In addition to this global strategy of stabilizing the heart rhythm, reducing sympathetic drive, and relieving any triggering mechanisms for the management of electrical storm, there are some specific therapies to be considered for patients with unique electrophysiologic substrate **(Fig. 263-4)**.

VT/VF IN THE SETTING OF MYOCARDIAL ISCHEMIA

Ischemia should be considered especially if polymorphic VT or VF is identified as the primary arrhythmia. If electrical storm is occurring in the setting of an acute coronary syndrome, emergent revascularization and alleviation of anginal symptoms should be attempted. Within the infarcted myocardium, surviving Purkinje cells can exhibit triggered automaticity and lead to recurrent episodes of polymorphic VT/VF requiring frequent cardioversions before and after revascularization. Catheter ablation of premature ventricular contractions (PVCs) that are observed to repeatedly initiate the arrhythmia can be effective **(Fig. 263-5)**.

PVC-INITIATED POLYMORPHIC VT/VF

Similar to the post–myocardial infarction electrical storm, patients without myocardial infarction or ischemia can have PVC-initiated polymorphic VT/VF storm. This idiopathic form of VF is usually caused by triggering PVCs originating from fascicular tissue or papillary muscles. Often, the ventricular ectopy is from scarred myocardial tissue detected on cardiac magnetic resonance imaging. Catheter ablation is indicated for this condition when antiarrhythmic medication is ineffective.

ACQUIRED OR CONGENITAL LONG QT SYNDROME

If QT prolongation causing torsades des pointes (TdP) is possible, intravenous magnesium should be administered for its immediate effect on repolarization. In addition, electrolyte repletion, especially potassium, should be aggressively pursued. Increasing the heart rate can sometimes normalize the QT interval, and thus, pharmacologic or pacing support should be considered. Isoproterenol can be used to increase a patient's sinus rate, but there is the possibility of increased ectopy with high doses of isoproterenol possibly exacerbating ventricular

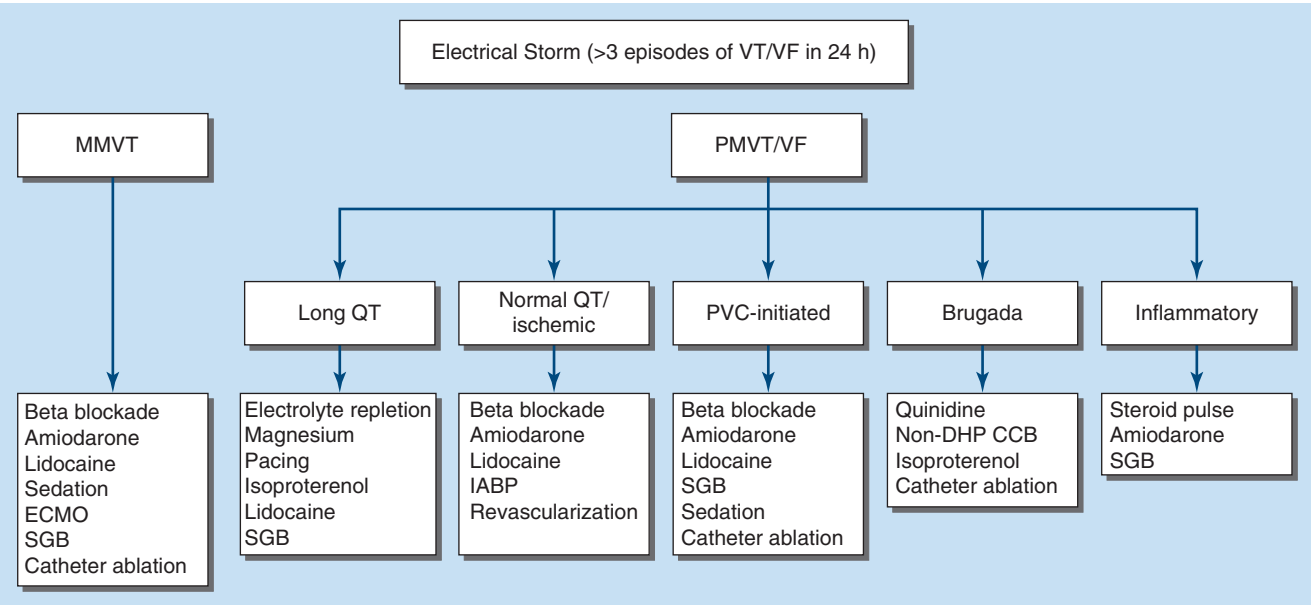

FIGURE 263-4 Management algorithm for electrical storm. Shown is a suggested strategy for managing electrical storm based on the underlying rhythm and substrate. CCB, calcium channel blocker; DHP, dihydropyridine; ECMO, extracorporeal membrane oxygenation; IABP, intra-aortic balloon pump; MMVT, monomorphic ventricular tachycardia; PMVT, polymorphic ventricular tachycardia; PVC, premature ventricular contraction; SGB, stellate ganglion block; VF, ventricular fibrillation; VT, ventricular tachycardia.

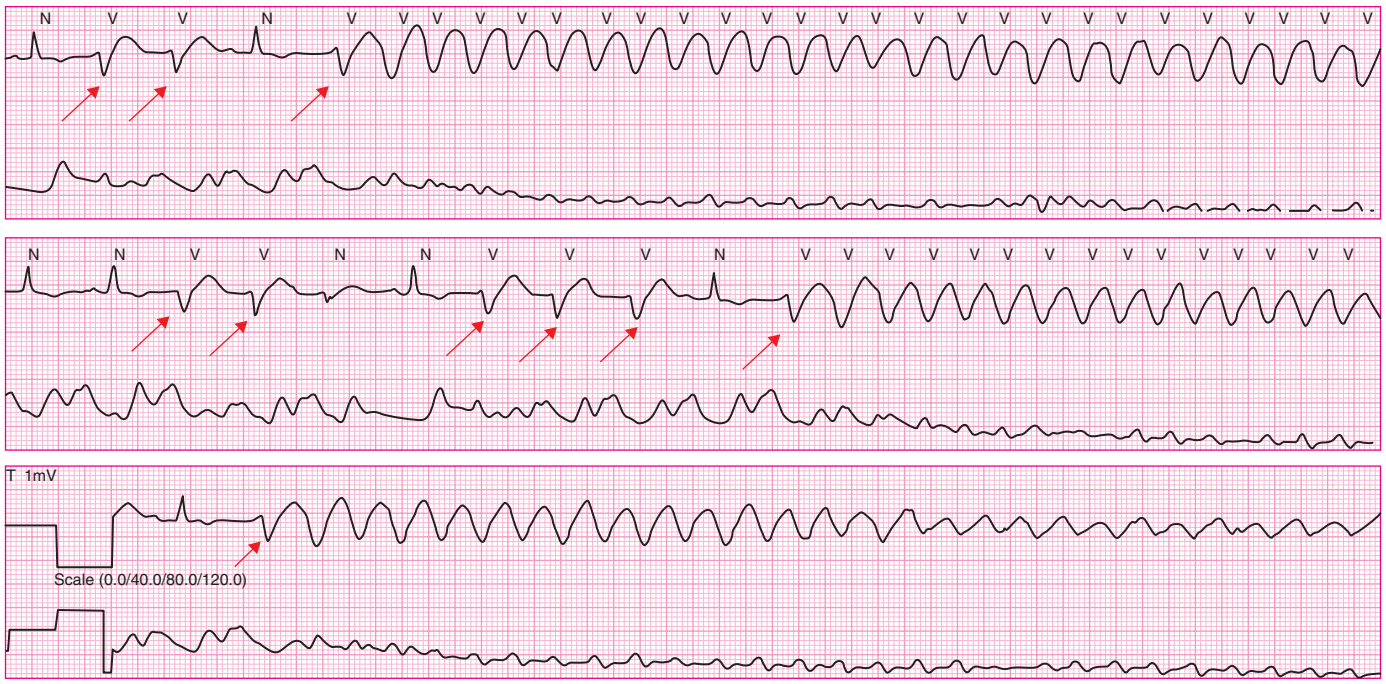

FIGURE 263-5 Premature ventricular contraction (PVC)–triggered ventricular fibrillation (VF) after myocardial infarction electrical storm. Shown is a series of monitoring strips from a patient with VF occurring in a PVC-triggered fashion after myocardial infarction. A single electrocardiogram lead and the blood pressure tracings are shown. The triggering PVCs are indicated with *red arrows*. The VF results in prompt hemodynamic collapse as evidenced by the blood pressure tracing.

arrhythmias. Although lidocaine can reduce the QT interval, other antiarrhythmic agents should be avoided because of their effect on repolarization.

BRUGADA SYNDROME

If the QT interval is not prolonged and a Brugada pattern of Rsr′ with ST elevation in leads V_1 or V_2 is seen on resting ECG, administration of quinidine and/or isoproterenol may abolish recurrent polymorphic VT/VF episodes. Nondihydropyridine calcium channel blockers and isoproterenol have also been used to reduce arrhythmic events. An epicardial substrate-based catheter ablation over the right ventricular outflow tract has been described as a strategy for drug-refractory ventricular tachyarrhythmias in Brugada syndrome.

INFLAMMATORY CARDIOMYOPATHY

If the patient has no known previous cardiac disease, consideration should be given to an inflammatory myocarditis causing the frequent ventricular arrhythmias. Giant cell myocarditis, cardiac sarcoidosis, and certain viral myocarditis can present with VT/VF storm. An endomyocardial biopsy should be considered to potentially identify new-onset inflammatory cardiomyopathies that may require urgent anti-inflammatory therapy. Once the acute episode is controlled, strategies to prevent recurrent VT or VF should be considered.

Section 4 Disorders of the Heart, Muscles, Valves, and Pericardium

264 Heart Failure: Pathophysiology and Diagnosis

Michael M. Givertz, Mandeep R. Mehra

CLINICAL DEFINITIONS, EPIDEMIOLOGY, AND PHENOTYPES

DEFINITIONS

Heart failure (HF) is a common final pathway for most chronic cardiovascular diseases including hypertension, coronary artery disease, and valvular heart disease. The American Heart Association/American College of Cardiology/Heart Failure Society (AHA/ACC/HFSA) guideline defines HF as a complex clinical syndrome with symptoms and signs that result from any structural or functional impairment of ventricular filling or ejection of blood. The European Society of Cardiology's (ESC) definition emphasizes cardinal symptoms (e.g., breathlessness, ankle swelling, and fatigue) that may be accompanied by signs (e.g., elevated jugular venous pressure, pulmonary crackles, and peripheral edema) due to a structural and/or functional abnormality of the heart that results in elevated intracardiac pressures and/or inadequate cardiac output at rest and/or during exercise. An international consensus conference proposed a universal definition of HF that is comprehensive and practical enough to encompass formal disease stages, with universal applicability, prognostic and therapeutic validity, and acceptable sensitivity and specificity **(Fig. 264-1)**.

Because some patients present without signs or symptoms of volume overload, the term *heart failure* is preferred over the older term

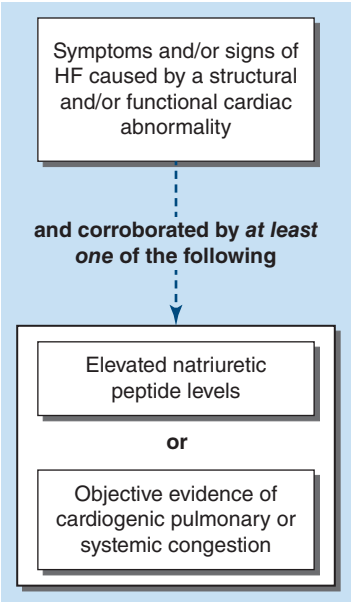

FIGURE 264-1 Universal definition of heart failure (HF). This contemporary universal definition of HF is simple but conceptually comprehensive, with near universal applicability, prognostic and therapeutic validity, and acceptable sensitivity and specificity. *(Reproduced with permission from B Bozkurt et al: Universal Definition and Classification of Heart Failure. J Card Fail 27:387, 2021.)*

congestive heart failure. *Cardiomyopathy* and *left ventricular dysfunction* are more general terms that describe disorders of myocardial structure and/or function, which may lead to HF. In pathophysiologic terms, HF has been defined as a syndrome characterized by elevated cardiac filling pressure and/or inadequate peripheral oxygen delivery, at rest or during stress, caused by cardiac dysfunction.

Chronic heart failure describes patients with longstanding (e.g., months to years) symptoms and/or signs of HF typically treated with medical and device therapy as described in **Chap. 265**. Such patients are at risk of *worsening heart failure,* and when the episode resolves, the use of the term *remission* rather than *stable* HF is preferred, since these patients continue to retain the risk for further decompensation and sudden death. *Acute heart failure*, previously termed acute decompensated HF, refers to the rapid onset or worsening of symptoms of HF. Most episodes of acute HF result from worsening of chronic HF, but ~20% are due to new-onset HF that can occur in the setting of acute coronary syndrome, acute valvular dysfunction, hypertensive urgency, or postcardiotomy syndrome. Similarly, *acute pulmonary edema* in HF describes a clinical scenario in which a patient presents with rapidly worsening signs and symptoms of pulmonary congestion, typically due to severe elevation of left heart filling pressures.

EPIDEMIOLOGY

Global Incidence and Prevalence HF is a major cause of morbidity and mortality worldwide. An estimated 6.7 million American adults are being treated for HF, with >600,000 new cases diagnosed each year. Globally, it is estimated that 56.2 million people are living with HF with prevalence varying greatly by country. The prevalence of HF increases significantly with age, occurring in 1–2% of the population aged 40–49 years and 10% or more in adults >80 years old **(Fig. 264-2)**. The lifetime risk of HF has increased to 24%; approximately one in four persons will develop HF in their lifetime. Projections based on National Health and Nutrition Examination Survey and U.S. Census Bureau data show that the prevalence of HF is expected to rise to 8.5 million Americans by 2030. According to the Nationwide Readmission Database, rates of HF hospitalizations in the United States declined from 2010 to 2014, followed by an increase from 2014 to 2017. HF readmissions after index hospitalization followed a similar trend. While prevalence of HF continues to rise, incidence may be decreasing due to improved recognition and treatment of cardiovascular disease

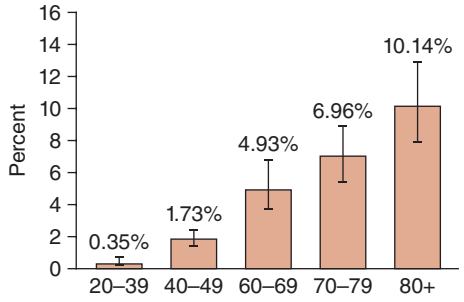

FIGURE 264-2 Heart failure prevalence by age categories. Prevalence of heart failure among U.S. adults ≥20 years of age by age, from the National Health and Nutrition Examination Survey (NHANES), 2017–2020. *(Reproduced with permission from B Bozkurt et al: J Card Fail 29:1412, 2023.)*

and its comorbidities as well as disease prevention. However, as rates of obesity rise globally, these favorable trends in HF incidence may reverse.

There are distinct racial and ethnic differences in HF epidemiology **(Fig. 264-3)**. In community-based studies, black individuals have the highest risk of developing HF, followed by Hispanic, white, and Chinese Americans. These differences are attributed to disparities in cardiometabolic risk factors (e.g., obesity, hypertension, diabetes) as well as social determinants of health including socioeconomic status and access to health care. Similarly, studies have shown that age-adjusted rates of HF hospitalization are highest for black men, followed by black women, white men, and white women. Accurate data on HF prevalence from emerging nations are lacking. As developing nations undergo socioeconomic development, the epidemiology of HF is becoming like that of Western Europe and North America, with coronary artery disease emerging as the most common cause of HF, although hypertension remains the highest population attributable risk for HF occurrence.

Morbidity and Mortality In primary care, the overall 5-year survival following the diagnosis of HF is ~50%. For patients with severe HF, the 1-year mortality may be as high as 40%. In the United States, one in eight deaths list HF on the death certificate. The majority of these patients die of cardiovascular causes, most commonly progressive HF or sudden cardiac death. A number of clinical and laboratory parameters are independent predictors of mortality **(Table 264-1)**. In a population-based study, hospitalizations were common after an HF diagnosis, with 83% hospitalized at least once, and 67%, 54%, and 43% hospitalized at least two, three, and four times, respectively. Following an HF admission, mortality rates range from 8–14% at 30 days to 26–37% at 1 year to up to 75% at 5 years. Readmission with HF is also common, ranging from 20–25% at 60 days to nearly

TABLE 264-1 Independent Predictors of Adverse Outcomes in Heart Failure

Clinical	Male sex Older age Diabetes mellitus Chronic kidney disease Coronary artery disease Advanced NYHA class[a] Presence of third heart sound or elevated JVP Decreased exercise capacity Cardiac cachexia Depression
Structural	Reduced left ventricular ejection fraction Reduced right ventricular ejection fraction Increased ventricular volumes and mass Secondary mitral or tricuspid regurgitation
Hemodynamic	Elevated pulmonary capillary wedge pressure Reduced cardiac index Reduced peak oxygen consumption Pulmonary hypertension Diastolic dysfunction
Biochemical	Worsening renal function Hyponatremia Hyperuricemia Elevated cardiac biomarkers (troponin and natriuretic peptides) Elevated plasma neurohormones (norepinephrine, renin, aldosterone, and endothelin-1)
Electrophysiologic	Tachycardia Widened QRS interval or LBBB Atrial fibrillation Ventricular ectopic activity Ventricular tachycardia and sudden death

[a]See Table 264-4.

Abbreviations: JVP, jugular venous pressure; LBBB, left bundle branch block; NYHA, New York Heart Association.

TABLE 264-2 Selected Causes of Heart Failure

Heart Failure with Reduced Ejection Fraction	
Coronary artery disease Myocardial infarction Myocardial ischemia	Nonischemic cardiomyopathy Infiltrative disorders Familial disorders Tachycardia induced
Valvular heart disease Aortic stenosis or regurgitation Mitral or tricuspid regurgitation	Toxic cardiomyopathy Chemotherapy, immunotherapy Drugs such as hydroxychloroquine Alcohol, cocaine
Congenital heart disease Intracardiac shunts Repaired defects Systemic right ventricular failure	Chronic lung/pulmonary vascular disease Cor pulmonale Pulmonary arterial hypertension
Infectious Chagas HIV	Autoimmune disease Giant cell myocarditis Lupus myocarditis
Heart Failure with Preserved Ejection Fraction	
Hypertension	Coronary artery disease
Valvular heart disease Aortic stenosis Mitral stenosis	Restrictive cardiomyopathy Amyloidosis Sarcoidosis Hemochromatosis Glycogen storage disease
Hypertrophic cardiomyopathy	Radiation therapy
Constrictive pericarditis	Aging
Myocarditis	Endomyocardial fibroelastosis
Obesity	End-stage renal disease
High-Output Heart Failure	
Thyrotoxicosis	Arteriovenous shunt
Obesity	Cirrhosis
Anemia	Vitamin B deficiency (beriberi)
Chronic lung disease	Myeloproliferative disorder

Abbreviation: HIV, human immunodeficiency virus.

50% at 6 months. With each subsequent admission, the risk of death rises. There are racial disparities in outcomes, with black patients having higher case–fatality rates compared to white patients. Men have higher age-adjusted mortality rates for death related to HF than women; and in the United States, mortality rate from HF varies by region (highest in Midwest) and population density (highest in rural areas). Despite these statistics, the overall prognosis for patients with HF is improving due to treatment of risk factors and increased use of guideline-directed therapies.

Costs The overall cost of HF care is high (estimated $22.3 billion in the United States in 2018) and rising. Projections for 2030 are that hospitalization costs for HF in the United States will increase to $70 billion. Indirect costs due to lost work and productivity may equal or exceed this amount. The global economic burden of HF in 2012 was estimated at $108 billion, with direct costs accounting for 60%. For pediatric patients with acute HF, inpatient costs are estimated at $1 billion annually and rising.

PHENOTYPES AND CAUSES

HF with Reduced Versus Preserved Ejection Fraction Epidemiologic studies have shown that approximately one-half of patients who develop HF have reduced left ventricular ejection fraction (EF; ≤40%), while the other half have near normal or preserved EF (≥50%) or are classified as having HF with mildly reduced EF (41–49%). Because most patients with HF (regardless of EF) have abnormalities in both systolic and diastolic function, the older terms of *systolic heart failure* and *diastolic heart failure* have been abandoned. Classifying patients based on their EF (HF with reduced EF [HFrEF], HF with mildly reduced EH [HFmrEF], or HF with preserved EF [HFpEF]) is important due to differences in demographics, comorbidities, and response to therapies (Chap. 265). Underlying causes of HF may be associated with reduced or preserved EF and include disorders of the coronary arteries, myocardium, pericardium, heart valves, and great vessels (Table 264-2). The diagnosis of HFpEF is often more challenging due to the need to rule out noncardiac causes of shortness of breath and/or fluid retention.

HF with Recovered EF A subgroup of patients who are diagnosed with HFrEF and treated with guideline-directed therapy have rapid or gradual improvement in EF to the normal range and are referred to as having HF with recovered EF (HFrecEF). Predictors of HFrecEF include younger age, shorter duration of HF, nonischemic etiology, smaller ventricular volumes, and absence of myocardial fibrosis. Specific clinical examples include fulminant myocarditis, stress cardiomyopathy, peripartum cardiomyopathy, and tachycardia-induced cardiomyopathy, as well as reversible toxin exposures such as chemotherapy, immunotherapy, or alcohol. Despite recovery of EF, patients may remain symptomatic due to persistent abnormalities in diastolic function, exercise-induced pulmonary hypertension, or related comorbidities (e.g., obesity). For patients who become asymptomatic, withdrawal of disease-modifying therapy can lead to recurrence of HF symptoms and decrease in EF in up to half of such patients within 6 months. In general, prognosis of patients with HFrecEF is superior to that of patients with either HFrEF or HFpEF.

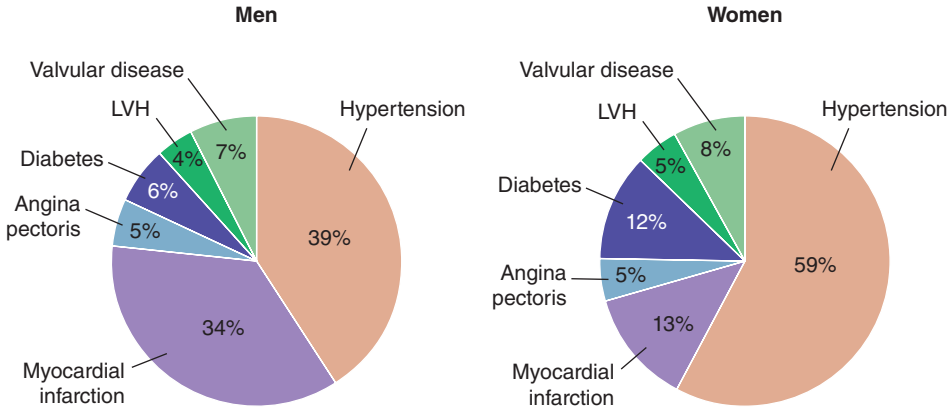

FIGURE 264-4 Population attributable risk of heart failure (HF) incidence. Based on longitudinal data from the Framingham Heart Study, the risk factors contributing most significantly to the population attributable risk (PAR) of HF in men were previous myocardial infarction and hypertension (in men, both represented equal contributions to HF PAR). In contrast, hypertension was the risk factor accounting for the majority of total PAR in women. In women, previous myocardial infarction accounted for only 13% of the PAR of HF compared with 34% in men. PAR values are developed based on individual calculations for each variable using hazard ratio and prevalence statistics. Thus, they may not, in aggregate, equal 100%. LVH, left ventricular hypertrophy. *(Reproduced with permission from Givertz MM and Colucci WS. Heart failure. In: Libby P, editor. Essential Atlas of Cardiovascular Disease. Philadelphia: Current Medicine; 2009.)*

HF with Mildly Reduced EF (HFmrEF) Patients with HF and an EF between 40 and 50% represent an intermediate group that are often treated for risk factors and comorbidities and with guideline-directed medical therapy similar to patients with HFrEF. They are felt to have primarily mild systolic dysfunction, but with features of diastolic dysfunction. They may also include either patients with reduced EF who experience partial improvement in their EF or those with initially preserved EF who suffer a decline in their systolic performance. The AHA/ACC/HFSA guideline requires evidence of spontaneous or provokable increased left ventricular filling pressures in their classification of HFmrEF.

Acquired Versus Familial, Congenital, and Other Disorders In developed countries, coronary artery disease is responsible for approximately two-thirds of the cases of HF, with hypertension as a principal contributor in up to 75% and diabetes mellitus in 10–40% **(Fig. 264-4)**. Notably, population attributable risk for hypertension, obesity, diabetes mellitus, and coronary artery disease varies according to sex, race, and ethnicity **(Fig. 264-5)**. While most cardiovascular disease underlying HF is acquired in mid and later life **(Chaps. 272, 284, and 288)**, a wide range of congenital and inherited disorders leading to HF may be diagnosed in children and younger adults. It is currently estimated that 13.3 million people globally and approximately 467,000 U.S. adults are living with congenital heart disease (CHD). In general, adults with CHD who develop HF can be divided into one of three pathophysiologic groups: uncorrected defects with late presentation due to missed diagnosis, nonintervention, or lack of access to care; repaired or palliated defects with late valvular and/or ventricular failure; or failing single-ventricle physiology. In addition, each adult with CHD often presents with unique anatomic and physiologic challenges that affect HF and its treatment.

Inherited cardiomyopathies are also increasingly recognized in adults presenting with HF. These include more common disorders, such as hypertrophic and arrhythmogenic cardiomyopathies, and lesser known heart muscle disease related to pathogenic variants in genes encoding lamin and titin, muscular dystrophies, and mitochondrial disease. Most forms of familial cardiomyopathy are inherited in an autosomal dominant fashion. Society guidelines have been published documenting the importance of taking a detailed three-generational family history and indications for (and limitations of) clinical genetic testing.

A myriad of systemic diseases with cardiac and extracardiac manifestations (e.g., amyloidosis, sarcoidosis), autoimmune disorders (e.g., systemic lupus erythematosus, rheumatoid arthritis), infectious diseases (e.g., Chagas, HIV), and drug toxicities (chemotherapy, other prescribed or illicit agents) can result in HF with either reduced or preserved EF. In Africa and Asia, rheumatic heart disease remains a major cause of HF, especially in the young. Finally, disorders associated with a high cardiac output state (e.g., anemia, thyrotoxicosis) are seldom associated with HF in the absence of underlying structural heart disease. However, diagnosis and treatment of high-output HF will be missed if not considered in the differential diagnosis of patients with predisposing conditions (e.g., severe obesity, severe anemia, cirrhosis, end-stage renal disease with arteriovenous fistula, Paget's disease, or nutritional deficiency such as beriberi).

PATHOPHYSIOLOGY

PROGRESSIVE DISEASE

HFrEF is a progressive disease that typically involves an index event followed by months to years of structural and functional cardiovascular remodeling **(Fig. 264-6)**. The primary event may be sudden in onset, such as an acute myocardial infarction; more gradual, as occurs in the setting of chronic pressure or volume overload (with valvular heart disease); inherited, as seen with genetic cardiomyopathies; or congenital disease in origin. Despite an initial reduction in cardiac performance, patients may be asymptomatic or mildly symptomatic for prolonged periods due to the activation of compensatory mechanisms (described below) that ultimately contribute to disease progression.

Ventricular Remodeling As demonstrated in both animal and human studies, different patterns of ventricular remodeling occur in response to excess cardiac workload. Concentric hypertrophy, in which increased mass is out of proportion to chamber volume, effectively reduces wall stress under conditions of pressure overload (e.g., hypertension, aortic stenosis). By contrast, an increase in cavity size or volume (eccentric hypertrophy) occurs in volume overload conditions (e.g., aortic regurgitation, mitral regurgitation). In both forms of remodeling, an increase in ventricular mass is accompanied by changes at the *cellular level* with myocyte hypertrophy and interstitial fibrosis, at the *protein level* with alterations in calcium-handling and cytoskeletal protein abundance and/or function, and at the *molecular level* by reexpression of fetal genes **(Table 264-3)**. In addition to cell loss from necrosis, myocytes that are unable to adapt to remodeling stimuli may be triggered to undergo apoptosis or programmed cell death. Further impairment in pump function and increased wall stress in the face of systemic vasoconstriction and loss of neurohormonal adaptation (discussed below) can lead to afterload mismatch. These events feed back on remodeling stimuli, setting up a cycle of deleterious processes resulting in clinical HF.

While our understanding of ventricular remodeling in HFrEF is well supported by animal and human studies, the mechanisms underlying HFpEF are less clear. The original descriptions of HFpEF focused on diastolic dysfunction as the primary mediator of HF

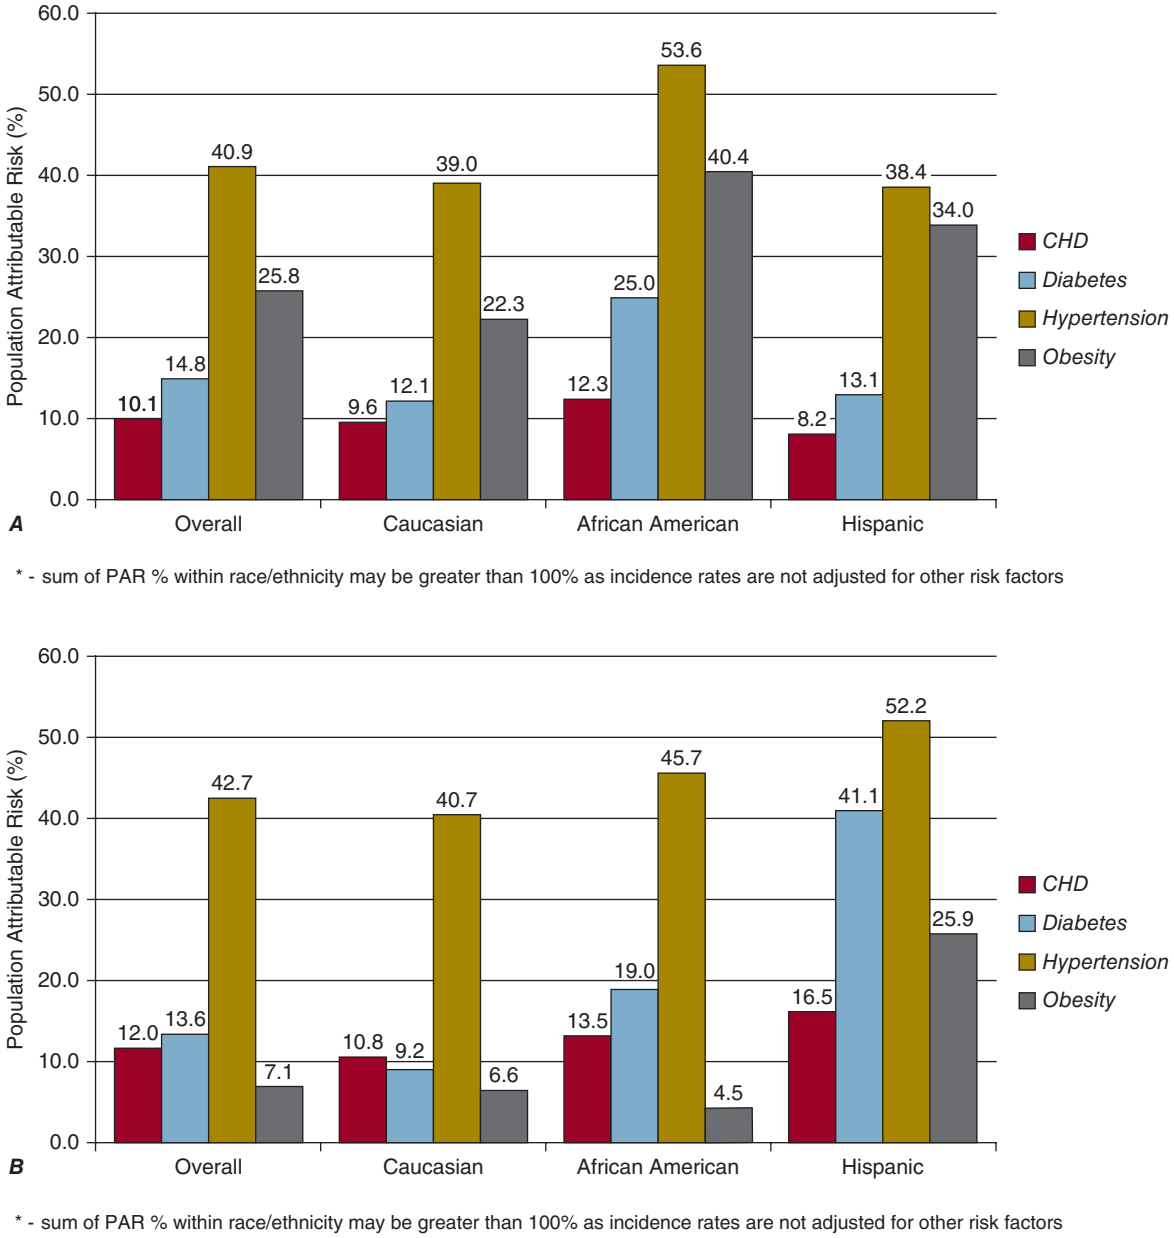

FIGURE 264-5 Population attributable risk (PAR) for heart failure (HF) by race and ethnicity. PAR* by race and ethnicity for (***A***) HF with preserved ejection fraction (HFpEF) and (***B***) HF with reduced ejection fraction (HFrEF). *Sum of PAR% within race/ethnicity may be >100% as incidence rates are not adjusted for other risk factors. CHD, coronary heart disease. *(Reproduced with permission from CB Eaton, M Pettinger, J Rossouw, LW Martin et al: Risk factors for incident hospitalized heart failure with preserved versus reduced ejection fraction in a multiracial cohort of postmenopausal women. Circ Heart Fail 9(10): e002883, 2016.)*

signs and symptoms as exemplified in older women with hypertension. At the myocyte level, impaired uptake of cytosolic calcium into the sarcoplasmic reticulum by reductions in adenosine triphosphate explained abnormalities in myocardial relaxation. As different phenotypes of HFpEF have emerged, many pathophysiologic processes that work in concert with each other, beyond diastolic dysfunction, have been implicated in disease progression, including vascular stiffness, renal dysfunction, sodium avidity, and inflammation related to regional adiposity. Furthermore, biologic alterations including oxidative stress, impaired nitric oxide signaling leading to nitrosative stress, and insulin resistance may play a role in disease activity and inform future therapies. Autophagy is a natural process that removes unwanted cellular components by forming autophagosomes that fuse with lysosomes. While autophagy is deemed cytoprotective and adaptive, unchecked induction of autophagy may be maladaptive and a target by which disease-modifying therapy may exert beneficial effects.

MECHANISMS OF DISEASE PROGRESSION

Several compensatory mechanisms become activated during the development of HF and contribute to disease progression. Our understanding of these mechanisms derives from preclinical studies, in vivo human studies, and randomized clinical trials demonstrating benefit of therapies targeted to attenuating or reversing these biologic processes.

Neurohormonal Activation Activation of the sympathetic nervous system (SNS) and renin-angiotensin-aldosterone system (RAAS) plays a critical role in the development and progression of HF. Initially, neurohormonal activation leads to increases in heart rate, blood pressure, and cardiac contractility and retention of sodium and water to augment preload and maintain cardiac output at rest and during exercise. Over time, these unchecked compensatory responses lead to excessive vasoconstriction and volume retention, electrolyte and renal abnormalities, baroreceptor dysfunction, direct myocardial toxicity, and cardiac arrhythmias. At the tissue level, neurohormonal activation

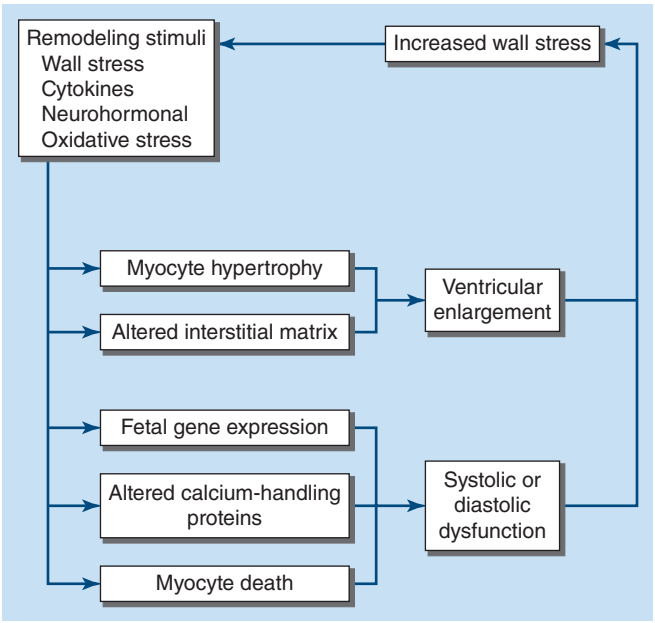

FIGURE 264-6 Remodeling stimuli in heart failure. Chronic hemodynamic stimuli such as pressure and volume overload lead to ventricular remodeling through increases in myocardial wall stress, inflammatory cytokines, signaling peptides, neuroendocrine signals, and oxidative stress. The myocardium responds with adaptive as well as maladaptive changes. Reexpression of fetal contractile proteins and calcium handling proteins may contribute to impaired contraction and relaxation. Myocytes unable to adapt might be triggered to undergo programmed cell death (apoptosis). The net result of these changes is further impairment in pump function and increased wall stress, thus completing a vicious cycle that leads to further progression of myocardial dysfunction. *(Reproduced with permission from Givertz MM and Colucci WS. Heart failure. In: Libby P, editor. Essential Atlas of Cardiovascular Disease. Philadelphia: Current Medicine; 2009.)*

contributes to remodeling of the heart, blood vessels (atherosclerosis), kidneys, and other organs **(Fig. 264-7)** and the development of symptomatic HF. Landmark clinical trials in HF have demonstrated that antagonism of the RAAS and SNS with renin-angiotensin system inhibitors, mineralocorticoid receptor antagonists, and beta blockers attenuates or reverses ventricular and vascular remodeling and reduces morbidity and mortality **(Chap. 265)**.
