be: “Your mother’s death was very stressful for you. You weren’t sleeping well and were using drugs to ease the pain. In that stressed-out state, you had some disturbing experiences, like thinking your neighbor was trying to poison you. We can now see that those beliefs were the result of the upset state of mind you were in at the time.” Or, a formulation based on identifying cognitive biases: “You have a cognitive bias that leads you sometimes to jump to the conclusion that people know you and want to hurt you. You tend to personalize events, believing people are referring to you when they are not.” Or, a fuller biopsychosocial formulation: “You felt that if you had set a better example for your brother, he might not have died so young. You felt guilty, and when you couldn’t get your life together after the Navy, you felt ashamed. You criticized yourself. Over the years, those feelings of guilt and shame built up, and you came to feel that shame everywhere you went, including in the eyes of the dogs in your neighborhood.” The therapist should determine whether the patient engages in safety behaviors that constrict life experience, precluding positive experiences that would contradict delusional beliefs.

As described in the earlier part of the section on technique, the CBTp work outlined above can lead into a final phase of therapy that seeks to find psychological explanations for the formation of the patient’s psychotic symptoms. CBTp is a preferred method for showing the patient what delusional beliefs are *not* the case. PDTp is well suited for showing the patient what *is* the case; that is, showing how the patient came to form delusional beliefs and what emotional truths the psychotic experience expresses.

Table 32.6–3.
Resistance to the Use of Logic in Cognitive-Behavioral Therapy for Psychosis

Telegram: @medical_k

www.konkur.in

Logic evasion	Evading the implications of logic by claiming to be an exception to whom logic does not apply
Logic monopolizing	Claiming to be a master logician who offers definitive logical proof of a delusion not open to any alternative line of logical reasoning
Logic blinding	Acknowledging a logical conclusion while remaining blind to the emotional implications of a logical inference
External expectancy	Relying on external agents and contingencies as instruments of change rather than one's own hard work in therapy
Logic partitioning	Conceding that logic suggests that some beliefs are likely untrue without changing core delusions or recognizing the psychological processes that continually generate new delusional beliefs
Equivocation	Offering vague, nonspecific noncommittal responses that provide little traction for logical thinking
Reactive reassertion	Expressing a reactive, strident reassertion of a delusion when the patient senses a conflict between the delusion and logic
Feeling-percept fusion	Ignoring the considerations of logic because of a strong "feeling" that the delusion is true, despite logical evidence to the contrary
Mind-guarding	Resisting alterations of beliefs because the change threatens to erode a vital psychological structure upon which the patient's identity, vitality, self-esteem, or emotional regulation depends
Peripheral preoccupation	Preoccupation with an underlying emotional

Telegram: @medical_k

www.konkur.in

	concern that is not embedded in a psychotic symptom per se that has not been recognized as a central focus of therapy

CBTp and PDTp both access logic, but compared with PDTp, CBTp places more emphasis on the use of logic to examine evidence to consider alternative beliefs that are more adaptive than delusions. However, even in a well-conducted CBTp treatment, patients may show a variety of resistances to the use of logic which may hinder a therapeutic approach that relies on logical cognition (see Table 32.6–3) as opposed to the interpretation of unconscious meaning (PDTp). CBTp therapists may reduce the impact of resistances to logic by identifying them and addressing them in the treatment.

Maintain Contact and Employ "Booster Sessions" as Needed. Therapists should develop with each patient a description of possible stressors and early signs of relapse to look out for. They need to anticipate what the patient should do if these signs appear. Working collaboratively, they should encourage the patient to practice the ability to identify signs of relapse and to implement the recommended course of action. Continuing to see the patient on a regular basis is critical for supporting positive changes.

ETHICAL ISSUES

The ethical constraints, such as maintaining professional boundaries that govern the practice of psychotherapy with non-psychotic patients, are well known and apply equally to the treatment of psychotic patients and so will not be addressed here. Because most individuals with chronic psychosis are treated in the public psychiatry sector or in hospitals or clinics funded by third-party government insurance, their well-being is directly affected by how resources are allocated and what kinds of care are reimbursed, a circumstance that poses ethical concerns.

In the study of ethics, there is a time-honored tradition of using a hypothetical situation to think through an issue. Consider the following hypothetical: Assume that chronic psychosis is a complex biopsychosocial disorder that has no single cause. Assume that no mental health system

Telegram: @medical_k

www.konkur.in

has developed a way of treating psychosis that avoids the prescription of neuroleptic medications in all patient cases, despite evidence that these drugs may cause structural damage to the brain. Also assume that individual psychotherapy is an effective treatment for psychosis that in some cases may resolve psychotic symptoms unresponsive to medication, improve quality of life, and reduce or even on occasion eliminate the need for medication. If we make these assumptions in our thought experiment, and assume that physicians are ethically bound to provide patients access to quality care, what ethical implications follow from the above assumptions?

The author suggests that psychiatry has an ethical obligation to consider the following:

1. At present, there are woefully insufficient numbers of therapists trained in psychotherapy for psychosis to meet patient needs, and there are not enough supervisors who can train additional therapists. Federal and state agencies should fund pilot training programs with a research component to develop supervisors and therapists with the needed skills. Psychiatric residency programs should find ways to teach psychotherapy for psychosis.
2. In understaffed public clinics, where too many patients are assigned to too few clinicians, administrators should pilot psychotherapy initiatives coupled with research that allow clinicians to see at least a few patients frequently enough to provide PDTp and/or CBTp.
3. To foster a therapeutic alliance that creates a bridge between inpatient acute care and outpatient PDTp and CBTp, suitable patients nearing discharge on inpatient units should begin working with an outpatient therapist while the patient is still in the hospital.
4. Granting agencies should encourage research that explores whether PDTp and CBTp can help reduce the total neuroleptic exposure patients receive.

Despite the enormous amount of information accumulated about the functioning of the brain, most psychiatrists regard neuroscience as still in its infancy. Psychiatry should also regard the psychotherapy of psychosis as still in its infancy, but as a childhood with much promise. Improvements in outcome seen in the last two decades with CBTp suggest there is much progress to be made in the psychotherapy of psychosis when a critical mass of researchers and clinicians put their minds to the challenge.

Telegram: @medical_k

www.konkur.in

Since Bleuler's time, there has always been a small chorus of voices in the clinical community who were convinced from personal experience that psychotherapy can be an effective mode of treatment for psychosis. If it is true (as personal experience and research evidence suggest) that psychotherapy can be an effective element of treatment, psychiatry has an ethical obligation to understand why patients with psychotic disorders have little or no access to psychotherapy and to devise the psychiatric educational, political, economic, and clinical vehicles that would allow psychotherapy to be delivered. As Karon put it a decade ago, "The real tragedy of schizophrenia is not the severity of the symptoms and the suffering that results for patients and for their families, but that we know psychotherapies that work and we are not using them."

RESEARCH AND EVALUATION

There is solid evidence for the efficacy of CBTp, supported by multiple randomized-controlled trials (RCTs) and meta-analyses. An early meta-analysis of 34 CBTp clinical trials found an effect size of .4, in the range of effect sizes for some neuroleptics (typically in the .4 to .5 range, with the exception of clozapine as high as .8). A more recent meta-analysis of CBTp RCTs showed a somewhat smaller average pooled effect size of .33. CBTp is included in the British National Institute for Health and Care Excellence (NICE) Guidelines. A recent review of six different psychological interventions for psychosis found that CBTp was significantly more efficacious than other interventions in reducing positive symptoms, while social skills training showed an advantage in improving negative symptoms. Thus it is clear that CBTp works. There are no head-to-head RTCs comparing psychopharmacology alone against CBTp alone.

The many published case histories, autobiographical accounts, and the testimony of many therapists and patients bear witness to the efficacy of PDTp, and the positive experiences of the Soteria Project and the Open Dialogues program lend support to treating psychosis without neuroleptics, but if one considers RCTs to be the gold standard of evidence, the RCT base for PDTp is small, methodologically flawed, and outdated. The Michigan State Psychotherapy Project, in which hospitalized patients with psychosis were randomly assigned to either individual psychotherapy without medication, therapy with medication, or

Telegram: @medical_k

www.konkur.in

medication without therapy, reported that psychotherapy produced significantly greater improvement than medication alone and was particularly effective in changing thought disorder. The investigators also concluded that more experienced therapists produced more improvement. A more recent study compared expressive insight-oriented therapy (EIO) with reality adaptive supportive therapy (RAS) and found that both were effective. RAS had a clearly greater impact on recidivism and social functioning, while EIO had a modestly more positive effect on ego functioning and cognition. The conclusion of a 2001 Cochran Database Review of randomized individual PDTp and psychoanalysis for schizophrenia, however, did not support the efficacy of those approaches. The review concludes by saying there is an urgent need for research in this area. It is apparent that while RCT support for CBTp is strong, research support for PDTp is not.

In addition to PDTp and CBTp, additional modes of psychotherapy for psychosis with demonstrable efficacy have emerged, including *mentalization* therapy (MBTp) and *metacognitive* therapy (MERIT). In MBTp the therapist aims to help the patient toward a more accurate understanding of the thoughts, feelings, and wishes that transpire in the patient's mind and the minds of other people in the context of social relations. The MBTp therapist provides psychoeducation about mentalization and fosters an interpersonal attachment that builds a positive therapeutic alliance that minimizes the distortions of affect arousal. MERIT encourages the patient's capacity to think about their thinking (metacognition) to strengthen the coherence of a personal narrative constructed from episodic memories that strengthens the patient's sense of personal agency and self-directed recovery. In MERIT sessions, the therapist is mindful of eight elements, including (1) encouraging personal agency; (2) focus on episodic memory (often of recent events); (3) identification of a plausible psychological problem; (4) setting reasonable goals; (5) reflection on the therapeutic relationship; (6) assessment of progress in therapy; (7) interactions matched to the individual's capacities for metacognition; and, (8) developing strategies to master psychological problems. *Avatar* therapy is another promising new psychotherapy for auditory hallucinations in which the patient creates an avatar in a computer program that represents the entity the patient experiences as persecuting them. The therapist helps the patient to engage in a dialogue with the avatar where the patient's control of the

Telegram: @medical_k

www.konkur.in

avatar fosters a change in the patient's relationship to the avatar from abusive to more friendly and supportive, a shift that is mirrored in the patient's voice-hearing experience.

FUTURE DIRECTIONS

CBTp is structured and brief compared with PDTp, which is less structured and more open-ended. This makes PDTp more difficult to study than CBTp. Developing new ideas and conducting research requires a critical mass of clinicians trained in the techniques to be studied. At present, there exists more than a critical mass of CBT-trained clinicians working and doing research in many centers. The same cannot be said for PDTp, where more teaching and practice opportunities need to be developed.

At this point, what do we know about the comparative efficacy of psychopharmacology and psychotherapy? We know that patients treated in a care system with a predominantly pharmacologic paradigm have a life expectancy of 15 to 20 years less than the general population. We know that all neuroleptics have potentially significant side effects and that psychotherapy for psychosis has never been proven to have any. We know that roughly a quarter of patients initially treated with medication after years of pharmacologic treatment can do well off medication, but we do not know how to identify these people or how to wean them off medication even if we could identify them.

We don't know how to teach psychotherapy and integrate it into current care systems. We don't know whether psychotherapy combined with medication can reduce dosage creep or reduce total neuroleptic exposure for patients on maintenance medication. We don't know if the current psychotherapeutic techniques are the best that can ever be devised. We don't know if psychotherapy is more effective for some symptoms and if medication is more effective for others. Many important questions remain to be answered, but until there is a more vibrant clinical community doing psychotherapy with psychotic patients that can collaborate doing research with psychopharmacologists, these questions will likely go unanswered.

CASE STUDY

Telegram: @medical_k

www.konkur.in

The author will now describe the psychotherapy of a psychotic woman who, prior to her beginning an integrated CBTp/PDPp treatment, had been an inpatient in a state hospital for 15 years after she stabbed both her parents to death while in an acute psychotic state. At the time she began psychotherapy, she had been taking 600 mg of clozapine for the prior 8 years, with no change in her core delusions and, accordingly, no hope of ever leaving the hospital. After a successful course of psychotherapy, she was discharged to a community residence.

Telegram: @medical_k

www.konkur.in

THE WOMAN WHO MURDERED HER PARENTS

Loretta was an only child who returned home after college and worked a number of low-demand jobs. She joined an Evangelical church and became preoccupied with church activities. Soon afterward, she suffered her first psychotic episode and psychiatric admission. After discharge, she was followed in a community clinic on psychotropic medication. Five years later, she again became preoccupied with the church. One evening after an altercation with her father, she murdered her parents. She recalled that prior to the homicides, “one of the Evangelicals had looked at me with a piercing stare” that she believed had placed her in a hypnotic trance that led her to murder her parents. Staff believed that she might seek revenge if she were discharged. In 15 years in the hospital, she had never been involved in a violent incident, though she feared assault by other patients and believed that nursing staff were intentionally provoking her to violence.

The therapist followed a CBTp approach for the first twenty sessions. At one point during this period, the therapist focused in detail on the subjective events that had occurred during the psychotic episode when Loretta killed her parents, framing these as “A”s to be investigated in A-B-C format. Loretta acknowledged that people might stare for a variety of reasons. The therapist drew two columns of the paper, one for the “Evangelical” explanation and one for the “mental health” explanation. He then asked which Loretta hoped was true. He had been imagining that the patient might welcome the mental illness explanation, but much to his surprise, she said the opposite. “If the Evangelicals hypnotized me, I was just stupid. But if I killed my parents because of mental illness, I am a piece of garbage, and I should rot in hell!”

Moving into the PDTp phase of treatment with more focus on life history and affect, the therapist conceived a role-playing exercise to explore the patient’s dissociated guilt. The therapist asked if she were familiar with the case of the woman who claimed to be David Letterman’s wife, who kept breaking into his house, and she said she was. The therapist then pretended to be an attorney who presented three different scenarios to Judge Loretta, asking whether she would recommend treatment or punishment. In the first scenario, the woman resists the police, but no one is hurt. She recommended treatment. In

Telegram: @medical_k

www.konkur.in

the second scenario, a policeman receives a minor physical injury; she again recommended treatment. In the third scenario, the woman strikes a policeman in the head with a lamp and kills him. Judge Loretta paused. She said she needed more information. Was the attack premeditated? If there was premeditation, Judge Loretta would recommend punishment. If not, she would rule for treatment. The therapist then asked Loretta if she had premeditated the murder of her parents. As if taken aback, she replied "No" with confidence and calm. In 15 years of inpatient treatment-as-usual, no one had ever given her an opportunity to talk about her terrible guilt over murdering her parents.

The next week as the therapist turned the key and stepped through the door into Loretta's ward, she rushed to greet him, a broad smile on her face, a brand new shawl around her shoulders. She announced she had recovered the ability to pray, and that she felt once again able to communicate with God! The therapist was taken aback. He feared that the previous session had undone her, and that she was now hallucinating. But this was not the case. She explained that after she murdered her parents, she had a feeling that God had turned his back and would no longer listen to her prayers. In the previous week, she had not heard the "voice" of God, but rather she had recovered a feeling that God was once again listening to her! The therapist's eyes welled with tears. Her psychotherapy had begun to mitigate the agonizing guilt that she had carried for 15 years in the Evangelical delusion. Her obsession with the Evangelicals faded, staff grew increasingly confident in her recovery, and she was discharged to a community residence within a year. The therapist met Loretta at Dunkin'Donuts after her discharge. She was doing well. Both ordered coffee and a jelly-filled donut, and both agreed the donuts were delicious.

Loretta's story and the stories of many patients like her who have benefited from PDTp and CBPp constitutes evidence, even if those stories have not been studied via RCTs, of the importance and efficacy of psychotherapy in the treatment of individuals with psychotic suffering.

32.7 Treatment of Borderline Personality Disorder

Lois Choi-Kain, M.D., M.Ed., Evan Iliakis, B.A., M.D./Ph.D., Grace Murray, B.A., and Ana Rodriguez-Villa, M.D., M.B.A.

All health care professionals clinically manage patients with borderline personality disorder (BPD) in the routine delivery of medical, surgical, and mental health services. The emotional reactivity, self-destructive impulsivity, relational dysfunction, and stress-induced departures from realistic thinking that define BPD can overwhelm, destabilize, or frustrate the efforts of clinicians to provide standard-of-care interventions. Understanding that these are symptoms of a common, disabling, but treatable disorder can enhance health care providers' likelihood of adhering to best practices in their domain. However, adequate education and training for the recognition and management of BPD are not widely available, even for mental health clinicians.

Empirically validated manualized psychotherapies for BPD have revolutionized attitudes toward this highly stigmatized, once thought to be untreatable, illness associated with severe morbidity, mortality, and costs

Telegram: @medical_k

www.konkur.in

to society. These *specialized* therapies for BPD, most notably dialectical behavioral therapy (DBT), mentalization-based treatment (MBT), and transference-focused psychotherapy (TFP), yield comparable effects. No pharmacotherapy has shown significant, consistent superiority over a placebo; therefore, there are no Food and Drug Administration (FDA)-approved medications for BPD treatment. There is a significant disparity between the short supply of therapists trained in these specialized therapy approaches and the demand created by the high prevalence of patients with BPD seeking treatment, especially in acute mental and general health care environments. The intensive, complex, and lengthy formats of these treatments limit broad implementation outside specialist programs.

Clinical professionals of all disciplines, as well as students and trainees, need pragmatic tools that distill up-to-date knowledge about what works for the treatment of BPD and how that knowledge can be applied in cross-sectional, brief, or acute care situations. To meet this need, this chapter will review common factors from prevailing specialized psychotherapies that clarify BPD's features in constructive terms. Since most clinicians, even in mental health, will not deliver these specialist therapies, we will also describe good psychiatric management (GPM), a generalist approach that medicalizes BPD as a treatable diagnosis to create objective ways of discussing its symptoms and emphasizes tasks such as diagnostic disclosure, psychoeducation, goal setting, management of safety and comorbidities, and conservative prescribing that most clinicians use for the treatment of other disorders. To further relate GPM's approach to common clinical scenarios that most medical trainees and practitioners will encounter, GPM's applications to inpatient psychiatric units, emergency departments (EDs), and general health care settings will be discussed.

WHAT IS BPD: A REVIEW OF SYMPTOMS

In order to best understand the problems of any personality disorder, it is essential to first understand how personality usually functions. Everyone has a personality, and it defines who we are, both in terms of our self-concept and how others see us. Just as we all have moods and can be prone to mood disorder, under specific conditions of stress and maladaptation, we are also all prone to personality dysfunction. Personality functions as a mental envelope for our psychologies. On the

Telegram: @medical_k

www.konkur.in

one hand, it encompasses self-management (i.e., coping styles, self-direction, self-esteem, and coherent identity). On the other hand, personality functioning also involves relational management, which relies on capacities for understanding and collaborating with others. Personality functioning is optimal when it balances reliable containment of our thoughts, emotions, and impulses with adaptive flexibility as we navigate through our journeys to developmental milestones. Stressors can challenge the integrity of that envelope. Resilient functioning occurs when individuals can learn new means of self and relationship management in changing contexts, while also maintaining consistency and coherence. When personality is too porous or rigid to contain and adapt to life stressors or transitions, our personalities may show disorder in a variety of ways that fulfill criteria of different personality disorders. With instabilities in emotion, cognition, behavior, social relationships, and sense of self, BPD is thought to be a prototype and severity indicator for all personality disorders.

The DSM-5's diagnostic definition of BPD requires five or more of the following nine criteria. The most discriminating features that distinguish it from other disorders are its interpersonal criteria which include (1) frantic efforts to avoid abandonment and (2) unstable interpersonal relationships that vacillate between devaluation and idealization. Self-destructive action often brings people with BPD to clinical attention in the form of (3) impulsivity in at least two potentially damaging areas (e.g., substance use, reckless spending, binge eating), and (4) recurring suicidal threats, gestures, or self-harm. Emotional instability in the form of (5) affective instability due to reactivity of mood, (6) chronic feelings of emptiness, and (7) intense, uncontrollable anger also occurs. Affective instability is the feature that has the most negative predictive value, meaning in its absence, the patient is less likely to have BPD. Last of the BPD criteria are symptoms of cognitive disorganization including, (8) identity disturbance and/or unstable self-image, and (9) stress-related paranoid thoughts or extreme dissociative symptoms. These symptoms destabilize major domains of functioning for individuals with BPD, interrupting their development, increasing risk for both not finishing school or unemployment as well as poor physical and psychiatric health overall. Even one symptom of BPD increases risk for inpatient psychiatric hospitalization, suicide attempts, other psychiatric disorders, and greater psychiatric severity and dysfunction.

Telegram: @medical_k

www.konkur.in

WHAT YOU NEED TO KNOW ABOUT BPD: PREVALENCE, COURSE, AND COSTS TO PATIENTS AND THEIR COMMUNITIES

BPD is common, affecting 1 to 3 individuals per 100 in the general adolescent and adult populations, and up to 6 individuals per 100 in terms of lifetime prevalence. This matches or exceeds the prevalence of other well-recognized disorders such as schizophrenia, obsessive-compulsive disorder, or bipolar disorder. Patients with BPD actively seek care and represent an even larger proportion of patients in clinical settings, so there is ample opportunity to provide them with care. In acute psychiatric settings, individuals with BPD are overrepresented, with studies demonstrating that patients with BPD account for 9% of all ED visits and 50% of recurrently suicidal patients in emergency rooms, and 20% to 25% of psychiatric inpatients meet criteria for BPD. They are also over-represented in primary care settings and psychiatric outpatient care practices. However, despite its high frequency, the BPD diagnosis is often missed or not disclosed.

Suicidality and deliberate self-harm are the most urgent features of BPD and often precipitate contact with health care. Four of five patients with BPD will have a history of engaging in some form of suicidal behavior, with an average number of attempts nearing three. Statistics show that 1 suicide per 23 attempts is completed, suggesting that in general, most attempts provide opportunity for intervention. Studies published early in the literature estimate that 10% of patients with BPD complete suicide, but the most recent studies, conducted since the introduction of multiple effective treatments became available, report rates of 3% to 5%. This figure still reflects a 54-fold increase in risk for completed suicide over the risk for the general population, based on data from published trials. Suicide attempts are associated with identity disturbance, frantic efforts to avoid abandonment, and emptiness for those with BPD, and these features are not routinely the focus of assessment and treatment planning. After suicidal crises temporize, the roots of these difficulties are often not identified or addressed, contributing to their chronicity and recurrence.

Despite the serious risks and severity of BPD, research on its longitudinal course reports that over 80% of individuals who at baseline were diagnosed with BPD achieved symptomatic remission over periods

Telegram: @medical_k

www.konkur.in

of 10 years or more with less than 25% experiencing relapse. These studies challenge the assumption that BPD is enduring and inflexible. Prospective studies of youths in the community describe fluctuations in BPD symptoms starting in childhood, peaking in adolescence, and normatively declining in early adulthood, highlighting the importance of maturational processes. These studies also show that youths who begin with more symptoms relative to peers maintain a higher level of BPD severity throughout time. These youths are more likely to meet criteria for BPD in adulthood, and also more likely to experience significant social and functional impairment with lower academic and occupational achievement, higher use of medical and psychiatric services, and more unstable social support even when BPD symptoms decline. Early identification of those at risk for BPD can curb the trajectory away from more chronic and severe forms.

While high rates of remission and low rates of relapse occur in adults with BPD, people with this disorder continue to struggle with significant functional impairment, medical comorbidity, extensive treatment utilization, suicide risk, and negative prognostic impact on major depression, anxiety disorders, and substance use problems, especially when BPD symptoms persist. The costs to society associated with BPD exceed that of most psychiatric conditions, including depression and anxiety disorders, and are comparable to severe psychiatric disorders such as schizophrenia. In addition, BPD symptoms increase risk of unemployment 22-fold and disability 15-fold, contributing to high indirect societal costs of the disorder. Moreover, the reduction of life expectancy is estimated to range between 13 and 25 years, when compared to the general population. People with BPD are more likely to encounter adversity. Treating BPD predicts better psychosocial functioning, improvement in relations with friends and family, greater resilience in the face of adverse life events, and fewer adverse life events overall.

These findings present a rationale for greater attention to BPD as a priority in clinical care rather than a diagnosis to be deferred as a last resort after treatment for comorbidities fails. Considering there are now numerous treatments that work for BPD and that remission can be facilitated in most patients, curbing some of the detriments of the disorder, there are few arguments against integrating attention to BPD early on in a patient’s treatment.

www.konkur.in

WHAT WORKS FOR BPD: COMMON FACTORS FROM EVIDENCE-BASED TREATMENTS COMBINED IN A GENERALIST APPROACH TO CARE

Various psychotherapeutic interventions can be used for BPD's treatment, spanning the gamut from cognitive behavioral to psychodynamic approaches. Common factors among these treatments likely lend a substantial degree of influence on outcomes. Human connection is a common factor in the effectiveness of psychotherapies. The fact that psychotherapies are the treatment of choice for BPD highlights the healing power of humanism. Human beings are highly social and rely on social networks for problem solving and healing. All of us naturally make sense of the world using folk psychology, using common wisdom of how people and the world work. For individuals with a personality disorder, their folk psychology, or their understanding of how the world works, is maladaptive. Their difficulties in understanding themselves and others in realistic and flexible ways limit their abilities to navigate the social world and use human connection in any healing practice, including traditional medical care. The development of a shared constructive therapeutic narrative between the patient and the provider can be used to enhance the social collaboration and human connection within any treatment relationship. The corrective experience in which patients have a more benevolent, empowering, and trust-building interaction with care providers can be the basis on which the patient can apply these healing myths in their activities outside of treatment.

A common maladaptive folk psychology for someone with BPD might be "I am bad" and "bad things happen to me" and/or "people aren't trustworthy, they always hurt me." The patient and clinician can work to replace that maladaptive belief with one that is more flexible and objective, such as "I am sensitive and when stressful things happen, I can't manage." This replacement narrative or healing myth serves as a foundation for creating expectations for change, for example, "stressful things happen so I need to find ways of coping reliably when they do." This replacement narrative reduces pessimism and fear while promoting a focus for a collaborative treatment process. The most transformative and integrative phase of treatment occurs when the patient can apply their healing narrative outside of treatment, starting to cope independently and building a life worth living despite ongoing vulnerabilities. This process of

Telegram: @medical_k

www.konkur.in

shared narrative building between the patient and their treater highlights how psychotherapy is a healing form of social influence. Figure 32.7–1 illustrates the therapeutic process of correcting maladaptive folk psychology.

Effective treatments for BPD share common ingredients. Fundamentally, they all propose various healing paradigms that define core factors that explain BPD's symptoms and also specify pathways to help patients optimize growth to remit and recover from the disorder. The ingredients of these healing paradigms are (1) a model of how BPD develops, emphasizing the transactional relationship between individual's particular innate characteristics and responsiveness (or lack thereof) in their immediate environment; (2) an explanation of how these BPD symptoms in turn continue to interrupt the development of social and emotional skills that are necessary to successfully navigate developmental milestones; and (3) recognition of how these difficulties leave those with BPD unable to develop an identity that is coherent and affirming.

FIGURE 32.7–1. The healing myth as a common factor in psychotherapy.

Leading evidence-based psychotherapies have transformed BPD from a diagnosis associated with hopelessness into a treatable entity by providing constructive healing myths that explain BPD, its symptoms, and possible remedies to reduce its detriments. They all employ healing paradigm that objectively describes BPD, including its origins, symptoms, and effects in a depersonalized and nonpejorative way. DBT proposes

Telegram: @medical_k

www.konkur.in

BPD is at its core a problem of emotional dysregulation and points to skills to enhance abilities to tolerate distress, regulate attention and emotion, and be more interpersonally effective. MBT highlights attachment insecurity and instabilities in being able to understand oneself and others accurately, flexibly, and coherently (i.e., mentalize) as the core engine of BPD's symptoms. MBT, therefore, points to the stabilization of the capacity to mentalize or better understand oneself and others in social exchanges as a way to interrupt the process that gives rise to BPD symptoms. These formulations of why patients with BPD struggle with this specific profile of symptoms provide a hopeful and productive focus for clinicians and patients to organize their interactions and efforts more reliably toward a shared goal of recovery. To date, there is no proof that one of these treatments is more effective than the other. This finding may suggest that the key formulation of how BPD works, rather than any specific concept or technique, is what works in these treatments.

Generalist treatments have more recently emerged as a realistic alternative to more intensive and specialized treatments such as DBT and MBT when such options are either unavailable or not feasible. The empirical foundation for generalist clinical management for BPD was established with the publication of the two largest outpatient BPD psychotherapy studies comparing DBT and MBT with less intensive but well-informed treatment for BPD. Based on John Gunderson's essential clinical guide, general (later manualized as "good") psychiatric management (GPM) led to similar reductions in suicidality and self-harm, BPD symptoms, and depression as did DBT, with no differences in improvement in social functioning or quality of life. These outcomes were maintained 24 months post-treatment. A more recent meta-analysis confirmed comparable efficacy of both specialized and generalist protocolized treatments for BPD in adults.

FIGURE 32.7–2. GPM's Interpersonal Coherence Model. (Reprinted from Gunderson JG, Links PS. *Handbook of Good Psychiatric Management for Borderline Personality Disorder*. American Psychiatric Publishing; 2014. Used with permission.)

Good Psychiatric Management

GPM is a principle-driven generalist approach to BPD grounded in the understanding of BPD as a problem of interpersonal hypersensitivity. GPM recognizes that most mental health care providers will not be trained intensively in psychotherapy, and few will have the specialized training

Telegram: @medical_k

www.konkur.in

and supervision that most evidence-based treatments for BPD require. Instead, it relies on the use of common factors in psychotherapy that most clinicians already know and use: diagnostic disclosure, psychoeducation, goal setting, multimodal treatment, crisis planning, a structured approach to psychopharmacology, managing comorbidities, and most importantly, functional rehabilitation. It is rooted in principles of the treatment of BPD shared by many other specialist and generalist treatments, substantiated by evidence from clinical trials and studies.

GPM's interpersonal coherence model (Fig. 32.7–2) provides a helpful roadmap to navigating the fluctuating states of an individual with BPD. It is another variant of a healing paradigm that allows the patient and clinician to discuss symptomatic events. Due to their interpersonal hypersensitivity, individuals with BPD are most stable and collaborative when they feel connected to someone who provides care in a way that makes them feel worthy. Their sense of self-worth is often rooted in the status of their exclusive relationships, leaving them intensely vulnerable and fearful of abandonment. In order to avoid abandonment, patients with BPD present as compliant and idealizing in a way that optimizes their existing capacities for collaboration. When interpersonal stressors invariably arise, patients enter a threatened state demonstrating anger amidst abrupt transitions between idealization and devaluation. In threatened states, people with BPD act aggressively toward caregivers and other important figures and frequently express this distress and anger toward themselves in the form of self-harm. Although threatened, patients are still desperately attempting to reinstate connection with important others.

Anger, cycling between idealization and devaluation, and self-harming behaviors predictably evoke fear, confusion, and anger in others, and often precipitate the very abandonment that people with BPD fear. As others withdraw, the patient with BPD enters a state of aloneness. In alone states, people with BPD lack the interpersonal anchor they rely on and become disoriented both cognitively and behaviorally. Here, patients with BPD are paranoid, disconnected from reality, recklessly impulsive and disregarding of consequences, and descend into the most unstable state of despair. Without the holding or grounding influences of others, people with BPD lose reasons to live and become more dangerously suicidal. At this point, concerned others may intervene unilaterally, putting patients in the hospital when suicidal, or prison when recklessly impulsive, in order to create a holding environment that reconstitutes either the

Telegram: @medical_k

www.konkur.in

connected or threatened state once again. The revival of interpersonal contact stabilizes the patient with BPD temporarily and while it may be necessary for short-term safety, without attention to the repeated patterns of interpersonal hypersensitivity underlying symptomatic states, this pattern will continue. Clinicians can expect that an individual with BPD will transition through the different states of this model. They can use the GPM model to understand how BPD symptoms manifest themselves in each state as well as how external factors, including the provider's own attitude and actions influence the patient and their reactions to care. Over time, this model can become a shared and explicit tool for both provider and patient.

While working toward greater understanding of the patients' symptoms through this model, GPM also promotes attention to patients' functioning with the imperative to get a life outside treatment. Informed by the outcomes of longitudinal studies showing that functional recovery remains challenged even with symptomatic remission, GPM focuses on promoting corrective experiences for people with BPD in work, school, or community-based activities where opportunities for contributing in specified roles and developing mastery are emphasized. By moving away from preoccupation with exclusive relationships, which are most prone to produce idealized expectations and dependency, people with BPD can benefit from a socializing environment that has more transparent social norms and expectations, as well as a larger social network for a more stable sense of connections. By understanding that people with BPD will have greater interpersonal hypersensitivity, tendencies to read others as untrustworthy, and difficulties with collaboration in behavioral exchange, clinicians and patients can work together to anticipate difficulties that will be encountered, aim to increase effectiveness of patients' social transactions in the service of patient's stated goals, and enhance social learning and self-esteem.

Table 32.7–1.
Principles of Good Psychiatric Management (GPM)

Telegram: @medical_k

www.konkur.in

Principle	Description
1—Be active, not reactive	A discussion on the BPD diagnosis generally helps the patient commit to treatment. GPM recommends that the diagnosis is openly shared and discussed with the patient. Its complex etiology (including genetic and environmental aspects), clinical course, and treatability are explained. Tailored psychoeducation is necessary for patients, as well as for their loved ones and relatives.
2—Provide support	The patient may find it difficult to explore and face their core problems, but doing so is important, and the patient is actively supported by the clinician in the session.
3—Focus on life outside treatment	Life challenges are assessed in therapy. These difficulties are experienced by the patient as obstacles to having a meaningful life outside treatment, from which the patient can develop an identity and be connected to others. Therefore, it is recommended to focus on life outside of treatment.
4—Therapeutic relationship is real and professional	The GPM clinician pays special attention to relational issues in the patient's life. Relational issues between the patient and therapist are not GPM's primary focus, but are expected. Instead, links between relational events, internal feelings, and behaviors, both in the therapeutic relationship and in outside life, are understood. The therapist provides both a professional relationship and a

Telegram: @medical_k

www.konkur.in

	personal one marked by authenticity when needed.
5—Change is expected	Change is expected in GPM. Symptomatic amelioration is expected when in treatment. A short-term treatment should already have some effects on certain aspects of BPD symptomatology since we assume that change starts with session one.
6—Promote responsibility	Psychoeducation and the clinician's attitude during the sessions promote responsibility. The patient should know that their active participation has an effect on their real-life difficulties and therapeutic outcomes.

BPD, borderline personality disorder; GPM, good psychiatric management.

Principles of Good Psychiatric Management of BPD

The following section elaborates on the core principles of GPM with tangible takeaways for clinical settings. Table 32.7–1 summarizes these principles.

Diagnostic Disclosure. Many clinicians fear that disclosing the diagnosis of BPD will cause harm to the patient. Secrecy around the diagnosis can increase the risk of iatrogenic harm (e.g., polypharmacy) and block the patient from receiving appropriate treatment. Disclosing the diagnosis informs the direction of care, allows accurate communication with colleagues, and is a good risk management strategy since it indicates a rationale for clinical decision making guided by evidence-based treatment. Diagnostic disclosure challenges the patient's maladaptive folk psychology through a clinical destigmatization process that localizes the patient's problems to a discrete disorder, rather than a pervasive "badness."

Telegram: @medical_k

www.konkur.in

Diagnostic disclosure can be done in collaboration with the patient. The clinician can use the DSM-5TR criteria list for BPD as a concrete reference point to return to throughout the discussion. For each item on the list, the clinician and patient review the ways in which the criterion plays a role in the patient's life. This discussion naturally leads to the diagnosis and helps the patient understand their own profile of symptoms. The process should be approached collaboratively, emphasizing that BPD is common so that they are not alone and that their problems are understandable. Oftentimes, BPD patients have been misdiagnosed and treated with heavy-handed and ineffective interventions. Reframing the clinical focus of treatment on BPD can therefore restore hope that more effective treatment may exist.

Psychoeducation. Psychoeducation around BPD can begin with diagnostic disclosure, followed by a discussion about the favorable prognosis of the disorder, common comorbidities, self-harm and suicide risk, and available treatments. Psychoeducation around BPD should be realistic and emphasize that (1) evidence-based treatment likely facilitates remission; (2) the risk of suicide needs to be considered, given data about significant rates of suicide completion in the BPD population, and (3) many patients with BPD will continue to have challenges engaging in meaningful work and relationships even when they technically no longer meet criteria for the disorder.

Growing evidence suggests psychoeducation about BPD symptoms, comorbidities, etiology, course, and available treatments is a useful form of pretreatment in and of itself, delivered in person or remotely using technology, reducing BPD symptoms at 12-week and 1-year follow-up. Besides review of diagnostic criteria, essential topics of GPM psychoeducation include etiologic factors such as heritability, frontolimbic dysfunction, and neurohormonal disturbance that combine with life adversity, in addition to longitudinal course and core formulation of BPD as a disorder of interpersonal hypersensitivity. The basic message conveyed by the heritability and biologic basis of BPD is "it is not your fault" to both patients and family members, while also communicating, "It is your responsibility to optimize your health and wellbeing."

Goal Setting/Functional Rehabilitation. Setting goals is a central task in the treatment of BPD that promotes agency, self-improvement, self-reliance, and productive collaboration rather than dependency on others.

Telegram: @medical_k

www.konkur.in

GPM encourages patients to refocus their energies to build a meaningful and functional life outside of treatment, rather than remain mired in an identity as a patient. Getting a job is an important task within GPM that provides structure and interaction with others to counteract the sensitivity BPD patients have to loneliness. It also provides a means of building self-reliance and self-esteem that is not staked in an exclusive relationship. GPM advises that this strategy helps people become more sustainable romantic partners if one's goal is to be in a stable life partnership.

Case-management strategies can help guide the patient toward necessary life skills that can be achieved in the short term, such as making a budget, improving physical health, or maintaining hygiene. While GPM integrates concepts from psychodynamic psychotherapy with more practical life management strategies, the focus on taking concrete steps to build a meaningful life should be prioritized over exploration of the patient's developmental history. Employment status has been identified as one of the best predictors of remission from BPD, and unemployment has been associated with rapid response to treatment followed by relapse.

Multimodality. The use of different treatment interventions either in sequence or together is a key aspect of GPM's flexibility. The GPM therapist is open to including whatever might be of use to the patient, including group treatment options (DBT skills groups, 12-step programs, family coaching, and psychoeducation, along with adjunctive pharmacotherapy). As noted, GPM itself borrows from various approaches to treatment. Rather than considering concurrent treatment interventions as a liability or distraction, the GPM therapist would remain open to whatever might be beneficial during treatment. In general, connecting patients who are sensitive to being alone to a broader network of reliable and well-defined community settings can allow the patient access to social support without an active crisis.

GPM also integrates guidelines for psychopharmacology, based on the American Psychiatric Association (APA) Practice Guideline for the disorder (see psychopharmacology section for more information).

Crisis Planning and Management. Suicidal and self-injurious symptoms are to be expected and prepared for in the treatment of BPD. These symptoms are expressions of distress that require response with expressions of concern and careful risk assessment (e.g., the Columbia Suicide Severity Rating Scale), with the understanding that the baseline

Telegram: @medical_k

www.konkur.in

risk for suicide is chronically elevated in this population. The generalist clinician responds with the knowledge that acute exacerbations of risk for any person relates to comorbid mood disorders, substance use, withdrawal of support (e.g., recent hospital discharge), and negative interpersonal events.

Crisis planning should involve the patient as an active participant in creating a crisis plan at the beginning of treatment rather than as a crisis is unfolding. Safety plans for suicidal crises include identifying warning signs for a suicidal crisis, reduction of access to lethal means, coping strategies that the patient can use independently, ideas for social interaction to reduce isolation, and contact information for both supportive interpersonal relationships and professionals. In GPM, the patient and clinician collaboratively develop alternative ways to cope with unbearable emotions, with their intolerance of aloneness and interpersonal hypersensitivity in mind. The patient is thus encouraged to recruit additional social support to be available when they are feeling distressed or alone and also discouraged from engaging in relationships that are likely to be rejecting during crises. Actively involving the patient in the safety planning process, rather than asking them to passively agree to a "safety contract," promotes a sense of agency and autonomy.

The suicidal or self-injurious patient predictably creates high anxiety in the clinician. Clinicians are therefore strongly encouraged to seek support, supervision, and consultation from colleagues. It is also important for a clinician treating BPD to be open and clear about their limits. No clinician is omniscient, omnipresent, or omnipotent, and it is therefore unreasonable for a patient's safety to depend on the clinician's availability. Having a plan that allows for different means of coping and gaining social support is most empowering to the patient, and their ability to rely on themselves to manage their safety over time is a constructive goal for treatment.

Psychopharmacology. Medications are adjunctive to psychosocial interventions for BPD. Medications can be helpful when they are targeted to specific symptoms (e.g., antipsychotics/mood stabilizers for anger, mood instability) or comorbidity (e.g., selective serotonin reuptake inhibitors for depression), but no medication is uniformly or consistently helpful, nor has been approved by the U.S. FDA for the treatment of BPD. Polypharmacy may increase the risk for side effects, promote

Telegram: @medical_k

www.konkur.in

dependency, and send the message that the patient can expect to improve by taking medications alone, as opposed to mobilizing to build a more satisfactory life. Due to the tendency to accumulate polypharmacy, especially with repeated hospitalizations, “collaborative deprescribing” or judicious and deliberate shared efforts with patients to taper medications when they are not working or reducing doses when possible, can become the focus of a treatment plan while inpatient or in primary care and outpatient psychiatric settings. Benzodiazepines should be avoided as they are habit forming and reinforce the belief of individuals with BPD that their emotions are unbearable and unmanageable.

Managing Co-occurring Disorders. Personality pathology should be prioritized in cases where the comorbid disorder is unlikely to remit otherwise or does not preclude learning. These disorders include major depressive disorder (MDD), non-manic bipolar disorder, panic disorder, bulimia, and post-traumatic stress disorder related to trauma that occurs in adult life. Recent findings suggest the presence of a substance use disorder does not impact the efficacy of brief GPM. However, comorbidities that interfere with active learning, including psychosis, manic states, or anorexia nervosa, should be prioritized before use of BPD treatment.

Duration and Intensity. GPM is distinguished by its relative flexibility about the length of treatment recommended and the intensity of the treatment as reflected in frequency of visits. In this regard, GPM differs from the other empirically validated treatments that require a set number of visits weekly and/or an expected duration of treatment. Greater flexibility allows for treatment of patients with BPD symptoms with a range of severity of illness and schedules. This means that relatively stable patients who are not in crisis, for example, may be seen sporadically, while those patients with prominent active difficulties can be seen more frequently as determined by the therapist. In situations where treatment is offered to patients who may not have a set schedule, such as college students who are away for vacations or summer break, this flexibility can allow for good enough treatment.

Treatment should continue only if the patient and therapist feel that progress toward stated goals is being made. The patient and provider should actively evaluate the benefit of the intervention. The idea that any medical intervention should only be continued if it is working frames the

Telegram: @medical_k

www.konkur.in

treatment as useful if improvement occurs, rather than solely required due to crises or desperate need. Patients vary in their readiness for and responsiveness to treatments, so if this occurs with generalist treatment, a referral for a different, more intensive treatment where available should be considered.

Applications of Good Psychiatric Management Principles to Different Care Settings. The minority of providers in inpatient, emergency, or general health care settings are trained in specialist treatments for BPD. What follows are principles of GPM of BPD in these settings so that any provider in these settings can become "good enough" in the treatment of this population. Table 32.7–2 summarizes the key principles of each application.

Inpatient Management of BPD. Patients with BPD constitute a large proportion of all psychiatric admissions (20% to 25%). These patients tend to spend more time in inpatient settings than many other disorders (14.3 weeks of hospitalization on average, compared to 2.4 weeks for patients with MDD) and have nearly five times as many separate hospitalizations. Given these facts, it is important that inpatient units are prepared to treat this patient population, but they are often not provided guidance on how to do so since most evidence-based treatments for BPD are not designed for implementation at this level of care. Hospitalization prevents unsafe action but often does not address the relationship between the patient's BPD and their presenting problem. Hospitalization can become addictive when patients view it as necessary to their basic survival, and it serves a secondary function of separating the patient from interpersonal stressors and unwanted responsibilities in the patient's life outside the hospital. To mitigate the harmful cycle of recurrent hospitalizations, inpatient units can implement the following basic principles: diagnostic disclosure and psychoeducation, structure, focusing on the patient's life stressors, and aftercare planning. See Figure 32.7–3 for recommended phases of inpatient treatment.

Telegram: @medical_k

www.konkur.in

Table 32.7–2.
Key Principles Guiding the Application of GPM in Health Care Settings

Telegram: @medical_k

www.konkur.in

Application	Key Principles
Inpatient Unit	1. **Psychoeducation.** Focus on BPD as the primary diagnosis rather than comorbidities such as mood or anxiety disorders. Educate the patient about the limited benefits of medication. 2. **Structure.** Set goals and expectations. Clearly communicate mandatory and prohibited activities. Daily schedules should include multiple hours of groups and homework. Unstructured milieus can be actively harmful. 3. **Focus on life stressors.** Staff should engage patients in discussing the stressors that contributed to their admission and ways to minimize these upon discharge. 4. **Aftercare planning.** Schedule the first week after discharge, including a safety plan. Involve the patient in a group (e.g., AA, spiritual community, structured outpatient therapy).
Emergency Department	1. **Disclosure of a possible BPD diagnosis** in the ED can provide patients with reasonable expectations and information to discuss with outpatient providers. 2. **Building rapport and managing interpersonal hypersensitivity.** A detached interpersonal style could be interpreted as dismissive or rejecting by patients with BPD. Remain active and curious to form a rapport. 3. **Self-harm** is not a good indicator of acute suicide risk. Focus on acute risk factors and warning signs (e.g., stressful interpersonal events,

Telegram: @medical_k

www.konkur.in

	concurrent major depression, substance abuse) to avoid unnecessary hospitalizations. 4. **Psychopharmacology.** Benzodiazepines and antipsychotics are the most commonly prescribed medications for BPD in the ED. These medications are not associated with significant benefits to the core symptoms of BPD and are associated with high rates of adverse effects.
General Health Care Settings	1. **Alliance Building**. Effective alliance building includes displaying concerned attention, active listening, validation of painful experiences, and demonstrating helpfulness through effective and practical assistance. GPM actively discourages overemphasis on rescuing a patient and splitting. 2. **Real Relationship.** Therapeutic relationships are two sided. A treater can own their mistakes, set limits about realistic expectations, and disclose their real emotional reaction to the patient's behavior where appropriate. 3. **Medication Management.** There are no FDA-approved medications for BPD treatment. Prescribe medication cautiously when needed, and where appropriate, explain its role as an adjunctive, short-term tool rather than a first-line defense. 4. **Diagnostic disclosure** of BPD can mitigate the iatrogenic effects of polypharmacy, derailing hospitalizations and aimless psychotherapies, as well as facilitating the patient's access to appropriate treatment.

www.konkur.in

AA, Alcoholics Anonymous; BPD, borderline personality disorder; FDA, Food and Drug Administration; GPM, good psychiatric management.

FIGURE 32.7–3. Recommended phases of care for BPD in inpatient settings.

DIAGNOSTIC DISCLOSURE AND PSYCHOEDUCATION. Mood or anxiety disorders are common primary diagnoses in inpatient settings. Listing BPD as the primary diagnosis is an important first step for inpatients with BPD to receive the care they need. Furthermore, in the United States, BPD falls under DRG 883 for Medicare patients, which is reimbursed at a higher rate than DRG 885, which includes MDD. Following diagnosis, clinicians can use standard GPM principles to proceed with psychoeducation.

STRUCTURE. A structured inpatient milieu benefits all patients, but it is especially important for patients with BPD. Unstructured time can lead to impulsive action and may reinforce a perception that the hospitalization is an escape from outside stressors. Useful structures in the milieu include active schedules and clear expectations. It is helpful for staff to clearly communicate both expected and prohibited activities, as well as resulting consequences and rewards that recognize their capacities for self-management (e.g., a privilege system). It is also beneficial for patients to set short-term goals that are achievable while holding a long-term goal in mind as motivation.

FOCUS ON LIFE STRESSORS. Since psychological growth is often not feasible in a short-term hospitalization, it may be more productive to focus on the real-life situations that need attention in discharge. Inpatient admissions are often preceded by self-destructive behaviors such as suicide attempts, which are usually triggered in BPD by real or perceived rejection or loss of support. It is important that staff engage patients in thinking critically about the stressors that contributed to their inpatient admission and support them as they develop a plan to mitigate the stressors after discharge. In some cases, this focus on life stressors can even lead to symptom remission (e.g., through disclosure of shameful stressors that once shared might bring support, leaving an abusive

Telegram: @medical_k

www.konkur.in

partner, or finding less stressful work). Group sessions in the milieu that focus on both identifying and mitigating stressors, as well as planning for educational or vocational activities postdischarge are especially useful to inpatients with BPD.

AFTERCARE PLANNING. A sound aftercare plan helps prevent relapse and readmission, as well as manage risk for suicide, which is 200 times the global rate for patients in the 3 months after discharge. Three key components of creating an aftercare plan are (1) identify in the *intake interview* the major life stressors, what additional supports are needed, and how school/vocational re-entry can be facilitated; (2) create a detailed schedule for the first week after discharge; and (3) develop a safety plan to manage suicidal crises that occur after discharge. With regards to the patient's network of support after discharge, it is helpful for friends and families to know and prepare for the fact that patients with BPD tend to become more symptomatic in times of transition, and in some cases, inpatient clinicians may wish to work with the patient to re-evaluate the helpfulness of their prior outpatient treater. It is also important to note that the patient may not be ready to fully re-engage in school or employment; taking a small number of classes or volunteering may be the first step. Another valuable way to introduce structure and support in the patient's life after discharge is to involve them in a group such as Alcoholics Anonymous, a spiritual community, or a structured outpatient group therapy. For more information on forming a safety plan, see the standard guidance outlined in the *Crisis Planning and Management* principle of GPM.

BPD in the Emergency Department (ED). Patients with BPD should be considered a special population warranting specific treatment guidelines in the ED due to their recurrent visits, increased disruptive behavior compared to other diagnoses, and chronic suicide risk. While an ED visit serves as a basic triage function for many patients with BPD, it can be an integral part of treatment for others. The following guidelines can help emergency room doctors make the visit a therapeutic experience for the patient with BPD.

DIAGNOSTIC DISCLOSURE AND PSYCHOEDUCATION. It's common for ED clinicians to hesitate in making a definitive diagnosis because patients in crisis may present with features that are not typical for them. However,

Telegram: @medical_k

www.konkur.in

GPM maintains that diagnostic disclosure and psychoeducation are beneficial, particularly in cases where collateral information is available that supports the diagnosis or for patients who have made recurrent visits to the ED. In all cases, even where less supporting information is available, suggesting the possibility of the diagnosis and providing more information gives the patient something to discuss with their outpatient care providers and can give families hope.

BUILDING RAPPORT. The fast-paced, often chaotic nature of the ED necessitates efficiency and expeditious disposition where possible. It is challenging to connect with an individual with BPD who is in crisis but demonstrating genuine concern and adopting an active interview style pave the way. The interpersonal hypersensitivity common in BPD is an important consideration when building a rapport. A detached interpersonal style could be interpreted as dismissive or rejecting by patients with BPD, and a passive style inhibits alliance development. A good strategy for fostering connection includes active curiosity about the patient's experience and validating the high stress situation and the patient's emotional intensity in order to demonstrate caring and potentially inspire a more open, honest conversation. Providers can emphasize that the patient's honest disclosure and active participation are important aspects of providing the right care, while also validating the difficulty of sharing intimate experiences.

MANAGING SUICIDALITY AND SELF-HARM. Clinicians in the ED should use a model of "acute on chronic" risk for patients with BPD. This population has high rates of chronic suicidal thoughts and behaviors and self-injury, and it is important for ED clinicians to understand whether the patient wants and intends to die or if they are expressing feelings of loneliness, depression, or rejection. An unnecessary hospitalization will likely not be beneficial and may be iatrogenic. A step-by-step analysis of the events leading to the ED visit is a useful activity to undertake with the patient in order for both parties to better understand what led to the patient's crisis and where earlier intervention could have occurred. Ultimately, the decision to hospitalize a patient with BPD should be made on the basis of acute risk factors, which may emerge in the case of stressful interpersonal events, concurrent major depression, or ongoing substance use. Acute changes in symptoms or deviations from the patient's baseline are also potential

Telegram: @medical_k

www.konkur.in

indicators of risk, and family members or the patient's outpatient team can often provide collateral information to assist in risk assessment. In the case that acute risk is apparent, short-term inpatient hospitalization should be considered until the crisis passes or sufficiently diminishes. If the patient is to be discharged to home from the ED, safety planning should include how to recognize warning signs, how to make their environment safer by means of reduction, and identifying who to contact when in crisis. ED staff can further mitigate risk in the days following discharge by placing follow-up phone calls to BPD patients. Also note that in the case of recurrent visits to the ED, clinicians may work with the patient and their outpatient therapist to evaluate the helpfulness of the current outpatient treatment.

PSYCHOPHARMACOLOGY. Patients with BPD tend to receive more medications in the ED than patients with other psychiatric diagnoses, but the medications commonly used for BPD in the ED (benzodiazepines, antipsychotics) do not significantly benefit the core BPD symptoms and often have adverse effects. In general, it is good practice to treat medication as a last resort, for use when acute agitation and/or anxiety endangers the patient or others, or when the patient's symptoms render a thorough interview impossible. It is also important to note that benzodiazepines are habit forming, and patients with BPD may be especially prone to this due to their reactivity, intense reactions to stress, and affective instability. As with all patients, in the absence of imminent safety risks, verbal de-escalation is an appropriate first-line strategy to managing agitation and anxiety. If medication is deemed necessary, the clinician should clearly communicate that the purpose for the medication is to move forward with evaluation and not to provide a long-term treatment.

Changing a medication regimen in the ED is typically not recommended, given the usual lack of historical information regarding the patient's baseline. However, if a medication change is deemed necessary, it is helpful to contact the outpatient provider for collaboration.

FAMILY INTERVENTIONS. The patient's family and loved ones can be especially helpful when a patient with BPD presents to the ED because they can provide collateral information about the patient's level of risk and baseline symptoms. BPD symptoms can be diminished or exacerbated by

Telegram: @medical_k

www.konkur.in

families, and an ED visit is also an intervention point where the clinician can provide psychoeducation and guidance to the family. Furthermore, some patients with undiagnosed and likely BPD present to the ED with several diagnoses and a history of ineffective treatments. In these cases, families may feel desperate or lost, and psychoeducation about the diagnosis of BPD itself, its appropriate treatment, and how the family may be able to help can be exceptionally useful.

Treatment of BPD in General Health Care Settings. Patients with BPD disproportionately experience medical complications compared with matched cohorts and have high rates of health care and surgical care utilization. Medical complaints that are more common among people with BPD include poor sleep, regular nightmares, obesity, metabolic syndrome, functionally incapacitating headaches, and polycystic ovaries. Health care providers are encouraged to keep their stated roles, goals, and standards of care in mind, using an understanding of BPD and its basic treatment strategies to minimize destabilization or departures from the routine provision of care. Providers who are not mental health professionals are not expected to provide definitive treatment for the patient's BPD-related problems. The following principles may be useful for treaters in nonpsychiatric, nonemergent health care settings to optimize their care for other conditions in patients who have BPD.

ALLIANCE. Effective alliance building often includes (1) displaying concerned attention, (2) active listening, (3) validation of painful experiences, and (4) demonstrating one's helpfulness through providing effective and practical assistance. GPM principles discourage overemphasis on rescuing a patient and splitting (both where the patient views part of the team as good and the others as bad, as well as where part of the team views the patient as innocent while others view them as problematic). According to GPM, a strong alliance is "real" (two sided), which includes (1) owning one's mistakes, (2) limit setting around unrealistic expectations, and (3) using self-disclosure of one's emotional reactions to the patient's behavior when appropriate. Grounding the terms and expectations of the roles of the patient and clinician by focusing on the diagnoses, treatment plans, and immediate goals at hand can provide focus or organization to the interaction. Making recommendations with a collaborative effort to understand risks and benefits, even if repeated like

Telegram: @medical_k

www.konkur.in

a broken record, is what clinicians can do in their role. The patient has the choice to follow them or not. The use of case management services to reduce obstacles may assist the patient in reducing barriers to follow through.

MEDICATION MANAGEMENT. There are a number of potential pitfalls with medication management that most medical and surgical professionals may not have been trained to know. First, it is important for both the care team and the patient to know that there are no FDA-approved medications for BPD, and many medications come with more risks than benefits. Low-dose antipsychotics can be helpful on a short-term basis for psychotic-like symptoms (paranoia, extreme agitation, hallucinations). In order to avoid reinforcing the idea that medications are first-line rescue interventions for distressing symptoms, anxiolytic medications can be prescribed as standing orders rather than as needed. Similarly, while non–habit-forming medications that promote sleep may reduce vulnerability factors, behavioral interventions are sufficient for some patients. If medication is necessary, the clinician can explain that medication for sleep promotion is a short-term intervention rather than a long-term treatment.

Antidepressants and mood stabilizers may be useful in the case of untreated comorbidity (e.g., mania) but are not the intervention of choice for BPD symptoms. If short-term medications have been used during hospitalization or medical treatment, GPM recommends that they be discontinued at discharge to avoid polypharmacy. Patients with BPD are at high risk of misusing analgesic medications, and referrals to structured pain management programs or expedited appointments with the primary care physician should be made as needed. The standard as-needed medications for mild symptoms such as constipation, nausea, indigestion, and headaches can be given if these symptoms are related to the underlying illness that requires hospitalization but minimizing their use where possible is encouraged to mitigate overreliance on medication.

DIAGNOSTIC DISCUSSION. GPM maintains the recommendation of discussing the diagnosis of BPD, even in nonpsychiatric settings. For those patients with a prior diagnosis of BPD, reviewing how it may influence care in other settings can be helpful when broached prior to conflict or crisis. Diagnostic discussion of BPD can mitigate the iatrogenic effects of polypharmacy, derailing hospitalizations and aimless

Telegram: @medical_k

www.konkur.in

psychotherapies, as well as facilitating the patient's access to appropriate treatment. Bringing up the question of the BPD diagnosis to the patient in helpful terms, rather than reactively and punitively, is what most health care providers can do without a definitive diagnosis if a referral or further information is needed. While many clinicians worry about a negative reaction after diagnostic disclosure, patients with BPD who are told about their diagnosis after an initial evaluation are as satisfied with the evaluation as patients without BPD.

CONCLUSIONS

In this chapter, we present tools for the clinical management of BPD, a common, disabling, and painful disorder that increases the risk for negative medical, psychiatric, and functional outcomes, including completed suicide. All health care professionals can benefit from knowing basic facts about BPD and applying constructive frameworks for understanding the instability of patients with this disorder as symptoms that require treatment and management rather than a reflection of a bad patient or poor care. The more consistently BPD is addressed in the patient's overall care across different clinical environments by different members of their care team, the more stable, organized, and predictable treatment can be. As the patient improves in their capacity to function, both in their roles and responsibilities as a patient and, more importantly, in life outside of treatment, they can attain a more stable sense of self and more positive expectations of others.

32.8 Behavior Therapy

JENESSA S. PRICE, PH.D.

HISTORY OF BEHAVIOR THERAPY

Behavioral treatment of psychiatric symptoms has existed since at least the first century, when Pliny the Elder used a type of aversion therapy to modify drinking behavior by putting spiders at the bottom of a drinker's glass. In the early 19th century, Alexander Maconochie set up a token economy wherein prisoners were awarded points for positive behaviors in a penal colony at Norfolk Island, Australia. The formal application of learning principles and the movement toward a behavioral approach to the treatment of abnormal behavior emerged in the 1900s.

The first reference to the concept of behavior modification occurred in 1911 by Edward Thorndike (*Provisional Laws of Acquired Behavior or Learning*). In 1920, the classic case of "Little Albert" was published, demonstrating the application of classical conditioning principles to the acquisition or learning of fear. In a variant of the famous Pavlovian conditioning paradigm, Little Albert was conditioned to fear a white rat when steel bars were banged together over his head while a white rat was presented to him. These principles were similarly applied to the deconditioning or unlearning of fear in another child, Peter, who was afraid of rats, rabbits, and other furry objects. To decondition the fear, a caged rabbit was gradually moved closer to Peter while he was eating a favorite food. Repeated and gradual pairings of the rabbit and the pleasant food led to a reduction in fear. Fourteen years later, another set of investigators utilized classical condition principles with the use of a *bell-and-pad* technique for treating enuresis or bed wetting. A bell (buzzer), embedded in a pad on the child's bed, sounded when the pad got wet, conditioning the child to awaken at the onset of urination and contract the sphincter. Ultimately, the child learned to awaken at the sensation of a full bladder without needing the bell/buzzer.

Telegram: @medical_k

www.konkur.in

Behavior therapy evolved rapidly in the mid-1950s in three distinct areas of the world: the United States (B. F. Skinner), South Africa (Joseph Wolpe), and the United Kingdom (Hans Eysenck, Stanley Rachman). A driving factor was the pursuit of scientifically based paradigms and the need for effective short-term therapies for anxiety and depression in World War II veterans returning with significant emotional problems. The characteristic feature of this "first-wave" behavior therapy movement was a focus on classical conditioning and operant learning.

The "second wave" of behavior therapy occurred in the 1970s, which was characterized by increased focus on information processing, rather than observable behaviors alone, and paved the way for a more integrated cognitive-behavior therapy (CBT). Much of this work derived from Albert Bandura's *social learning theory,* which posited that people learn not only through the process of classical and operant conditioning but also by observing the actions of others in their environments. The process of *observational learning* emphasized the roles of thoughts, images, and expectations in the development of psychological or psychiatric disorders and set the stage for treatments that target these internal components of behavior more directly. The first two major cognitive-behavioral treatments, Aaron Beck's CBT for depression and Albert Ellis' rational emotive therapy (RET), had major impact on the field.

Although "second-wave" CBT is at present the dominant contemporary system of psychotherapy worldwide, the "third-wave" movement largely emerged from a component analysis study directed by the late Neil Jacobson, wherein a behavioral activation (BA) intervention was as effective as the more comprehensive CBT treatment of individuals with major depression. This finding was further highlighted in a 2006 study where Sona Dimidjian and colleagues demonstrated that BA was as effective as antidepressant medication and more effective than cognitive therapy for individuals with severe depression. This "third wave" of behavior therapies is characterized by themes new to behavior interventions: metacognition, cognitive fusion, emotions, acceptance, mindfulness, dialectics, values, spirituality, and the therapeutic relationship. Today, behavior therapy (including CBT) has become one of the most well-accepted and well-researched approaches for treating many psychiatric symptoms and disorders.

PRINCIPLES OF BEHAVIOR THERAPY

Telegram: @medical_k

www.konkur.in

Here, “behavior therapy” refers to the many interventions and programs combining behavioral (and cognitive) techniques demonstrated as efficacious for a range of psychiatric disorders. Despite the breadth of these techniques and treatments, however, all variations in behavioral treatments share certain basic assumptions or principles.

- *Maladaptive behaviors are acquired through learning, according to the same principles that govern the learning of adaptive behaviors.*
- *It is not necessary to identify an underlying cause or motive for maladaptive behaviors.*
- *Learning principles can be used to modify maladaptive behavior.*
- *The focus of treatment is on operationally defined factors that maintain current behavior rather than on historical issues.*
- *Psychologists and therapists should be knowledgeable about scientific literature relevant to the patients they treat.*
- *It is important to set specific, measurable treatment goals and measure outcomes.*

TECHNIQUES OF BEHAVIOR THERAPY

Assessment and Conceptualization

The primary goals of an initial behavioral assessment are to identify and define target behaviors and the variables that maintain them and to conduct a *functional assessment*. This would include historical information about the onset and course of symptoms, relationships with environment and/or others, and other related factors (e.g., substance use, medical issues). A functional assessment should lead directly to a treatment plan as it establishes causal (or functional) links between problematic behaviors and the internal and external antecedents and consequences that serve to maintain them. When these links are identified, learning principles and treatment techniques from empirically supported interventions can be applied to modify antecedents, behaviors, and consequences such that problematic symptoms are reduced. Assessment continues as treatment is implemented to ensure that appropriate changes are occurring.

Methods of Behavioral Assessment

Telegram: @medical_k

www.konkur.in

As with many other theoretical approaches, the individual conducting behavior therapy often begins the assessment with clinical interviews. Additional strategies help establish links between target behaviors and maintaining factors, evaluate symptom severity against normative data, and set the stage for measuring outcomes over the course of treatment.

Unstructured and Structured Interviews. The clinical interview has tremendous variability, ranging from a primarily unstructured and completely flexible approach to structured methods that are more restrictive and goal directed. Several positive correlates are associated with unstructured methods, including increased rapport (and thus engagement in psychotherapy), observation of the patient's response style, and opportunity to gather unique details of a patient's history. Most contemporary practitioners allow for some degree of flexibility, although most also make use of some type of intake form or checklist relevant to their particular practice to facilitate the assessment process. The goals of initial interviews involve gathering data on target behaviors and maintaining factors, toward the goal of *operationalizing* all components specifically for the individual patient. In addition, the interview includes psychoeducation about the behavioral philosophy, including expectations about day-to-day approaches taken outside of the session. Behavioral approaches typically emphasize individualized assessment given that target behaviors and maintaining factors may vary greatly across patients with common presenting complaints.

Nevertheless, those conducting behavior therapy typically assign DSM-5-TR based diagnoses because they help guide selection of appropriate evidence-based techniques (while also providing evidence to payors of the utility of treatment). As a means to optimize reliability and validity across providers (and in the context of research), the most commonly used structured (clinician-rated) interviews are the Structured Clinical Interview for DSM-IV (SCID), for which there are both Axis I and Axis II versions; the Mini-International Neuropsychiatric Interview (MINI), a brief interviews are the Structured Clinical Interview for DSM-5 (SCID-5); the Mini-International Neuropsychiatric Interview (MINI), available for both adults and children/adolescents; and the Primary Care Evaluation of Mental Disorders (PRIME-MD), which also is brief and was designed for use by primary care clinicians. Other diagnostic interviews such as the Anxiety Disorders Interview Schedule for DSM-5 (ADIS-5), the Schedule

Telegram: @medical_k

www.konkur.in

for Affective Disorders and Schizophrenia (SADS), and the Addiction Severity Index (ASI; typically used alongside a substance use history/frequency interview) are available for collecting more detailed information on a limited set of diagnostic categories and functioning.

Questionnaires and Clinician Rating Tools. Self-report questionnaires allow for normative comparison of symptom severity. They can screen and augment assessment data, monitor progress across sessions or at longer follow-up intervals, and assess change associated with various psychological and pharmacologic interventions. The majority of these instruments have adequate excellent psychometric properties and assess a wide range of symptoms. The Patient Health Questionnaire (PHQ-2; PHQ-9) is brief and commonly used to screen for depression in primary care or other health settings. The clinician-rated Hamilton Rating Scales for Depression (HRSD) and Anxiety are useful toward assessing the severity of depressive and anxiety symptoms and measuring patient progress and treatment outcome. The 24-item *Brief Psychiatric Rating Scale (BPRS)* is one of the most commonly used clinician-rated scales of depression, anxiety, psychotic symptoms, and other unusual behaviors. More comprehensive personality tests such as the *Minnesota Multiphasic Personality Inventory (MMPI) and Personality Assessment inventory (PAI)* may provide useful assessment data on various psychological symptoms such as anxiety, depression, hypochondriasis, psychosis, and symptoms of personality disorders; these questionnaires require significant time for the patient to complete and comprehensive training to ensure accurate interpretation.

Self-Monitoring. Self-monitoring techniques are in contrast to retrospective assessments, wherein the patient observes, measures, and records behavior as it occurs. Self-monitoring can be used to evaluate the frequency and duration of symptoms as well as to identify sequences of events, behaviors, thoughts, and feelings that may provide information about antecedent and consequent factors that maintain problematic behaviors. Techniques can be simple, such as noting each time they smoke a cigarette, have a panic attack, binge eat, or perform a ritual. Daily diary logs can augment frequency data to explore the difficulty, enjoyment, and reward value of activities and behaviors. More complicated monitoring procedures can be used to evaluate behavioral sequences and environmental or internal antecedents and consequences;

Telegram: @medical_k

www.konkur.in

for example, one can record precipitating situations, associated thoughts and feelings, physical symptoms, and consequent behaviors with an anxiety experience. Self-monitoring can be used to assess treatment progress. Data plots of symptom severity over time can be a highly useful visual indicator of treatment efficacy for both the patient and psychologist or therapist. Self-monitoring is also a behavioral component of the treatment program, not just of the assessment process. Recording one's own behavior is a *reactive* process, meaning that awareness of behavioral antecedents and the behavior being recorded often change as a result of monitoring.

Behavioral Observation. Like self-monitoring, behavioral observation involves someone other than the patient measuring the operationalized target behavior as it occurs, with attention to frequency, duration, and associated contextual variables. Observations of this type might involve *event recording,* where each episode of the target behavior is monitored, or *interval recording,* where the frequency of the behavior is monitored as it occurs during a restricted interval of time. In the case of children with behavioral problems, parents and teachers may track retrospectively through use of measures such as the *Child Behavior Checklist (CBCL)* or *Behavior Assessment Scale for Children (BASC-3)* or they may conduct direct observation in the classroom environment using a structured *Student Observation System.* The patient may be observed in the natural environment or engage in *analog* or *simulated* situations in session (e.g., having a conversation with a patient with social anxiety disorder). *Role plays* are a common method of simulated observation and provide opportunity to observe interpersonal skills. Patients in these natural or simulated environments also can be asked to rate the severity of their anxiety or depression using a standardized rating scale or Subjective Units of Distress Scale (SUDS), in which patients rate distress from 0 to 10 (or 100).

Case Conceptualization. A *case conceptualization* integrates assessment data and information about historical context and formulates a behaviorally focused treatment plan to address multiple disorders and their presenting features impacting functioning. The core difficulties then are examined in terms of predisposing, precipitating, and maintaining factors. *Predisposing factors* reflect both biologic components (e.g., genetic influences) and those elements of patients' learning histories that

Telegram: @medical_k

www.konkur.in

put them at high risk of developing significant symptoms. For example, a patient may be predisposed to develop anxiety or depression due to a strong family history of mental health problems, being raised by authoritarian parents who provided minimal nurturance and were overly controlling and manipulative, or experiences with parents that were perceived as cold, rejecting, and invalidating. *Precipitating factors* are those events that occur at the start of significant psychiatric difficulties. For instance, this same patient may have recently ended an unpleasant interpersonal relationship in which she frequently tried to express her thoughts and feelings that largely were ignored, minimized, and invalidated by her partner. She also might have simultaneously lost her job, resulting in decreased income and less frequent contact with her social support system. *Maintaining factors* are those antecedents and consequences that reinforce and maintain problem behaviors once they have started. The patient who is experiencing chronic worry may be receiving feedback from parents or significant others that inadvertently reinforces the patient's fears and worry behaviors. Careful analysis of these factors identifies targets for empirically supported behavioral interventions and consideration of each patient's unique learning history.

"First-Wave" Behavior Therapy Treatment Strategies

Here, we discuss a number of behavioral interventions, following the course of the three "waves" (or movements) discussed in the introduction.

Progressive Muscle Relaxation. Relaxation often is used as a component of systematic desensitization therapy (presented below), as a primary intervention for stress and some medical disorders (headache, pain, postsurgical distress), and as part of a comprehensive intervention strategy for reduction in anxiety. Relaxation therapy increases parasympathetic nervous system activity, thereby decreasing the opposing sympathetic nervous system activity and decreasing arousal. Several different approaches can be used to produce a relaxation response. The most popular is progressive deep muscle relaxation (PDMR), in which patients are taught to tense and relax muscle groups in their bodies while focusing on the differing sensations of tension and relaxation. PDMR begins with diaphragmatic breathing, followed by tensing and relaxing each of the identified muscle groups (e.g., feet, legs, hands, arms, shoulders, face). The act of tensing before relaxation serves

Telegram: @medical_k

www.konkur.in

to help patients identify tension, including tension they may have not been aware of, and facilitate relaxation. A few negative side effects have been associated with relaxation. These include muscle soreness or strain, depersonalization (when practiced continuously for several hours per day, or trauma re-experiencing in the context of general relaxation or visualization techniques), and relaxation-induced panic attacks (occasionally seen among patients with panic disorder who are attuned to physical sensations).

Exposure Therapies. Exposure therapies are based on the premise that fears are acquired through associative learning (classical or operative conditioning). Interventions to eliminate fear require exposure (contact) with the feared object, event, or situation. Exposure therapy is based on two models: The *counterconditioning model* pairs a feared object with an incompatible response. The *extinction model* is based on habituation of the feared response.

Systematic desensitization consists of relaxation therapy (usually PDMR) and the presentation of fear-producing stimuli arranged within a hierarchy representing successive approximations to the feared object, situation, or event. SUDS are rated for each item on the list. The intervention focuses on achieving a relaxed state and pairing with the first item on the list, with interruptions to imagining if anxiety returns. When the patient reports the imagery no longer elicits anxiety, the psychologist or therapist proceeds to the next item, and over sessions, the cycle is repeated until the patient is able to imagine the items at the top of the hierarchy without reporting any anxiety symptoms. In *in vivo desensitization,* partial relaxation, deep breathing, or no competing response is used as the patient is actively moving. Real-life hierarchical steps are developed, but each step represents only a small incremental increase in arousal in comparison with the preceding step.

An exposure procedure that uses the extinction process to reduce anxiety is known as *flooding.* The term *extinction* describes the process of decreasing fear and maladaptive anxiety. In flooding, the patient is exposed immediately to the fear-producing stimuli at its full strength and without relaxation. In most cases, flooding (exposure) is accompanied by response prevention (RP) or discontinuing all avoidance and other anxiety-reducing behaviors, so as to eliminate the emotional response over time (used in obsessive-compulsive disorder).

Telegram: @medical_k

www.konkur.in

When a feared stimulus is first presented, anxiety typically rises significantly. Over time, with continued exposure, indicators of anxiety (SUDS levels, physiologic indices like heart rate, skin temperature) should decrease. Reduction in anxiety is often referred to as *within-session extinction.* Across a number of sessions, the key elements for successful treatment are that the peak anxiety level is reduced and the time to return to minimal anxiety is shortened. These responses to treatment are called *between-session extinction,* when the fear-producing stimulus produces reduced amounts of anxiety and faster within-session extinction over sessions.

Two relatively new strategies may hold promise. In *virtual reality exposure,* the patient wears a head-mounted display that produces computer-generated images of feared situations and "interacts" with what feels like a real-life situation. This has been used to treat phobias, posttraumatic stress disorder (PTSD), social anxiety disorder, and panic disorder. Second, eHealth utilizes technology-based self-help (i.e., computer or smartphone applications) techniques.

Operant Strategies. *Operant* is a term used to describe a mechanism whereby a behavior operates on the environment. In this learning model, behavior is not evoked or elicited (as in classical conditioning) but independently occurs, and environmental responses influence whether the behavior is continued or stopped. Changes in behavior occur as a result of consequences that reinforce or punish emitted responses. For a consequence to alter a certain behavior, the consequence must be *contingent* on the behavior, meaning it is delivered only after the target behavior is performed, and it is otherwise not available. *Reinforcement* is a contingent event that strengthens the response that precedes it. See Table 32.8–1, which outlines reinforcement of target behaviors, schedules, and outcomes associated with each subtype.

Several behavioral interventions exist to assist patients in the acquisition of new behaviors. *Shaping* is a process of reinforcing (rewarding) successive approximations that come increasingly close to a desired behavioral goal. Intermediary behaviors may be reinforced because they resemble the desired behavior or include a component of the desired behavior. BA is a good example; longer-term goals like running a 5k, can include reinforcement for successive approximations along a trajectory, such as researching training schedules, signing up for

Telegram: @medical_k

www.konkur.in

the race, walking increasing distances, and eventually running increasing distances consistent with the chosen schedule. *Chaining* refers to the series of specific, small behaviors or steps that when performed in sequence, form a chain. One response produces the conditions for the next response, and so forth, and at the end of the chain, the final behavior is reinforced. *Forward chaining* consists of teaching the sequence of behaviors beginning with the initial step in the chain and reinforcing along the series. In *backward chaining,* the final response is taught first. Behavior chain analysis is particularly useful for exploring maladaptive behaviors (e.g., self-harm) as well as behaviors not met (e.g., assigned homework for a therapy session), as it incorporates processing the connections between series of behaviors as well as negative reinforcement for target behaviors.

Table 32.8–1.
Operant Theory Principles

BEHAVIOR		
Action	**Increases**	**Decreases**
Given	*Positive reinforcement*	*Positive punishment*
Taken away	*Negative reinforcement*	*Negative punishment*
SCHEDULES		
Type	**Application**	**Utility**
Continuous reinforcement	Applied with each target behavior	Establishing new behavior; increasing low-level response
Intermittent reinforcement	Applied with a subset of target behaviors	Maintaining behaviors over time; reducing extinction
Fixed interval	Applied at consistent time points or number of behaviors	
Variable interval	Applied randomly	

Telegram: @medical_k

www.konkur.in

Contingency Management. Contingency management is defined as the general application of operant principles in the process of behavior change and relies on consistent administration of reinforcement to strengthen target behavior (and ultimately reduce or extinguish the undesired response). This has been efficacious in the treatment of substance use disorders (SUDs) and smoking cessation among teens and adults, including those with comorbid mental illness. Vouchers or gift cards are received for meeting behavioral expectations (e.g., negative drug screens, treatment attendance) at fixed or variable intervals/quantities; this is also implemented in the context of larger treatment programs including CBT or other relapse prevention skills. It is challenging to implement in practice, as stigma surrounding substance use and limited interpretations of "reward" breed controversy, and it is difficult to identify funding for vouchers.

Token economy programs are a formalized method of contingency management often used in adult and child inpatient settings, day treatment programs, and classrooms. Token economy systems clearly spell out a series of behaviors that are expected and the contingencies for compliance/noncompliance with these behavioral goals. Achievement of behavioral goals leads to the acquisition of tangible rewards (snacks, poker chips that can be redeemed for prizes) or privileges (time off the ward, home visit privileges). Noncompliance does not result in privileges or rewards. Some programs include a provision called *response cost* (a form of punishment), which is the removal or withdrawal of a reward following inappropriate or problem behavior (e.g., fining a child for swearing). The combination of token reinforcement and response cost may be more effective than either alone. Token economies also are most effective when administered in a patient's natural environment and when reinforcers eventually are shifted from tangible rewards (e.g., food and points) to social and more natural reinforcers (e.g., praise, feeling good about oneself). Shaping procedures can be used to facilitate this transition.

A number of behavioral procedures incorporate contingency management strategies as part of an overall intervention. For example, *parent–child interaction therapy* (PCIT) is a structured program that teaches parents child-directed interaction (CDI; e.g., praising, reflecting, imitating, describing, being enthusiastic, and providing contingent attention) and Parent-Directed Interaction (PDI; e.g., giving good

Telegram: @medical_k

www.konkur.in

commands, praising compliance, using time-out in a chair for noncompliance, and establishing structured house rules). PCIT is a short-term intervention that has been used successfully with a range of behavioral problems, including oppositional behavior, aggression, eating behaviors, and homework completion.

Aversion-Based Approaches. Like exposure therapies, aversion-based approaches consist of interventions based on operant principles or counterconditioning strategies. Here, punishment is defined functionally as the reduction in the future probability of a response as a result of the immediate delivery of a noxious stimulus for that response. Punishing stimuli include loud noise, aversive tastes, mild electrical shock, or chemical agents, used as a last resort when other behavioral methods such as time-out or response cost are ineffective. Punishment is also used when the negative behavior is very dangerous to the person (e.g., self-mutilative behaviors). To be effective, punishment must be of high intensity (only enough to disrupt the behavior), immediate, and continuous (at least initially). Less aversive stimuli, such as a drop of lemon juice applied to the tongue, are tested prior to escalating intensity. Punishment may produce undesirable effects such as negative emotional reactions, avoidance, and aggression, in addition to the increased response of problem behavior when intensity is insufficient. Numerous ethical issues are also considered, and consultation and review are necessary to ensure overall patient well-being, particularly for children and those with developmental disabilities.

Other aversive procedures, such as *aversion therapy,* are based on a classical conditioning paradigm. Used to treat sexual deviations and SUD, an aversive physical and/or emotional state is paired with cues that elicit abusive behavior or sexually deviant behavior, resulting in an aversion to the sensory aspects associated with the behavior and ideally, suppression of the behavior. *Chemical aversion* may be administered via the olfactory or gustatory systems. *Olfactory aversion* is the pairing of extremely noxious but harmless odors (such as ammonia) with either sexual fantasies or sexual behaviors, typically in the setting of the deviant sexual behavior. For SUD, *emetic aversion* (a chemical that induces vomiting; such as disulfiram or Antabuse) has also been used, as implementing immediate consequences may help to promote sobriety. Similarly, electrical stimulation to the forearm (*faradic aversion*) and *verbal aversion*

Telegram: @medical_k

www.konkur.in

(covert sensitization: presentation of an imaginal scene involving deviant behavior immediately followed by a scene that produces nausea) have been used. Recent evidence supports the superior effectiveness of disulfiram (relative to oral naltrexone or acamprosate) in treating alcohol use disorder, such that it can serve as adjunct to a comprehensive treatment program rather than as aversive therapy alone.

Skills Training. Skills training approaches have a long history of use in behavioral therapy. From a behavioral perspective, lack of skill may play a role in the onset and maintenance of various types of psychopathology. For example, people with social phobia or schizophrenia may have limited functionality related to social isolation, whereas those with personality disorders have difficulty maintaining relationships with other people. In these and other instances, *social skills training (SST)* may need to be an integral part of the treatment program. SST is a broad-based program designed to teach a wide variety of social skills applicable to individual needs. Social Environment Awareness involves teaching the nuances of when, where, and why to initiate and terminate interpersonal interactions. Interpersonal Skill Enhancement utilizes education about the mechanics of successful social encounters (e.g., initiating, maintaining, and ending conversations; establishing and maintaining friendships; and assertiveness). Techniques used for SST include instruction in the skill, modeling the skill, behavioral rehearsal, corrective feedback, and positive reinforcement. Role-playing assesses baseline skill and facilitates behavioral rehearsal of new skills which research identifies as the critical element in social skill acquisition.

“Second-Wave” Behavior Therapy Treatment Strategies

In the late 1960s, neo-behaviorists began to question operant and respondent principles alone and turn to potential mediators introduced in cognitive theory. The “cognitive revolution” emerged in the context of social psychology, where pioneers such as Fritz Heider, Harold Kelley, and Bernard Weiner were beginning to research and understand the complex ways in which individuals interact and think about one another’s behaviors.

Cognitive Therapy. A founding co-father of cognitive therapy is Aaron Beck, and the fundamental premise of cognitive therapy is that abnormal

Telegram: @medical_k

www.konkur.in

behavior is the result of distorted cognitive processes. Beck frequently referred to the *cognitive triad* in depression: a negative view of the self, the world, and the future. These negative beliefs are often called *cognitive distortions,* or patterns in thinking that affect individuals' mood and behavior. The focus of intervention is on increasing awareness of such *automatic thoughts* and engaging in the process of *cognitive restructuring* or reframing, which examines the validity and/or utility of automatic thoughts and modifying content when in the face of inconsistent evidence from their life and daily experiences. The other founding co-father of cognitive therapy was Albert Ellis, who developed rational emotive behavior therapy (REBT), previously called rational emotive therapy and RET. One of the fundamental premises of REBT is that the major cause of human suffering is that people are largely distressed by events and adversities because of how they construct their views of reality through their language, evaluative beliefs, meanings, and philosophies about the world, themselves, and others. In REBT, the patient begins to understand how beliefs about adversity and consequences maintain distress and instead engages in adaptive perspectives.

Several other cognitive therapies subsequently have been developed, including Patricia Resick's *cognitive processing therapy* (1993) and Jeffrey Young's *schema therapy* (1990), interventions demonstrated to be effective for problems such as depression, suicidal ideation, anxiety, trauma and PTSD, SUD, eating disorders, personality disorders, and marital problems. Although beyond the scope of the chapter to describe in detail, the important point is that all cognitive therapies, to a greater or lesser degree, include behavior-based assessment and intervention methods.

Problem-Solving Therapy. Psychological difficulties can result from ineffective methods by which to approach life's problems. Problem-solving therapy (PST) teaches the necessary skills to adapt to challenges and discover effective solutions and is effective for psychiatric disorders and stress associated with chronic medical disorders. The specific goals of PST are to increase understanding of the connection between current mood symptoms and everyday problems, increase the ability to clearly and accurately define current problems, teach patients a specific problem-solving method to allow for a more structured skill set to address life problems, and develop an increased sense of self-efficacy. During the

Telegram: @medical_k

www.konkur.in

course of PST, patients increase agency in modifying their problem list and tackling solutions.

Self-Control Approaches. Common self-control strategies include physically restraining oneself, chaining the stimuli conditions, depriving or satiating oneself, using mild aversive events, using drugs or alcohol, administering self-reinforcement or self-punishment, and doing something else to avoid aversive consequences. Self-control therapies are efficacious for changing maladaptive and excessive behaviors that contribute to an unhealthy lifestyle, such as overeating and smoking.

Self-control therapies generally involve three basic processes. The first stage is self-monitoring of behaviors (described earlier, e.g., keeping a food diary), self-evaluation (wherein data is aggregated and compared to a standard or normative information, such as number of calories per day), and self-reinforcement (setting contingencies based on performance). Self-control programs are most likely to work when reinforcement is directed at a specific behavior (e.g., reward for engaging in exercise) and not effects of behavior (e.g., weight loss). Another type of self-control strategy is called *stimulus control.* Adjusting stimulus presence and cueing can reduce problematic behavior, as seen in sleep hygiene techniques for insomnia.

Habit Reversal Training. Habit reversal training (HRT) is a behaviorally based treatment approach designed to reduce repetitive behaviors (habits) such as hair pulling (trichotillomania), nail-biting, and tics. From a behavioral perspective, these habits emerge through classical conditioning and operant reinforcement to reduce stress. HRT, as developed by Nathan Azrin and his colleagues, was designed to break the conditioned habit cycles using a combination of procedures. In *awareness training*, self-monitoring increases patient awareness of internal and external precipitants of the habit, considering a pattern of behaviors preceding the motoric responses, internal states, and consequences. *Habit control motivation* explores challenges and motivations associated with the behavior. *Competing response training* is the core of HRT. This process involves identifying a motoric behavior that is incompatible with the habit and engaging alternatively engaging in this in the context of associated precipitating behaviors or internal cues. For example, fist clenching (or clenching a book, or firmly grasping a steering wheel) is considered incompatible with body-focused repetitive behaviors.

Telegram: @medical_k

www.konkur.in

Relaxation training discussed earlier, is also used to help break the conditioned habit cycles, particularly when stress or another negative mood is a precipitant for the target behavior. Finally, reinforcement from others or through contingency management or self-control mechanisms can help to facilitate and maintain treatment gains.

"Third-Wave" Behavior Therapy Treatment Strategies

According to Hayes, "Grounded in an empirical, principle-focused approach, the third wave of behavioral and cognitive therapy is particularly sensitive to the context and functions of psychological phenomena, not just their form, and thus tends to emphasize contextual and experiential change strategies in addition to more direct and didactic ones. These treatments tend to seek the construction of broad, flexible, and effective repertoires over an eliminative approach to narrowly defined problems and to emphasize the relevance of the issues they examine for clinicians as well as clients. The third wave reformulates and synthesizes previous generations of behavioral and cognitive therapy and carries them forward into questions, issues, and domains previously addressed by other traditions, in hopes of improving both understanding and outcomes."

Behavioral Activation. Based on the premise of behavioral theory, individuals with depression get less positive reinforcement via anhedonia (finding limited or no enjoyment in activities) and behavioral withdrawal (limited engagement in enjoyable activities). Positive or negative reinforcement from others or exposure to aversive or unpleasant life experiences may also serve to maintain depression.

BA emphasizes structured attempts to increase overt behaviors that bring patients into contact with reinforcing environmental contingencies and corresponding improvements in thoughts, mood, and quality of life. Within the BA model, the process of increasing response-contingent reinforcement follows the basic behavioral principles of extinction, shaping, fading, and in vivo exposure. Initial sessions involve assessing the function of depressed behavior, establishing patient rapport, motivational exercises focusing on the pros and cons of behavioral change, depression psychoeducation, and introduction of the treatment rationale. Once efforts are made to reduce reinforcement for depressed behavior, a systematic approach for increasing healthy behavior is

Telegram: @medical_k

www.konkur.in

initiated by increasing the value of reinforcers for such behavior and devaluing reinforcers for depressed behavior.

BA has been effectively used with patients in community mental health centers, inpatient psychiatric facilities, college psychology clinics, and primary care settings, even when administered by previously untrained mental health nurses. In addition to major depression experienced by younger and older adults, BA has been shown to be effective for individuals with grief and bereavement, SUD, anxiety disorders such as PTSD and GAD, schizophrenia, and depressed patients with cancer, obesity, and HIV/AIDS. Data suggest BA leads to greater improvement than cognitive therapy for patients with severe depression, with equivalent outcomes to antidepressant medication.

Acceptance and Commitment Therapy. Originally referred to as comprehensive distancing, acceptance and commitment therapy (ACT) was developed in the 1990s by Steven Hayes and colleagues. ACT encompasses acceptance and mindfulness strategies together with behavior change strategies to increase psychological flexibility toward the goal of adapting cognitively and behaviorally to stressors and one's reactions to these. Tenets include contacting the present moment fully as a conscious human being and, based on what the situation affords, changing or persisting in behavior in the service of chosen values. The core premise of ACT is that much of human (psychological) suffering is a consequence of *experiential avoidance,* or the unwillingness to experience negative feelings, thoughts, and sensations. Through metaphor, paradox, and experiential exercises, clients learn how to make healthy contact with thoughts, feelings, memories, and physical sensations that have been feared and avoided. Clients gain the skills to recontextualize and accept these private events, develop greater clarity about personal values, and commit to needed behavior change. ACT views the core of many problems to be due to the concepts represented in the acronym, *FEAR*: *F*usion with your thoughts, *E*valuation of experience, *A*voidance of your experience, and *R*eason-giving for your behavior. According to ACT, the healthy alternative is to *ACT*: *A*ccept your reactions and be present focused, *C*hoose a valued direction, and *T*ake action.

Mindfulness-Based Therapy. Mindfulness-based treatments are a relatively new variation in behavioral (and cognitive) interventions that integrate various techniques based on Eastern philosophies of

Telegram: @medical_k

www.konkur.in

contemplation and meditation. Mindfulness-based therapies (MBTs), such as mindfulness-based stress reduction (MBSR) and mindfulness-based cognitive therapy (MBCT), show promise as effective interventions for anxiety, depression, and other psychological problems. The fundamental principles of MBT involve attention regulation, openness to present experience, curiosity, acceptance of the “here-and-now,” and nonjudgmental awareness of thoughts, emotions, sensations, and the environment. The efficacy of MBT in treating emotional disorders is believed to be a function of an increased ability to manage life stressors, enhanced concentration and mindfulness, and reduced rumination. In MBSR, the primary strategies include learning mindful eating (e.g., the raisin exercise), mindfulness meditation, body (scanning) awareness, mindful walking, urge surfing, and yoga. Originally developed in the mid-1990s as a treatment to prevent relapse into depression, MBCT integrates fundamental theories and applications of MBSR with those of more traditional CBT. Unlike CBT, however, MBCT does not emphasize changing thoughts themselves; rather, the goal is to develop an awareness of and relationship to thoughts. Aspects of CBT included in MBCT are primarily those designed to facilitate “decentered” views, such as “thoughts are not facts” and “I am not my thoughts.” Although interventions such as MBSR and MBCT are predominantly administered over 8 (3-hour) weekly sessions followed by a daylong retreat, some data support abbreviated formats of these protocols as well as the use of these strategies as part of a comprehensive treatment approach for specific presentations (e.g., anxiety, adjustment difficulty, or pain).

Dialectical Behavior Therapy. Developed by Linehan in the early 1990s, dialectical behavior therapy (DBT) was originally developed as an intervention for chronically suicidal individuals. DBT blends behavioral and crisis intervention theories with an emphasis on acceptance and tolerance based on Western contemplative and Eastern meditation practices. The theoretical framework emphasizes exchange and negotiation in the therapeutic dyad, between the rational and the emotional, and between acceptance and change (hence the term “dialectical”). Treatment targets are agreed upon, with self-harm taking priority. The learning of new skills is a core component, including mindfulness (e.g., nonjudgmental awareness of one’s own feelings and actions), interpersonal effectiveness (e.g., assertiveness and social skills), coping adaptively with distress and

Telegram: @medical_k

www.konkur.in

crises, and identifying and regulating emotional reactions. DBT can be implemented in individual and/or group formats; in particular, DBT skills groups for adolescents and adults can provide psychoeducation, skills training, and feedback normalizing the intensity of emotional experiences.

Cognitive-Behavioral Analysis System of Psychotherapy. Developed by James McCullough in the late 1990s, cognitive-behavioral analysis system of psychotherapy (CBASP) is an integrative therapy for chronically depressed adults that combines components of cognitive, behavioral, interpersonal, and psychodynamic therapies. According to this model, those with chronic depression experience disconnectedness from their environment and therefore have decreased access to important feedback on problematic interpersonal patterns and relationships. The therapeutic relationship is actively used to help patients generate empathic behavior, identify and change interpersonal patterns related to depression, and heal interpersonal trauma. CBASP consists of three techniques: (1) *situational analysis,* a problem-solving technique designed to help the patient realize the consequences of their behavior on others and modify it; (2) *interpersonal discrimination exercises,* an examination of past traumatic experiences with others and differentiation of those from healthier relationships; and (3) *behavioral skill training/rehearsal,* such as assertiveness training, to further help depressed individuals modify maladaptive behavior. McCullough also strongly recommends that all patients beginning CBASP begin a regime of antidepressant medication.

Functional Analytic Psychotherapy. Functional analytic psychotherapy (FAP) is a treatment based on a contextual behavior-analytic understanding of the therapeutic relationship as an agent of change. Although much of behavior analysis is centered on environmental manipulation, FAP presumes that significant change occurs in the context of the therapeutic relationship during the traditional weekly psychotherapy session, such that the focus is on clinically relevant behaviors (CRBs) that occur in the therapeutic relationship rather than processing life problems. In FAP, the psychologist or therapist seeks to reduce (functionally punish or extinguish) the client's dysfunctional behavior occurring in session (CRB1) while increasing the probability of (functionally reinforce) more appropriate alternative behavior occurring in session (CRB2). This is done by using naturalistic feedback and reactions in session. The psychologist or therapist also becomes an important mediator of interpersonal

Telegram: @medical_k

www.konkur.in

reinforcement. Awareness of CRBs and contingent responding to clinical problems and improvements that occur in therapy support change that can be maintained outside the therapy setting. Kohlenberg, Tsai, and colleagues recommend the following: create trust and safety, move the conversation from content to in-the-moment process, evoke and naturally reinforce client target behaviors related to authentic expression, instill hope, be aware of clinical impact, and promote generalization of in-session gains to daily life.

CLINICAL ISSUES

Developmental Considerations

Effective behavioral treatments have been developed for use across the full developmental spectrum, including children. These approaches are particularly valuable for patients whose verbal skills are not appropriate for more traditional therapeutic approaches. However, it is important to select and implement treatment techniques with careful attention to cognitive, social, and other developmental considerations. In children, assessment and treatment may utilize more visual representations (e.g., rating scales with faces or other pictures to describe mood instead of words). Further, children have not yet developed the cognitive skills to participate effectively in interventions that have a large cognitive component. For example, prior to midchildhood, few children have metacognitive skills (i.e., the ability to think about thinking). Therefore, interventions with children often de-emphasize cognitive strategies in favor of more behavioral interventions. Finally, treating children also involves consistent feedback with a broader treatment team, including parents, teachers, and other caretakers, and may occur exclusively in schools to increase access to services. A broad assessment of ability in younger populations may also yield individualized treatment recommendations, as seen in applied behavior analysis (ABA) for children with autism spectrum disorders (ASDs). While positive reinforcement and patterns of antecedents, behaviors, and consequences are core components, treatment is tailored according to individual factors and skill deficiencies.

Among older adults, consideration of sensory limitations (e.g., written documents prepared with larger fonts) and any medical issues are relevant. In addition, there are expected cognitive shifts in normal aging, and neuropsychological testing can be especially useful in identifying

Telegram: @medical_k

www.konkur.in

cognitive impairment that may impact treatment choice and engagement (e.g., in dementia, cognitive approaches are not appropriate). In such cases, exploration of relative strengths may help to elucidate potential avenues for therapy, whereas noted weaknesses may indicate needed resources (e.g., the inclusion of collaterals or caregivers who can assist with the assessment and treatment process). Indeed, case studies have also demonstrated that older adults with dementia and anxiety are able to learn coping skills such as relaxation, self-talk, and BA with the help of a psychologist or therapist and a collateral or caregiver. For these patients, different learning strategies are used to teach skills, including increased repetition and practice, the use of more cueing procedures to facilitate memory, and spaced retrieval, a procedure based on classical conditioning that repeatedly pairs questions (e.g., What can you do when you feel nervous?) and answers (e.g., I can breathe deeply) over increased intervals to facilitate memory. Reminiscence can also serve to optimize mood, particularly when utilized in a BA context.

Cultural Considerations

Cultural competence is an integral part of ethical, patient-centered care and is included as one of the American Psychological Association (APA)'s core competencies for psychologists. Yet attention toward this tenet has historically been limited with respect to empirical review according to race/ethnicity and thus generalizability of efficacious findings to marginalized groups. In general, data supports improved effectiveness when empirically supported therapies, including CBT, are culturally adapted to better represent language and nuanced meaning in treatment protocols and subsequent delivery. We must do better in the inclusion of underrepresented groups and analysis according to individual factors like race. A recent review noted less than half of RCTs of behavioral treatment for weight loss reported outcomes by race or considered race in design, and overall, Black patients lost less weight relative to White patients. Indeed, while differences according to race and ethnicity may reflect access to and request for mental health services, the paucity of individualized intervention approaches is a fault of our community that may maintain these disparities. An ideal approach to address this clinical need is FAP, which allows a safe, nonjudgmental environment to explore interpersonal components of minority stress (e.g., gender and sexual

Telegram: @medical_k

www.konkur.in

minority patients) and contingencies associated with vulnerability with others.

Implementation Variables

Behavioral treatments typically are of relatively brief duration, although the total length of treatment depends on the nature of the target problem(s) and the maintaining variables. The use of homework assignments in behavioral treatments, in effect, extends the actual duration of treatment. Sometimes, sequential phases of treatment are required; for example, the ideal approach for SUD treatment is longitudinal and multidisciplinary to account for the chronically relapsing nature of the disease as well as the varying presentations according to severity. The initial intensive phase of treatment may require physician- or psychiatrist-supervised detoxification to safely manage withdrawal symptoms while coincidentally also limiting exposure to environmental cues. Step-down treatment may then incorporate relapse-prevention strategies to maintain sobriety and engagement in alternative coping behaviors. A variety of self-help treatments not involving traditional therapy have also derived from behavioral approaches (e.g., bibliotherapy and internet- or phone-based treatments).

Strengths of a Behavioral Approach

The strong foundation in empiricism and the continued reliance on efficacy to drive treatment selection is a strength of behavior therapy and minimizes the potential for harm. The scientific base for behavioral treatments is larger than for any other psychosocial approach, and behavioral treatments are the treatment of choice for many psychiatric disorders, including depression and anxiety. Specifying targets for change and evaluating outcomes in an objective fashion helps ensure that treatment is appropriately administered (i.e., with regard to content and duration) as well as suitable for the problem. As such, accountability is high; it should be relatively clear to the clinician and the patient (and insurance companies) when treatment has the desired effects. In addition, the collaborative nature of the interventions allows for active patient engagement and flexibility in approach to best meet the patient's needs across the treatment continuum. Behavior therapy is also efficient and cost-effective. Many treatment techniques described above have an immediate effect (e.g., when a sufficiently powerful reinforcement is used

Telegram: @medical_k

www.konkur.in

to change behavior, when intensive exposure is used to treat anxiety), and the course of behavioral treatment can be a few sessions with much of the work of treatment occurring outside of therapy. Finally, behavioral approaches often match well with the requirements of managed care, which require ongoing documentation of identified problems and outcomes.

Limitations, Complications, and Contraindications

Behavior therapy is an action-oriented approach that requires a patient's readiness to change. Behavioral treatment, therefore, may not be appropriate for patients who perseverate on the historical origins of their problems without wanting to take action. Treatment approaches such as *motivational interviewing* have been designed to help move patients toward readiness to change such that behavioral treatments can be effective. However, reinforcement for not making a change may be more powerful than reinforcement for making a change (particularly in substance use). If personality factors underlie limited engagement in behavior therapy sessions, DBT approaches, centered on the balance of validation of distress and the expectation to do more, may be more appropriate. However, patients who are consistently uninterested in making real changes are not optimal candidates for behavior therapy, or for that matter, virtually any form of therapy.

At times, although behavioral treatments generally match well with managed care reimbursement practices, some forms of behavior therapy may be at odds with insurance-based practice and reimbursement availability. Intensive exposure treatments, longer and more frequent than the traditional 50-minute weekly session or home visits, may not be fully reimbursed. Finally, in many places, psychologists and therapists with appropriate expertise are simply not available. With the swift implementation of telehealth practices since the onset of the COVID-19 pandemic, virtual sessions have increased access to care at the expense of factors that may be central to behavior therapy (e.g., interpersonal interaction and environmental reinforcement).

ETHICAL ISSUES

Ethical considerations are inherent in this work, particularly in aversion and exposure treatments. Aversion-based interventions are used only as

Telegram: @medical_k

www.konkur.in

a last resort when the patient has not responded to other interventions and is at risk of harming themselves or someone else. These treatments involve informed consent and are reviewed by a full team of providers, including physicians evaluating medical risk. The provider should have sufficient training in a particular treatment and seek supervision or consultation as needed. In many cases, ethical and legal review boards also have input. And perhaps most importantly, these procedures should be used in conjunction with alternative techniques that promote other, more adaptive behaviors. With exposure, there is a risk of increased anxiety and distress in the context of inconsistent or poor treatment. The choice to use exposure should be based on the scientific literature, a thorough case conceptualization, and a collaborative decision between the psychologist or therapist and patient following thorough discussion and evaluation of the cost–benefit ratio. In addition, ensuring the patient does not have a medical condition that contraindicates increased arousal and monitoring that reductions in arousal are occurring as expected is important.

In summary, although less than 100 years old, behavioral interventions are now considered established, standard-of-care interventions. They have been applied to a range of psychiatric disorders, functional deficits, medical disease states, and a combination of these presentations across the developmental spectrum, including children, adolescents, adults, and mature adults. They are translatable across settings, including traditional inpatient, outpatient, and integrated medical settings. Finally, unlike some other schools of therapy, the success of behavior therapy is not limited by intellectual or disability status, having been successfully used for those with various developmental disorders and sensory limitations. Clearly, behavioral interventions are broad based, rooted in science, and applicable across contexts.

32.9 Cognitive Behavior Therapy

JUDITH S. BECK, PH.D., AND ROBERT HINDMAN, PH.D.

Cognitive behavior therapy (CBT) was developed by Aaron T. Beck, M.D., in the 1960s and 1970s. He and colleagues worldwide have continued to expand and refine the underlying theory and treatment ever since and Beck's work, emphasizing the central role of cognition in psychopathology, has led to a paradigm shift in the field. It is a comprehensive biopsychosocial system of psychotherapy, with an operationalized treatment based on an elaborated and empirically supported theory of psychopathology. CBT has become the most heavily researched and widely practiced form of psychotherapy in the world. It has been demonstrated in approximately 2,000 outcome trials to be effective for a wide range of psychiatric disorders. The benefits of CBT persist after the discontinuation of treatment, resulting in a lower relapse rate in comparison to those taking psychotropic medication. CBT has also been demonstrated to be effective for a range of psychological problems (such as stress, anger, procrastination, and relationship distress) and medical conditions with psychological components (such as tinnitus, chronic pain, and hypertension).

CBT has been adapted and research has demonstrated its effectiveness in a variety of settings, including outpatient clinics, psychiatric hospitals, primary care offices, schools, forensic settings, and community mental health centers. Its efficacy has been demonstrated for populations from young children through older adults, and for individuals who vary in gender, sexual orientation, socioeconomic status, and racial

Telegram: @medical_k

www.konkur.in

or ethnic background, and who come from a variety of cultures around the world. Studies also support its efficacy in individual, couples, family, and group treatment. A substantial number of studies now demonstrate its efficacy in computer-based programs and telehealth formats.

CBT is based on the cognitive model, which has been widely studied and has received substantial empirical support. The cognitive model posits that it is not situations that directly impact one's reaction (emotional, behavioral, and physiological). Rather it is one's *perception* of the situation, expressed in automatic thoughts, that is more closely associated with the reaction. One important component of CBT involves teaching patients to identify their thoughts that lead to emotional distress or dysfunctional behavior, to evaluate the accuracy and/or utility of their thinking, to effectively respond to these cognitions, and to reduce negative emotion and/or maladaptive actions. Figure 32.9–1 depicts the cognitive model.

Beck and colleagues developed a manual for CBT for depression to facilitate treatment fidelity in research studies (Beck et al., 1979). Manuals, however, often fail to allow clinicians to vary therapy as appropriate for the individual patient, and most clinicians find their treatment is significantly more effective when it is based on a cognitive formulation of the patient's disorder(s), an individualized cognitive conceptualization of the patient, and the patient's personal values and aspirations. A strong therapeutic alliance is essential for effective treatment and the relationship is collaborative. Both patients and clinicians are active in solving problems, evaluating cognitions, and modifying behavior. CBT is educative; clinicians teach patients how to use the techniques at home that they have employed in session. The clinician's stated goal is to help patients become their own therapists. They emphasize that the way patients get better is to apply what they have learned in session to make small changes in their thinking and behavior every day.

Telegram: @medical_k

www.konkur.in

FIGURE 32.9–1. Cognitive model.

Originally designed as a short-term treatment for depression, CBT has evolved over the years. Patients with straightforward cases of anxiety and depression, who were relatively psychologically healthy before the onset of their disorder, often benefit from a short course of treatment, perhaps 6 to 12 sessions. At the other end of the spectrum are patients whose disorders are chronic or complex, or those for whom standard treatment needs to be varied due to comorbidities such as substance use disorders (SUDs) or personality disorders. They may need many more sessions over a significantly longer period of time. Those with recurrent episodes or with serious mental illnesses may require intermittent treatment throughout their lifetime. This latter group of patients often benefit from a modified version of CBT: Recovery-Oriented Cognitive Therapy, which emphasizes empowerment, purpose, and resilience, and focuses on helping patients operate in an adaptive mode where they are able to live in alignment with their values and aspirations instead of focusing on problems and symptoms.

HISTORY

Aaron T. Beck, who was Emeritus professor of psychiatry at the University of Pennsylvania, had trained and practiced as a psychoanalyst. A scientist at heart, he conducted a series of studies starting in the late 1950s to test psychoanalytic theories of depression. Much to his surprise, his research demonstrated that depression was not a result of retroflected hostility and did not support a need to suffer. Instead of viewing depression as a result of unconscious drives, wishes, and defenses, Beck proposed that depression was associated with highly negative, distorted, and

Telegram: @medical_k

www.konkur.in

dysfunctional beliefs and thoughts, the result of biased information processing. When he began to tailor treatment toward helping his patients identify and evaluate their biased thinking and change their behavior, they began to rapidly improve.

In his landmark monograph, Beck (1967) detailed the cognitive triad of depression: negatively biased cognitions about oneself, one's world (including other people), and the future. He described the role of schemas, hypothesized mental structures that organize information, and he outlined a treatment approach that emphasized testing the accuracy of patients' cognitions. Ten years later, the first randomized controlled trial of CBT for depression was published (Rush et al., 1977). Patients in the CBT group responded slightly better to treatment than patients in the psychopharmacological group and had fewer relapses after treatment. Later studies confirmed these findings and showed that CBT was effective for severe depression.

Throughout the decades, Beck and colleagues studied other disorders. They used clinical material to identify and specify key cognitions and behaviors characteristic of a number of psychiatric problems. They used existing rating scales or constructed and validated new instruments to measure relevant clinical variables, adapted the general cognitive model and treatment interventions for each disorder, and created treatment manuals for randomized controlled trials.

In developing CBT, Beck was influenced by Greek Stoic philosophers and theorists contemporary to the time, such as Adler, Alexander, Sullivan, and Horney, as well as Kelly, Lazarus, and Arnold. Behaviorists and cognitive behaviorists such as Ellis, Meichenbaum, Mahoney, Lewinsohn, and Bandura were also influential in the development of his theories and treatment.

THEORETICAL ISSUES

Most automatic thoughts are verbal in nature, but some are in the form of mental images.

Telegram: @medical_k

www.konkur.in

As Kevin was thinking about looking for job opportunities on the internet, he pictured telling a potential interviewer how long he had been out of work. He imagined the interviewer looking scornfully at him, shaking his head.

Core Beliefs

Individuals display characteristic, recurrent themes in their thoughts which are associated with a deeper level of cognition, their core beliefs, representing the content of cognitive schemas. Core beliefs are one's most central ideas about the self, other people, and the world. These beliefs are generally identified by asking patients for the *meaning* of their thoughts. Core beliefs develop during childhood. The interaction between one's genetic predisposition (toward certain personality traits and styles of thinking) and their experiences affects the way they interpret their experiences.

People without significant psychological difficulties tend to view themselves throughout their lives as reasonably effective, able to protect themselves, likable, and worthwhile. If they develop an acute disorder such as depression, however, previously latent negative schemas may become activated and dysfunctional beliefs become manifest. Patients begin to view themselves, their worlds, and/or other people through a negative lens, interpreting their experience in a highly negative way, and may then overgeneralize the meaning of a situation. They may see themselves as ineffective, vulnerable, inferior, unlikeable, and/or worthless. They may view others as potentially hurtful, rejecting, or superior. They may see their world as unpredictable or unsafe. During times of psychological distress, these individuals tend to regard their negative core beliefs as fixed, absolute truths, which make these deeper-level ideas less amenable to change than automatic thoughts.

Telegram: @medical_k

www.konkur.in

Throughout his school years, Kevin performed at a level slightly below average but more or less at the level of most of his friends. He did not value getting good grades and was more interested in developing his above-average athletic skills. He felt competent enough academically and saw himself as a success athletically. His parents, however, had unrealistic academic expectations for him and criticized him when he did not perform as well as they desired (which was much of the time). Accordingly, from time to time, especially when his parents were harsh, he viewed himself as a failure. Fortunately, these episodes were generally fleeting, and his view of himself as basically adequate and competent predominated. It was not until Kevin was fired from his job and could not quickly obtain another one that he began to view himself as a failure. The dominance of this negative core belief contributed to the onset and maintenance of his depression.

Coping Strategies

The activation of a negative core belief typically leads patients to engage in maladaptive coping behaviors as an attempt to decrease or avoid distress.

As Kevin began to view himself as a failure, he started to avoid tasks that he assessed were difficult, at which he could fail. He gave up job hunting after a few weeks and spent a considerable amount of time sleeping, watching television, or playing video games. He began to withdraw from his wife, family, neighbors, and friends, believing that they all saw him as a failure, too.

Intermediate Beliefs

Intermediate beliefs are ideas at a deeper level than automatic thoughts but are more malleable than core beliefs. They consist of generalized rules, attitudes, and assumptions, and can be a link between patients' deeper core beliefs and their coping strategies. Patients generally believe that if they engage in certain coping strategies, their negative core beliefs may not be evident; however, if they do not, they believe these beliefs will likely be shown to be true.

Telegram: @medical_k

www.konkur.in

Once Kevin became depressed, several key assumptions became activated. “If I take on challenges, I’ll fail, but if I avoid difficult tasks, I’ll be okay (at least for the moment).” He also held the attitudes that “It’s terrible to fail” and “Failing means I’m a failure as a person.” His related rules, which often took the form of “should” statements, included “I should do great at everything I do.”

Schemas and Modes

Schemas are responsible for processing, storing, and retrieving different types of information, including perceptions, goals, expectations, memories, fantasies, and prior learning. They provide meaning and, when activated, affect the way individuals process their experiences. Their function is to aid the individual in selecting the most relevant information from the practically infinite amount of information in the environment. Schemas may be cognitive, behavioral, motivational, or affective. They range from adaptive to dysfunctional and vary in complexity, strength, flexibility, permeability, level of abstraction, and valence.

When Kevin is depressed and his maladaptive depressive schemas are activated, he is likely to process information in a distorted manner that confirms his core beliefs. For example, he views his difficulty getting out of bed in the morning as a sign that he is a failure, even after receiving psychoeducation about the effect depression has on patients’ thinking, motivation, and behavior. He fails to register the tasks he completes at home or the ways he is helpful to his wife even in the face of severe depression. He discounts his wife’s positive comments, believing that she is “just trying to be nice.”

The diathesis-stress model (Beck, 1967) posits that schemas are triggered when individuals experience events relevant to their underlying vulnerability.

Telegram: @medical_k

www.konkur.in

Kevin had had negative experiences from time to time throughout adulthood, such as the death of his best friend, arguments with coworkers, and conflict with a neighbor. These incidents, however, did not activate his depressive schemas as they did not match his underlying vulnerability toward interpreting a deficit in performance as signifying failure. His depressive mode was activated only after he was fired from his job for “negligence and incompetence” and was unable to secure a new job. These events matched stimuli from his “failure” schema, which led to its activation.

Modes are a complex organization of multiple schemas related to individuals’ self-evaluations, rules, memories, and expectancies. Primal modes are related to survival; constructive modes allow the individual to increase resources. Modes help explain the complex symptoms that patients experience and their global, systematic bias. Each psychiatric disorder is characterized by a particular mode. One constellation of schemas, for example, characterizes a depressive mode, while a different constellation is involved in an anxious mode.

The Generic Cognitive Model

In recent years, Beck has described an expansion of the cognitive model. This “generic cognitive model” explains how cognitive schemas contribute to the development and maintenance of psychopathology. Neurophysiologic hyperactivity is genetically influenced and may, in turn, negatively bias individuals’ attention and memories, resulting in dysfunctional cognitive schemas. Beck also describes the nature of individuals’ functioning along a continuum from adaptive to maladaptive, the process by which schemas are activated, the nature of dual processing (through the automatic and then reflective processing systems), and protoschemas (which quickly but crudely detect and interpret critical stimuli), along with an expanded theory of modes and common processes (such as rumination, worry, attentional fixation) across psychopathologic states.

Strength-Based Cognitive Conceptualization

Increasingly, the field has recognized the importance of adding a strength-based conceptualization and focus on understanding and treating

Telegram: @medical_k

www.konkur.in

patients. CBT clinicians identify patients' historic *adaptive* cognitions and coping strategies, often by questioning them about the best period in their lives and focusing on their achievements, strengths, positive qualities, and resources. During these best periods, individuals often had core beliefs such as "I'm reasonably competent/safe/likeable/worthwhile." They usually had relatively benign and realistic beliefs about people: "Many people are trustworthy or neutral and will not intentionally harm me" and their worlds: "The world is reasonably safe and predictable." Their intermediate beliefs tend to be functional ("If I try, I can succeed, at least to some degree"; "If I interact with most people, they'll accept me.") When they face challenges, they tend to persevere because of their adaptive automatic thoughts. ("I can probably solve this problem, but if I can't, I can ask for help.")

In contrast to a more traditional, problem-based treatment, therapists ask clients for their goals for each session. They help them draw realistically positive conclusions about the positive experiences they had in the previous week. They use standard techniques to resolve obstacles that could interfere with their ability to take steps in alignment with their values and aspirations.

Applications Across Specific Disorders

According to the cognitive model, psychiatric disorders are characterized by an interaction among triggers, cognitions, behaviors, emotions, and common psychological processes. Each psychiatric disorder is characterized by a specific set of beliefs and behavioral strategies. The following is an overview of the cognitive theories for several disorders.

Depression. The maladaptive cognitions specific to depression are referred to as the cognitive triad: negative beliefs about oneself, one's life experience (and the world in general including other people), and one's future (Beck, 1967). Depressed patients often predict that they will inevitably face only unending problems and pain; these predictions affect both their mood and their behavior. They tend to be excessively self-focused. They are likely to disproportionately allocate attention to their negative thoughts, feelings of sadness, and physiologic symptoms. Depressive rumination typically results in an exacerbation of symptoms and continued inactivity. As the depressive mode continues to be active, individuals' sense of hopelessness about the future may increase and

Telegram: @medical_k

www.konkur.in

lead to increased suicidal ideation when they believe suicide is the only solution to their problems.

Bipolar Disorder. The schemas of bipolar patients are activated when biologic and psychological processes interact with external and internal triggers, leading to depression, mania, or mixed-mood episodes. In a depressed state, these patients display the same kinds of cognitive biases and dysfunctional beliefs as patients with unipolar depression, especially negative cognitions about the self, the world and other people, and the future. In a manic state, patients with bipolar disorder tend to view themselves in an inflated, expansive way. Hyperpositive core beliefs ("I am powerful"; "I am invulnerable"; "I am amazing") predominate. Their behavior changes are consonant with the changes in their thinking. They become impulsive, minimize potential threats, and take risks. Typical conditional assumptions include: "If something seems like a fantastic idea, it must be"; "I should follow my impulses and take action immediately"; "If I'm feeling great, I don't have to take meds or be careful about my daily habits." In a euthymic mood, patients with bipolar disorder may think, "I have to drive myself hard to make up for how little I accomplished when I was depressed." This belief may lead them to overextend and over-stimulate themselves, particularly in reference to goal-oriented behavior; they may then sleep poorly and ultimately become hypomanic.

Anxiety Disorders. When patients have anxiety disorders, they tend to significantly overestimate the risk of a situation and greatly underestimate their ability to cope. Worry about a variety of events or activities is common, especially among individuals with generalized anxiety disorder (GAD), as are futile attempts to control the worry process.

Many clients with anxiety disorders have maladaptive core beliefs such as "I'm incapable and vulnerable," and "The world is a dangerous place." Individuals with social anxiety disorder (SAD) tend to see themselves as defective and unlikable and predict that others will reject them; they become hyperalert for signs of anxiety which they try to hide from others; paradoxically, they therefore sometimes behave in a way that others find odd.

Cognitive models for obsessive-compulsive disorder (OCD) propose that intrusive thoughts, images, or urges develop into obsessions when they are given excessive importance. Patients with OCD believe that their intrusive thoughts and images are uncontrollable, that they will be

Telegram: @medical_k

www.konkur.in

responsible if bad things happen, and that they cannot overcome the urges to engage in compulsive behaviors that they hope will neutralize the threat.

The automatic thoughts of patients with anxiety tend to center around potential future catastrophes. Their attention becomes fixed on signs of threat, danger, and/or uncertainty. When clients have panic disorder, for example, they predict that a bodily or mental sensation (or a small set of sensations) will precipitously increase and lead to a catastrophe.

Behaviorally, clients with anxiety disorders tend to engage in maladaptive "safety behaviors," coping strategies to ward off anxiety, such as avoidance of situations in which they feel vulnerable, reassurance seeking (from other people and the internet), and excessive checking. These strategies prevent individuals from being exposed to situations that would have demonstrated to them that anxiety, while uncomfortable, is not dangerous.

Anxiety and worry are often triggered by an intolerance of uncertainty, or a view of ambiguous or uncertain situations as upsetting and stressful. When worrying about uncertainties, individuals experience a negative problem orientation. They do not trust their ability to solve the problems that are the focus of worry, and they perceive problems as threats. They continue to predict unfortunate or even catastrophic outcomes and they continue to worry, hoping to find just the right solutions. Worry has also been proposed to be a form of cognitive avoidance.

Eating Disorders. Anorexia nervosa and bulimia nervosa have been extensively studied and a cognitive model has been developed for each disorder. However, Fairburn and colleagues (2003) proposed that the disorders share the same underlying psychopathology. Their transdiagnostic model postulates that individuals diagnosed with eating disorders evaluate their self-worth disproportionately both in terms of their eating habits, shape, or weight and in their ability to control these factors. Their preoccupation with how they see themselves may have been influenced by early life factors, such as parents or peers who placed too much emphasis on or were overly critical of their weight or shape.

The difference between the two disorders is hypothesized to be the result of the compensatory behavior used to cope with negative self-evaluations or other triggers related to eating, body image, or sense of control. Patients with anorexia predominantly cope by restricting food

Telegram: @medical_k

www.konkur.in

intake and/or engaging in excessive exercise, while individuals diagnosed with bulimia use a compensatory strategy such as purging when they perceive they have overeaten or engaged in binges. In contrast, patients with binge-eating disorder do not use compensatory strategies after a perceived binge.

Many patients with binge eating disorder or bulimia have difficulty with emotion regulation and turn to food as a means of eliminating negative affect. Although their mood temporarily improves while they are eating, negative affect returns more intensely afterward in the form of disgust, embarrassment, guilt, or depression, further strengthening negative beliefs about the self.

Substance Use Disorders. Individuals may begin to use substances to obtain pleasure; feeling “high” may improve their experience of activities. Or they may begin to use substances to decrease or eliminate unwanted experiences such as negative emotion or physical pain. Once substance use has started, several factors may contribute to becoming dependent on the substance, including beliefs such as, “If I use, I can endure the stress and frustration of life;” “I can escape or avoid distress.” Individuals for whom substance use is a problem also tend to have negative core beliefs. The activation of these beliefs leads to dysphoria; the individual focuses on the negative emotion and then has a permission-giving cognition which leads to the compensatory behavior of substance use to alleviate or cope with the distress. They may also use because of their belief, “I won’t enjoy myself if I don’t use.” As substance use becomes more frequent, external, and internal triggers become associated with use. These triggers also become associated with the experience of cravings and urges; they may believe “I have no choice; I have to give in to urges,” “Cravings are uncontrollable,” and “This craving will never go away unless I use.”

As substance use increases, individuals are likely to encounter financial, social, and/or medical problems about which they have negative cognitions, leading to negative mood states and subsequent substance use. Their focus of attention is excessively inward, as they monitor themselves for dysphoria. They generally minimize potential consequences or develop additional permission-giving beliefs. The cycle of substance use is maintained by the dysfunctional beliefs about the self, substance use, cravings and urges, permission to use, and negative mood states.

Telegram: @medical_k

www.konkur.in

Schizophrenia. The negative symptoms of schizophrenia are mediated by dysfunctional beliefs: “I’m powerless”; “I’m defective”; “People will reject me”; “I’ll fail at anything I try.” Delusions are believed to develop, in part, due to information processing biases, cognitive errors, and impaired reality-testing. Individuals experiencing delusions tend to perceive themselves to be the center and central focus of events, while also interpreting their subjective experiences as having an external causation. A cognitive model of hallucinations describes factors that are precursors to hallucinations, lead individuals to fixate on them, and then maintain their occurrence. One predisposing factor is a low threshold for internal auditory and visual imagining that seems real or almost real. This low threshold interacts with activated cognitive schemas that produce cognitions related to the schema and not to reality. For instance, an individual with a “failure” schema may have an intrusive, automatic thought that is perceived as an auditory hallucination saying, “You can’t do anything right.” The hallucination is perceived as coming from an external source due to externalization bias, cognitive errors, and impaired reality testing. Hallucinations are maintained by dysfunctional beliefs such as “These voices are real.” Safety behaviors, such as avoidance, are also used to minimize the presence or impact of hallucinations.

Beliefs about positive symptoms, in addition to the symptoms themselves, influence the development and maintenance of negative symptoms of schizophrenia. Moreover, as positive symptoms are often triggered in social situations, individuals may develop an aversion to socialize and choose to reduce social contact. Overall activity level may also decrease as individuals become excessively focused on delusions and/or hallucinations and less focused on engaging in valued activities. Additional factors that influence the development and maintenance of negative symptoms are negative beliefs about one’s performance, low expectations for obtaining pleasure and success, and the perception of having limited resources for engaging in activities, for example, too little energy.

Personality Disorders. As with the previously discussed disorders, personality disorders develop from the interplay of genetic and epigenetic factors and the meaning individuals put to their early adverse or traumatic experiences. The schemas present in individuals with personality

Telegram: @medical_k

www.konkur.in

disorders resemble those present in other syndromes, but they tend to be more rigid and remain activated on a more or less continuous basis.

Each personality disorder is characterized by a specific set of beliefs, assumptions, and coping strategies. An individual with dependent personality disorder, for example, may have a belief of helplessness and cope by attaching to and depending on others. An individual with avoidant personality disorder usually has core beliefs of emotional vulnerability and unlovability and avoids not only social interactions but also thinking about situations that could lead to emotional distress. When individuals have comorbid personality disorders, they often hold multiple sets of dysfunctional beliefs that cross diagnostic lines.

TECHNIQUES

The goal of CBT is to help clients reach collaboratively set treatment goals, live a valued life, facilitate remission of their presenting problems and/or psychiatric disorders, and prevent or reduce relapse by teaching patients skills they can use for their lifetime, within a highly supportive, collaborative relationship. Both patients and clinicians are active participants, jointly resolving current issues, especially those that interfere with goal attainment, through a variety of strategies, including teaching patients to evaluate their cognitions and working toward needed behavioral change. As a result, patients' symptoms are reduced, their mood and day-to-day functioning improve, they are able to live in greater accordance with their values and aspirations, they are more resilient, and they have an increased sense of purpose, hope, and well-being. Many patients achieve treatment goals and remission without exploration of childhood issues. When longstanding highly dysfunctional beliefs acquired in childhood interfere with "standard" treatment focused on present-moment experiences, as may be the case when working with patients with personality disorders, clinicians may help patients restructure the meaning of early experiences and apply what they have learned to help them overcome current difficulties.

In this section, we describe how clinicians use CBT techniques in a standard 50-minute appointment with an individual outpatient. Many of the techniques, however, can be used in brief sessions.

Clinicians may adapt techniques from almost any psychotherapeutic modality, using them in the context of a cognitive conceptualization of the

Telegram: @medical_k

www.konkur.in

patient. In recent years, cognitive therapists have drawn on techniques from the range of evidence-based therapies, including dialectical behavior therapy, exposure therapy, cognitive processing therapy, acceptance and commitment therapy, and compassion-focused therapy. Techniques from positive psychology, psychodynamic psychotherapy, mindfulness-based therapies, interpersonal therapy, and others are adapted and used with some patients.

As part of the initial assessment, clinicians collect data to diagnose patients' difficulties. Treatment is guided by both a problem-focused and a strength-focused formulation. Clinicians begin to formulate a cognitive conceptualization of individual patients and their strengths and difficulties; they refine this conceptualization at each session, as they receive additional data. They hold their hypotheses as conditional, subject to confirmation by the patient.

Clinicians use this ongoing conceptualization to plan treatment across sessions and within sessions. An accurate conceptualization allows the clinician to appropriately select and adapt techniques. Clinicians also take into consideration the patient's goals, stage of treatment, degree of distress, personal characteristics and preferences, and values and aspirations. They consider the strength of the therapeutic alliance, the nature of the problem or goal under discussion, the amount of time remaining in the session, and other factors. When suggesting an intervention, they provide a rationale and elicit the patient's agreement. They often check on the intensity of patients' emotions before and after an intervention, to assess whether additional strategies might be needed. Two questions also help guide the selection of techniques: How can I help the patient feel better by the end of the session? How can I help the patient have a better week?

The strategies described below are somewhat artificially grouped, as many techniques fall into more than one category. For example, most behavioral techniques contain both cognitive and behavioral components and vice versa.

Therapeutic Relationship Techniques

Clinicians use good Rogerian counseling skills: warmth, support, accurate understanding and reflection, genuineness, empathy, realistic optimism, and compassion. They use positive reinforcement to praise and encourage change. They show genuine interest in their patients and may

Telegram: @medical_k

www.konkur.in

deliberately be more conversational at times, for example, when inquiring about positive experiences patients had in the previous week. They also make judicious use of self-disclosure. Clinicians are highly collaborative and seek patients' feedback. During sessions, they are attuned to patients' affect, and when they notice a negative shift, they ask patients how they are feeling and what they are thinking. When patients provide negative feedback, clinicians positively reinforce them and mutually develop a plan to address patients' concerns. Clinicians also routinely ask for feedback at the end of sessions: "What did you think of the session?… Was there anything that bothered you or anything you thought I didn't understand? . . . . . Is there anything you want to do differently next time?"

Some patients, especially those with personality disorders, bring dysfunctional beliefs about other people and relationships to treatment and may react to clinicians in dysfunctional ways. Clinicians work through therapeutic relationship problems, helping patients evaluate their beliefs about the clinician. They then help clients generalize what they have learned to other relationships. It is essential for clinicians to vary their interpersonal style according to the preferences and sensitivities of patients. Some patients prefer a close, warm relationship while others react poorly to direct expressions of empathy or self-disclosure and prefer a more clinical approach.

Finally, research has demonstrated that a reduction in symptoms leads to a better therapeutic alliance. Therefore, it is important to spend sufficient time developing a good working relationship with patients, but clinicians need to keep as their central focus the facilitation of cognitive, emotional, and behavioral change so patients are equipped to deal more effectively with their difficulties outside of the therapy session.

Structuring Techniques

CBT sessions tend to follow a standard structure, as it allows patients to gain the most from the appointment. The structure is implemented flexibly, though, and sometimes has to be modified, especially initially, if patients react negatively.

At the beginning of sessions, clinicians do a mood check. Research has shown that psychotherapy is more effective when including feedback on treatment progress. Clinicians ask for an update (of positive and negative events) since the previous session, and elicit patients' conclusions about their positive experiences, successes, or improvement to foster positive

Telegram: @medical_k

www.konkur.in

beliefs and build confidence. Patients' Action Plans (therapy homework) are reviewed; these self-help assignments have been demonstrated to enhance therapy outcomes. Clinicians also set an agenda for the current session ("What problems/issues do you most want my help in solving today?" or "What are your goals for today's session?"). Clinicians may contribute items to the agenda, too. Then they collaboratively prioritize agenda items. If later in the session patients bring up items that were not on this initial agenda, the clinician notes the change of topic, and they make a collaborative decision about whether to return to the initial item under discussion or to continue discussing the newly identified topic or difficulty.

In the middle of sessions, clinicians focus on the problem or goal that is most important to the patient. They ask patients to recall a specific recent instance in which they felt the most distressed about the problem or they may ask clients to identify a problem they expect to encounter in the coming week as they are pursuing an important goal. Therapists then seek additional data, summarize their perception of the patient's experience in the form of the cognitive model, and ensure that they correctly understood the patient.

The clinician might then propose an intervention aimed toward any part (or at several parts) of the cognitive model. For example, they might do problem-solving about the problematic situation, evaluate the client's automatic thoughts, elicit, and examine the patients' deeper beliefs, teach the patient emotional regulation skills, or do behavioral skills training. When they have finished discussing the problem or goal, patients are asked what they want to remember (and clinicians might suggest additional points). This summary is recorded as therapy notes that clients read daily as part of their Action Plan. At the end of sessions, clinicians ensure that patients have a good grasp of key points of the session and are highly likely to read their therapy notes and carry out their Action Plans. Then they elicit and respond to feedback.

Cognitive Techniques

The clinician elicits patients' thinking when they have experienced a significant affect shift, have engaged in significantly dysfunctional behavior, or have experienced an obstacle to progress. Clinicians generally ask, "What was just going through your mind?" or "What were you thinking?" Automatic thoughts may be in verbal and/or imaginal form.

Telegram: @medical_k

www.konkur.in

Clinicians share their conceptualization with the patient; then they often collaboratively decide to evaluate the patient's thoughts.

Guided discovery, primarily through Socratic questioning, is the major methods for helping patients assess their thinking. Typical techniques involve labeling distortions, reality testing the evidence for and contrary to the thoughts, seeking alternative explanations, decatastrophizing, examining the utility of the thought, and asking patients to consider how they would advise another person who had the same thoughts (Fig. 32.9–2).

If the process of evaluation results in a positive affect shift, the clinician makes sure patients' new understandings are recorded, on cards, in a notebook, or on a smartphone so patients can reflect on these new ideas daily. When thoughts are in imaginal form, clinicians often use imaginal techniques in addition to or instead of verbal techniques.

Sometimes a realistic appraisal of patients' thinking indicates that a given thought is largely valid. In this case, the clinician may engage them in problem-solving, identifying, and assessing the deeper meaning they have attached to their thoughts, and/or moving toward acceptance of the situation, along with focusing on ways to enrich other parts of their lives.

What is the evidence that your thought is true? What is the evidence on the other side?

What is an alternative way of viewing this situation?

If the worst happened, how could you cope? What's the best that could happen? What's the most realistic outcome of this situation?

What is the effect of believing your automatic thought, and what could be the effect of changing your thinking?

If your [friend or family member] were in this situation and had this automatic thought, what advice would you give him or her?

What would be good to do?

FIGURE 32.9–2. List of Socratic questions. (Reprinted from © Beck J. *Cognitive Behavior Therapy: Basics and Beyond*. 3rd ed. Guilford Press; 2020.)

Behavioral experiments are commonly used to help patients evaluate their predictions. Examples of techniques used in session include panic inductions (so patients can learn that no matter how intense their symptoms become, a feared catastrophe does not happen), reading a

Telegram: @medical_k

www.konkur.in

paragraph in a book (so depressed patients can learn that they have not lost the ability to concentrate), or rubbing their hands on the bottom of their shoes and refraining from washing (so patients with OCD and a fear of contamination can learn that their obsessions are inaccurate, they can withstand the anxiety, and the anxiety that arises does not increase indefinitely without resolving when they prevent themselves from engaging in a compulsion). Clinicians also help patients devise behavioral experiments to test predictions about situations that arise outside of session (such as expressing a strong preference to see if a friend becomes angry).

To identify patients' underlying beliefs (their assumptions and basic beliefs about themselves, their worlds, and others), clinicians ask patients for the meaning of their thoughts (referred to as the "downward arrow technique"), examine the recurrent themes in patients' thoughts, directly elicit a rule or attitude, review a questionnaire patients have completed, such as the Personality Belief Questionnaire (J. Beck, 2005), or provide a list of common core beliefs to see which one(s) resonate.

Clinicians use a variety of techniques to help patients assess and respond to their deeper-level cognitions. They use psychoeducation to explain how the patient's information processing system automatically processes data that seems to support their beliefs but discounts or fails to register data that contradicts it. Socratic questioning, examining advantages and disadvantages of maintaining a given belief, formulating a more adaptive, realistic belief, and historical tests of the belief are frequently used techniques. Clinicians also teach patients how to continually identify and reframe evidence that seems to support the old belief and how to identify evidence that is contrary to this belief but supports the new belief. These techniques help patients change their ideas at an intellectual level. To modify their ideas at a deeper, "gut" or "emotional" level, other techniques may be necessary. Imagery, behavioral experiments, acting "as if" the patient fully accepts the new belief as true, metaphors, and experiential techniques (such as roleplaying or psychodrama to restructure the meaning of specific current or childhood experiences) can facilitate a new understanding.

Behavioral Techniques

Problem-solving is a key technique for most patients unless they have a circumscribed problem with anxiety (e.g., specific phobia). Some patients

Telegram: @medical_k

www.konkur.in

also need to learn effective methods for solving problems and making decisions on their own. For younger patients or those with limited problem-solving skills, a more structured problem-solving approach can be used (e.g., ITCH: Identify the problem; Think about solutions; Choose one solution to put into action; “How did it work out?”).

Behavioral activation, accomplished through activity scheduling, is very important for most depressed patients and others, especially those with entrenched avoidance. Clinicians ask patients to verbally describe or track their hour-to-hour activities. They discuss which activities, usually passive and solitary, are maladaptive if overused because they maintain or worsen their mood (for example, napping, resting, watching excessive television, surfing the web, and playing video games) and which activities have the potential to bring patients a sense of mastery and pleasure or are more in line with their values. Then they formulate a plan in session to increase their active engagement, either creating a model schedule with specific activities for the full day or scheduling specific activities throughout the week. Clinicians help patients predict and respond to unhelpful thoughts just before, during, and after their activities and help them set up reminders (e.g., by setting alarm reminders or posting their schedule in a prominent place).

Some patients, especially those who are depressed, have difficulty making decisions. Creating a four-square chart of costs and benefits or advantages and disadvantages of one option versus another option can help.

Graded task assignments are important for patients who are depressed, procrastinating, or overwhelmed by what they have to do. The clinician teaches them to break a large task into smaller components. A patient whose apartment is quite messy might initially just tackle the dishes in the sink or go one room at a time with a trash bag, looking for obvious things to throw away. Tasks can also be broken down by time: spend 10 minutes separating junk mail from important mail, spend 10 to 15 minutes paying bills.

Exposure Exercises

Exposure exercises are used with anxiety disorder clients to counteract avoidance and test feared predictions. Prior to engaging in the exposure exercise, clinicians identify the patient’s predictions. They then develop a plan to engage with the stimulus, including how to determine if their feared

Telegram: @medical_k

www.konkur.in

predictions are accurate and how to cope more effectively. Clinicians emphasize an inhibitory learning approach during the exposure, which involves taking note of discrepancies between the feared predictions and what actually occurs. Patients are instructed to record the outcome immediately after the exposure, and clinicians help them draw helpful conclusions.

Various forms of exposure exercises are used based on what stimulus the patient fears and avoids. Interoceptive exposures are used to expose panic disorder clients to feared sensations (heart racing; dizziness). Imaginal exposures expose patients to feared memories or images (intrusive memories of a traumatic event). In-vivo exposures expose patients to feared and avoided external situations (driving over a bridge; answering a question during a class).

Exposure and response prevention is often used with patients who have OCD. In a graded fashion, the clinician exposes patients to feared situations that often trigger obsessions, coaching them to refrain from engaging in compulsions so they can test their predictions related to feared outcomes and increase their tolerance of anxiety.

Motivational Techniques

Patients vary in their interest and engagement in therapy. To boost motivation to engage in treatment, work collaboratively in sessions, and follow through with Action Plans between sessions, clinicians may use a variety of techniques including motivational interviewing, reminders of patients' key values and goals, an examination of advantages and disadvantages of various behavioral options, and Socratic questioning of cognitions that decrease their willingness to change.

Emotional Regulation Techniques

An important therapeutic goal is for patients to understand and accept their negative emotions and to discover that they can tolerate negative emotion without turning to maladaptive strategies such as avoidance, self-harm, aggression, or the use of substances. Psychoeducation, Socratic questioning of beliefs about the experience of emotion, and behavioral experiments to test these beliefs are often used to facilitate this understanding.

Patients also benefit from learning specific skills to better regulate their emotional arousal. They include mindfulness techniques, relaxation

Telegram: @medical_k

www.konkur.in

exercises, refocusing on an engaging or valued activity, reading therapy notes, evaluating automatic thoughts, positive social interaction or seeking support from others, and self-soothing activities such as listening to music, physical contact with a pet, walking in nature, or focus on a sensory experience. Patients may also benefit from learning self-compassion skills if their distress is related to a high degree of self-criticism.

Environmental Interventions

Some patients continually face such adverse circumstances that an environmental change is required. Patients who are emotionally or physically abused in their living environment, for example, may need help to identify a new place to live for some period of time. Other patients might benefit from an examination of the pros and cons of staying in a hostile work environment, and, if needed, coaching on job-seeking and interviewing skills.

Interpersonal Techniques

Techniques focus on solving interpersonal problems, teaching social skills, and modifying maladaptive beliefs about themselves, others (including, at times, the clinician), and relationships. Roleplaying is often used to help patients increase their facility in initiating and sustaining casual conversation, being appropriately assertive, accurately reflecting what an intimate has said, and skillfully conversing during emotional interactions. Including a family member or intimate in session, whether or not there is friction in their relationship, can help clinicians round out their conceptualization of patients and their problems and provide an opportunity for psychoeducation and cooperation in helping patients reach their goals.

Biologic Interventions and Treatment Adherence

It is important for clinicians to look broadly at patients and, for some, to encourage healthier habits: facilitating change, for example, in eating habits, caffeine intake, use of substances, and exercise. CBT for insomnia (CBTi) has been shown to be effective (van der Zweerde et al., 2019). Medication adherence can be increased by considering advantages and disadvantages of taking medication, examining interfering cognitions,

Telegram: @medical_k

www.konkur.in

promoting tolerance of side effects, behavioral experiments (such as taking the first dose in the office), and checking on practical matters such as potential problems in affording and obtaining the medication or remembering to take it.

CLINICAL ISSUES

Indications

CBT may be used to (1) eliminate or moderate the symptoms of a psychiatric disorder or psychological distress as an independent treatment or in combination with medication and/or other biologic treatment; (2) modify underlying beliefs and schemas that contribute to the development and maintenance of disorders; (3) address psychosocial problems (e.g., marital discord, job stress, caregiver burnout) that may have preceded, coincided with, or been caused by the disorder; (4) reduce the likelihood of relapse or recurrence of a disorder after symptoms have resolved; (5) increase adherence to recommended medical treatment (e.g., medication, weight-loss, diabetes management); or moderate the impact of a medical condition on level of functioning (e.g., chronic pain, cancer); (6) live a more valued, fulfilling life.

Patients. Ideal CBT patients quickly learn to recognize and label their emotions, automatic thoughts, behaviors, and the connection between these experiences. Nonetheless, patients who initially have difficulty with this kind of self-monitoring are typically able to learn these skills through instruction and practice. When patients have learning difficulties or impaired intellectual skills, they often learn better when clinicians arrange experiences and help them draw conclusions that fortify their adaptive cognitions. Accordingly, even average intelligence is not a prerequisite for treatment. Motivation for therapy is also helpful, but not required, as patients who are hopeless, unmotivated, or lethargic may become more invested in treatment as they begin to experience improvement. Patients who are new to psychotherapy often report appreciating the CBT approach as they see it as being pragmatic and comprehensible. Some long-term patients of other psychotherapy approaches may have an initial period of adjustment due to CBT's more structured nature. Nonetheless, most patients are able to make the transition, and structure can be employed flexibly for others.

Telegram: @medical_k

www.konkur.in

Clinicians. The ideal cognitive therapist is attentive, empathic, and nonjudgmental, as is desired in most models of psychotherapy. To be maximally effective in an active treatment such as CBT, clinicians need to be moderately directive in a collaborative manner. They also must be able to ask for and receive feedback in a nondefensive manner. Although a skilled clinician knows how to sit back and listen when appropriate, they do not allow long silences as a matter of routine, and they are willing to answer most questions with a therapeutically direct answer. CBT clinicians aim to be transparent and share their conceptualization and rationales for interventions. Treatment frequently lasts for weeks or months, but not usually years.

As would be expected, several studies have demonstrated a high correlation between a clinician's level of competency, as measured by the Cognitive Therapy Rating Scale (Young & Beck, 1980) and successful treatment outcomes. Competency in CBT requires more than a passive knowledge of the theory and techniques. Clinicians who wish to specialize in CBT usually require a minimum of 1 year of supervised clinical experience based on the theoretical formulation of the cognitive model, though periodic training and supervision are recommended as research validates refinement in cognitive formulations and associated treatment. Ideally, supervision is performed by an expert cognitive therapist who reviews, rates, and provides feedback on recordings of therapy sessions.

Limitations

Early outcome studies on CBT indicated that depressed patients could show significant improvement in approximately 12 weeks (of biweekly and weekly sessions). Likewise, individuals with panic disorder evinced a significant reduction in panic attacks after 4 to 8 sessions of CBT. While the short-term results are impressive, they have, at times, been interpreted too broadly, creating an inaccurate perception that all types of pathology and clinical presentations will respond as rapidly.

Research on CBT for individuals diagnosed with bipolar disorder, chronic depression, schizophrenia, and personality disorders allow for a longer course of treatment (e.g., 1 year), and results have been promising. Moreover, even for uncomplicated cases, booster sessions at longer intervals (e.g., 3 or 6 months) after termination of the course of regular treatment can help with the maintenance of treatment gains and prevent relapse.

Telegram: @medical_k

www.konkur.in

Complications

At present, there are no known complications caused by CBT when it is used properly and in the appropriate context. The model is designed to teach patients a variety of skills to manage their presenting problems, which gives them a sense of empowerment and self-efficacy. Accordingly, the CBT model does not encourage patient dependence on the clinician. Termination issues, which are relevant in any form of psychotherapy, are dealt with proactively by the clinician who explicitly educates the patient about the time-effectiveness of treatment, the importance of learning to be one's own therapist, and the use of booster sessions and self-therapy sessions. Unhelpful cognitions related to termination are addressed through standard techniques.

Clinical crises are handled with a combination of standard risk-reduction procedures (e.g., increased frequency of sessions, inclusion of significant others, emergency consultations, hospitalizations), along with a cognitive conceptualization of the crisis situation. Once an acute crisis subsides, clinicians explore the patient's vulnerability (the activation of their schemas) that was triggered by the activating event and help the patient develop alternative coping strategies for similar future situations. The goal is to help patients prevent such instances, gain confidence in their ability to cope in the future, and become generally less vulnerable to life stressors.

Contraindications

CBT has been demonstrated to be efficacious as part of a treatment package for severe and persistent mental illness, although it is generally recommended that pharmacotherapy options be assessed as part of the treatment regimen for disorders such as schizophrenia and bipolar disorder.

GOALS OF TREATMENT

CBT has three major goals. The first is to reduce patients' symptomatology and suffering as quickly as possible and help them reach remission. The second is to help clients live a more fulfilling life consistent with their values. The third is to teach them skills that they can employ long-term to increase their resilience, maintain improvement, and reduce relapse.

Telegram: @medical_k

www.konkur.in

ETHICAL ISSUES

The ethical issues that arise in many forms of psychotherapy also may arise in CBT: eliciting informed consent, reporting child abuse, breaking confidentiality when the patient's life or the lives of other people are in imminent danger, maintaining appropriate boundaries, and avoidance of dual relationships. Additionally, clinicians are cognizant of not continuing regularly scheduled sessions when ongoing treatment is no longer deemed necessary. Once patients have made strides in accomplishing their goals, are no longer experiencing acute symptoms, and have demonstrated an ability to maintain treatment gains, clinicians may suggest tapering the frequency of sessions, followed by scheduling only periodic "booster" sessions.

RESEARCH AND EVALUATION

CBT has more research evidence in support of its efficacy and effectiveness than any other form of psychotherapy, and as a result, has been argued to be the gold standard of psychotherapy (David, Cristea, & Hofmann, 2018). Systematically controlled studies have demonstrated the efficacy of CBT for a range of psychiatric disorders, including serious mental health conditions. A review of meta-analyses concluded that the strongest support for CBT therapy exists in the treatment of anxiety disorders, somatoform disorders, bulimia, anger, and general stress. CBT has been successfully adapted across populations of different ages, ethnicities, gender and gender identities, sexual orientation, socioeconomic status, and cultural backgrounds, in a wide variety of settings, including real-world settings.

A common misconception in psychological intervention research is the notion of the Dodo Bird verdict, which concludes that all psychological treatments are equal in their effects. A meta-analysis, however, concluded that CBT was significantly more efficacious than other bona fide interventions (e.g., psychodynamic, interpersonal, and supportive therapies) for anxiety and mood disorders and is considered the first-line treatment for anxiety disorders. CBT has also demonstrated superiority to other treatments when comparisons are limited to studies with high methodologic quality (e.g., random assignment, evaluator blind to condition). Additionally, Hofmann and colleagues (2012) noted that 7 of 11

Telegram: @medical_k

www.konkur.in

meta-analyses demonstrated higher response rates for CBT than comparison conditions, while only one identified lower response rates for CBT.

Researchers have used functional neuroimaging to study the influence of psychological interventions on brain function. Neuroimaging studies have demonstrated that individuals with psychological disorders tend to have different brain functioning than nonclinical controls. Interestingly, studies have found that following CBT, the brain functioning of individuals with certain psychological disorders resemble control subjects (who did not receive CBT). Neuroimaging research has also compared brain functioning of individuals undergoing treatment with CBT to those taking psychotropic medication. The results indicated that CBT causes similar changes in brain function to psychotropic medication in the treatment of OCD, SAD, specific phobias, and depression. Nonetheless, there are differences in how disorders present in terms of both symptoms and brain function. A more nuanced study found some differences in brain function between successful CBT and pharmacotherapy.

CBT has been adapted to be administered using telehealth, the internet, and computer-based formats. Video-delivered CBT has been demonstrated to be as efficacious as in-person treatment when compiling outcomes across studies. A meta-analysis concluded that internet- and computer-based CBT demonstrated large effect sizes when compared to a control group in the treatment of all disorders that were studied (depression, panic disorder, SAD, and GAD). Moreover, patient adherence was good, and patients reported being satisfied with treatment.

In sum, although CBT was originally developed as a treatment for unipolar depression and anxiety disorders, it has been successfully adapted to treat various clinical populations, including patient groups who were traditionally thought to be unresponsive to psychosocial treatments (e.g., schizophrenia). A growing body of research has demonstrated the efficacy and effectiveness of CBT in addressing various disorders and patient populations. While some researchers study mechanism of change, additional studies, using mediational analyses, should be conducted to continue to establish empirical support for the cognitive model and to aid in refining treatment. Additionally, as researchers become better able to identify biologic processes of psychological disorders, future research may attempt to integrate biologic processes with the cognitive model, consistent with the National Institute of Mental Health Research Domain

Telegram: @medical_k

www.konkur.in

Criteria initiative, which was implemented to develop an alternative, more homogenous and etiologically relevant, psychological disorder classification system to the DSM. Finally, efforts to disseminate CBT to clinicians have lagged behind the growing efficacy and effectiveness research base. Future research should place a greater emphasis on determining the most effective and efficient methods to disseminate CBT to clinicians so that patients have greater access to competently delivered evidence-based treatment.

32.10 Interpersonal Psychotherapy

ROBERT W. GUYNN, M.D.

It is more accurate to speak of the interpersonal psychotherap*ies* (plural). There have been long-term, insight-oriented, dynamically based, and open-ended interpersonal psychotherapies, and there are more modern, short-term, time-limited approaches that avoid both extensive theory and insight. What all these therapies hold in common is the belief that the interpersonal relationships of a patient, now and in the past, to a greater or lesser extent, have a role in the etiology of his or her psychopathology and its treatment. It is unfortunate that all forms of the interpersonal psychotherapies bear the same name. In order to minimize confusion, for the rest of the discussion the field will be split into the insight-oriented interpersonal psychotherapies (IO-IPT) and non–insight-oriented interpersonal psychotherapies (IPT in keeping with the current usage of that abbreviation).

HISTORY

To the American psychiatrist Harry Stack Sullivan (1892–1949) goes the honor of the title of the Father of Interpersonal Psychiatry. It was from the 1920s through the 1940s that Sullivan developed his ideas as an alternative formulation to classic psychoanalytical theory. Simply put, Sullivan theorized that everything people consider human comes from their interactions with others. He postulated that there are two basic drives: (physical) satisfaction (food, warmth, shelter, sex…) and (interpersonal) security. Security here is the sense that one is an adequate human being (having a healthy self-esteem, feeling confident to handle stress, being comfortable among others, being interpersonally competent, being relatively anxiety-free, etc.). Sullivan pointed out that not only do humans learn language and culture from the members of their family, but they also learn how to separate fantasy from reality, develop a sense of self and self-esteem (or lack thereof), develop strategies for coping with anxiety, etc. Sullivan postulated social stages of child development (rather than psychosexual ones), the normal outcome of

Telegram: @medical_k

www.konkur.in

which being the more-or-less enduring patterns of thinking and behaving that constitute one's personality. These patterns develop not so much because of inner conflicts, according to Sullivan, but as an attempt to deal with the human environment of one's family, school, and community. To the extent that these patterns are significantly maladaptive, one has a mental illness.

It is probably fair to say that, although Sullivan himself was a clinician, he is primarily remembered for his theories, through his lectures and largely posthumous books. It was left to others to flesh out the therapeutic techniques. Some, such as Frieda Fromm-Reichmann (1889–1957), Harold Searles (1918–2015), Karen Horney (1885–1952), and Hilda Bruch (1904–1984) blended some of Sullivan's ideas with more classic psychoanalytic thinking. They, thereby, were able to adapt the traditional theory and therapy to nontraditional populations, including schizophrenia. Others, such as Donald Kiesler (1933–2007), proposed alternative therapeutic strategies. Of note, among all of these early writers is the recognition that a therapist is not and cannot be a neutral observer.

The general tasks of an insight-oriented interpersonal psychotherapist are to identify patterns of behavior and thinking from the patient's history, support the self-esteem of the patient and re-enforce it appropriately, address the positive aspects of the patient, and his or her successes. The therapist is friendly, even an advocate, but not a friend. An important element of the therapy is the assumption that the therapist is a participant, and, therefore, cannot be entirely objective and cannot avoid being the target of the patient's stereotypical behavior. If the patient tends to interact with others by being manipulative, challenging, provocative, or suspicious, sooner or later they will interact with the therapist in the same way. The ability of the therapist to read his or her own reactions to the patient objectively and reflect them therapeutically is an essential part of the treatment.

Kiesler, to take but one specific example, built on Sullivan's ideas and developed a more formal therapeutic strategy. He very much emphasized that the therapy sessions are dyadic—that is, the therapist is a participant observer. He uses the term "impact messages" to designate all the feelings, thoughts, and behaviors of the therapist in response to the patient. Kiesler distinguishes several groups of impact messages: direct feelings, action tendencies, cognitive attributions, and fantasies. The therapist consciously and continuously monitors his or her reactions

Telegram: @medical_k

www.konkur.in

(impact messages) and assumes that the patient is provoking in the therapist what they provokes in other significant relationships. That is, the therapist, far from being aspiring to be neutral, uses his or her own reactions to the patient to understand the patient's maladaptive interpersonal style. The impact messages are not considered counter-transference, as such, but the essentially normal response that anyone might have to the repetitive interpersonal patterns that the patient has developed as a strategy for living, perhaps because it is what worked in the nuclear family. The difference is that the therapist's response and reactions will attempt to be therapeutic rather than "usual." In fact, the therapist's failure to respond to the patient's interpersonal psychopathology in the expected way begins to undermine the "usefulness" of the psychopathology.

For example, if a person treats people in his or her life as objects to be controlled, then there is no reason to think that the patient would treat the therapist any differently. In this example, the therapist might find themself becoming progressively irritated with the patient as the sessions go on. The therapist would then internally analyze the source of the irritation and, hopefully, ascribe it to the subtle, or not so subtle, attempts at control by the patient. This strategy makes the therapist a very active participant, monitoring his or her own feelings and reactions as a strategy to both understand and treat the patient. If the insight-oriented interpersonal psychotherapist were to choose to share his or her own reaction with the patient, in this case, the interpretation would not be to reflect back on a specific early relationship of the patient but point out to the patient what the therapist is sensing ("I feel that you are trying to control me") and wonder aloud if this is not an example of the patient's automatic and well-established behavioral pattern presumably identifiable from the patient's interpersonal history. The therapist might then discuss with the patient alternative and less stereotypic strategies.

Another example might be the shy and anxious person who treats interpersonal interactions as painful reminders and proofs of their inadequacy ("I never know what to say and must come across as stupid") will probably be looking for judgments from the therapist and be unusually sensitive to any reaction of the therapist that implies criticism. One might expect such a patient to provoke in the therapist feelings that the patient must not be criticized. The IO-IPT therapist might choose to comment to

Telegram: @medical_k

www.konkur.in

the patient that they are feeling that the patient is projecting a sense of fragility and vulnerability—is that really necessary?

In fact, Kiesler suggests for any given statement by the patient, the therapist can choose among any of the six categories of reply. They may simply respond to the manifest content of the statement or may ignore it and change the subject. One may also interpret the statement of the patient as an unconscious message either of the patient to himself or the patient to the therapist. Finally, the therapist may choose to share either his personal reflection or his reaction to the patient's statement.

In this example of IO-IPT, Kiesler therapy has four phases: (1) hooking, (2) uncovering, (3) resolving, and (4) termination. No set number of sessions is proposed. The last three phases would seem to be self-evident and do not need exposition here. The first phase ("hooking") might be worth addressing. It was an assumption that many individuals seek to come to therapy not so much to become better but to become better at their psychopathology. Such patients will quickly tire of therapy once whatever provoked their anxiety and drove them to seek help abates. The "hooking phase" is a conscious attempt by the therapist to intrigue the patient in the goal of health.

In other instances, the problem may at least partially reside outside the patient's own interpersonal style. An example would be the case of the depressed woman married to a perfectionist. Without a trace of insight, the patient pinpointed the onset of her depression to the date of her marriage. Being not as educated as her husband, she readily accepted him as an authority at all levels. His pattern was to "lovingly" make suggestions about how the patient might do things better, from how she cooked to how she held the leashes when walking the dogs. After a couple of years, the patient gradually lost much of her self-esteem and had become paralyzed when trying to make any decision. During the exploration of the pattern of the interpersonal relationship between the patient and her husband, he announced that he had found another. Much to the surprise of all, the patient was not devastated but actively threw him out and never looked back. The depression resolved.

The caveat to all of the above is the fact that such approaches have not been subjected to rigorous scientific study. However logical and attractive the theories and approaches may appear, they have not been put to sufficient testing.

TIME-LIMITED INTERPERSONAL PSYCHOTHERAPY

A more modern version of interpersonal psychotherapy, IPT, is a nonpsychodynamic, time-limited psychotherapy developed in the 1970s by Gerald Klerman and colleagues for the treatment of nonbipolar, nonpsychotically depressed outpatients. This version of IPT makes no assumptions about the causes of psychiatric illness, other than that the development and maintenance of some psychiatric illnesses occur in a social and interpersonal context and that the onset, responses to treatment, and outcomes are influenced by the interpersonal relations between the patient and significant others. Klerman's approach is reminiscent of cognitive-behavioral therapy in that the focus is on the here and now. There are, also, a set number of sessions, transference may be ignored or undermined, and a workbook may be used. As with all interpersonal psychotherapies, in IPT the focus is primarily on the patient's current and recent interpersonal relationships. Other differences between IO-IPT and IPT are that in the latter there is less interest in the origin of the problem and the therapist does not necessarily reflect on the relationship between the therapist and the patient. A major advantage of ITP over the other interpersonal approaches is that IPT can be researched.

Time-limited IPT moves through defined phases, each of which is associated with specific strategies and tasks for the therapist and patient. Its well-defined treatment strategies are aimed at resolving problems within four social domains: grief, interpersonal role disputes, role transitions, and interpersonal deficits. The overall goal is to reduce and/or eliminate psychiatric symptoms by improving the quality of the patient's current interpersonal relations and social functioning. Time-limited IPT has been found to be efficacious for major depression and has also been successfully adapted to treat other types of mood and nonmood disorders. IPT has also been successfully applied to a group format and is being evaluated in a number of trials. The extensive empirical background and theoretical foundation, as well as the strategies and techniques of IPT, are fully described in comprehensive books by Myrna Weissman and her colleagues.

Differences from Other Psychotherapies

Telegram: @medical_k

www.konkur.in

Time-limited IPT is, of course, not the only psychological approach for the treatment of psychiatric disorders. The methods and techniques of many schools of psychotherapy share common ground, including attempts to help patients gain a sense of mastery and reduce social isolation. A major difference among the therapies lies in their conceptualization of the causes of the patient's problems and the typical length and foci of treatment. Although they use similar techniques, IPT also differs from cognitive and behavioral approaches in that maladaptive thoughts and behaviors are addressed only as they apply to problematic interpersonal relations, with the goal to change the relationship pattern rather than associated cognitions. In contrast to other therapies, IPT recognizes but does not necessarily focus on the patient's personality characteristics.

The focus of IPT is on identifying and changing the maladaptive interpersonal context in which the psychiatric problem has developed and is perpetuated. It is designed to help patients identify and address largely current interpersonal problems within four domains: grief, identified as the problem area when the onset of the patient's symptoms is associated with the loss of a person or a relationship, either recent or in the past; interpersonal role disputes, which are conflicts with a significant other (e.g., a partner, other family member, coworker, or close friend) that emerge from differences in expectations about the relationship; role transitions, which include difficulties associated with a change in life status (e.g., graduation, leaving a job, moving, marriage/divorce, retirement, change in health status); and interpersonal deficits, which apply to those patients who are socially isolated or are in chronically unfulfilling relationships.

TECHNIQUES

Therapeutic Stance

Similar to the other therapies, IPT places importance on establishing positive therapeutic alliance between therapist and patient. Specifically, the interpersonal psychotherapeutic stance is one of warmth, support, and empathy. The interpersonal psychotherapist is active and advocates for the patient rather than remaining neutral. Moreover, the therapeutic relationship is not viewed as a classic manifestation of transference/countertransference, nor is it treated as a friendship. As noted, IPT is similar to many other therapies at the level of

Telegram: @medical_k

www.konkur.in

psychotherapeutic techniques and therapeutic stance but is distinct at the level of strategies.

Timeline of Treatment

The typical course of IPT lasts 12 to 20 sessions over a 4- to 5-month period. The initial phase is dedicated to identifying the problem area that will be the target for treatment. The intermediate phase is devoted to working on the target problem area(s). The termination phase is focused on consolidating gains made during treatment and preparing the patients for future work on their own (Table 32.10–1).

Initial Phase. Sessions one through five typically constitute the initial phase of IPT. After assessing the patient's current psychiatric symptoms and obtaining a history of these symptoms, the therapist explains the rationale of IPT, underscoring that therapy will focus on identifying and altering dysfunctional interpersonal patterns related to psychiatric symptomatology. To determine the precise focus of treatment the therapist will conduct an interpersonal inventory with the patient and will develop an interpersonal formulation based on this. In the interpersonal formulation, the therapist will link the patient's psychiatric symptomatology with the therapist's identification of the problem area(s). The patient's concurrence with the therapist's assessment of the problem and agreement to work on this area are essential before beginning the intermediate treatment phase.

Telegram: @medical_k

www.konkur.in

Table 32.10–1.
Phases of Time-limited Interpersonal Psychotherapy

Initial phase: Sessions 1–5
Give the syndrome a name; provide information about the prevalence and characteristics of the disorder
Describe the rationale and nature of the therapy
Conduct the interpersonal inventory to identify the current interpersonal problem area(s) associated with the onset or maintenance of the psychiatric symptoms
Review significant relationships, past and present
Identify interpersonal precipitants of episodes of psychiatric symptoms
Select and reach consensus about the interpersonal problem area(s) and treatment plan with patient
Intermediate phase: Sessions 6–15
Implement strategies specific to the identified problem area(s)
Encourage and review work on goals specific to the problem area
Illuminate connections between symptoms and interpersonal events during the week
Work with the patient to identify and manage negative or painful affects associated with his or her interpersonal problem area
Termination phase: Sessions 16–20
Discuss termination explicitly
Educate the patient about the end of treatment as a potential time of grieving; encourage the patient to identify associated emotions
Review progress to foster feelings of accomplishment and competence
Outline goals for remaining work; identify areas and warning signs of anticipated future difficulty
Formulate specific plans for continued work after termination of treatment

DIAGNOSIS AND ASSIGNMENT OF THE SICK ROLE. After a thorough psychiatric interview has been conducted, the therapist gives the patient a formal diagnosis from the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), and the patient is formally diagnosed and assigned the sick role. Therapist and patient then discuss the diagnosis, as well as what might be expected from treatment. Assignment of the sick role during this phase

Telegram: @medical_k

www.konkur.in

serves the dual function of granting the patient both the permission and the responsibility to recover. The purposes of assigning the sick role are both theoretical and practical. Consistent with the theoretical model, receiving a formal diagnosis reinforces the idea that the patient has a known condition that can be treated. The giving of a diagnosis also explicitly identifies the patient as being in need of help.

The sick role is not assigned to condescend to the patient but, rather, is designed temporarily to exempt the individual from the responsibilities in order to devote full attention to recovery. This is particularly important for patients who tend to set aside their needs and desires to care for and please others. If this applies in a particular case, the therapist may explicitly highlight the patient's excessive caretaking tendencies and encourage the patient to redirect this energy from others toward his or her recovery. In doing so, the therapist clarifies the rationale behind IPT—that by improving the patient's patterns of interpersonal functioning, the patient's psychiatric symptoms are expected to improve as well. Symptom relief starts with helping the patient to understand that his or her psychiatric symptoms are part of a known syndrome that responds to several treatments and has a good prognosis.

IDENTIFY CURRENT INTERPERSONAL PROBLEMS: THE INTERPERSONAL INVENTORY. The therapist conducts an interpersonal inventory, which includes a review of the patient's past and current social functioning and close relationships. A thorough interpersonal inventory is essential for adequate case formulation and development of an optimal treatment plan. The clinical importance of investing the time involved in conducting a comprehensive interpersonal inventory cannot be overemphasized; accurate identification of the patient's primary problem area can be difficult, but it is the key to success in therapy.

For each individual who is important in the patient's life, the following information is assessed: frequency of contact, activities shared, satisfactory and unsatisfactory aspects of the relationship, and ways in which the patient would like to change the relationship. The interpersonal inventory provides a structure for elucidating the social and interpersonal context of the onset and maintenance of psychiatric symptoms and delineates the focus of treatment. Of particular importance are changes in relationships (e.g., the death of a significant other, a change in jobs, an increase in marital discord, and disconnection from a friend). The therapist

Telegram: @medical_k

www.konkur.in

obtains a chronologic history of significant life events, fluctuations in mood and self-esteem, interpersonal relationships, and psychiatric symptoms. From this review, the therapist can make a connection between certain life experiences and psychiatric symptoms. As this interrelationship is delineated, patients understand more clearly the rationale of IPT.

ESTABLISH THE RELEVANT PROBLEM AREAS. On completion of the interpersonal inventory, the therapist develops an individualized interpersonal formulation, linking the patient's symptoms to one of the four interpersonal problem areas—grief, interpersonal deficits, interpersonal role disputes, or role transitions. Although the therapist explicitly assigns a problem area, the patient needs to concur with the salience of the problem area proposed and agree to work on it in treatment. Because the four problem areas are relatively inclusive, it is usually easy for the therapist to provide an individualized formulation. Although some patients may present for treatment with difficulties in several problem areas, the time-limited nature of the treatment necessitates a focused approach. The therapist, with the agreement of the patient, should assign one or, at most, two problem area(s). If more than one problem area is identified, the problem area that seems most likely to be responsive to treatment is addressed first. Tackling the most soluble problem first has the advantage that progress on one front often leads to progress on others. Not only are the patient's morale and overall sense of competence enhanced when progress is made on a problem, but also barriers to progress in other areas may be eroded or disappear.

COLLABORATIVELY DEVELOP TREATMENT GOALS. After the major interpersonal problem area(s) associated with the onset or maintenance of the disorder is identified, the therapist and patient work together to formulate a treatment plan with specified goals. The goals developed at this stage will be referenced at each future session and will guide the day-to-day work of the treatment. Goals should flow from the identified problem area and be designed to address it. After identification of a goal, the therapist and patient collaboratively identify specific steps the patient will take to improve relationships and socialization. To the extent possible, goals should be summarized in such a way as to include reference to specific individuals, events, and interpersonal themes to help ensure that they are as personally meaningful to the patient as possible. Before the end of the

Telegram: @medical_k

www.konkur.in

initial phase, patients may be given a written summary of their goals, which serves as a treatment contract to guide their work for the remainder of treatment.

Intermediate Phase. The intermediate phase typically lasts from 8 to 10 sessions and continues the "work" of the therapy. Once the patient and therapist have agreed on the primary problem area and have set treatment goals, the intermediate phase of treatment begins. An essential task throughout the intermediate phase is to strengthen the connections the patient makes between the changes they are making in their interpersonal life and the changes in his or her psychiatric symptoms.

During the intermediate phase, the therapist implements the treatment strategies specific to the identified problem area as specified by Weissman and colleagues (Table 32.10–2). For an in-depth discussion of the IPT goals and strategies, the therapist is encouraged to read the comprehensive text by Weissman and colleagues.

PROBLEM AREAS

Grief. Grief is identified as the problem area when the onset of the patient's symptoms is associated with the death of a loved one, either recent or past. Grief, however, may not be limited to the physical death of a loved one. Grief can also result from the loss of a significant relationship or the loss of an important aspect of one's identity. The goals for treating complicated bereavement include facilitating mourning and helping the patient to find new activities and relationships to substitute for the loss. Reconstructing the relationship—both its positive and its negative aspects—is central to the assessment of not only what has been lost, but also what is needed to counter the idealization that commonly occurs. As patients become less focused on the past, they should be encouraged to

Telegram: @medical_k

www.konkur.in

consider new ways of becoming more involved with others and establishing interests.

Role Transitions. Role transition (which can overlap with grief) includes any difficulty resulting from a change in life status. Common role transitions include a career change (promotion, firing, retirement), a family change (marriage, divorce, birth of a child), the beginning or end of an important relationship, a move, graduation from school, or diagnosis of medical illness. The goals of therapy include mourning and accepting the loss of the old role, recognizing the positive and negative aspects of both the old and new roles, and restoring the patient's self-esteem by developing a sense of mastery in the new role. Key strategies in achieving these goals include thoroughly exploring the patient's feelings related to the role change and encouraging the patient to develop new skills and adequate social support for the new role.

Interpersonal Role Disputes. Such disputes are conflicts with a significant other (e.g., a partner, other family member, coworker, or close friend) that emerge from differences in expectations about the relationship. The goals of treatment include clearly identifying the nature of the dispute and exploring options to resolve it. It is important to determine the stage of the dispute; once the stage of the dispute becomes clear, it may be important to modify the patient's expectations and remedy faulty communication to bring about adequate resolution. It may be particularly helpful to explore how nonreciprocal role expectations relate to the dispute. If resolution is impossible, the therapist assists the patient in dissolving the relationship and mourning its loss.

Interpersonal Deficits. Interpersonal deficits refer to patients who are socially isolated or who are in chronically unfulfilling relationships. The goal is to reduce the patient's social isolation by helping them to enhance the quality of existing relationships and encouraging the formation of new relationships. To help these patients, it is necessary to determine why they have difficulty forming or maintaining relationships. Conducting a review of past significant relationships will be particularly useful in making this assessment. During this review, attention should be given to both the positive and negative aspects of each relationship, as well as to an investigation of potentially recurrent patterns in these relationships. It may also be appropriate to examine the nature of the patient–therapist

Telegram: @medical_k

www.konkur.in

relationship because this may be the patient's only close relationship, and it can be observed and commented on.

FACILITATE PATIENT'S WORK ON IDENTIFIED GOALS. In structuring the intermediate phase, the IPT takes a moderate position between the extremes of being highly active and merely reactive to the patient's concerns. The therapist actively guides the patient to cover material that is relevant to the treatment goals. If the patient does not bring in material, the therapist may elicit an update or more detailed information in one of the agreed-on problem areas and goals. The need for the patient to change is stressed at regular intervals. It is important to note that this constitutes a general encouragement to change rather than pressure to take a specific course of action. Meetings during the intermediate phase should not pass without reference to the interpersonal problem areas and attendant goals. Phrases such as "moving forward on your goals" and "making important changes" are used to encourage patients to be responsible for their treatment while reminding them that altering interpersonal patterns requires attention and persistence. In sessions, unfocused conversations are redirected to central themes of treatment, and abstract and vague discussions are minimized to maintain focus. Therapists avoid asking questions that elicit general or passive responses, such as general inquiries about the patient's week. Instead, sessions open with questions such as "What would you like to work on today?" and "How have things been since we last met?" These questions keep the patients focused on recent interpersonal events and psychiatric symptoms, which the therapist attempts to link. Above all, unfocused, unproductive complaining about others should be discouraged, in which case it should be pointed out that neither the patient nor the therapist is likely to change someone else in the patient's life.

A critical goal in the intermediate phase is to facilitate and help to strengthen the patient's connections between their psychiatric symptoms and the difficulties they have in their interpersonal lives. As the patient continues making these connections and develop strategies to alter the interpersonal context in which his or her symptoms occur, the patient will disrupt the cycle. The patient is encouraged to explore the problem areas and consider ways of changing; the attempts to change then become the focus of subsequent sessions. The therapist helps the patient to remain focused by ensuring that the subject matter is relevant and by providing

Telegram: @medical_k

www.konkur.in

clarification when needed. Clarification takes the form of pointing out themes and inconsistencies or highlighting points that the patient might miss. Clarification does not extend to making interpretations, in which reference is made to a theoretical view of the disorder and its treatment. Throughout, the focus remains on the present.

The behavior of the patient toward the therapist is expected sooner or later to reveal the patient's well-practiced behavioral patterns toward significant others. These may become more obvious during the intermittent phase. It may be useful for the therapist to comment on them.

By the end of the intermediate phase, patients are often acutely aware that treatment will soon be ending. The therapist begins to discuss termination explicitly and addresses any anxiety that the patient may be experiencing regarding it. The therapist also begins to prepare the patient for emotions that may arise with termination, including grief related to the ending of treatment.

Termination Phase. In the termination phase (usually four to five sessions in length), the therapist discusses termination explicitly with the patient and assists them in understanding that the end of the treatment is a potential time of grief. During this phase, patients are encouraged to describe specific changes in their psychiatric symptoms, especially as they relate to improvements in the identified problem area(s). The therapist also assists the patient in evaluating and consolidating gains, detailing plans for maintaining improvements in the identified interpersonal problem area(s), and outlining remaining work for the patient to continue on his or her own. Patients are also encouraged to identify early warning signs of symptom recurrence and identify plans of action.

DISCUSS TERMINATION EXPLICITLY. The therapist systematically raises the issue of reactions to impending termination in each of the last several sessions. Introducing the idea that termination is an explicit stage will plant the seed that it is an important topic to discuss. Therapists always ask patients how they feel about the ending of treatment—not least because this provides an opportunity to emphasize what has been achieved and to stress the patient's competence in dealing with future areas of difficulty.

DISCUSS TERMINATION AS A POTENTIAL TIME OF GRIEF. Patient reactions to the conclusion of treatments are often varied. As therapy nears completion,

Telegram: @medical_k

www.konkur.in

and sometimes well before that, patients may develop anxiety about saying goodbye and going it alone. Because termination marks the end of a connection to the therapist, it has a theme of loss, an analog of grief. It is important to state this possibility explicitly because unacknowledged sad feelings may lead to fears of relapse and an increase in symptoms.

REVIEW PROGRESS. An important aspect of the termination phase is encouraging patients to talk about the progress they have made and giving feedback about the changes that have been seen. This review helps to consolidate the work that has been done. It is not uncommon for individuals to attribute changes in treatment to the therapist rather than to their own hard work. Misplaced credit may erode the patient's confidence in the ability for continued success and improvement without treatment. Therefore, the therapist needs to emphasize how the patient has begun to successfully manage his or her outside relationships.

ENCOURAGE MAINTENANCE OF THERAPEUTIC GAINS. Patients are encouraged to maintain the interpersonal behaviors that have led to changes in their psychiatric symptom profile, and therapists work to develop a plan for continued work on identified goals. However, there are always goals that are not accomplished within the time frame of IPT, and patients need to be aware of this. Indeed, future difficulties can be expected, and the therapist needs to cultivate a discussion of how to handle them. Patients should also be encouraged to view their psychiatric disorder as vulnerability or an "Achilles' heel," in the sense that it may recur at future times of difficulty. Guiding the patient in a discussion of strategies for managing future problems will bolster feelings of competence. It is vital to assist patients in thinking about warning signs and symptoms that suggest a need for intervention.

General Therapeutic Techniques

Throughout therapy, the therapist should maintain a consistent focus on the interpersonal context of the patient's life. Symptoms should thus be analyzed in light of the interpersonal difficulties constituting the backdrop of those symptoms. Although this approach is unique to the interpersonal psychotherapies, some of the therapeutic techniques used in IPT are similar to techniques used in other therapies. These include exploratory

Telegram: @medical_k

www.konkur.in

questions, encouragement of affect, clarification, communication analysis, and the use of the therapeutic relationship.

Exploratory Questions. The use of general, open-ended questions can facilitate the free discussion of material. This is particularly true in the initial phases of a session. For example, the therapist might say, “Tell me about your relationship with your husband.” Once this has generated discussion, progressively more specific questioning will ensue.

Encouraging Affect. IPT focuses on affect evocation and exploration. Specifically, the therapist helps patients to (1) acknowledge and accept painful affects—as the feelings are expressed, it is important for the therapist to validate and help the patient to accept them; (2) use affective experiences to bring about desired interpersonal changes—the goal is to help the patient to act more constructively in interpersonal relationships, and this may involve learning when his or her needs are met by expressing affect and when they are better met by suppressing affect; and (3) experience suppressed affects—frequently patients are emotionally constricted in situations in which others would typically experience strong emotions. For example, sometimes patients will deny feeling upset when it is clear that an upsetting interaction has just occurred. In this situation, the therapist might say, “Although you said you were not upset, it appears to me that you have shut down since mentioning the situation with your husband.” By explicitly noting the discrepancy, the therapist attempts to draw out the affect that has been suppressed.

Clarification. This technique is useful in calling attention to contradictions that may have occurred in the patient’s presentation of material and increases the patient’s awareness about what they has actually communicated. For example, contradictions between the patient’s affect and speech may be noteworthy (e.g., “While you were telling me how upset you are about your father, you had a smile on your face. What do you think that’s about?”).

Communication Analysis. This technique is used to identify any communication difficulties that the patient may be experiencing and to help the patient change ineffective communication patterns. Typically, the therapist will ask the patient to recall in great detail an important recent interaction or argument with a significant other. Together, patient and

Telegram: @medical_k

www.konkur.in

therapist work to identify any communication difficulties and find more effective communication strategies.

Use of Therapeutic Relationship. The premise behind this technique is that people have characteristic patterns of interacting with others. Use of the therapeutic relationship in IPT is less routine. If appropriate, however, the patient's thoughts, feelings, expectations, and behavior in the therapeutic relationship are explored and related to the patient's characteristic way of behaving or feeling in other relationships. In IPT it is particularly relevant and useful for patients with interpersonal deficits (the patient develops a relationship with the therapist as a model for other relationships) and interpersonal role disputes (the patient receives feedback on how they come across and thereby has the opportunity to understand the nature of his or her difficulties in relating with others).

INTERPERSONAL PSYCHOTHERAPY DELIVERED IN A GROUP FORMAT

A relatively recent approach in the ongoing development of IPT has been its use in a group format. Interest in this area emerged from the successful adaptation by Denise Wilfley and colleagues of two individually-based treatments—cognitive-behavioral therapy and IPT—to a group format for the treatment of overweight individuals with binge-eating disorder. Subsequently, Wilfley and colleagues published a book that details the procedures for implementing IPT in a group format. Numerous investigators are using group IPT to treat other patient populations and psychiatric disorders.

IPT delivered in a group format has many potential benefits in comparison to individual treatment. For example, a group format in which membership is based on diagnostic similarity (e.g., depression, social phobia, eating disorders) can help to alleviate a patient's concerns that they are the only one with a particular psychiatric disorder while offering a social environment for patients who have become isolated, withdrawn, or disconnected from others. Given the number and different types of interpersonal interactions in a group setting, the interpersonal skills that are developed may be more readily transferable to the patient's outside social life than the relationship patterns that are addressed in a one-on-one setting. Moreover, a group modality has therapeutic features not

Telegram: @medical_k

www.konkur.in

present in individual psychotherapy (e.g., interpersonal learning). The group format also facilitates the identification of problems common to many patients and provides a cost-effective alternative to individual treatment.

Techniques

Timeline and Structure of Treatment. The typical course of group IPT lasts 20 sessions over a 5-month period. It is recommended that group size ranges from six to nine members, with one or two group leaders, depending on resources and training needs. In contrast to the initial phase of individual IPT, in group IPT, the assignment of the sick role, the interpersonal inventory, the development of the problem area(s), and the development of treatment goals occur in a structured, individual, 2-hour pregroup meeting. The initial phase (sessions 1 through 5) of group IPT is then devoted to the development of positive group norms as group members test out and refine their individual target problem area(s). The intermediate phase (sessions 6 through 15) of group IPT is dedicated to group members' work on their identified problem area(s). At the midpoint of the intermediate phase, a 1-hour individual meeting is held between therapist(s) and each group member. The termination phase (sessions 16 through 20) of group IPT is devoted to the consolidation of gains made by group members over the course of treatment and the preparation of the group members for termination of the group and for future work on their own. Within 1 week of the final session of the termination phase, a 1-hour post-group meeting is held between therapist(s) and each group member. The three individual meetings (pre-, mid-, and postgroup), sequenced to correspond with critical time points in the three phases of IPT, in combination with other techniques, were designed to maintain the exclusive and strategic focus on individual patients' interpersonal problem areas—the hallmark of IPT.

Therapeutic Stance. Similar to individual IPT, the therapeutic stance of the group interpersonal psychotherapist is one of warmth, support, and empathy. The therapist is active and advocates for the group members rather than remaining neutral. The open-ended group approach used in group IPT, with its emphasis on fostering direct communication between group members, is also highly compatible with the therapeutic stance, goals, and structure of individual IPT. The approach provides a framework

Telegram: @medical_k

www.konkur.in

for facilitating interaction among group members and emphasizes the establishment of a safe environment in which patients can receive feedback on how they are perceived by others and can experiment with new and risky interactional styles. Successful implementation of an open-ended group approach requires specific training for the therapist and attention to important developmental processes.

Pregroup Meeting. The pretreatment meeting is crucial for facilitating a patient's individualized work in the first phase of group IPT. In individual IPT, the first five sessions are devoted to a detailed examination of the patient's interpersonal history (i.e., an interpersonal inventory) and the formulation of problem areas and goals, which will guide the therapeutic work. In these critical sessions, the patient is also oriented in a more general way to the work of psychotherapy and is educated about the nature of his or her disorder and the means by which the work is used to bring about a recovery. Although it is possible to undertake individual preparation in the presence of other group members, such an approach would simply not be an efficient or therapeutically valuable use of group time. Thus, in group IPT, the 2-hour pretreatment meeting is used to focus on identifying interpersonal problem areas, establishing an explicit treatment contract to work on problem areas, and preparing patients for group treatment. After identifying a patient's interpersonal problem(s) (interpersonal deficits, role disputes, role transitions, or grief), the therapist works collaboratively with the patient to formulate concrete prescriptions for change, in addition to the specific steps the patient will take to improve social relationships and patterns of relating. These goals of treatment are expressed in language that is as specific and personally meaningful to the patient as possible. Before the start of the group, each group member is given a written summary of his or her goals and told that these goals will guide his or her work in the group.

Another important element of the pregroup meeting involves adequately preparing patients for group treatment. That is, patients are encouraged to think of the group as an "interpersonal laboratory" in which they can experiment with new approaches to handle challenging interpersonal situations. In this regard, patients are informed about the important interpersonal skills that are learned while participating in a group (e.g., interpersonal confrontation, honest communication, expression of feelings) and are encouraged to learn from others as they see changes

Telegram: @medical_k

www.konkur.in

occur. The therapist stresses to patients the importance of keeping their work in the group focused on changing their current interpersonal situations or intensifying important existing relationships and not using the group as a substitute social network.

Initial Phase. The first five sessions of group treatment comprise the initial phase of group IPT. During this phase, the therapist works to cultivate positive group norms and group cohesion while emphasizing the commonality of symptoms among members and how they will be addressed in the group context. During this phase, group members are encouraged to review their goals with the group and begin to make some initial changes in their respective interpersonal problem areas. As members begin to experiment with the changes outlined in their goals, the therapist works collaboratively with each group member to refine and make any alterations in the target areas before the beginning of the intermediate phase.

Intermediate Phase. During the intermediate "work" phase of group IPT (sessions 6 through 15), the therapist works to facilitate connections among members as they share the work on their goals with one another. In contrast to open-ended group approaches, the group interpersonal psychotherapist is much less likely to focus on intragroup processes and relationships unless they are specific to the work on the member's interpersonal problem area (e.g., interpersonal deficits). However, the therapist consistently and continuously encourages group members to practice newly acquired interpersonal skills both inside and, most important, outside of the group. As is the case with individual IPT, an essential task throughout the intermediate phase is to strengthen the connections that the group members make between difficulties in their interpersonal lives and their psychiatric problems. As with individual IPT during the intermediate phase of treatment, the interpersonal psychotherapist implements treatment strategies that are specific to the four problem areas as specified by Weissman and colleagues (Table 32.10–2).

MIDTREATMENT MEETING. The midtreatment meeting is held midway through the intermediate phase (usually between sessions 10 and 11). This meeting provides an opportunity to conduct a detailed review of each group member's progress on his or her individual problems and to refine

Telegram: @medical_k

www.konkur.in

interpersonal goals. The therapist(s) recontract with group members during this meeting as a means of outlining and emphasizing the work that remain, both inside and outside of the group, before the conclusion of treatment.

Termination Phase. In the termination phase (sessions 16 through 20), the therapist discusses termination explicitly with the group members and begins to help them to recognize that the end of treatment is a time of possible grief and loss. The therapist helps members to recognize their own progress and the progress made by other group members. During this phase, group members are encouraged to describe the specific changes in their psychiatric symptoms, especially as they relate to improvements in the identified problem area(s) and relationships. Although it is common for group members to want to keep meeting on their own or to have frequent reunions, group members are encouraged to use this phase of the group to formally say goodbye to one another and to the therapist(s). The therapist(s) also uses this time to encourage members to detail their plans for maintaining improvements in their identified interpersonal problem area(s) and to outline their remaining work. In the final session, a specific structure is established to allow each group member to give feedback to other members.

		connection with other group members	work; assist members in grieving the loss of the group

From Wilfley DE. *Interpersonal Psychotherapy for Group*. Basic Books; 2000.

POSTTREATMENT MEETING. The posttreatment meeting is scheduled within 1 week after the final group session. The therapist(s) use this final individual meeting to develop an individualized plan for each group member's continued work on his or her interpersonal problem area(s). The therapist(s) reviews the group experience and the changes the patient has made in his or her interpersonal problem area(s) and significant relationships.

Maintaining the Interpersonal Focus in Group Interpersonal Psychotherapy

Use of Group Summaries. In contrast to individual IPT, in which patients have the undivided attention of the therapist, in the early phases of group formation, patients may feel overlooked or confused about how others' interpersonal problems relate to their own. One way to address this issue is to provide weekly group summaries to group members. These four- to five-page summaries focus on the transactions that occurred during each session and their implications for each patient's recovery. Summaries include information about the group process, the common interpersonal problems of those in the group (e.g., difficulty expressing feelings, excessive caretaking of others to the detriment of meeting their own needs, conflict avoidance), and how to use the group most effectively (e.g., how to use feedback and learn from other members' work on problem areas). Wilfley and her colleagues used group summaries in their treatment study for binge-eating disorder. However, writing group summaries can be quite time intensive. Therefore, one alternative to the use of group summaries may be the use of self-help manuals. With this approach, all group members (assuming diagnostic similarity among the group membership) would receive the self-help manuals and be instructed to read them over the course of treatment. For example, Weissman developed self-help manuals for mastering

Telegram: @medical_k

www.konkur.in

depression that would be useful companions to an IPT group for depressed patients.

Use of Interventions That Are Informed by Group Stage Development Theory. As discussed earlier, maintaining the important individual focus in group IPT also requires attention to important developmental processes noted in other time-limited groups. The developmental sequence of a group merges naturally, but successful movement from one stage to another can be disrupted by an ineffectual leadership style and ill-informed intervention strategies. At the very least, a therapist unaware of group development may use interventions that lead to stagnation, and, at the worst, they may use strategies that are detrimental to an individual's progress. Therefore, to manage the group effectively while maintaining the interpersonal focus required in group IPT, it is essential that therapists understand the stages of group development. Attending to these normative transitions in the group intensifies group cohesiveness, prevents premature dropouts, and assists patients in making otherwise difficult interpersonal transitions. In addition, therapists who can predict critical transition points in the group and make stage-appropriate interventions are more likely to facilitate the work of the group and its members (Table 32.10–3).

CLINICAL ISSUES

The following case example illustrates the individual treatment of a 51-year-old woman with binge-eating disorder. This vignette highlights the therapist's presentation to the patient of the interpersonal formulation linking the onset of her eating disorder to one of the four interpersonal problem areas. As discussed earlier, the therapist's ability to discern patterns in interpersonal relationships rapidly, connect events with the onset and maintenance of the disorder, and formulate goals is crucial to the time-limited nature of IPT. In addition, this case illustrates several of the strategies and techniques used in treating the interpersonal problem area.

Telegram: @medical_k

www.konkur.in

G, a 51-year-old woman, presented for treatment of binge-eating disorder. She was college educated, had her own business, and was a divorced mother of one adult son in his early 20s. Before treatment, G had a body mass index (BMI) of 42 and had been binge eating approximately 10 to 15 days per month for the last 8 years. Along with her current diagnosis of binge-eating disorder, G struggled with recurrent major depression.

During the initial phase, G and her therapist began to review her history and the interpersonal events that were associated with her binge eating. G shared that she began overeating and gaining weight at the age of 14 years. When she was 18 years old, she moved to another country with her parents. Soon after the move, G's father left her and her mother to return to the United States. G was enraged at her father for leaving them and would still get very tearful and angry when discussing the separation. G and her mother decided to stay abroad because G had started university and her mother was working. Both had developed strong social ties and felt comfortable in their new home. During this time, G continued to gain weight and started dieting. Shortly after graduating from university, G met and married a foreign national and, at the age of 28 years, delivered their only son. Two years later, G and her husband went through a very bitter divorce. G described this as a terrible time in her life. She maintained close ties with her friends and her mother. During this time, she began to diet and reached her lowest adult weight. At the age of 35 years, when her mother died of a heart condition, G had her first episode of major depression, which was treated and resolved with antidepressants and a brief course of psychotherapy. Although G had previous cycles of weight loss and weight regain, she did not evidence any sign of eating disturbance at this point. She continued to maintain close social ties and enjoyed her close relationship with her son. When G was in her early 40s, an economic downturn in her adopted country forced her to return to the United States. Having lost all of her savings, G struggled financially while she looked for work. During this time, she started binge eating and gaining weight. Within 1 year of this move, G's son decided to return to live with his father (who was very wealthy). G felt angry and betrayed. Yet, when her son would visit, she would assume a subservient role with him because she was afraid of losing his affection. He, in turn, became quite demanding and critical of her.

Telegram: @medical_k

www.konkur.in

Before seeking treatment, her heightened feelings of isolation and loneliness were leading to increased binge eating, depression, and weight gain.

By session three of the initial phase, G's therapist began to consider which problem area would be the focus of the remainder of treatment. G had a history of important relationship losses and subsequent grief—the loss of her father, her husband, her mother, and, most recently, her son. However, none of these losses was associated with the development of binge-eating problems (although her dieting was clearly linked to her feelings of anger after the divorce from her husband, and her depression was intimately linked with her mother's death). G's anger at her son for returning to live with the enemy was clearly a role dispute, yet her binge eating had begun 2 years before his departure (although it clearly worsened after he left). Because neither of these problem areas was directly linked to the onset of the eating disorder, G's therapist decided that the focus of treatment would be to assist G in managing her role transition. Her move back to the United States, with the subsequent loss of her support and friendship networks, was clearly associated with the onset and continued maintenance of her binge eating. During the fourth session of the initial phase, G's therapist shared her formulation of the problem area with her:

"From what you have described, your binge eating really began after you returned to the United States. After that transition, you were more isolated and alone than you have ever been. It seems that binge eating was a way for you to manage that transition and the subsequent feelings of isolation and loneliness. Your transition has also had a negative impact on your relationship with your son. Even though you are a very social person and enjoy the company of others, you have yet to develop the kind of support that you had before you moved. Although you have struggled with some very significant issues over the course of your life—your father's leaving, the pain of the divorce, and the death of your mother—your friends and support systems sustained you. If we work together to help you find and develop more intimate and supportive relationships here, I believe you will be much less likely to turn to food and binge eating as a source of support or comfort."

Telegram: @medical_k

www.konkur.in

G agreed with the formulation and worked with her therapist to establish some treatment goals to help her resolve the problem area. First, she was encouraged to become more aware of her feelings (especially isolation and loneliness) when she was binge eating and of how binge eating seemed to be the way she managed those feelings. A second goal was for G to take steps to increase her social contacts and develop more friendships. The third goal, which was identified as a secondary problem area, centered on helping G to resolve the role dispute with her son. Specifically, the therapist developed a goal with G to help her to establish a clearer parental role with her son. During the intermediate phase, the therapist helped G to grieve the loss of her previous role and the extensive support that she once had. G and her therapist worked to identify several sources of support and friendships of which she had not been aware. Soon after, G reported significant progress in initiating and establishing relationships with others. This change appeared to help give her confidence in her new roles. In fact, she had begun to receive a few social invitations. She was more attuned to the ways that she would rely on food, especially when she felt lonely or felt that she was not receiving enough time from others. The connection between the lack of supportive contacts and binge eating was becoming very clear to her in these intermediate sessions. During this phase, the therapist also assisted G in setting appropriate limits in her relationship with her adult son and in recognizing his adult-like responses in return.

By the termination phase, G reported that she no longer felt so lonely and isolated and that her binge eating had all but disappeared. She remarked how the quality of her relationship with her son had changed dramatically. He was more supportive and respectful, visited more frequently, and stayed with her for longer periods of time. In the final sessions, she talked about her need to let go of the past and move on with her life as it was at that point, assuming her new roles more fully. She worked closely with her therapist to develop a plan to maintain the gains that she had made in treatment and used the final session to review the important work that she had accomplished.

Indications

Telegram: @medical_k

www.konkur.in

Indications for time-limited–oriented IPT have been defined by several efficacy trials. IPT has been shown to be effective in the treatment of mood disorders and eating disorders (bulimia nervosa and binge-eating disorder). IPT is also described by the American Psychiatric Association's (APA) *Practice Guidelines for Major Depressive Disorder in Adults* as useful for patients who face conflicts with significant others or who are having difficulty adjusting to a life transition.

Limitations

IPT has not been shown to be effective in treating substance abuse. The literature on the treatment of anxiety with IPT is evolving.

Complications

IPT is a very straightforward treatment that is highly acceptable to patients. In fact, very few, if any, complications from IPT have been noted. However, after a full course of IPT, treatment nonresponders should be evaluated for the possible prescription of an alternative, evidence-based treatment.

Contraindications

IPT was not developed to treat psychotic depression or other forms of psychosis, such as schizophrenia.

Goals of Treatment

As indicated earlier, the goal of IPT is to reduce or eliminate psychiatric symptoms by improving the quality of the patient's current interpersonal relations and social functioning.

ETHICAL ISSUES

To maintain high ethical standards, therapists wishing to conduct IPT should seek training and supervision to develop proficiency. Specific IPT training guidelines are available in the comprehensive text by Weissman and colleagues, and specific group training guidelines are available in the group text by Wilfley and colleagues. In general, interpersonal psychotherapists need to be mindful of imposing their goals and values onto their patients (e.g., pushing a patient to end a relationship). As with

Telegram: @medical_k

www.konkur.in

any psychological treatment, it is critical to thoroughly evaluate (medically and psychiatrically) all patients entering treatment to determine the best evidence-based treatment and most prudent course, including the range of treatment options.

RESEARCH AND EVALUATION

Outcome Research

IPT has been found efficacious for major depression and has also been successfully adapted to treat other types of mood and nonmood disorders.

IPT has demonstrated efficacy in the treatment of several disorders, including nonpsychotic major depression, recurrent depression, bipolar disorder, postpartum depression, dysthymic disorder, bulimia nervosa, and binge-eating disorder. In addition, a number of new research applications are under investigation for various disorders, some of which include traumatic grief, social phobia, body dysmorphic disorder, chronic somatization, borderline personality disorder, and anorexia nervosa.

IPT has been adapted for various populations, including older adults, posttraumatic stress disorder (PTSD) patients, adolescents, and patients with comorbid medical conditions (e.g., human immunodeficiency virus [HIV] infection and cancer). IPT also has been modified for long-term treatment, groups, couples, telephone intervention, primary care, and adjunctive self-help, as well as been translated into several languages. Together, these findings indicate that IPT is not only an effective and promising treatment for a range of psychiatric disorders, but also has the potential for wide dissemination.

Research Using Group Interpersonal Psychotherapy

Group IPT has recently become a topic of various research interests. It has been used to treat depression by K. Roy MacKenzie and colleagues, postpartum depression by Claudia Klier and colleagues, and binge-eating disorder by Wilfley and colleagues. Studies are underway to look at group IPT for depressed adolescents, depressed older adults, and individuals with eating disorders, PTSD, and social phobia.

FUTURE DIRECTIONS

Telegram: @medical_k

www.konkur.in

There are a number of important areas within the study and practice of IPT that warrant further consideration. First, although a number of outcome studies in IPT document its efficacy, little is known about the mechanisms by which IPT exerts its effects. How much is specific; how much is nonspecific, held in common with other psychotherapies? A greater understanding of the mechanisms by which change occurs in IPT would assist in further refinements of the treatment and yield insights into the nature of the psychiatric syndrome under investigation. Second, increased efforts to improve the effectiveness of IPT are warranted. Timing, duration, frequency of the sessions, and identifying specific therapist behaviors and patient responses associated with better outcome could be studied. Third, refining the definitions of the target populations is advisable, which would define those for whom IPT is most indicated or the treatment of choice. Fourth, there exists a need to translate IPT efficacy data into effectiveness studies and appropriate clinical practice. The decade and more has seen the expansion of applications of IPT to a wider circle of situations, many needing replication. It has also seen continued expansion beyond the English-speaking world.

32.11 Dialectical Behavior Therapy

M. Zachary Rosenthal, Ph.D., Jacqueline Trumbull, B.A., Ph.D., and Rachel Guetta, B.A.

DEFINITION

Dialectical behavior therapy (DBT) is a multimodal, cognitive-behavioral treatment originally developed to treat women who meet the criteria for BPD with a history of chronic self-harm and suicide attempts. BPD is a severe, costly, and difficult-to-treat psychiatric disorder characterized by problems across interpersonal, behavioral, cognitive, and emotional domains of functioning. Most individuals diagnosed with BPD report high rates of nonsuicidal self-injury (NSSI) and multiple suicide attempts. The lifetime mortality rates by suicide are estimated to be 50 times higher among BPD patients compared to the general population. Individuals with BPD require more mental health services and evidence higher rates of treatment dropout and relapse compared to patients with other psychological disorders. Moreover, BPD is associated with therapist burnout and is one of the most stigmatized psychological disorders. According to the American Psychiatric Association (APA), there is no single efficacious pharmacologic intervention for BPD. However, current practice guidelines recommend psychotherapy as the primary treatment for BPD, and, to date, DBT is the psychosocial treatment that has received the most empirical support for patients with BPD.

DBT was developed in the context of the broader rise of behavioral therapies and CBTs. Although behavioral and cognitive interventions are fundamental treatment strategies in DBT, this is a therapy based on the amalgamation of principles from diverse sources, including interpersonal systems, theories, and scientific research related to emotional functioning, and Eastern mindfulness and Western contemplative spiritual practices. A biosocial model featuring the reciprocally interactive effects of nature and nurture, along with a dialectical worldview, together influence case conceptualization and are woven into the transactional process between

Telegram: @medical_k

www.konkur.in

patients and therapists. As a result, DBT offers a comprehensive treatment approach that uses a wide range of interventions to create a compassionate and hopeful therapy for patients who have been historically considered “manipulative,” virtually untreatable, or even deliberately resistant.

Structurally, there are four primary modes of treatment in DBT: group skills training, individual therapy, telephone skills consultation, and a consultation team of DBT therapists. Preliminary data suggest that DBT skills training may hold promise as a stand-alone treatment for emotion dysregulation among a transdiagnostic sample. Still, there is inconclusive empirical evidence to determine which specific components and processes within DBT are necessary. Until further dismantling and component analysis studies have been completed, it is inappropriate to consider a treatment as DBT unless all of the four primary modes are being implemented. Accordingly, this chapter focuses on DBT as originally developed for the treatment of BPD. However, it also highlights several areas where DBT has been adapted for specific populations and mental health problems.

HISTORY

DBT was developed by Marsha Linehan at the University of Washington in the beginning of late 1970s. For years, she had used standard CBT strategies to work with suicidal and actively self-injurious patients. However, Linehan found that therapists’ unrelenting focus on trying to help patients change their problematic behaviors often led patients to feel invalidated. In turn, patients responded by expressing anger, ambivalence about engaging in treatment, and even threats of self-harm. Therapists working with patients diagnosed with BPD tended to report higher levels of burnout, in part, because of the sheer volume of severe and highly complex problems their patients presented during and between sessions and, in part, because they could not realistically address all of these problems in session and still have time to teach patients new skills.

Accordingly, Linehan and her team developed a multifaceted approach aimed at helping these high-risk patients who suffer tremendously from chronic and pervasive problems across many areas of their lives to create “a life worth living.” They adopted acceptance and validation strategies to balance the change-focused strategies of cognitive and behavioral

Telegram: @medical_k

www.konkur.in

therapies; they implemented skills training groups and phone coaching to ensure that patients learn new skills and generalize their learning into the naturalistic environment to cope with everyday stressors; and they added consultation team meetings in order to provide therapists with support, structured problem solving, and a context for ongoing learning and assessment of fidelity to the treatment model.

The first randomized controlled trial (RCT) for DBT was published in 1991. This study demonstrated the superiority of DBT over treatment as usual for women with BPD. Subsequently, Linehan published the DBT treatment manual and skills training manual in 1993. In her book, Linehan introduced a novel conceptualization of BPD, reframing it as a dysfunction of the emotion regulation system that can be addressed with the different components of DBT. When Linehan and her team published positive results for a second RCT in 1999, DBT became the first psychological treatment that could claim to be an evidence-based treatment for BPD, according to the criteria outlined by the APA Division 12 Task Force.

In order to facilitate the dissemination of DBT and the training of DBT clinicians around the world, Dr. Linehan established a nonprofit organization, Behavioral Tech LLC, in 2004. Around the same time, Linehan and her team developed a coding scale for rating individual and skills group sessions for adherence to the DBT treatment manual. In order to enhance adherence and competence, the DBT-Linehan Board of Certification has recently begun to offer DBT certification for individual therapists. To date, hundreds of clinicians in the United States have been certified through the DBT-Linehan Board of Certification. In 2014, the revised skills training manual was published, which features both a revision of many original DBT skills as well as the addition of select skills (e.g., the nightmare protocol for emotion regulation, walking the middle path skill for mindfulness, and new distress tolerance skills to be used) to be used with specific clinical problems (e.g., substance use).

As an empirically driven treatment, it is expected to evolve over time as a function of further research. To date, RCTs have been published from many investigators around the world examining applications of DBT for different problems (e.g., eating disorders, substance abuse problems, and depression with co-occurring personality disorders) and in different settings (e.g., outpatient private practices, inpatient psychiatric hospitals, and forensic settings). Indeed, in 2012, DBT was officially recognized by the Cochrane Review as the treatment of choice for BPD. In little over 20

Telegram: @medical_k

www.konkur.in

years, DBT advanced from a novel behavioral therapy to a gold standard intervention for BPD.

THEORETICAL ISSUES

The basic elements of DBT are outlined here. For a comprehensive description of this treatment approach, interested readers are referred to the treatment manual and group skills training manual by Marsha Linehan. The following section includes an outline of the dialectical philosophy and biosocial theory that together bind the various treatment modes and strategies of DBT. Treatment techniques and a case example are then presented, followed by a discussion of ethical issues and empirical findings related to DBT.

Dialectics

For DBT, dialectics subsumes both a worldview and a process of change. The dialectical worldview refers to an ontologic perspective of interrelatedness and wholeness applied to the understanding of human suffering. Accordingly, behavior is conceptualized contextually and systemically, across private (e.g., thoughts, feelings, physiologic sensations) and publicly observable (e.g., overt motoric behavior) experiences. The patient as a whole is treated rather than a discrete disease, disorder, or symptom. Dialectical thinking provides a solution to the tension between formalistic universalistic thinking (there is absolute truth) and relativistic thinking (there are many “truths”). Dialectics adds a third way of thinking; there is both absolute truth, and truth that is contextual and always evolving. A core feature of dialectical thinking is understanding that for every point (a thesis), an opposite position (an antithesis) can be held while searching for a synthesis between these apparent contradictions.

Throughout the course of DBT, polarities are repeatedly identified in how the patient is thinking or behaving. For example, patients might express anxious thoughts in catastrophic but unrealistic terms or, at an overt behavioral level, might repeatedly try to reduce guilt by excessively apologizing. Through consideration of opposing or contradictory ways of thinking (e.g., the catastrophe will never happen) or behaving (e.g., perhaps no apology is necessary), natural tensions arise between two possible ways of thinking or behaving. The dialectical process of change

Telegram: @medical_k

www.konkur.in

promotes the resolution of apparently contradictory stances by yielding an integrated alternative, or a synthesis, that takes into account the fluidity of a constantly dynamic context. The catastrophe is highly unlikely to occur but could still happen; apologies are necessary in some situations but not all. As another example, a patient might insist that expressing anger in a certain way helps to improve mood in the moment, whereas the therapist might insist that this anger expression actually is the problem, resulting in a polarized stalemate. Dialectical thinking would help the therapist to create a synthesis with the patient by identifying how anger expression may be effective when done in some ways and in some contexts, and, that at the same time, anger expression in some contexts can exacerbate problems, not solve them. Working together, the therapist and the patient may look for ways to effectively express anger in some contexts and not express anger in others contexts to minimize the extent to which anger expression is an enduring problem. In other words, the synthesis would be to neither totally inhibit anger nor express anger, but inhibit or express, depending on the context. This sensitivity to context—seeking what is needed in any given moment and moving away from extreme or rigid ways of thinking or behaving—is a principle that lies within the core of interventions in DBT.

Not only does a dialectical approach reduce extreme ways of thinking or behaving, it also explicitly provides the therapist with a process designed to give up on always being right about every issue, without losing perspective. In addition, dialectics acknowledges that the patient influences the therapist while being influenced by the therapist. Dialectical strategies, because they can be implemented in a way that is not always perfectly predictable by the patient, also may keep the patient slightly off balance (e.g., lose the rigid conviction that their perception is the literal truth). This has advantages for patients learning new behaviors, in that the conditions under which adaptive ways of thinking or behaving in session are broad and not restricted to a narrow topographical therapist behavioral repertoire. In other words, the dialectical process is designed to promote broad repertoires of patient behavior and cognitions. For patients with BPD, this means less rigid, extreme, or otherwise problematic behavior, emotions, and patterns of thinking. Of importance, this also means more flexible ways of thinking and behaving that are sensitive to coupling the patient’s values and goals with the contingencies of the present context.

Telegram: @medical_k

www.konkur.in

Although there are many dialectical tensions in DBT, the fundamental dialectic is that of *acceptance and change.* For the therapist, this entails balancing an acceptance of patients as they are in the moment with an explicit goal of meaningful change. This dialectic requires that patients and therapists accept the reality that painful emotions and thoughts exist (but not necessarily the literal truth of the content of thoughts) while simultaneously working to change dysfunctional and seemingly intractable problems. A perfectly balanced “middle-of-the-road” compromise between acceptance and change is not necessarily the goal. Instead, a synthesis of polarities may be more acceptance based in one moment and more change focused in another, depending on the context and what is likely to be most effective. This notion is akin to the need, when playing golf, to factor in the speed and direction of the wind when teeing off. The goal is to get the ball to land on the fairway, not to hit it in the air over the exact middle of the fairway; thus, the ball is sometimes hit to the left or to the right, factoring in the intensity and direction of the wind in the moment before the ball is struck.

Biosocial Theory of BPD

If dialectical thinking is the philosophical heart of DBT, then the biosocial theory of BPD forms the backbone. In articulating this theoretical model, Linehan suggested that BPD is fundamentally a disorder of the emotion regulation system and results from continuous reciprocal transactions among an invalidating environment, emotional vulnerability, and emotion dysregulation (Fig. 32.11–1). Prototypical examples of environmental invalidation are childhood sexual or physical abuse. Childhood sexual abuse may be a key etiologic feature of the disorder, with an estimated 40% to 70% of borderline individuals reporting a history of childhood sexual abuse. Childhood sexual abuse, however, does not appear to cause BPD. Indeed, meta-analytic data from 21 studies found only a moderate effect size (r = 0.28) in the association between BPD and childhood sexual abuse. As such, sexual abuse may be an important etiologic factor for some individuals with BPD, but the development and maintenance of BPD is complex and determined by a wide range of neurobiologically and socially mediated factors.

Telegram: @medical_k

www.konkur.in

FIGURE 32.11–1. Components of the biosocial theory of borderline personality disorder.

The Invalidating Environment. According to Linehan's biosocial model, the emotion dysregulation characteristic of BPD commonly emerges among individuals with emotional vulnerabilities raised within (and often still living in) an invalidating environment. The invalidating environment is broadly characterized by pervasive criticizing, minimizing, trivializing, punishing, or erratically reinforcing communication of internal experiences (e.g., thoughts and emotions), and oversimplifying the ease of problem solving. For example, a parent may pervasively communicate "You're not that upset, you're just faking it" or "You say no, but you don't really know what you want." Verbal communication is indiscriminately rejected, and the individual may be chronically pathologized as having socially undesirable personality traits (e.g., too sensitive, paranoid, or lazy). This leads to a lack of trust in self, such that those with BPD learn that what they think, feel, and do is inappropriate, untrue, unimportant, or due to shameful personal flaws. Instead, an excessive reliance on the social environment for cues on how to think, feel, or behave develops, resulting in a hypersensitivity to interpersonal cues and often impairment with the interpretation of such cues. In addition, appropriate emotional displays are pervasively punished, and extreme emotional displays are intermittently reinforced, increasing the likelihood of emotionally escalated behavior. For example, individuals with BPD may not be taken seriously at home (e.g., dismissed, criticized, etc.) until they threaten suicide or self-injury, after which they may receive nurturance, respect, soothing, and the like, which may maintain or increase the likelihood of future self-injurious behavior in similar contexts.

Telegram: @medical_k

www.konkur.in

Emotional Vulnerability. In addition to environmental invalidation, the biosocial model predicts that the emotion dysregulation problems characteristic of BPD are exacerbated by emotional vulnerability. Emotional vulnerability refers to a biologically mediated predisposition for affective instability involving genetic, intrauterine, and temperamental factors. As a construct, emotional vulnerability is defined as heightened sensitivity, heightened reactivity, and slow return to a baseline level of emotional arousal. That is, individuals with BPD respond quickly to a wide range of contextual emotional stimuli, respond with a high magnitude of physiologic arousal, and take a long time before arousal decreases to baseline. Once emotionally aroused, the slow return to baseline makes it increasingly likely that subsequent events will evoke extreme emotional responses. Similar to the searing physical pain a burn victim feels when the wind gusts, emotionally vulnerable individuals feel lasting emotional pain in response to seemingly ordinary daily events. Parents with emotionally vulnerable children are commonly frustrated and have difficulty managing their child's behavior. However, this may be particularly true for parents with existing psychopathology or significant deficits in parenting skills. In addition, high emotional vulnerability may make an already invalidating environment even worse, with a mismatch between child and parent emotionality contributing to additional invalidation, even if inadvertent. According to the model, in a reciprocal fashion, such increased invalidation may further exacerbate emotional vulnerability.

Impulsive behavior
Self-injurious behavior
Cognitive dysregulation
Dissociation
Paranoia
Interpersonal dysregulation
Chaotic relationships
Fears of abandonment
Self-dysregulation
Identity disturbances
Chronic feelings of emptiness

Emotion Dysregulation. In the context of environmental invalidation and emotional vulnerability, the biosocial model states that emotion dysregulation occurs across behavioral/motoric, physiologic, and cognitive/experiential emotional systems. In a transactional, back-and-forth manner, problems with emotion dysregulation can aggravate emotional vulnerability and intensify environmental invalidation, and these problems can then further exacerbate emotion dysregulation. As shown in Table 32.11–1, the biosocial model asserts that BPD criterion behaviors stemming from emotion dysregulation can be organized across domains of functioning (i.e., emotional, behavioral, cognitive, interpersonal, and self). Processes of dysregulation thought to mediate borderline symptoms include problems with up- or downregulation of physiologic arousal, inhibition of mood-dependent behavior, reliance on avoidance strategies, attentional dyscontrol, processing of emotional information, self-soothing, and self-validation. For example, an inability to readily up- or downregulate physiologic arousal may lead to the development of extreme behavioral dyscontrol, such as self-injurious, impulsive, and aggressive behavior. Extreme emotional arousal may narrow attention, making it difficult to turn attention away from emotionally evocative stimuli,

Telegram: @medical_k

www.konkur.in

thereby biasing interpretations of events in a fashion consistent with mood state. For DBT therapists, the biosocial model provides a framework for understanding how a variety of topographically distinct problems (e.g., self-injury, substance use, anger problems, dissociation) may be actively targeted for change through interventions aimed at similar mechanisms. Of importance, it also provides a nonpejorative, compassionate, and accepting approach sometimes difficult to adopt when working with BPD patients.

TECHNIQUES

DBT is a principle-driven, flexible, and comprehensive treatment for multidiagnostic patients. As a behavioral therapy, it is quite change focused and driven by behavioral principles and models of classical and operant conditioning. Yet, at the same time, DBT incorporates numerous acceptance-based strategies to implement when changing behavior may not be possible or effective.

There are four primary modes of treatment in DBT: group skills training, individual therapy, phone consultation, and consultation team. Other, ancillary treatments that are typically uncontrolled in DBT are pharmacotherapy and acute inpatient psychiatric hospitalization. To practice DBT, it is necessary to include all standard modes of treatment into a treatment program. Patients must be seen by a DBT-trained therapist, and therapists must participate in a DBT consultation team. The following section briefly reviews the function, process, and structure of DBT treatment modes.

Skills Training

Skill training occurs in the group format and is a skill class rather than a traditional interpersonal process-oriented psychotherapy group. The primary function of the group is the acquisition of new coping skills. The assumption is that these patients must learn specific behavioral, emotional, cognitive, and interpersonal skills not learned earlier in life. On the other hand, it is also assumed that group members are not fragile, and that emotional arousal during group provides natural opportunities for skills practice.

Groups occur on a weekly basis, typically last for 2 hours, and usually include between 4 and 10 patients, as well as two DBT-trained co-leaders.

Telegram: @medical_k

www.konkur.in

The first hour is usually devoted to a brief mindfulness practice and homework review from skills learned the previous week. During homework review, group members take turns discussing their successes and challenges in implementing skills learned the previous week. Group participation is strongly encouraged, but observations about others in the group and traditional “process” therapy are actively discouraged. During the second hour of group, new skills are taught didactically from the skills training manual. This workbook provides a wide variety of handouts and worksheets designed to decrease emotion dysregulation, including separate skill modules for distress tolerance, emotion regulation, and interpersonal effectiveness, as well as the core skills of mindfulness that are taught recurrently after each skills module.

Skills Modules: Mindfulness

Mindfulness is considered the core set of skills in DBT. Derived from Eastern meditative and Christian contemplative traditions, mindfulness is the practice of paying attention in a particular way: on purpose, in the present moment, and without judgment. Patients learn that their behavior is a function of current emotions (emotion mind) or logical analysis (reasonable mind). “Wise mind” knowing is emphasized as an integration of emotion and reasonable minds. The concept of wise mind relates to a synthesis between emotional and logical thinking, such that coping decisions are both effective and remain within personal values but do not need to be free of all of emotions. For instance, this can translate into suspension of short-term behaviors that have harmful consequences (e.g., drinking) for long-term gains in self-esteem or feelings of mastery, even if negative emotions are elicited. Wise mind can also be experienced as spiritual or “knowing from the gut” that a decision or action makes sense, given the context.

Mindfulness skills also include the ability to observe, describe, and participate fully in one’s actions in a nonjudgmental, one mindful, and effective manner. Observing refers to noticing experiences without becoming attached, allowing thoughts or other internal experiences to flow freely with full awareness. Describing follows observing and involves labeling or putting words on experiences. Participating is somewhat different and involves behaving effectively without necessarily observing and describing internal experiences (e.g., an athlete at peak performance). Being nonjudgmental, including being aware of judgments

Telegram: @medical_k

www.konkur.in

and letting go of their literal truth, is a central skill repeatedly practiced by DBT patients and therapists. Being one mindful entails a sharpening of attentional focus on one thing or activity at a time. This skill involves staying in the present moment and not becoming distracted by events in the past or concerns in the future. Finally, the focus on effectiveness is a key aspect of mindfulness. Effectiveness refers to behaving in a way that is consistent with one's values and long-term goals, which often translates to not immediately reducing distress despite adverse consequences. The emphasis on effectiveness as a DBT skill illustrates how mindfulness is a behavioral, psychological, and spiritual practice—not purely a meditational pursuit.

Skills Modules: Distress Tolerance

Patients with BPD frequently experience extreme emotional distress. Many symptoms may develop as a means of reducing chronic and intense distress, albeit in maladaptive fashion. For example, self-injurious behavior may function temporarily to reduce distressing emotional states. Beyond overtly self-injurious behavior, a wide variety of topographically distinct behaviors may function abruptly and dramatically to reduce emotional distress, such as impulsivity, risk taking, anger, and dissociation. The distress tolerance module is designed to teach patients how to tolerate aversive emotional experiences without behaving maladaptively. A list of crisis management skills is taught, including strategies for effective temporary distraction, such as activities, eliciting opposite emotions, and squeezing ice or a rubber ball. Self-soothing skills are introduced; by which patients learn intentionally to soothe themselves during periods of crisis with calming visual stimuli, sounds, smells, tastes, and objects to touch. In addition, other skills such as imaginal and relaxation exercises are taught to improve the current moment in order to avert doing something that would make a crisis even worse. Other distress tolerance skills include awareness, breathing, and half-smile exercises, as well as radical acceptance of reality in the current moment. Overall, distress tolerance skills are intended to interrupt and change habitual and problematic responses to acute emotional distress, allowing the opportunity for newer, more effective behaviors to emerge.

Skills Modules: Emotion Regulation

Telegram: @medical_k

www.konkur.in

The emotion regulation skills module is designed to help patients to better understand their emotions, reduce emotional vulnerability, and decrease emotional suffering. Specific skills taught include increasing awareness of emotions, identifying and challenging distorted ways of thinking about emotions, learning how emotions are related to problem behaviors, accurately labeling emotions, understanding the functions of emotions, reducing emotional vulnerability, increasing pleasant emotions, and *acting opposite* to behavioral urges associated with emotions. Although all of these skills are useful, the opposite-action skill is particularly helpful for most borderline patients because it can be applied in many contexts to change a variety of problematic behaviors.

The opposite-action skill provides an algorithm for knowing when to try to change an emotional response, in order to develop a new and more effective way of responding in the future. This includes first determining whether the emotion or the intensity of the emotion is justified or effective based on the current situation. Next, it is important to know the action urge of the emotion being experienced. Each emotion has its own urging component (e.g., anger—attack, fear—run, sadness—withdraw, guilt—repair, shame—hide). When the patient is experiencing an unjustified emotion that they wish to change, the skill is to go opposite to the action urge of the emotion. For example, if a patient is feeling ashamed or guilty after telling a friend that the patient feels excited about doing a new activity, opposite-action skills would teach the patient to ask first whether their behavior was egregious according to the patient's value system. If so, then a repair (e.g., apology) would be in order and would function to lower justified guilt. However, if the shame or guilt was unjustified (i.e., the patient did no wrong), then the patient would be instructed not to repair but to repeat the behavior (i.e., expressing enthusiasm about new activities) multiple times. This leads to less guilt over time as the patient learns that giving opinions does not always result in negative outcomes.

Skills Modules: Interpersonal Effectiveness

Because chaotic interpersonal relationships are a hallmark characteristic of BPD and because interpersonal stressors are a common trigger preceding suicide attempts, the development of interpersonal skills is crucial in the treatment of BPD. This skill module teaches group members how to identify factors interfering with interpersonal effectiveness, challenge common cognitive distortions associated with interpersonal

Telegram: @medical_k

www.konkur.in

situations, and determine the appropriate level of intensity for making requests or saying no in a given situation. Patients are taught what to say and how to say what they say depending on their priority in an interpersonal situation. In addition, group members are strongly encouraged to practice these skills in a wide variety of new situations. Guidelines for being taken seriously, attending to relationships, and preserving self-respect are introduced, and patients are instructed to practice developing new interpersonal skills based on these guidelines.

FIGURE 32.11–2. A typical diary card.

Individual Therapy

Individual therapy sessions with a DBT-trained therapist are typically 50 to 60 minutes once per week, but this can vary, depending on whatever is needed for a given patient in a given week. A primary function of individual therapy is to improve and maintain patient motivation. A validating environment is created in which patients are treated with compassion and acceptance. Within this context, the therapist and patient relentlessly pursue behavioral change. Skills learned during group sessions are woven into skill plans in anticipation of upcoming events. In addition, episodes of emotion dysregulation from the previous week are

Telegram: @medical_k

www.konkur.in

discussed in light of skills that could have been used. Factors interfering with progress in treatment are also discussed in individual therapy sessions, preventing problems that might impede the development of new skills and helping patients to remain engaged in treatment despite urges to dropout.

Because it may take a long time for a patient's arousal to return to baseline, care must be taken to structure sessions in a way that facilitates learning and does not lead to a depletion of attentional resources. Once they are highly aroused in session, it is common for patients with BPD to become so emotionally dysregulated that new learning is not likely to occur during the session. A mindfulness or relaxation exercise may be used toward the end of session to facilitate return to baseline arousal before the patient leaves.

Diary Cards

To monitor a variety of targets, a daily diary card is used. For example, patients rate their mood, monitor the frequency of self-injurious behavior and urges, and track other relevant targets. Figure 32.11–2 shows a prototypical diary card. The diary card is reviewed at the beginning of each session, and the therapy session is organized around targets evident on the diary card. Given the plethora of treatment targets and the possibility that patients will not remember salient events from the week, the diary card is instrumental in directing therapy sessions toward highly relevant targets.

Behavioral Analysis

To change dysfunctional behaviors, DBT uses a number of problem-solving strategies. Behavioral analysis is frequently used to identify problem behaviors and understand the relevant context in which these behaviors occur. In a nutshell, behavioral analysis involves an active, directive effort by the therapist to identify specific antecedents and consequences associated with the problem behavior being analyzed. A thorough elaboration of events before, during, and after problem behaviors facilitates the selection of appropriate treatment interventions. Based on a functional-analytic approach to behavioral assessment, the goal of behavioral analysis is prediction and control of functional classes of problem behavior rather than traditional diagnostic assessment of disease entities. In other words, in DBT, borderline symptoms are

Telegram: @medical_k

www.konkur.in

conceptualized as problem *behaviors.* These may be external, publicly observable behaviors such as self-mutilation or impulsive aggression. Alternatively, problem behaviors often are internal, publicly unobservable experiences such as self-judgmental thoughts or urge to use substances. In sum, behavior refers to anything a person does or experiences (e.g., thoughts, emotions, sensations, and overt actions). The inclusion of internal experiences as targets is consistent with other contemporary behavioral therapies and is crucial to understanding the phenomenologic experiences of the patient associated with treatment targets.

Because behavioral analysis involves explicating the links in a chain of events, it is often referred to as a chain analysis. During a chain analysis, the topography, intensity, duration, and frequency of the target problem, all are discussed. As links in the chain are explored, the DBT therapist considers the role of classical and operant conditioning. Classically conditioned behaviors are under the control of an antecedent stimulus, and operantly conditioned behaviors are under the control of consequent events. For example, strong urges to self-injure may be classically conditioned to occur after arguing with a partner. On the other hand, self-injurious behavior may be operantly conditioned by the consequences that follow, such as less hostility or increased attention from a partner. Knowing the controlling variables (i.e., antecedent or consequent) of a problem behavior informs the choice of interventions. Strategies for changing antecedents include behavioral exposure (e.g., rehearsing arguments) and stimulus control (e.g., avoid partner). In addition, other behavioral principles used during chain analyses are positive and negative reinforcement, punishment, extinction, and shaping. Doing a chain analysis is like being a detective solving a crime. All of the events that lead to and follow the problem behavior are uncovered, revealing critical links in the chain amenable to change.

Dysfunctional links in the chain are examined and replaced with more adaptive responses during a *solution analysis.* Typically, this is guided by three questions: (1) Can the patient change the circumstance? (2) Can the patient change their emotional reaction? (3) Can the patient better tolerate the pain associated with the problem? Together, the patient and the therapist collaboratively develop strategies to replace problematic links and then commit to using new solutions the next time the problem behavior emerges.

Telegram: @medical_k

www.konkur.in

Skill Enhancement

Skills learned during group sessions are enhanced in individual therapy. It is often fruitful to have patients rehearse behavior in session. Behavioral rehearsal may occur in the form of covert rehearsing of challenges to distorted cognitions or cheerleading statements said silently. Rehearsal also includes role-playing interpersonal scenarios with an emphasis on skill use. Therapists provide reinforcement and coaching, and rehearsal occurs with repetition. Whenever effective behavior occurs in session, it is the DBT therapist's job to reinforce such behavior. Alternatively, ineffective behavior evoked during session is often ignored or punished. In this way, the therapist is actively involved in *contingency management.* Positive regard is applied contingently. For example, when the patient is behaving inappropriately (e.g., threatening self-injury), the therapist remains cool and matter of fact, whereas skillful behavior (e.g., committing to not self-injure and using skills) is greeted with therapist's warmth.

Another method of facilitating skill use is to use behavioral exposure and response prevention in session. Patients will often become angry, ashamed, or fearful in session, and a range of behavioral problems may emerge in response to these emotions. Patients feeling angry may lash out, whereas patients feeling ashamed may look down or dissociate, and patients feeling fearful may abruptly terminate the session. Behavioral exposure and response prevention applied to these emotions in session would target paying attention to these emotions nonjudgmentally, observing urges to behave ineffectively, and blocking these urges by not lashing out, keeping eye contact, or remaining in the therapy room. In addition to changing the behavioral pattern, maladaptive cognitions are modified through standard cognitive therapy techniques aimed at identifying and challenging unhelpful ways of thinking.

Validation

All efficacious therapies require verification of what the patient does effectively and disconfirmation of what is ineffective. Indeed, verification of self-constructs may reduce physiologic arousal, and validation as an intervention may function to enhance patient learning by modulating arousal and enhancing the therapeutic relationship.

Although validation may mean many different things, in DBT validation is operationalized on several levels. These levels of validation are shown in Table 32.11–2 and are integral to doing DBT. In addition, validation may

Telegram: @medical_k

www.konkur.in

be explicitly verbal, or it may occur more implicitly and functionally, as when the therapist offers a tissue when an emotionally inhibited patient appears on the verge of tears. Validation may be used as pure acceptance, with no directed effort toward change. DBT therapists attempt to validate what is valid and usually ignore or if needed can invalidate what is invalid. For example, a therapist may say, “It makes sense that you felt angry in that situation, because your colleague lied about you, but cussing at her in the break room is not effective.” This requires the DBT therapist to discern carefully what is valid (i.e., feeling anger) and to apply validation thoughtfully. In addition to fostering a positive therapeutic relationship and providing a compassionate environment, validation by the therapist functions as a model for patients and may be taught directly as a set of skills.

Table 32.11–2.
Levels of Validation in Dialectical Behavior Therapy

1. Listening and observing
2. Accurately reflecting patient experiences
3. Helping patients to articulate unverbalized emotions, thoughts, and patterns of behavior
4. Communicating an understanding of behavior as valid, given past learning history or biologic vulnerability
5. Communicating an understanding of behavior as valid, given a current context or what is deemed normative
6. Providing radical genuineness, treating the individual as an equal and not as a sick and fragile patient

Telegram: @medical_k

www.konkur.in

Table 32.11–3.
Dialectical Strategies Used in Dialectical Behavior Therapy

1. Providing acceptance and change-focused interventions
2. Nurturing the patient and demanding that patients help themselves
3. Being stable and persistent, as well as flexible
4. Highlighting the patient's strengths and deficits
5. Structuring the session with an agenda, and responding to in-session patient behaviors as they occur
6. Highlighting both ends of continua, and making synthesizing statements
7. Pointing out paradoxes when present (e.g., patient's behavior, therapeutic process)
8. Using metaphors
9. Playing devil's advocate
10. Extending the seriousness or implications of patient's communication
11. Helping the patient to activate "wise mind"
12. Helping to make lemonade out of lemons
13. Allowing natural changes in therapy without attempting to control all outcomes

Dialectical Strategies

As mentioned, efficacious therapy and learning requires both confirmation and disconfirmation. Dialectical strategies are fundamentally based on this notion and revolve around behavioral acceptance (e.g., validation) and change (e.g., problem solving). Dialectical reasoning is pursued with the patient, by which the therapist helps the patient to move from a polarized position of "either-or" to a dialectical synthesis of "both-and." There are a number of specific dialectical strategies used with patients (Table 32.11–3). Of importance, to be effective, these strategies must be used with therapist genuineness, not as gimmicky techniques. On the other hand, the therapist must be willing to let go of the truth or rightness of any dialectical strategy and instead must continually search for other ways to help patients change maladaptive patterns.

Telephone Consultation

To enhance the generalization of skills, patients in DBT may contact their individual therapists for telephone consultation between sessions.

Telegram: @medical_k

www.konkur.in

Because DBT patients may experience unrelenting crises, it is crucial that therapists observe personal limits associated with telephone consultation. Telephone calls are intended to be brief and usually last less than 10 minutes. Patients are oriented during pretreatment to the purpose of skills calls and are told to call when they are unable to implement skills in necessary situations but before crises occur. To reduce inadvertent reinforcement of self-injurious behavior using warmth and validation over the telephone, DBT uses a *24-hour rule*: Patients will not receive skills help from their individual therapists until 24 hours after any self-injurious behavior. Instead, early in treatment, a contingency plan is created for occasions when patients self-injure, and DBT therapists may refer patients to this plan in the event that they call after self-injuring. In all consultation calls, DBT therapists assess for immediate danger and provide appropriate assistance when the patient is deemed to be in imminent danger of harming themself or others.

Table 32.11–4.
Consultation Team Agreements in Dialectical Behavior Therapy

1. Meet weekly for 1–2 hours
2. Discuss cases according to the treatment hierarchy (i.e., self-injurious/life-threatening behavior, treatment-interfering behavior, and quality-of-life–interfering behavior)
3. Accept a dialectical philosophy
4. Consult with the patient on how to interact with other therapists, and do not tell other therapists how to interact with the patient
5. Do not expect consistency of therapists with one another (even across the same patient)
6. Allow all therapists to observe their own limits without fear of judgmental reactions from other consultation group members
7. Search for nonpejorative, empathic interpretation of patient's behavior
8. Acknowledge that all therapists are fallible

Consultation Team

As mentioned earlier, the use of a consultation team is a necessary mode of treatment. Team members commit to weekly meetings and agree to a team structure and process (Table 32.11–4). There have been

Telegram: @medical_k

www.konkur.in

modifications and new consultation team agreements delineated, including how to develop and maintain a DBT team culture, as well as skills such as being willing to call out the “elephant in the room” when others do not. In important ways, team members treat each other with DBT by providing validation, support, and motivational enhancement strategies. This support is invaluable and can help DBT therapists with a more balanced approach toward their patients. A consultation team also provides opportunities for fresh perspectives and new solutions, helping therapists to get unstuck and become hopeful. It is not uncommon for DBT therapists periodically to become rigid in their thinking and behavior with a patient. The consultation team offers problem solving and validation for the therapist, and team members actively use a dialectical process to help find effective syntheses between polarized positions. For example, the team can help remind the therapist to continue managing contingencies in session appropriately (e.g., not being warm in response to patient hostility). If possible, it is extremely helpful to videotape therapy sessions and watch important segments during the consultation team meeting because this engenders a full appreciation for the difficulty a therapist may be having and allows the team to ensure that all members are indeed adhering to the treatment.

CLINICAL ISSUES

In DBT, problem behaviors are seen as the inevitable sequelae of dysregulated emotions or as maladaptive methods of altering emotional experiences. For example, self-injury may function to regulate dysregulated emotional responding. This theoretical stance has resulted in a treatment package that largely focuses on modifying various aspects of the patient’s emotional system and treatment formulations are apt to focus on reducing ineffective action tendencies linked with dysregulated emotions. In DBT, the problem behavior is targeted as a priority, in an effort to break cycles of reinforcement (Fig. 32.11–3). The present section begins with an outline of the assumptions and agreements of DBT, followed by a discussion of the levels and targets of treatment. A brief case example has been included to illustrate some of the strategies in DBT.

Telegram: @medical_k

www.konkur.in

FIGURE 32.11–3. How dialectical behavior therapy (DBT) works.

Assumptions and Agreements

Most therapeutic approaches have underlying assumptions about what is expected from patients and from the treatment. In DBT, these assumptions are openly discussed with patients in the first few sessions, during what may be called pretreatment (Table 32.11–5). Patients are also oriented to the philosophy, theories, levels, and modes of treatment. Patient and therapist agreements for treatment are also discussed during pretreatment sessions (Table 32.11–6). In addition, it is important for the therapist to discuss the requirement that patients commit to participating in DBT. Indeed, commitment to treatment may wax and wane over time for many psychotherapy patients. Thus, the therapist providing DBT needs

Telegram: @medical_k

www.konkur.in

continually to be alert to changes in commitment by the patient and be willing to go back and work on commitment to treatment again and again if needed.

Table 32.11–5.
Patient and Therapy Assumptions in Dialectical Behavior Therapy (DBT)

Patients

1. Patients are doing the best they can
2. Patients want to improve
3. Patients need to do better, try harder, and be more motivated to change
4. Patients must solve their current problems, regardless of who caused them
5. Patients are living lives that are unbearable as they are currently being lived
6. Patients must learn new behaviors in all relevant contexts

Therapy

1. Patients cannot fail in DBT, but the therapy or therapist can fail the patient
2. Helping patients work toward their ultimate goals in life is the most caring thing a therapist can do
3. DBT therapists need support
4. The therapeutic relationship is a relationship of two equals
5. Principles of behavior are universal, affecting both patients and therapists alike

Levels of Treatment and Treatment Targets

There are four stages of DBT. During stage I, patients often present with severe behavioral dyscontrol and life-threatening problems, including self-injurious behavior such as cutting, burning, or otherwise deliberately harming oneself physically with or without the intent to die. Patients in this stage commonly meet criteria for multiple Axis I disorders as well as BPD. In addition, unrelenting crises that may vary from week to week in content, as well as a multitude of treatment-interfering behaviors, commonly occur for these individuals. To provide a framework for therapeutic targets, a hierarchy is used to guide the therapist toward specific goals in a given

Telegram: @medical_k

www.konkur.in

session: (1) reduce life-threatening and self-injurious behaviors; (2) reduce treatment-interfering behaviors, such as arriving late to session, not attending skills training group, lying, not completing homework (e.g., diary cards), arriving to therapy intoxicated, avoiding emotions during therapy, talking excessively about topics that are not germane to the problems being targeted, etc.; and (3) reduce quality-of-life–interfering behaviors, such as drug use, dysfunctional eating behavior, anxiety, depression, and physical health problems.

Table 32.11–6.
Patient and Therapist Agreements in Dialectical Behavior Therapy

Patient Agreements

1. Stay in therapy for a specified period of time, usually 1 year
2. Attend all therapy sessions
3. Therapy will be discontinued if four consecutive sessions are missed
4. Work toward terminating self-injurious behavior and other therapeutic targets
5. Participate in skills training
6. Abide by relevant research conditions of therapy
7. Pay agreed-on fees for service

Therapist Agreements

1. Maintain competence and effort
2. Provide ethical and professional treatment
3. Be available for weekly sessions and phone consultation
4. Treat patients humanely, with respect and integrity
5. Maintain confidentiality
6. Seek appropriate consultation

Within and across therapy sessions, this hierarchy largely informs the selection of treatment targets. Often, treatment- or quality-of-life–interfering problems occur in the context of life-threatening or self-injurious behavior. In these cases, it is crucial that the DBT therapist refers to the hierarchy, targeting the reduction of life-threatening/self-injurious behavior first, even if this is less desirable than talking about something else to the patient.

Once skillful behaviors learned during treatment have replaced major life-threatening/self-injurious, treatment-interfering, and quality-of-life–

Telegram: @medical_k

www.konkur.in

interfering behaviors, patients begin stage II. During this stage of treatment, post-traumatic stress is often treated using empirically supported exposure therapy protocols while continuing to increase the patient's ability to experience aversive emotions skillfully. When post-traumatic stress is not present, longstanding difficulties with emotional experiencing and expression are targeted. For example, patients may need further to develop skills such as emotion labeling, reducing vulnerability to emotion dysregulation, emotional acceptance, or adaptive emotional change. These skills may have been learned already in stage I, but in stage II, they are generalized more directly to contexts that do not involve acute behavioral dyscontrol. Patients in this stage of DBT may revert to behavioral dyscontrol characteristic of stage I. Thus, it is crucial that stage I treatment targets (e.g., severe behavioral dyscontrol) are closely monitored while patients are in stage II.

For those who persist in DBT beyond stage II, in stage III of DBT, the therapist and patient target problems in living that are not debilitating but that interfere with experiencing *ordinary* happiness and unhappiness. This includes addressing unresolved problems with social and occupational functioning. Finally, stage IV targets a sense of completeness, spiritual growth, insight, enhanced awareness, sustained joy, and other fulfilling life endeavors. Although Linehan articulated these four stages of DBT, the first stage has been developed most thoroughly and is what has been tested and implemented for the most egregious and out-of-control behavioral problems among those with BPD.

Telegram: @medical_k

www.konkur.in

In this transcript, the patient was a 32-year-old Black man presenting for psychotherapy with BPD and substance abuse. In this prototypical example of DBT, the therapist conducted a behavioral analysis of self-injurious behavior, identified possible skills, and began to obtain a commitment to skills-based solutions.

T: It sounds like this week you hurt yourself by punching the basement wall repeatedly and then you drank a lot of alcohol. Let's do what we do and go through a chain analysis to slow the situation way down and figure out exactly what happened. Does that sound okay?

P: I know what happened. My ex-wife told me I couldn't talk to my kid on the phone because I'd had a couple drinks with my buddy Sean. She's always using the kids to try to control me and make me feel like a monster. So I lost it.

T: I know you've been really hurt by her in the past, and this kind of thing will probably keep coming up. How do you feel about the way you reacted?

P: Pretty terrible. I think I probably drank after so I wouldn't feel so ashamed.

T: Did you punch the wall in order to hurt yourself?

P: Yeah. Sometimes it seems better to feel physical pain than what I'm feeling after I talk to her. But then I wind up feeling worse.

T: How do you feel about committing to not hurting yourself again?

P: I think that's also why I feel so terrible. I had committed and I broke it. But yeah, I'm willing to commit again.

T: I know your word is important to you, and I can see that it feels really awful to have broken a commitment. But that's exactly why we do these behavioral analyses—so that we can look at what happened together that made you hurt yourself again. That way, we can stay firm to the commitment. As you know, it's really, really important to keep a strong commitment to not hurt yourself so we can get you out of this pain you've been experiencing for so long.

P: Yeah, I hear you. Okay, let's go.

T: Okay, so tell me exactly where you were when you called your wife.

P: I was in my basement because Sean and I were having beers and tooling around on the guitars. Then he left because it was my time to call my kid, so I said "bye" to him and called my ex.

T: And how were you feeling when you called her?

Telegram: @medical_k

www.konkur.in

P: I mean I never like calling her, but I was in a decent mood. Sean and I were having a good time.

T: So your mood was relatively high, and then you called your ex-wife and what happened?

P: I asked to speak to MaKayla and she said no, because I'd been drinking. She said she can always tell when I've had a drink.

T: And how did you feel then?

P: Really angry. I wasn't even drunk, and it felt like she was just trying to keep me away from MaKayla. It's like I can never just get any peace. There's always a roadblock, always a reminder of how I screwed everything up.

T: You actually look pretty overwhelmed and sad right now. You're moving around a lot in your chair and rubbing your face. Are these emotions coming up for you now?

P: Yeah, I guess (patient looks down at the floor and shakes his head).

T: Is this how you felt on Wednesday when you hurt yourself?

P: I felt a lot of things. Overwhelmed, angry, sad, frustrated, hating myself, hating her. All of them. You name it.

T: That's a whole lot of emotions to hold inside. I can understand why you would want to let them out.

P: Yeah. Well, they're all back.

T: I know going over this stuff can feel really, really hard. I appreciate you sticking it through with me. Can you tell me what happened when she said you couldn't talk to your daughter?

P: I kind of froze up and panicked. I asked nicely one more time and she said no, that I'd hurt MaKayla enough with my drinking and needed to stay away from her until I could learn to be a man.

T: That must have been awful to hear. What did you do next?

P: I had like 2 seconds of control left that kept me from cussing her out so I threw the phone and everything kind of went black. Like not literally black, but it's like the way I felt got so huge I couldn't feel anything anymore except this total loss of control.

T: Is that when you punched the wall?

P: Yeah, it's like I started punching the wall so I could get myself back in control. That's the messed up part. It actually works. I just punched the crap out of the wall and I came back into my body.

T: How did you feel when you came back?

Telegram: @medical_k

www.konkur.in

P: Like a total loser. She told me to go be a man and then I punched the wall like a teenager. So, I guess I failed at being a man again. With my wife, with my kid, and now even when I'm just alone in the basement. I even tried to dunk my face in the beer cooler full of ice, so I'd at least have tried a skill to calm myself down. Even though it was too late.

T: That's actually great you thought of using a skill, Devon. Did it help bring down your emotional arousal?

P: Maybe a little bit. Sometimes these skills feel like using duct tape to keep a house upright in a hurricane.

T: I hear you. You've gotten used to using other means to calm you down, and it can be hard to try something new. That's why it's important to get really clear on what sets these big emotions off so we can intervene when the skills have the biggest chance of working. Tell me what happened after you dunked your head in the cooler.

P: I just felt so bad I couldn't stand it. Like I couldn't look at myself, so I just blacked myself out on alcohol. I finished the cooler and then found a half-bottle of bourbon and finished myself off.

T: What do you mean by "finished yourself off?"

P: Drank until I passed out and couldn't feel anything anymore.

T: Devon, you've done a great job filling in these details for me. It's really helped me to understand. I can also see that it's a similar pattern to other times you've left interactions with your wife feeling really trapped, angry, and ashamed. Is there any point in this chain where you think you could have tried a skill earlier?

P: Maybe I could have used those 2 seconds of control I had to dunk my face in the cooler.

T: That's exactly right. Are there any other times you could have tried?

P: Maybe when she first told me I couldn't see MaKayla and I started to get really upset.

T: Absolutely. What kind of skills you could you have tried?

P: Maybe I could put my face in the cooler and then do 40 push-ups. Or just take a few breaths and try to use the mindfulness skills y'all have been teaching me. Or instead of throwing my phone, I could have called you. It's just really difficult to try this stuff when I feel like I only have 2 seconds of control.

Telegram: @medical_k

www.konkur.in

T: Yeah, it's really hard for most people to use these skills in the moment. We can't go back and fix the past, but, the good and bad news is that we can expect that you'll have more confrontations with your ex, and we can plan for the next time that happens. Are you willing to commit to practicing skills in anticipation of future conflicts with her?

P: Yes. I really don't want to punch anything again.

T: Good. Any of these skills can work. Let's choose at least two that feel most effective for you. What do you think? Which would work best, and which would you be most able to do?

P: Probably. I feel like I need something really intense and fast.

T: Would you be willing to practice one right now?

P: Okay. I'll do mindfulness practice with you

T: Fantastic. Before we do, let's just remember that when these situations arise and your emotions get really big, you are at risk for wanting to hurt yourself again, because that's calmed you down many times before. This could happen even if you use the skills. But it's really important to stay very committed to not hurting yourself. Just know if your commitment starts to waiver, I am always here for you to call, but only before you harm yourself. Deal?

P: Deal. I'm committed.

T: Okay.

ETHICAL ISSUES

Most ethical issues faced by DBT therapists are not specific to the practice of DBT. The following section includes a discussion of ethical issues commonly faced by DBT therapists across the four modes of treatment. One such example could include a patient disclosing self-harm or suicidal ideation in the context of skills group where it is not possible to do a full risk assessment in front of other group members. These types of situations are not uncommon, which is one of the reasons why it is important to have two group leaders so that one group leader can take the patient outside to assess risk and develop a safety plan. Furthermore, as discussed previously, the consultation team can also provide assistance to the therapist in managing these situations and documenting appropriately.

Telegram: @medical_k

www.konkur.in

The *Four-Miss Rule,* whereby a patient is dropped out of therapy after missing four consecutive sessions of individual or group therapy, presents an ethical dilemma for DBT therapists. On the one hand, if a patient is not receiving therapy, then they are, in a matter-of-fact way of thinking about it, simply not in therapy. Similarly, irrespective of reasons for not taking a dose of medicine, if one does not take the dose, the medicine is not going to take effect. On the other hand, there may be many reasons why patients miss 4 consecutive weeks of individual or group therapy visits. Still, after missing 4 consecutive weeks, in DBT, the patient is considered out of treatment. Ethically, at this point, the therapist or clinic is responsible for the patient until they have been successfully referred to a provider in the community. As such, the interim period presents an ethical challenge. Therapists should, therefore, carefully discuss and frequently review with their patients the DBT treatment agreement and its rationale. The intent of the *Four-Miss Rule,* for instance, is to prevent patients from simply drifting out of therapy. It is also important for therapists to be proactive in communicating with and motivating patients to remain engaged in therapy if they notice a patient is approaching four missed sessions. If a patient is out of therapy due to the *Four-Miss Rule,* the treatment team needs to support the therapist in helping the patient find treatment elsewhere, or develop opportunities to overcome the problems that led to them missing treatment in the first place. After some time and evidence that the problems have been resolved, the patient can petition to the therapist, who can consult with the team, about the pros and cons of the patient being permitted back into DBT.

Another common set of ethical challenges in DBT occurs when therapists take telephone coaching calls to generalize skills in everyday contexts where the skills need to be used. Telephone coaching introduces unique concerns related to confidentiality and risk assessment. For example, sensitive personal information is at risk if a patient loses their phone or if someone overhears the content of a coaching call. Although the purpose of telephone coaching is skills generalization, therapists often need to assess the risk for self-injurious behaviors. Doing an assessment over the course of a brief conversation on the phone can cause complications. Although there are many possible solutions to this problem, ultimately, the individual therapist leverages the individual sessions (e.g., by motivating patients to use skills and problem-solving skills use) to prevent self-harm–related crisis calls.

Telegram: @medical_k

www.konkur.in

Another ethical issue occurs in the context of DBT team consultation, and is related to the dialectical tension between communicating with other treatment team members on behalf of a patient versus allowing the patient to speak to their provider directly. Ethical guidelines require consultation among treatment providers. Although it would often be easier to provide certain information about a patient to other members of the treatment team, one important aim of DBT is to help patients learn the skills necessary to get their needs met autonomously. Across each of the modes of DBT, therapists must balance apparent conflicts between what is required ethically and what is indicated clinically.

RESEARCH AND EVALUATION

DBT has garnered sufficient empirical evidence for its efficacy in treating BPD, warranting designation as well established when utilizing criteria outlined by the Division 12 Task Force. Well established, according to these criteria, means that treatment must have demonstrated efficacy in at least two rigorous RCTs with superiority over placebo control conditions or another bona fide treatment. To date, more than 20 RCTs on full-model DBT have been conducted across multiple independent research teams, examining diverse populations, including veterans, community samples, individuals with eating disorders and substance use, and varying severities of BPD. DBT efficacy studies have been conducted in various countries, including the United States, Canada, Germany, the Netherlands, New Zealand, Spain, and Sweden. In addition, 15 RCTs on skills-only DBT have been conducted across the world, as more emerging literature highlights the centrality of skills training to the effectiveness of DBT. DBT has also been implemented and evaluated in inpatient, outpatient, school, forensic, military, and community settings. A comprehensive summary of DBT studies and adaptations is beyond the scope of this chapter; however, this section will review some recent research findings.

In a recent meta-analysis of 16 studies, 8 of which were RCTs across different research teams, DBT was associated most with reductions in suicidal and self-injurious behaviors. A more recent meta-analysis of five RCTs corroborated these findings. Although DBT was designed for individuals with BPD, research on standard DBT protocols has paved the way for more studies examining adaptations for a variety of other

Telegram: @medical_k

www.konkur.in

populations. DBT has demonstrated efficacy in the treatment of substance use disorders, eating disorders, chronic depression in older adults, and depression with co-occurring personality disorders. The use of DBT with substance use disorders leads to enhanced emotion regulation. DBT in the treatment of eating disorders can lead to decreased bingeing and purging behaviors. In depression, DBT has been found to lead to faster remission compared to medication alone. The effects of DBT may last after treatment ends. For example, at a 6-month follow-up, in one recent study, DBT was associated with reduced visits to the emergency room (ER).

In the treatment of posttraumatic stress disorder (PTSD), studies have yielded promising results suggesting that DBT is effective in the treatment of women who are actively self-harming, victims of sexual assault or harassment in the military, and adults with a history of childhood sexual abuse. For instance, DBT was found to lead to reductions in depressive symptoms and hopelessness among female victims of domestic abuse. More recent evidence has substantiated the effectiveness of DBT for PTSD (DBT-PTSD) to specifically target trauma treatment–resistant individuals. Patients undergoing DBT-PTSD, as compared to cognitive processing therapy, demonstrated lower dropout, higher rates of PTSD symptom remission, overall symptom improvement, and sustained recovery.

Recent research suggests that DBT is also effective in treating patients characterized by dysfunctional eating behaviors. This includes adaptations of DBT used to treat binge eating, as well as those designed to address co-occurring BPD and anorexia or bulimia. Another adaptation of DBT, Radically Open-DBT (RO-DBT), was associated in a pilot study with improvements in eating disorder–related psychopathology symptoms among patients with anorexia nervosa–restrictive type. A more recent multiple baseline single-case experimental design study demonstrated the efficacy of RO-DBT among 13 adult female patients with anorexia nervosa, with all completers meeting full remission after treatment.

DBT also has been adapted for children and adolescents. This development is important because the evidence suggests that DBT helps to reduce suicidal ideation and suicide risk behavior, and suicide is the third leading cause of death among youth aged 10 and 15 years. The first RCT of DBT for adolescents (DBT-A) demonstrated greater reductions in self-injurious behaviors compared to enhanced care as usual. A second

Telegram: @medical_k

www.konkur.in

multisite RCT indicated a significant advantage of DBT-A for reducing repeat suicide attempts, NSSI, and self-harm following treatment. To date, 5 RCTs, 3 controlled clinical trials, and 13 prepost evaluations of DBT-A have been conducted. Some of the ways DBT-A is different from standard DBT include the following: families are included in skills training, interventions directly target the invalidating environment (in family therapy), the length of treatment is abbreviated (from 1 year to 6 months), new skills are added (e.g., the "Middle Path"), and skills examples more relevant to teens are included in the treatment manual by Rathus and Miller. In school contexts, DBT-A has demonstrated promising results (e.g., reduction in the number of referrals to the assistant principal, detention/suspensions, and visits to the ER) in an open trial study conducted at a high school in New York. More recently, DBT-A has also been successfully applied to adolescents with bipolar disorder, street-involved youth, adolescents with binge eating, purging, NSSI, suicidal behavior, and BPD. In addition to DBT-A, DBT has also been adapted to help children (aged 8 to 11 years) to reduce self-injurious behaviors. Perepletchikova et al. found that the 6-week DBT skills group intervention led to significant decreases in depressive symptoms and suicidal ideation.

Despite its strong empirical foundation and growing list of promising adaptations, a number of gaps remain in the scientific literature examining DBT. Chief among the gaps in research is the lack of research on males and other gender, sexual, racial, and ethnic minorities. Similarly, the literature must address the increasing need to adapt DBT globally. In addition, there continues to be a need for research investigating what predicts treatment response via component, dismantling, or process-analytic studies, as well as large-sample effectiveness research in community settings. Finally, as recent modifications of DBT to diagnoses other than BPD have yielded promising results, future research will likely increasingly target transdiagnostic processes, such as emotion regulation, that are common in, but not specific to, BPD.

32.12 Solution-Focused Brief Therapy

ANNE BODMER LUTZ, B.S.N., M.D.

Solution-focused brief therapy (SFBT) is a short-term goal-focused evidence-based therapeutic approach that helps clients change by constructing solutions rather than dwelling on problems. In the most basic sense, SFBT is a hope-friendly, positive emotion–eliciting, future-oriented vehicle for formulating, motivating, achieving, and sustaining desired behavioral change. This approach to treatment is in accordance with the positive psychology movement that emphasizes well-being and optimal functioning instead of pathology and etiology. Empirically derived rather than theoretically based both in construct and practice, the SFBT approach is a goal-directed collaborative approach to psychotherapeutic change primarily conducted through direct clinical observation of clients' responses to a series of carefully constructed questions. SFBT has continued to grow in popularity, both for its usefulness and its brevity, and is currently one of the leading schools of psychotherapy in the world. Besides psychotherapy, solution-focused (SF) thinking has become a major influence in such divergent fields of education, social policy, and business.

SFBT starts by developing a detailed understanding of the patient's best hope for their future and collaboratively looks for patient-related resources and actions that build this outlook. The focus is on detailing what a patient will be doing when their problem is solved rather than diagnosis and symptom exploration. Based on the premise that people have the necessary resources to solve their problems, SFBT amplifies these strengths and abilities by building a shared dialect that focuses on what has worked and is working in a patient's life. Perhaps, there was a time that a patient was able to manage their pain and get to work on time,

Telegram: @medical_k

www.konkur.in

even if only 1 day that week. Perhaps, there was a day that a patient was able to get up and go for a walk, even if only for 10 minutes. Perhaps there was a day they were able to manage their anxiety and depression in a tolerable way. These moments are easily missed. The SFBT is skilled at listening for these moments and amplifying with patients how they were able to have these times of success. This awareness enhances hope as patients have already had success and thus can do it again.

SFBT focuses on the patient's expertise in knowing their condition best. Asking patients (and their loved ones) what they know about their condition and what they have tried that helps attest to their competence. Many patients' problems can be relapse remitting and/or change over time which can lead to a sense of uncontrollability. SFBT helps patients to focus on how they have adapted and managed to deal with their symptoms and condition in a "tolerable/bearable" way. This increases their self-efficacy in managing their condition.

EMPIRICAL EVIDENCE

SFBT is one of the few approaches in psychotherapy that began as "evidence based" versus being "theory driven." SFBT developers Steve de Shazer and Insoo Kim Berg and their team spent countless hours carefully observing real-life therapy sessions, meticulously noting any words or behavior on the part of the therapist that resulted in progress toward the client's stated goal. Language or behavior that reliably led to positive movement in the direction of the client's goal was preserved and incorporated into the SF approach, and those that did not were discarded.

There has been a great deal of empirical research on SFBT, most of it occurring over the past 15 years. The conclusion of eight meta-analyses, a number of systematic reviews, and the overall conclusion of the most recent scholarly works on SFBT are that SFBT is an effective approach to the treatment of psychological problems, with effect sizes similar to other evidence-based approaches, such as cognitive behavior therapy and interpersonal therapy, but that these effects are found in fewer average sessions, and using an approach style that is more benign. That is, the more collegial and collaborative approach of SFBT does not involve confrontation or interpretation. Given its equivalent effectiveness, shorter duration, and more benign approach, SFBT is considered to be an

Telegram: @medical_k

www.konkur.in

excellent first-choice evidence-based psychotherapy approach for most psychological, behavioral, and relational problems.

- There have been approximately 150 randomized clinical trials (RCTs, the “gold standard” of clinical research).
- Seventy-four percent of SFBT RCT studies reported significant positive benefit.
- There are been eight meta-analyses.
- Most of the research was done in “real-world” settings, so the results are more generalizable.
- Effect sizes found in these meta-analyses are in the low to high range, suggesting that SFBT is an effective approach for the populations studied.
- SFBT’s effectiveness is equivalent to other evidence-based practices, such as cognitive behavior therapy and interpersonal psychotherapy.
- While effect sizes are similar to other evidence-based approaches, these effects are attained in fewer sessions, averaging about 5 sessions and rarely extending over 8 or 10.

CORE SFBT SKILLS

Engaging in SFBT is similar to learning a new language because it requires therapists to “speak” in a way that focuses on solutions rather than their “first” language, which tends to focus on problems. The order of the SF sessions is also important. Early and throughout the interview, rigorous attention is paid to engagement through activating resources, including the patient’s individual and social strengths. This is followed by goal negotiation, exploring best hopes for treatment, and utilizing scaling questions to develop small “doable” next steps to move forward. See Figure 32.12–1 for a visual representation of the key components of SFBT.

Engagement-Activating Resources From the Start

Activating resources at the onset of the conversation is critical and helps build patient engagement. *Resource activation* is realized in interventions that focus not on the patient’s problems but rather on the sound and healthy parts of their life.

Telegram: @medical_k

www.konkur.in

Example questions to promote the activation of resources:

- What do you enjoy?
- What are you good at?
- How did you learn these skills?
- How else did you learn them?

Engagement Complimenting

Patients coping with complex challenges and conditions endure many symptoms affecting the quality of their daily life. Asking patients what they know and have tried regarding their diagnosis, condition, treatments, and medications affirms their knowledge in managing their condition. Compliments can impart much-needed energy and stamina to both patients and their loved ones. Most clinicians are fluent in what is known as the direct compliment with phrases such as “Wow!” “Congratulations!” “Good job!” Clinicians are much less fluent in the powerful and highly effective indirect compliment. Indirect compliments are in the form of a question and are used early and throughout an SF conversation.

Examples of indirect compliments:

- How did you do it (e.g., manage your pain, get to work)?
- How did you decide to do it (e.g., to take your medication, to make healthy food choices, to get the rest you require)?
- How did you choose to do it (e.g., to stop smoking, to seek help)?
- How did you manage to do it (e.g., get a better night’s sleep, get to your medical appointment)?

Engagement–Building the “Yes-set”: “For You” Statements

The yes-set is a SF skill that involves creating a conversation in which both the clinician and patient say yes and agree on as many aspects of the conversation as possible. “For you” statements enhance the “yes-set” while providing validation and acknowledgment of the patient’s predicament. Patients and families coping with complex conditions often experience feelings of lack of control, exhaustion, fear, frustration, and anxiety, requiring a great deal of “for you” responses. “For you” statements

Telegram: @medical_k

www.konkur.in

are often combined with coping questions, enabling patients to recognize how they have been managing.

Yes-set “for you” responses:

- This must be very difficult “for you.”
- This must be so frustrating “for you.”
- This must be painful “for you.”
- This must be grueling “for you.”

Coping Questions

Coping questions are based on the appreciation of how painful and intense life experiences are for many patients. Coping questions are especially helpful in shifting a patient’s narrative from one of victim and self-blame to one of courage, strength, and self-efficacy. Incorporating the one-word “cope” within the question attests that patients already have managed to have some measure of success. Other verbs can also be used in coping questions, such as endure, manage, deal with, hold up, persevere, bear, and tolerate.

Telegram: @medical_k

www.konkur.in

FIGURE 32.12–1. Key components of solution-focused brief therapy.

Coping questions:

- How have you coped with this? How else?
- How have you endured this? How else?
- How have you managed? How else?
- How have you tolerated this? How else?
- Where do you get your strength? Where else?

Effective solution building requires getting as many details as possible about prior successes. Questions that amplify details of positive coping (e.g., *How else* did you manage your symptoms? *How else* was it helpful?) leave no potential resource uncovered. It is also important to ask patients about their "good reasons" for seemingly unhelpful behaviors (e.g., medication nonadherence), as these "good reasons" can reveal how patients view these behaviors as beneficial. The question does not condone the behavior. Rather it helps patients understand their own motivation and elucidate what they could do differently. Examples include:

Telegram: @medical_k

www.konkur.in

"You must have a good reason to … not take your medications/make it to your appointments/follow-up with treatment recommendations."

Punctuating Positive Differences

Positive differences, also known as exceptions, are those times when the expected problem could have occurred but did not or was less severe. Listening for *past successes* and discovering positive differences when patients have had or are having some measure of success is crucial. These times may include when patients were able to have periods of relief from their symptoms—even if very brief. Perhaps they were able to manage a specific symptom in a tolerable way. Perhaps they had the strength to work and manage their family responsibilities despite their symptoms. Perhaps they persevered in their efforts to care for their needs and remembered to take their medications.

Questions to identify and amplify positive differences:

- Was this different for you?
- How was it different for you?
- Was it helpful for you?
- How was it helpful for you?
- How did you do it?
- How else did you do it?

Identify Those Who Are Most Important in Their Life (VIPs)

Inviting a patient to identify their VIPs and what they most appreciate about them is especially critical when engaging patients who are coping with complex conditions. Mapping out a patient's social context is essential in understanding and assisting them in building solutions. Identifying VIPs also helps patients broaden their perspective about possible unused or underutilized resources in their situation.

Telegram: @medical_k

www.konkur.in

Exploring VIPs:

- Who are the most important people in your life?
- Who else?
- What do you most appreciate about them?
- What else?
- Who has been most helpful for you in managing your situation?
- Who was concerned about you that they thought coming here would be helpful for you?
- Who relies on you?
- What do your VIPs know about you that you can get through this? What else?

Goal Negotiation—Exploring Best Hopes for Their Preferred Future

SFBT's translation of the chief complaint is, "What are your best hopes for this appointment so you can say it was helpful and worth your time?" This question is future directed, assists in goal negotiation, and conveys that patients *do have hopes*.

Asking for a patient's "best hopes" is only the beginning of goal negotiation. Moving from their "best hopes" to specific actions requires discovering with patients what they would be "doing" when they have achieved their "best hopes"? Many patients are more fluent in what they "don't want" and have greater difficulties describing what they "do" want. A patient may say their best hopes are to not have anxiety or pain. Asking patients what they would be *"doing instead" when they are managing* their pain and anxiety in a good enough way can assist patients in what they have control over.

Inviting patients to imagine a satisfying week is another way to explore their best hopes. Supposing when you wake up on a Sunday morning, and you look back at your week, you say to yourself, that was a satisfying week. I managed my condition in a "tolerable" "good enough" way. What would you have done? What else? What would others have noticed you did? What else? An important question is, "what else." This question compels the patient to persevere in detailing as yet undiscovered positive differences and prior successes.

Telegram: @medical_k

www.konkur.in

Questions to explore “best hopes”:

- What are your best hopes for this appointment so you can say it was helpful and worth your time?
- How can I be most helpful for you today so that this meeting is worthwhile?
- What do you know about your condition? What else?
- What do you know about yourself that you can get through this? What else?
- What do your VIPs know about you that you can get through this? What else?
- What have you tried to help with your condition? What else?
- What will you be “doing instead” when your problem is solved? What else will you be “doing instead”?

Goal Negotiation–Scaling Questions

Scaling questions invite patients to rate their goals on a numerical scale from 1 to 10. Scaling questions are used to rate solutions, different from many other scales which rate problems. They are developed from the patient’s best hopes and can be amplified by asking patients to predict how their VIPs would rate them. Scaling questions convey empathy, are patient centered, and can assist patients and clinicians in understanding perspectives from multiple viewpoints quickly. They are extremely useful in even brief medical encounters.

It is essential to amplify scaling questions. “Working the scale” provides additional opportunities to activate resources. Asking patients what keeps the number from being lower, and what else? What’s the highest number it has been? What would be a “good enough” number? Patients often do not need the “best” but are very satisfied with “good enough.”

Telegram: @medical_k

www.konkur.in

Scaling questions:

On a scale from 1 to 10, where 10 is the best:

- How well are you managing your condition?
- How helpful are your medications and current treatments?
- How well are you (coping/enduring/dealing) with your condition?
- How satisfied are you with how you are managing your daily tasks?
- How well are you remembering to take your medication?
- How well would your VIPs say you are coping with your condition, remembering to take your medications, and managing your daily task?
- How confident are you that you can manage your condition in a good enough way?
- How confident are your VIPs that you can manage your condition in a good enough way?

Working the scale:

- What's the highest it's been (another way to explore positive differences)?
- What's a good enough number?
- What would you be doing at that "good enough" number?
- What else?
- What keeps the number from being lower? What else?
- What would you be doing when the number goes up by one point?
- What else?
- What number would your VIPs give you?

End of Session

In SFBT, the end of a session is embedded with the compliments, positive differences, VIPs, and successes that were discovered in the conversation. Scaling questions challenge patients to consider the next small steps to take toward achieving their goals. Feedback should also confirm that there is no other information patients think would be helpful for the clinician to know in order to be most helpful for them.

Follow-Up Sessions

Follow-up sessions should begin with searching for positive differences and opportunities to amplify what is already working in a patient's life. If

Telegram: @medical_k

www.konkur.in

things are worse, offer the patient enough “for you” responses, followed by coping questions. Follow-up sessions also include exploring their best hopes for the appointment, illuminating positive differences, incorporating VIPs, and asking scaling questions.

Telegram: @medical_k

www.konkur.in

Follow-up session questions:

- What's been better since we last met? What else?
- What's been even a little bit more tolerable since we last met? What else?
- What's been happening that you want to continue to happen? What else?
- If things are worse: This must be very difficult "for you," how have you been coping/enduring/dealing with this? How else?
- What are your best hopes for today's appointment that would tell you it was helpful for you? What else?
- What have you tried?

Scaling questions from 1 to 10 (10 being the best):

- How well are you managing your pain/nausea/diarrhea/constipation/bloating/gas/heartburn?
- How well are you managing your anxiety/stress?
- How well are you remembering to take your medication?
- How well are they managing to get through their daily tasks?
- How well would your VIPs rate these areas from 1 to 10?

Working the scale:

- What would be a good enough number?
- What keeps it from being lower? What else?
- What would they be doing when it goes up by one point?

Pearls of wisdom:

- Translate language to highlight solutions.
- Notice opportunities to provide indirect compliments, attend and amplify positive differences, use and explore patient's exact words, and provide "for you" statements bridged to coping questions all enhance treatment engagement and promote self-efficacy.
- Assess a patient's VIPs to broaden "who" the patient is by detailing their social context to enhance possibilities for building solutions.
- Explore a patient's vision and their "best hopes" to assist them in detail with what they will be doing when their problem is solved.
- Scale questions quickly to enhance goal negotiation, detail what has worked, and the next actionable steps to move forward. Questions are patient centered, collaborative, and empathic.

www.konkur.in

SUMMARY

SFBT is an evidence-based approach that promotes change by building on a patient's strengths, exploring past successes, and assisting in developing with patients a clear vision of what they hope to do moving forward when they are managing their condition in a "good enough" way. It is a pragmatic patient-centered collaborative approach based on solution building rather than problem solving. This approach has a belief in patient competence, assumes patients have the necessary resources to live a more satisfying life, and enhances hope and possibilities.

32.13 Single-Session Therapy

MICHAEL F. HOYT, PH.D.

"A journey of a thousand miles begins with a single step."

—Lao Tzu (6th century BCE)

"Remember then: there is only one time that is important – Now!
It is the most important time, because it is the only time
when we have any power."

—Leo Tolstoy (1885, *What Men Live By, and Other Tales*)

"… the fierce urgency of NOW …"

—Dr. Martin Luther King, Jr., "I Have a Dream" (28 August 1963)

The term *single-session therapy* (SST) refers to therapy in which each session is approached with the expectation that there *may* only be the one therapeutic meeting. There is the option that more sessions may follow, but it is a therapy that is understood, from the beginning, to be deliberately a single session. It is not just therapy that could have gone on (and on …) and happens to end after one visit. It is one session *by plan*, not by default. Each session is *one-at-a-time (OAAT).* The basic concept is to "view each encounter as a whole, complete in itself."

As Hymmen, Stalker, and Cait have succinctly written:

> *SST refers to a conscious approach to make the most of the first session knowing it may be the only session the [patient/]client decides to attend – not to the situation where there is an expectation that the [patient/]client will attend multiple sessions but chooses to attend just one.*

The idea that one session could be enough—and often is—may seem contrary to and disruptive of a more-is-better ethos, but there is abundant quantitative and qualitative that a single session of therapy is *de facto* the most common length of treatment, and that SST is often effective with a wide variety of clinical problems (including anxiety, depression, eating disorders, sleep disturbances, autism-spectrum issues, addictions and substance misuse, and family conflicts). SST does not claim to cure or solve all problems in one visit, of course, but even with conditions likely to be long-term or chronic, some patients may prefer to be seen on a OAAT basis, and "continuity of care" and treatment compliance may be

Telegram: @medical_k

www.konkur.in

facilitated by honoring those preferences via the availability of as-needed focused episodes. There is clear and growing support for the value of SST with children and adolescents. There are also assorted health-psychology single-session programs and protocols (e.g., stress reduction, stop smoking, improve your sleep) with empirical support of efficaciousness.

Sometimes a problem is “solved” or “resolved”—other times, things just get “unstuck” and “processed” and maybe coped with or managed better. A patient may use a single session to make a significant life change, take a step in the right direction, consider options, and/or validate their efforts, or perhaps gain support and avoid a worsening of symptoms. Each session is bespoke: one size does not fit all. Thus, Hoyt, Rosenbaum, and Talmon noted:

> *The therapist needs to be versatile, innovative, and pragmatic, asking: “What would help this patient today”? Patients may need to begin a process or complete a process; they may need to take hold or to let go; they may need reassurance or confrontation; they may need to look at something deeply or to shift perspective. […] Nothing works all the time, but what might work this time?* (Used with permission from Hoyt MF, Rosenbaum R, Talmon M. Planned single-session psychotherapy. In: Budman SH, Hoyt MF, Friedman S, eds. *The First Session in Brief Therapy.* Guilford Press; 1992:63.)

There are certain common practices—discussed below—that increase the likelihood of successful results in a single session. Without suggesting that one session is always enough, these can inform and enhance a range of clinical interventions—not just those intended to be potentially “stand-alone” single sessions. Evidence about treatment contacts clearly documents that many patients will only come once, whether we like it or not, so it is best to make the most of that session. However, even if approached as if one meeting may be enough, OAAT does not necessarily mean “only one time.” SST patients may sometimes return for additional assistance regarding the same or another problem.

Although there are many positive SST reports drawn from different theories of psychotherapy, SST/OAAT may be thought of more as a format or delivery system (Young, 2018) and an affirmative and hopeful expectation and mindset rather than as a particular theoretical or technical approach. Making the possibility of a single session available has been shown to be very helpful in addressing waiting lists and in making services more available to more people.

Single-session thinking is not necessarily restricted to only one session. Rather, it can be useful for approaching and organizing each session—

Telegram: @medical_k

www.konkur.in

establishing an alliance and determining session goals, identifying and applying resources, staying on task, planning next steps, and follow-through—even when there are subsequent meetings. Single-session thinking can also inform other types of consultations, including educational and career counseling, hospital social work, sports coaching, and postdisaster responses; and can help organize the agenda of each session of ongoing meetings.

A BRIEF HISTORY OF SST

Throughout the psychotherapy literature, there are scattered case reports of successful one-session treatments. Indeed, several of Freud's early cases involved a single session. He met one time, for example, with an emotionally upset young woman named Katharina while he and his family were on vacation in the Alps (the innkeepers were Katharina's parents); and, in another instance, he went for a long walk around Leyden, Holland with the great music composer, Gustav Mahler, who had requested a meeting while they were both there to discuss sexual and marital problems that seemed related to issues Mahler had with his mother. We don't know exactly what Katharina and Freud, and Mahler and Freud, talked about, but we do know that they knew they would only have one meeting, and we know from reports that the single sessions were helpful. A myriad of subsequent positive SST reports has come from cognitive-behavioral therapy (CBT), psychodynamics, solution-focused brief therapy (SFBT), narrative therapy, motivational interviewing, strategic interactional therapy, hypnotherapy, structural family therapy, and others.

Statistical studies have repeatedly documented that one session, usually unplanned, is the most common length of treatment. (Actually, *no* session is the most common length of treatment—people think about seeing a psychiatrist or psychologist, but never do—and "no treatment" may be the prescription of choice for those who can solve their problems without professional help.) Researchers have also repeatedly demonstrated the *medical utilization offset phenomenon*, the finding that unnecessary medical utilization is often reduced after one session of psychotherapy.

The Kaiser SST Study

Telegram: @medical_k

www.konkur.in

In the late 1980s, Moshe Talmon, a psychologist then working at the Kaiser Permanente Medical Center (a large HMO) in Hayward, California, noticed that many clinic patients who were seen for a single outpatient visit did not return for further sessions—regardless of the staff therapist's respective theoretical orientation or the patient's diagnosis. Intrigued, Talmon reviewed charts and contacted patients for follow-up. Despite the anticipation that many seen-only-once patients would be dissatisfied, it was found that the great majority actually expressed satisfaction with their session and indicated that they had not felt a need for additional meetings. This was very different from what was expected and was termed *unplanned SST*.

Encouraged by the retrospective finding of one-session successes, Talmon then collaborated with two psychologist colleagues (Robert Rosenbaum and Michael Hoyt) to conduct the first prospective study of possible (planned) SST. A series of outpatients, ages 8 to 80 with a wide range of potential diagnoses, were told on the telephone while making their appointment and then at the beginning of the session, that an effort would be made to provide what they wanted in the one meeting and that, at the end of the session, they would be asked whether the session had been sufficient or if they wanted to return for more meetings.

Early in each session, the therapist would say something along these lines:

"Hi! I'm Dr. _____. The purpose of our meeting today is to find out what brings you here and what would be helpful. Sometimes we may be able to get everything dealt with today in one visit; if we are not able to, then we will figure out what the next steps might be. Are you interested in that, eh?" (*Comment*: Insistence produces resistance, imposition produces opposition, push produces pushback—so it is important to offer and invite, but not demand, a one-session format.)

And at the end of the session:

"Would you like to wait and see how it goes when you use some of what we've discussed—or would you prefer to make another appointment now?"

Comment: Suggesting waiting until what has been discussed is used emphasizes that the patient has an active role in making desired changes.

The basic findings of the Kaiser study were:

- 34 of 58 patients (58.6%) elected to complete their therapy in one session even when more sessions were available;

Telegram: @medical_k

www.konkur.in

- more than 88% of the one-session patients reported significant improvement in their original “presenting complaint,” with more than 65% also reported “ripple” improvements in related areas of functioning; and
- while not experimentally assigned to one session or longer, on follow-up, there was no difference in satisfaction and outcome scores between those who chose to stop after one visit versus those who continued for more sessions.

Other Early Single Sessions

In the late 1960s, walk-in psychological (and medical) services were founded at the Los Angeles Free Clinic, at the Haight-Ashbury (San Francisco) Free Clinic, and at the Minneapolis Walk-In Counseling Clinic. These sessions often involved single visits. In the early 1990s, clinicians at the Eastside Family Centre in Calgary, Canada developed planned single-session walk-in services. Walk-in SST services were subsequently taken to Our Lake of the Lake University in San Antonio, Texas, where they have been taught to graduate students, provided to the community, and promulgated in the United States and Mexico. By 1994, The Bouverie Centre at La Trobe University in Melbourne, Australia began to offer extensive by-appointment SSTs and began training large numbers of professionals. In the mid-2000s, The Bouverie Centre, recognizing that many SST workshop participants (such as youth workers and vocational counselors) found single-session ideas very relevant and helpful but did not identify as clinical therapists, broadened the terminology and began referring to *Single Session Work* (SSW). In 2019, The Bouverie introduced the umbrella term *single-session thinking* to refer to the mindset common to all single session approaches—the characteristics of which are discussed in what follows.

So far, four international SST and Walk-In Services conferences have been held in:

1. March 2012, on Phillip Island near Melbourne, Australia
2. September 2015, in Banff, Canada
3. October 2019 in Melbourne
4. June 2023 in Rome

Telegram: @medical_k

www.konkur.in

Reports of successful SSTs have come from the United Kingdom, Sweden, Ireland, Italy, Mexico, Haiti, France, Spain, Germany, China, Cambodia, South Korea, Chile, Canada, Israel, Turkey, New Zealand, Australia, the United States, and elsewhere. Public interest has also continued to expand; in 2018, an article featuring SST appeared in *O: The Oprah Magazine* (monthly circulation of 2.5 million copies).

SINGLE-SESSION THINKING: ONE AT A TIME

Although Talmon defined SST "as one face-to-face meeting between a therapist and patient with no previous or subsequent sessions within one year," that specification was somewhat arbitrary and was used for research purposes. It also did not emphasize the possibility of repeat single sessions. Hence, Hoyt's group proffered this more preferred general description:

> *The essence of single-session thinking is to approach the first session as if it will be the only session while creating opportunities for further work if it is requested by the client. What emerges is a collaborative, direct, and transparent approach to providing services that put the client in a very active role in determining the focus and length of the work.* (Used with permission of Hoyt MF, Young J, Rycroft, P. Single session thinking and practice going global one step at a time. In: Hoyt MF, Young J, Rycroft P. *Single Session Thinking and Practice in Global, Cultural, and Familial Contexts.* Routledge; 2021:3.)

One session may yield the positive results that patients are seeking—as discovered when Talmon followed up with many clinic patients who had only been seen once—but not recognizing that patients may have achieved what they wanted in the one session, these are sometimes (mistakenly) called *drop-outs* or *premature termination*.

Planned single sessions can occur either (1) *by appointment* or (2) *by walk-in* (which, with the advent and increasing use of teletherapy, may be via phone or the internet). In addition to private offices and mental health clinics, SSTs also often occur in primary-care medical settings, hospital and E.R. meetings, college counseling centers, inpatient psychiatric groups, second-opinion consultations, and clinical demonstration interviews. *Crisis intervention* is not generally considered an SST—unless that is what is indicated in a particular situation.

Telegram: @medical_k

www.konkur.in

FIGURE 32.13–1. Context of competence.

Although the possibility of a single session may be available when therapy takes more than one session, it is not an "SST failure"—it just means it took more than one session.

SST/One-at-a-Time Basics

Regardless of how the patient gets there (by appointment or walk-in), once they have arrived, there are general principles that guide SST. When patients are asked what they want, the therapist and patient can work collaboratively to honor those hopes and intentions. Underlying effective single-session thinking and practice are issues of (1) *mindset*, (2) *time*, and (3) *empowerment/client activation*.

Four common themes thus cut across single-session thinking and practice:

1. *Attitude*—treating the session "as if" it might be the only one and hence making the most of every encounter, underpinned by the

Telegram: @medical_k

www.konkur.in

paramount acceptance that one session could be (and often is!) enough.

2. *Accessibility*—responding in a timely manner without any unnecessary barriers to patients/clients receiving help when they are most ready.
3. *Acting now*—accepting that the best opportunity to address change is NOW, no matter the diagnosis, severity, or complexity of the problem.
4. *Alliance*—asking what patients/clients want to achieve by the end of the session so that the therapist and patient/client can work collaboratively, in the here and now, toward that goal.

Context of Competence. Effective therapy, whether one session or longer, occurs within a Context of Competence that we cocreate with the patient. As seen in Figure 32.13–1, therapy takes place where ALLIANCE/GOALS/RESOURCES overlap. If you identify GOALS (or PROBLEMS) and have an ALLIANCE but don't access RESOURCES, nothing happens. If you have an ALLIANCE and RESOURCES but don't identify GOALS (or PROBLEMS), there's nothing to do, no purpose. If the patient could match up their GOALS and RESOURCES on their own, bringing to bear competencies to deal with problems, they wouldn't need the therapist. Even if Shakespeare was right in *All's Well That Ends Well* (Act I, Scene1) when he wrote, "Our remedies oft in ourselves do lie," all three are often needed: the *Context of Competence* is where GOALS and RESOURCES come together through the ALLIANCE. Effective therapy, one session or otherwise, involves all three.

THE TEMPORAL STRUCTURE OF SESSIONS AND THERAPY

In SST, each session is a stand-alone, potentially complete-unto-itself "event." There is often a temporal structure to single sessions, with different issues and tasks associated with the early, middle, and late phases of a meeting (see Fig. 32.13–2).

The course of each therapy session can be conceptualized as having five phases or stages: pretreatment, early, middle, late, and follow-through. They tend to be pyramidal or epigenetic—that is, they tend to occur in sequence, and each flows from the preceding so that successful work in one preconditions the next. The patient elects therapy before forming an alliance; the alliance establishes the ground for defining goals;

Telegram: @medical_k

www.konkur.in

goal setting leads to focusing on specific change strategies, homework, relapse prevention, and leave-taking; and points toward continued growth and a possible return to treatment.

Change begins even before meeting the patient—he/she/they have decided there is a problem and would like assistance. When the patient arrives in the office, it is important to establish a focus, finding out about any developments since the patient decided to seek therapy and emphasizing the patient's initiative. Mid-session involves various change techniques and keeping track of the patient's goals. Later in the session, termination—extracting the therapist from the successful equation—becomes central. Issues to be considered include goal attainment, homework/post-session tasks, relapse prevention, and leave-taking. Everything may not be resolved by the end of the session, of course, but the patient has learned or recalled some useful skills, has enhanced motivation, and ideas for how to move forward. Benefit and change continue after the meeting, and the patient can be invited to call or return as needed. Extensive lists of guideline SST questions associated with the different phases are provided in Hoyt (in preparation).

FIGURE 32.13–2. The temporal structure of single-session therapy (SST).

KEY SINGLE-SESSION THINKING AND PRACTICE IDEAS

Over the years, a variety of useful general SST attitudes have been described. Bobele and Slive, for example, list a number of ideas that

Telegram: @medical_k

www.konkur.in

inform a OAAT mindset:

- Patients/clients know what works best for them.
- Patients/clients are far less interested in psychotherapy than therapists and usually prefer brief therapeutic encounters.
- Patients/clients frequently choose to attend only one session and overwhelmingly express satisfaction with that session.
- Research demonstrates that most change occurs early in therapy, followed by ever-decreasing improvements as sessions continue.
- Rapid change is not only possible but also common in human experience.

There are different ways to translate single-session thinking into practice. Various lists have been offered, all emphasizing the importance of clear goals and accessing resources. An early investigator, Bernard Bloom, for example, offered 15 SST transtheoretical suggestions:

1. Identify a focal problem
2. Do not underestimate patients' strengths
3. Be prudently active
4. Explore, then present interpretations tentatively
5. Encourage the expression of affect
6. Use the interview to start a problem-solving process
7. Keep track of time
8. Do not be overambitious
9. Keep factual questions to a minimum
10. Do not be overly concerned about the precipitating event
11. Avoid detours
12. Do not overestimate a patient's self-awareness (i.e., don't ignore what may seem obvious)
13. Help mobilize social supports
14. Educate when patients appear to lack information
15. Build in a follow-up plan.

Drawing from their experiences in the Kaiser SST study, Rosenbaum, Hoyt, and Talmon highlighted:

1. "Seed" change through induction and preparation

Telegram: @medical_k

www.konkur.in

2. Develop an alliance by cocreating, with the patient/client, an attainable treatment goal
3. Allow enough time for the session to be a complete process or intervention
4. Look for ways to meet patients/clients in their worldview while, at the same time, offering a new perspective or hope about the possibility of seeing and acting differently
5. Go slowly and look for the patient's/client's strengths and resources
6. Focus on "pivot chords," ambiguous situations that can be reframed in therapeutic ways
7. Practice solutions experientially, using the session to help patients/clients rehearse a solution or solutions—thus inspiring hope, readiness for change, and forward movement
8. Consider taking a time-out, break, or pause during the session to think, consult, focus, prepare, and punctuate
9. Allow time for last-minute issues to help the patient/client have the sense that the session has been complete and satisfactory
10. Give feedback, emphasizing the patient's/client's understanding and competency to make changes
11. Leave the door open, follow up, and let the patient/client decide if the session has been sufficiently helpful or if another session (or more) is needed.

Another list, offered more recently by Rycroft and Young (also see https://events.bouverie.org.au/sst) at The Bouverie Centre in Melbourne, contains a distillation of 10 SST core elements:

1. Negotiating a client/patient-led outcome
2. Establishing the client's/patient's (or clients'/patients') priorities
3. Finding a focus and talking about the most important things ("cutting to the chase")
4. Checking in with the client(s)/patient(s) at regular intervals
5. Interrupting respectfully when necessary (to help clients/patients get what they want)
6. Making time your friend—collaborating with the client/patient to optimize use of the time available, however short or long
7. Preparing to end well (reaching closure even if no solution or resolution)
8. Sharing your thoughts openly with clients/patients

Telegram: @medical_k

www.konkur.in

9. Leaving the door open (an “open door” policy)
10. Listening to client/patient voices (following up, seeking feedback, and utilizing it).

SOME EXAMPLES OF SST

SST thinking can be flexibly applied in a wide variety of situations. Here are some typical clinical scenarios drawn from published reports. Each is offered as a prototype with many possible variations and applications—readers are encouraged to extrapolate and modify to suit their situations.

SST With an Individual

Telegram: @medical_k

www.konkur.in

Mary was a 30-year-old woman who contacted the clinic because she wanted help learning to cope better with her highly intrusive biologic father (who had been divorced from her Mum since Mary was a child). She was offered a choice of either a by-appointment session or the option of walking in. She chose to make an appointment so that she could schedule childcare for her 4-year-old.

When she met with the therapist and they began to talk, he remarked: “Sometimes we may be able to get everything dealt with today in one visit, figuring out your next steps. Are you interested in that?” to which the client responded: “Yeah, that’s what I need.”

After briefly reviewing the history of her father’s misdeeds, she clarified as her session goal her wanting to handle him better in the present when he attempted to intrude on her and her husband and child. In the course of the session, she recognized how other family members had successfully dealt with the father, as well as lingering feelings of responsibility and guilt that impeded her. She then was guided, in session, to role-play, being assertive, saying “No,” and practicing ways to set what she felt would be healthier boundaries. Although quite anxious when she had first called, by the end of the one session, she felt ready with skills and motivation and did not feel she needed to make another appointment.

Patient: It makes me feel better already …. As long as I see the light.
Therapist: You can lighten the load you’ve got by taking control and not letting him run your life anymore. So you’re not trapped.
Patient: Exactly.
Therapist: Good.
Patient: Be in control and not get trapped.
Therapist: All right. Let’s speak in a month or so … If something comes up before and it is a question that can wait, wait. But if it’s something that you have to know or have to ask, do not hesitate to call me.
Patient: Like if he comes up with a new trick.
Therapist: You’ve got tricks, too. You can fight back.
Patient: Yeah. Now that I know how!
Therapist: Yes! *[they shake hands]*
Comment: On follow-up, she reported that she was doing well and that no further appointments were needed. She expressed appreciation

Telegram: @medical_k

www.konkur.in

and agreed to return on an as-needed basis.

Couple/Family Conflict

Georgie and Anne were a couple who sought an appointment to discuss their concerns regarding their 14-year-old son's angry outburst, during which he had threatened his younger brother with a knife. The parents wondered whether they had responded appropriately and/or whether their son needed psychiatric evaluation. After completing an intake questionnaire and having a brief telephone contact, they were then seen in session with the son. Careful attention was paid to connecting with all the participants, complimenting Georgie and Anne for their concern, and recognizing the son's strengths and not just his temper. To keep things focused on the search for solutions (Context of Competence), at one point, the therapist remarked: "Given that we have about 20 minutes left … I'm wondering what hasn't been said—or asked—at this point?" The son had talked things out with his brother. He acknowledged his role in the altercation, was remorseful and pledged to do better. Both Georgie and Anne felt reassured and validated, both in their concern and also in their parenting.

Comment: Further discussion revealed no indication for additional psychiatric evaluation or treatment. They agreed to a phone follow-up in 2 weeks and to recontact the therapist sooner if needed. At follow-up, the family reported that at home, they had talked more about the incident and the session. They were doing well, did not feel a need for another session, and expressed appreciation for the open-door invitation to return if/when appropriate.

Serial (or Sequential) Single Sessions

OAAT doesn't necessarily mean only one time. Many patients may come for a single session and later decide to return for either another single session or for a longer course of therapy—sometimes for more work on the original presenting issue, sometimes to discuss other issues.

Telegram: @medical_k

www.konkur.in

One family with a disabled parent with acquired brain injury (ABI) was seen for a total of 32 SSTs! After each session, when they were asked if they wanted to make another appointment, they responded: “Not now. This is what we need for now. We’ll call when we’re ready for another meeting.” These repeated single sessions came to be called “coming in for tune-ups. Although OAAT, the family was seen, with varying combinations of attendees, over a 5-year period with an average of 6.5 times per year. Each session addressed different problems as determined by individual and family needs.

Comment: *Serial* (or *sequential*) SST is sometimes called *episodic*, *intermittent*, *repeat*, *booster*, *targeted,* or *catalytic*. SST is often useful when working with patients and families coping with new or ongoing medical-psychiatric problems (ranging from infants to adolescents and adults to seniors, including those with Alzheimer disease and other illnesses involving cognitive decline).

In the Course of Ongoing Medication Management

Telegram: @medical_k

www.konkur.in

Mrs. Jones had been doing very well on an antidepressant for several years. One day she called Dr. Jenkins:

Patient: Hi, Doctor. I've been having a lot of anxiety about some problems with my job, and I'd like an appointment to see you to talk about what's been going on.

Doctor: Has your depression gotten worse or been interfering?

Patient: No, not really. This is more about problems with my boss at work.

Doctor: Would you like me to refer you to someone who specializes in working with occupational problems? I would be glad to see you, but as you know, I primarily do biologic psychiatry. I have a couple of colleagues, one a psychologist and the other a licensed clinical social worker, who are very good.

Patient: Thank you, doctor, but I think I'd really rather come to see you. I already know you and trust you, and you know me. I think I may only need one visit. And I'll be glad to pay for a full appointment, not just a brief medication check.

Comment: While Dr. Jenkins' main professional focus was on the use of medications to treat mood disorders, she also appreciated the opportunity to use a range of her biopsychosocial therapeutic skills. They met, and by focusing on the patient's specific session goals and the skills she could utilize to achieve those goals, Mrs. Jones got the psychotherapeutic support and direction she had sought; and she continued with her medication regimen.

Single-Session Family Consultation (SFCC)

As described by O'Hanlon and Rottem, SSFC is a model of brief family engagement and inclusion in the care of an individual client, typically involving between one and three sessions and then as needed. It includes a meeting organized by a practitioner with their client (a service user) and their family to collaboratively respond to family-identified needs and to clarify how the family will be involved in the individual's ongoing care.

Telegram: @medical_k

www.konkur.in

Noel was a 57-year-old man who had been on disability leave from work after a recent acute episode of bipolar affective disorder in which he had become disinhibited and aggressive toward his work colleagues. He was now on medication and restabilized but having difficulty bringing himself to return to work. He felt it would be helpful for his wife and 21-year-old live-in daughter to understand more about what he had been through and how he was feeling. With the patient's consent, the mental health practitioner contacted the family, and a meeting was arranged.

Comment: An SSFC has three parts: (1) *Convening*, which refers to the key tasks and activities associated with the therapist getting the patient's consent and the therapist then setting up the session with the family; (2) *Conducting*, which refers to the actual session with the patient and family. This will typically involve welcoming, scoping the issues, finding a focus for the session, working on prioritized issues, summarizing progress, and agreeing on the next steps; and (3) *Following-up*, typically a phone call (to the patient and possibly involved family members) to check on the status of the problem, follow up on any actions or referrals decided at the patient and family meeting, and to decide upon next steps (which might include the patient's ongoing therapy, and possibly another single family session or referral to another service).

Clinical Supervision

Single-session thinking can also be used to structure each supervision meeting to have a clear beginning, middle, and end with specific goals for the particular session. Useful single-session supervision questions might include the following:

- If this could be as useful as possible _____?
- Are we talking about what we need to be focusing on, or are we getting off track?
- Of everything you have tried, what has gone well, and what has not gone so well?
- What do you know about yourself/your client(s)/patient(s) that tells me that you are ready to try something different?

Telegram: @medical_k

www.konkur.in

- Before I tell you what I'm thinking, is there anything further I need to know, do you think, to be helpful to you?
- How far have we come in meeting what you had hoped for?
- Any last questions/concerns?
- What are you going to be taking away?

There is also sometimes a parallel process between therapy and supervision, in which single-session/OAAT phase-specific (beginning, middle, ending of a therapy session) aspects of the patient–therapist relationship get repeated in the therapist–supervisor relationship.

Many Psychiatric Medication Consults Involve One Session

A planning session with colleagues informed by SST/OAAT principles also can be helpful before consulting with a patient.

As Rosenberg and McDaniel have written:

Single session interventions are common in collaborative, biopsychosocial health care. Certain clinical scenarios are best suited for these kinds of interventions. These scenarios include interdisciplinary meetings in the hospital as well as in outpatient clinics, around critical moments in clinical care, and as consultations with existing care relationships or teams.

Comment: Rosenberg and MçDaniel describe different types of planned single-session medical family therapy meetings, including hospital-based family meetings; outpatient family meetings around a new diagnosis, treatment adherence, or bad news; consultation by behavioral health or biomedical provider; and team-based preclinic "huddles."

THE ROLE OF ASSESSMENT AND RISK MANAGEMENT IN SST

As Yalom (2002, p. 4, emphasis in original) has noted, "Though diagnosis is unquestionably critical in treatment considerations for many severe conditions with a biological substrate […] diagnosis is often counterproductive in the everyday psychotherapy of less severely impaired patients."

—Irvin Yalom, The Gift of Therapy

SST involves seeking a pragmatic and parsimonious solution for the problem presented by the patient. As Talmon has described, this way of thinking, in which the search for psychohealth replaces the search for

Telegram: @medical_k

www.konkur.in

psychopathology, represents an alternative to the traditional model in psychiatry and psychotherapy. Focusing on *what works* is usually better in therapy as in life. Psychiatrist Anne Lutz and many others have written about the profound shift and "new direction" entailed in interviewing to identify strengths and resources rather than focusing on symptoms and weaknesses.

Bobele and Slive observe the frequent concern clinicians express about possibly "missing something" in a single session, including potential risk factors. They note that the need for possible further risk assessment can be identified with one item in a client's intake materials, such as "Do you now, or have you had, any fears that you (or your child, or anyone with you) is at risk of harm to themselves, others, or pets"? Along related lines, Paul Denborough, a psychiatrist in Melbourne, Australia, familiar with SST, remarked, "It's actually the perfect model to deal with risk—Single Session—because you see people quickly. You get the whole social network and family around them, and you try and fix the problem as soon as possible. You couldn't get a better way to manage risk, in my opinion."

Whatever questions are asked, it is good to remember that the word *diagnosis* comes from Greek and Latin words (*via gnosis),* meaning *the way of knowledge*. We never know everything; information should be sought that will point the way forward.

SST: TOWARD THE FUTURE

It is hard to make predictions because there are so many possible influencing factors, but these seem likely:

1. More SSTs, both by appointment and by the open-access option of "no appointment needed" walk-ins. This will call for more attention to implementation and administrative support.
2. More use of the internet—"Counselors are available now waiting for your call."
3. More clinics (including public and private healthcare organizations, university counseling centers, employee assistance programs, training institutes, and freestanding services) offering SST around the globe
4. More publications and more training.
5. More research—which groups and problems respond best to which approaches, and what actually happens—what are the "active ingredients" that make SST effective? In his Foreword to Talmon's

Telegram: @medical_k

www.konkur.in

Single Session Therapy, psychiatrist Jerome Frank wrote about how people making changes in one session challenges a lot of the assumptions that therapists have had: the beliefs that you have to gradually form an alliance, that you have to gradually uncover the underlying schemas or neuroses, that you then have to gradually work your way through or there will be too much resistance. When things happen relatively quickly, it's an interesting question for researchers, what really happened, because it can't be a gradual working-through process; something shifted more quickly. SST, because it is circumscribed and concise, should be an excellent research ground.

6. More emphasis on patient/client strengths, resources, and competencies.
7. More attention to cultural nuances. Appreciating, respecting, and sometimes clinically utilizing the different strengths of different cultures, valuing the various belief systems people are coming from and how they go about it. It is important to work with, and especially to not work against patients' cultural orientations.

SST is responsive to patients' natural help-seeking behavior. SST was really "invented" by patients—even Freud's patients Katharina and Mahler knew in advance that there would be only the one session. Many hundreds of thousands of patients since have chosen to be seen for one session, even when more visits were available, and have found one session beneficial and sufficient. These sessions were approached and concluded as single sessions complete unto themselves (a "one-and-done," or a "one-off," as our Brit and Aussie colleagues might say)—with the possibility of return as needed. Clinicians and researchers are endeavoring to define and refine what facilitates those successful outcomes.

Patients, clinicians, managers, policymakers, and funders are all interested in the benefits of single-session thinking and practice. Offering the option of SST—by appointment and/or by walk-in—allows patients and therapists to efficiently "capture the moment" and "strike while the iron is hot." SST is responsive to the natural help-seeking behavior patterns of patients, has strong empirical support for increasing patient satisfaction, and can help conserve resources for those patients who want and need additional services. Increasing accessibility and affordability is also a social justice issue, and recognizing the potential of SST is especially important nowadays as so many more people would benefit from mental

Telegram: @medical_k

www.konkur.in

health services if they were affordable and did not carry the often daunting stigma of seemingly endless dependency. Resources are limited, and SST has a valuable ecologic function: it preserves time and money. More is not better; *better* is better—and *better* can sometimes be achieved here and now, even in one visit.

CODA

SST is a treatment that is approached one session at a time. Each meeting is conceived as an event, potentially complete until the next round. It is not intended as a replacement for other therapy modalities. It is not an abbreviated form of conventional therapy, nor even a substitute for other "brief" or "time-sensitive" therapies. SST should not be "forced" and is most appropriate for those patients who desire and choose to attend one session, with the option of more as needed. Single-session thinking can also infuse other nonclinical situations. SST is a common, effective, flexible, increasingly recognized, and important component in the landscape of mental health service delivery.

32.14 Mentalization-Based Treatment

ANTHONY W. BATEMAN, M.A., F.R.C.PSYCH., AND PETER FONAGY, O.B.E., F.MED.SCI., F.B.A., F.AC.S.S.

Telegram: @medical_k

www.konkur.in

DEFINITION

Mentalization-based treatment (MBT) is an evidence-based treatment for borderline personality disorder (BPD). Randomized controlled trials (RCTs) have demonstrated their effectiveness in reducing the core symptoms of BPD and it is adapted for the treatment of other conditions, including antisocial personality disorder (ASPD) and avoidant personality disorder, substance abuse, depression, and eating disorders, and complex post-traumatic stress disorder.

This chapter will outline the theoretical basis of MBT and the core treatment model in relation to BPD.

What Is Mentalizing?

Mentalizing is the social cognitive ability to understand actions of other people and oneself in terms of mental states, including thoughts, feelings, wishes, and desires. It is a very human capability that underpins everyday interactions. In nontechnical language, it is attentiveness to thinking and feeling in oneself and others. It is beyond question that mental states influence behavior. Beliefs, wishes, feelings, and thoughts, whether within or outside people's awareness, always influence what people do. Mentalizing involves a whole spectrum of capacities: critically, this includes the ability to experience one's *own* behavior as coherently organized by mental states and to differentiate oneself psychologically from others. These capacities are reduced in individuals with a personality disorder, who lose cognitive and emotional coherence, particularly at moments of interpersonal (relational) stress, which challenge one's mentalizing capacities. In the authors' view, many symptoms characteristic of BPD emerge in association with a distortion or reduction in mentalizing.

The general reduction in mentalizing capacities leads to fear of social isolation and experience of loneliness; the loss of integrated and balanced mentalizing results in a reduction in joint intentionality and a sense of togetherness, which leaves people with BPD feeling isolated from others and unable to engage in and feel part of everyday social interaction. The key to constructive prosocial interaction is the capacity to coordinate perspectives between oneself and others and thus appreciate the distinction between the subjective (one's own view) and the objective (actual physical reality "out there"), and then intertwine these with

Telegram: @medical_k

www.konkur.in

knowledge of another individual's mental state. Joining of minds—the so-called "we-mode"—is the crucial ingredient of social mentalizing and friendship making. The route to this, often obstructed for people with BPD, is the experience of joint attention, which defines a commonly regarded object while also acknowledging that different individuals may have different perspectives on it.

Based on this understanding of BPD, MBT is a psychotherapy that focuses specifically on the mentalizing vulnerabilities of the patient in the context of an understanding of attachment process, which is the developmental context in which mentalizing is originally acquired.

HISTORY

The word "mentalizing" has been in existence for two centuries and in the *Oxford English Dictionary* for the past century. French psychoanalysts introduced the concept into the professional psychotherapy literature in the second half of the 20th century. Mentalizing came into the English professional literature on the cusp of the final decade. It was conceived initially as a deficit in autism and as a transiently impaired process associated with profound insecurity in attachment relationships in the developmental psychopathology of BPD. This proposal was the origin of the development of MBT.

The MBT approach is rooted in attachment theory and psychoanalytic ideas, but in the interest of parsimony, it sheds many of the core assumptions of both theoretical approaches while negating neither body of work. Its historical origin is born from the authors' wish to extend what they saw as the clear benefits of using a psychotherapeutic approach to professionals (nurses, rehabilitation or addiction counselors, activity therapists) who normally did not have opportunities to undertake extensive training in particular psychotherapeutic modalities. The authors wished to extract core elements of a therapeutic approach that could be linked to experimentally observed distortions of mental function in personality disorders.

THEORETICAL ISSUES

The Role of Mentalizing in Therapy

Telegram: @medical_k

www.konkur.in

MBT is based on the assumption that failures of mentalizing, while common to everyone, become a dominant feature in individuals with personality disorders, leading to both serious interpersonal problems and profound psychological distress. A number of therapies that have been shown to be successful in addressing the difficulties experienced by individuals with BPD appear to strengthen the patient's capacity to mentalize; for example, transference-focused psychotherapy, conversational therapy, cognitive analytic therapy, and certain aspects of dialectical behavior therapy (DBT). MBT is unique in attempting to understand the problematic and distressing aspects of severe personality disorder in terms of a failure of mentalizing (see later) and to focus a structured therapeutic approach on addressing problems of mentalizing as they occur in a therapy session. The overarching principle of MBT is to enhance mentalizing in the context of the therapeutic relationship (in both individual and group sessions) by systematically addressing instances of nonmentalizing and using these moments of discourse as opportunities to work with the patient to achieve a fuller psychological understanding of behavior.

The significance of this process rests on the fact that mentalizing is the fuel that drives learning from life experiences in the social environment. It allows the individual to be discerning and to know from whom they can learn and who they can trust in the world. Epistemic trust encourages social learning by enabling individuals to be open to benefit from their social environment. This mechanism for opening the channel to social learning exists because it cannot be left open by default: it is adaptive for humans to adopt a position of epistemic vigilance toward another person unless they are reassured that that person's intentions in communicating are not malign. The disruption of epistemic trust—or the emergence of outright epistemic mistrust as a result of environmental adversity, genetic propensity, or an interaction between the two—can lead to a fundamental breakdown in the capacity for meaningful social communications that are necessary for change to occur in how others or the self are seen.

Learning from others and calibrating oneself in a trusting relationship improves emotional regulation, reduces impulsivity, and facilitates social function. These are the problematic areas that characterize individuals with entrenched and severe mental health difficulties—particularly those with BPD. MBT trains the individual in mentalizing in the hope of generalizing their abilities from the therapeutic situation to the wider social

Telegram: @medical_k

www.konkur.in

context. In doing so, MBT can reduce mistrust, isolation, and rigidity and enhance the capacity for trust and, with it, the capacity to benefit from social experience.

The Multidimensional Nature of Mentalizing

Mentalizing is not an entirely stable, consistent, or unidimensional capacity. Neuroscience has identified four distinct components to mentalizing, which the authors have organized into dimensions that they see as helpful for therapists to identify in the clinical practice of MBT:

1. Automatic versus controlled mentalizing
2. Mentalizing the self versus others
3. Mentalizing with regard to internal versus external features
4. Cognitive versus affective mentalizing.

To mentalize effectively requires the individual not only to be able to maintain a balance across these dimensions of social cognition but also to apply them appropriately according to context. Consistent favoring of one or other side (or *pole*) of these dimensions leads to distorted understanding of mental states, associated with profound social and emotional difficulties.

In an adult with personality disorder, consistent distortions of social cognition consequent on imbalanced mentalizing on at least one of these four dimensions would be evident. Commonly, one or more of the dimensions underperforms at one end, and consequently, the opposite pole comes to dominate social cognition. For example, excessively emotional thinking emerges in the absence of cognitive mentalizing, or the influence of others dominates if subjective experience of self-states is reduced. From this perspective, different types of psychopathology can be distinguished on the basis of different combinations of impairments along the four dimensions. In other words, personality disorders (and, to some extent, other psychiatric disorders) can be understood according to different characteristic *mentalizing profiles.*

Automatic Versus Controlled Mentalizing. The most fundamental dimension of mentalizing is the spectrum between *automatic* (or *implicit*) and *controlled* (or *explicit*) mentalizing.

Telegram: @medical_k

www.konkur.in

Controlled mentalizing reflects a serial and relatively slow process, which is typically verbal and demands reflection, attention, awareness, intention, and effort. For example, a person might misunderstand someone, so they stop them and ask them to explain more clearly what is underlying their statements, or they focus their own mind to work out what their opinion may be. People tell stories to others about their mental states; they think back into their past and report how they felt long ago; they enjoy autobiographical coherence in their personal lives and tell others about it.

The opposite pole of this dimension, *automatic mentalizing,* involves much faster processing, tends to be reflexive, and requires little or no attention, awareness, intention, or effort. In day-to-day life and ordinary social interaction, most mentalizing tends to be automatic because most straightforward exchanges do not require more attention. People in conversation naturally take turns, adapt their tone and posture to others' emotional states, and reflexively take into account their knowledge.

Self Versus Others. This mentalizing dimension involves the capacity to become aware of one's own state—the *self* (including one's own physical experiences)—or the state of *others.* The two are closely connected, and an imbalance signals vulnerability in the understanding of both others and/or the self. Individuals with mentalizing difficulties are likely to preferentially focus on one end of the spectrum, although they may be impaired at both. Awareness of the mental states of others is in part mediated by neural structures that organize one's own actions (the *mirror neuron system*), moderated by explicit reflective processes that reinforce the self–other distinction. If explicit mentalizing is weakened, the influence of the current mental state of the other will increase.

Internal Versus External Mentalizing. Mentalizing can involve making inferences on the basis of the *external* indicators of a person's mental states (e.g., facial expressions, tone of voice, body posture) or figuring out someone's *internal* experience from what one knows about them and the situation they are in. This dimension does not simply refer to a process of focusing on the externally visible manifestations versus the internal mental state of others. It also applies to the self—it includes thinking about oneself and one's own mind state versus considering one's current (external) situation and physical (interoceptive) state. Someone who has poor access to and great uncertainty about their subjective experience, for

Telegram: @medical_k

www.konkur.in

example, as is often seen in individuals with BPD, may come to a conclusion about what they are feeling from the reactions of others as well as from observing their own behavior: for example, their legs are restless. Therefore they must be feeling anxious; they took an overdose, so they must have felt suicidal.

Cognitive Versus Affective Mentalizing. *Cognitive* mentalizing involves the ability to name, recognize, and reason about mental states (in both oneself and others), whereas *affective* mentalizing involves the ability to experience and understand associated *feelings* (again, in both oneself and others). Both are required for any genuine experience of empathy or true sense of self-coherence. Some individuals give undue weight to either cognitive or affective mentalizing. People with obsessional characteristics may be masters at explicating in detail the internal states of themselves and others, but this may be devoid of emotional content and meaning. Conversely, people with BPD are flooded with emotion and so prone to automatic process, reactivity, emotional contagion, and poor self–other differentiation. Intense emotion can disrupt the process of cognitive appraisal that normally helps to regulate it.

Dimensional Mentalizing Profile and BPD

The clinician and patient work on a personalized mentalizing profile in the assessment phase of MBT treatment, identifying which dimensions the patient tends to over- or underuse when under stress, and which modes are commonly prominent. This profile forms part of the shared formulation. Particularly when arousal increases, as is typical in the context of intense attachment relationships, individuals with BPD easily find themselves switching to automatic mentalizing. Stress and arousal, especially in an attachment context, bring automatic mentalizing to the fore and disengage the neural systems that are associated with controlled mentalizing. Under these conditions, interactions become nonquestioning precisely when they need to be more controlled and contextualized. Thinking becomes impulsive: the individual makes quick assumptions about others' thoughts and feelings, which are not reflected upon or tested. Logic is intuitive, unreasoned, and nonverbal; it is marked by an unwarranted certainty, which betrays its unreflective origin. As a consequence, patients show severe impairments in interpersonal and intimate relationships; for

Telegram: @medical_k

www.konkur.in

example, they may be overly distrustful (paranoid) or, indeed, overly trustful (naive).

Patients with BPD may show excessive concern about their own internal state and those of others, that is, they *hypermentalize* in relation to the self and attribute motives to others without any basis in reality. At the same time, these views of the self-develop without reference to social reality, namely an awareness of how others perceive one. Failure to balance self-perception with sincere curiosity about how one is perceived by others can lead to exaggerations of the self-image, in both positive and negative directions. A balanced, adaptive form of self-mentalizing conditioned by the social context is lost.

Patients with BPD pay more attention to external indicators of mental states, and their initial ideas arising from automatic mentalizing are left unchecked by controlled/reflective mentalizing. For example, if the clinician frowns, perhaps pensively, the patient may interpret this as looking angry or disgusted with them; seeing the clinician look at the clock during a session can stimulate an internal state of overwhelming unease and an experience that the clinician wants to be rid of them when, in reality, the internal state of the clinician is concern about the time left to work on the issue being discussed. A focus on external features, in the absence of reflective mentalizing, makes an individual highly vulnerable in social contexts, as it generates interpersonal hypersensitivity.

The Reemergence of Nonmentalizing Modes and BPD

While the dimensions of mentalizing can reflect anomalies in terms of mechanisms, that is not what the clinician sees. What the patient and the mentalizing clinician experience is a product of a malfunctioning mentalizing system, driven by imbalances in the dimensions of mentalizing. The outcomes of these malfunctions can be grouped into three typical modes of subjectivity for the purpose of illuminating clinical experience. The modes are termed *psychic equivalence mode, teleologic mode,* and *pretend mode.* These modes are summarized in Tables 32.14–1 through 32.14–3, which also outline MBT interventions to address each nonmentalizing mode.

The nonmentalizing modes are important for the clinician and patient to recognize and understand, as they tend to emerge in the consulting room and reflect core aspects of the patient's experience. It is important to

Telegram: @medical_k

www.konkur.in

address them because they cause considerable interpersonal difficulties and result in destructive behaviors.

Table 32.14–1.
Modes of Nonmentalizing: Psychic Equivalence

Clinical appearance	Certainty/suspension of doubt Absolute Reality is defined by self-experience Finality—“It just is” Internal is seen as equivalent to external
Clinician’s experience	Puzzled Wish to refute Statement appears logical but is obviously overgeneralized Not sure what to say Angry or fed up and hopeless
Intervention	Empathic validation with subjective experience Curious—“How did you reach that conclusion?” Presentation of clinician’s puzzlement (marked) The “Mentalizing Loop”: Linked topic diversion to trigger mentalizing, then revisit the area of psychic equivalence
Iatrogenic	Argue with patient Excessive focus on content Cognitive challenge

Telegram: @medical_k

www.konkur.in

Table 32.14–2.
Modes of Nonmentalizing: Teleologic Mode

Clinical appearance	The expectation of things being "done" Outcomes in the physical world determine the understanding of the inner state—"I took an overdose; I must have been suicidal"; "You were late; you don't want to see me" Motives of others are based on what actually happens Only actions can change mental process "What you do and not what you say"
Clinician's experience	Uncertainty and anxiety Wish to do something—medication review, letter, telephone call, extend session
Intervention	Empathic validation of need Do (or do not do) according to the exploration of need Affect focus of dilemma of doing or not doing The "Mentalizing Loop": Linked topic diversion to trigger mentalizing, then revisit teleologic understanding
Iatrogenic	Excessive "doing" "Prove" clinician cares in the belief it will induce positive change Elasticity (extending what clinician does, e.g., providing extra sessions, only to rebound with extra constraints) rather than flexibility

Psychic Equivalence Mode. In the *psychic equivalence mode*, thoughts and feelings become "too real" to a point where it is extremely difficult for the patient to entertain possible alternative perspectives. When

Telegram: @medical_k

www.konkur.in

mentalizing gives way to psychic equivalence, what is thought is experienced as being real and true, leading to what clinicians describe as “concreteness of thought” in their patients.

Patients with BPD who are in this mode describe an overriding sense of certainty about their beliefs, for example, “the therapist does not like me” or “I am a wicked person.” Such a state of mind can be extremely frightening, adding a powerful sense of drama and risk to life experiences. The sometimes extreme reactions of patients are justified by the seriousness and realness with which they can experience their own and others’ thoughts and feelings. The vividness and bizarreness of subjective experience can appear as quasi-psychotic symptoms and are also manifested in the physically compelling memories associated with trauma.

www.konkur.in

Table 32.14–3.
Modes of Nonmentalizing: Pretend Mode

Clinical appearance	Inconsequential talk/groundless inferences about mental states Lack of affect. Absence of pleasure Circularity without conclusion —"spinning in sand" (hypermentalizing) No change Dissociation—self-harm to avoid meaninglessness Body and mind decoupled
Clinician's experience	Boredom Detachment The patient agrees with the clinician's concepts and ideas Identification with clinician's model Feels progress is made in therapy
Intervention	Probe extent of mode—is it embedded in all content? Explore immediate patient-therapist interaction Counterintuitive Challenge
Iatrogenic	Nonrecognition Joining in with acceptance as real Insight-oriented/skill acquisition intervention

More important to appreciate is that negative affect in this mode will be overwhelming and cause very deep distress to the sufferer. Psychic equivalence permits no alternative perspectives to be taken. The patient can feel locked into an extraordinarily profound sense of pain without the slightest possibility that matters could be any different from how they

Telegram: @medical_k

www.konkur.in

currently are. This state of hopelessness makes suicidality comprehensible.

Teleologic Mode. In the *teleologic mode,* states of mind are recognized and believed only if their outcomes are physically observable. Hence, the individual can recognize the existence and potential importance of states of mind, but this recognition is limited to very concrete situations. For example, affection is perceived to be true only if it is accompanied by physical contact such as a touch or caress. The teleologic mode shows itself in patients who are imbalanced toward the external pole of the internal–external mentalizing dimension—they are heavily biased toward understanding how people (and they themselves) behave and what their intentions may be in terms of what they physically do.

Impulsivity involves function in teleologic mode and a heavy emphasis on the automatic pole of the automatic–controlled dimension. There is insufficient reflection concerning the impact of one's actions on others, or on oneself. In teleologic mode, the individual cannot accept anything other than a physical action as a true expression of the other person's intentions. Friends of a patient might constantly assure the patient of their love and support, and yet none of that feels real: it does not address the "hole" that the patient falls into at certain, especially lonely, times when they feel terrible emptiness. Feeling that interpersonal affection can only be real if it is accompanied by physical behavior explains some risky sexual behavior, but also the need to create physical distractions that help with the feeling that all verbal expressions of interpersonal affection are without real meaning (see case example, later).

The teleologic mode makes the need for action and generation of "real" change overwhelming. The so-called "manipulativeness" of patients with personality disorder is little more than the experience of a pressing need to feel genuine reactions from others in terms of actions rather than words.

Pretend Mode. In the *pretend mode,* thoughts and feelings become severed from reality. Taken to an extreme, this may lead to feelings of derealization and dissociation. Patients in pretend mode can discuss experiences without contextualizing these in any kind of physical or material reality as if they were creating a pretend world. The patient may *hypermentalize* or *pseudomentalize,* a state in which they may say much about states of mind but with little true meaning or connection to reality.

Telegram: @medical_k

www.konkur.in

Attempting psychotherapy with patients who are in this mode can lead to lengthy but inconsequential discussions of internal experience that have no link to genuine experience and will achieve no change. The limited capacity to experience a sense of an internal world gives rise to a deep and extremely distressing sense of emptiness. Dramatic action—for example, sometimes violent action against the self—may be experienced as the best way of addressing such feelings.

In summary, imbalances within the dimensions of mentalizing predictably generate the nonmentalizing modes. Psychic equivalence is inevitable if emotion (affect) dominates cognition. Teleologic mode follows from an exclusive focus on external features to the neglect of the internal. Pretend mode thinking and hypermentalizing are unavoidable if reflective, explicit, controlled mentalizing is not well established.

Attachment

It is a central tenet of the mentalization-based approach that a sense of self and the capacity to mentalize both develop in the context of attachment relationships. The child observes, mirrors, and then internalizes their attachment figures' ability to represent and reflect mental states. So the reflections need to be *contingent*—that is, related to the child's internal experience—accurate, and *marked*—that is, indicating, for example, using "motherese" (a special tone of voice), that what is being expressed is a representation of the mind of the child and not that of the caregiver. Hence, the self and others—and the capacity to reflect on the self and others—are inevitably closely intertwined.

Disorders that are characterized by severe impairments in feelings of self-identity, a central tenet of the pathology of BPD—are also characterized by severe deficits in the ability to reflect about others' mental states. However, this should not be taken to mean that an individual whose capacity to mentalize themselves is impaired will always show similar impairments in their ability to mentalize others. For example, individuals with ASPD can often be surprisingly skilled in "reading the mind" of others only then to use this skill for exploitation but typically lack any real understanding of their own inner world.

In BPD there is commonly a history of early (in particular emotional) neglect, and a disrupted early social environment in general, and this may contribute to undermining the ability of some individuals to develop full mentalizing capacities. Subsequent adversity or trauma may further

Telegram: @medical_k

www.konkur.in

disrupt mentalizing, in part as an adaptive maneuver on the part of the individual to limit exposure to a brutalizing psychosocial environment, and in part because the high level of arousal generated by attachment hyperactivation and disorganized attachment strategies serve to disrupt less well-practiced and less robustly established higher cognitive capacities. In addition, genetic influences may be expressed through the mediation of mentalizing.

In sum, the mentalizing model is not strictly an etiologic model, although it clearly prioritizes a social psychiatry perspective; it points to a final common developmental pathway that a range of biologic, family, and broader social contextual influences may take to generate the range of difficulties that are normally considered under the term “personality disorder.”

TECHNIQUES

MBT is a group and individual treatment focusing on three primary areas of personality function:

1. Mentalizing
2. Emotion processing and management
3. Attachment process

It is anticipated that, at times, the patient will experience strong affect while focusing on identified problems in treatment sessions. At these times their mentalizing will be limited or failing, and/or the patient’s understanding of the way mental states link to behavior will be inadequate.

The clinician addresses this through a structured process (the sessional intervention trajectory) of:

1. Empathy and validation of problem areas
2. Clarification, exploration of affective narratives, and, where necessary, challenge
3. Following a structured process to gently expand mentalizing when it is out of balance and encourage the patient to identify the mental states and relational processes previously outside their awareness.

Telegram: @medical_k

www.konkur.in

The therapeutic process is primarily in the here and now of the session but increasingly, as the patient's mentalizing improves, it comes to concern core attachment relationships, including how these are activated with the clinician and key figures in the patient's life and how they influence mentalizing itself. Gradually, improvements in mentalizing serve to enable the patient to address their distorted representations of personal and social relationships.

Therapeutic Alliance and Engagement in the Model

The assessment and introductory process in MBT facilitates the alliance between patient and clinician (see Table 32.14–4) and introduces the patient to the treatment frame. An MBT-Introductory group of 10 to 12 sessions assists in the development of the formulation and facilitates the alliance. This psychoeducational intervention covers all areas of mentalizing, attachment processes, personality disorder, emotion management, and treatment itself. This preparatory work aims to ensure patients know what they are facing in trying to address their problems and are fully aware of the method and focus of treatment.

MBT is collaborative and democratic. Nothing can occur without joint discussion, taking into account the mental experiences and ideas of both patient and clinician. The process of mentalizing requires an authentic desire to understand the mental processes of oneself and others. This applies as much to the clinician as to the patient. So the MBT clinician focuses on the patient's mind and attempts to understand their experience. Similarly, the patient is asked to aim to do the same in relation to the clinician—for example, the patient's perspective "Why does my clinician want me to focus on this at the moment?" may be paired with the clinician's, "Why does my patient *not* want to focus on this at the moment?" The therapeutic process has to become a shared endeavor aimed at extending the influence of explicit, reflective, cognitive, internally focused mentalizing. Initial goals, on the road to improved mentalizing, are jointly developed and focused on. The goals cannot solely be those of the patient, although the patient's aims take priority unless they are antithetical to the whole process of treatment. The sharing of responsibility for the therapeutic process is at the core of the effectiveness of the treatment approach in the pursuit of improved mental state understanding.

Table 32.14–4.
Alliance Building in MBT

Identification of patient's mentalizing vulnerabilities presented to the patient in an understandable form
Identification of attachment strategies commonly activated in relationships
Formulation of problems—agreed between patient and clinician
Identification of patient's risk profile and crisis management strategies
Agreement on short-term and long-term goals

Assessment involves delineation of the patient's mentalizing vulnerabilities and mentalizing profile, identification of nonmentalizing cycles (see case example, later), and a shared formulation, which includes specific detail of attachment patterns and areas of vulnerability to emotional dysregulation. This has to be understood by the patient and is for both patient and clinician.

The formulation identifies common relational fears, for example, abandonment, which stimulates the patient's attachment system and results in the use of maladaptive attachment strategies in interpersonal interactions. In brief, the pattern of the patient's relationships informs an understanding of the relationship in treatment, and the relationship in treatment is used to reappraise the relationships in life outside treatment.

Finally, it is important that the patient and clinician consider establishing a goal of improving social function. This will include work, social activity, voluntary work, education, and other constructive life-affirming activity.

Clinical Principles in MBT

Clinicians follow a number of principles when treating patients with MBT (see Table 32.14–5). MBT recommends an authentic "not-knowing" stance that forms the bedrock for exploration of the patient's perspective. The not-knowing stance refers to respecting the opacity of mental states. Minds can never be "known" and it is important that the clinician recognizes that mental processes generate experiences imbued with uncertainty. The clinician's task is to take an inquisitive stance—a wish to inquire and a willingness to be surprised by the patient's response—with the aim of facilitating the patient's increased awareness of their internal states through a social process.

Telegram: @medical_k

www.konkur.in

This may be particularly important around the point at which experiences of ideas and feelings begin to collapse into nonmentalizing modes, leading to destructive behaviors or intolerable feeling states. It is not for the clinician to compensate for the patient's mentalizing failure with their own high-level mentalizing, "explaining" to the patient what they may have experienced. Nonmentalizing in the patient cannot be met by mentalizing in the clinician; it can be met only by "switching on" mentalizing in the patient via the range of techniques that MBT uses in the clinical situation.

Primarily, the clinician is alert to nonmentalizing in terms of the different manifest modes of nonmentalizing, but also in terms of the indications that the patient's functioning is fixed at one pole of any of the dimensions of mentalizing. In general, as described earlier, mentalizing is optimal when the dimensions—for example, emotion and cognition, or representation of self and other—are in balance and nonmentalizing modes are inactive. The key for the clinician is to be constantly aware of imbalance and lack of flexibility in terms of the dimensions and if any dimension is in danger of becoming fixed or rooted at one pole, intervention is necessary.

Table 32.14–5.
Clinical Principles in MBT

The clinician:

- Remains alert to imbalances of the mentalizing dimensions and emergence of nonmentalizing modes
- Monitors the patient's arousal levels to maintain optimal mentalizing
- Seeks moments of mentalizing vulnerability related to events in the patient's life or in the session itself
- Maintains their own mentalizing
- Avoids meeting nonmentalizing in the patient with high-level mentalizing
- Avoids joining with nonmentalizing
- Matches interventions to the patient's mentalizing capacity
- Sensitively presents their own state of mind in relation to the patient's state of mind to generate an understanding of the reciprocity of interaction

The clinician engages in "contrary moves" to activate the dormant pole of the dimension. For example, an exclusive focus on feelings and ideas

Telegram: @medical_k

www.konkur.in

in relation to the self should suggest to the clinician that exploring the mental states of the other is called for and they direct the session accordingly. Similarly, dominance of emotional mental experience without calibration from cognition suggests the need to bring cognitions into the foreground through judicious rational inquiry. Fluidity and adaptability of the dimensions to context and content are hallmarks of good mentalizing.

Second, the clinician monitors arousal levels carefully, ensuring that anxiety is neither too low nor too high, as both interfere with mentalizing. Similarly, if attachment feelings (e.g., in relation to the therapist) become too strong, a shift to less charged relationships may help restore mentalizing. Attachment stress triggers mentalizing vulnerabilities and may overwhelm the patient's capacities so they panic just as they are learning to balance the two effectively as part of their focus on improving relationships. Once mentalizing is restored, the relationship can be revisited for further learning.

Third, the focus of a session is maintained through the clinician always seeking moments of mentalizing vulnerability either in relation to events in the patient's life or in the session itself. Mentalizing failure is best indicated by the clinician's experience of being challenged to understand the patient and consequently feeling a degree of confusion about how to respond. At these times, rewinding to moments when shared understanding characterized the discourse is the best solution.

Fourth, the clinician makes sure that their own mentalizing is maintained. It is not possible to deliver effective treatment if the clinician's mentalizing is compromised. So the MBT clinician always monitors their own capacities and may even have to explicitly own this experience, for example, by saying that their mind has become muddled and they cannot think. This type of self-disclosure of the mind state of the clinician should not be confused with sharing personal information. Sharing the effect that a patient's actions and state of mind is having on the clinician acts in the service of asking the patient to consider another mind as well as their own and has the implicit aim of enhancing mentalizing.

Sessions are focused. They do not consist of free-associative dialogue that seeks to illuminate unconscious process, as may be the case in psychoanalytic therapy. The target area in MBT is working memory or preconsciously held experience. It is expected that a focus for a given session will have been achieved after 10 to 15 minutes of the session, and this focus will then become the pivotal point around which the

Telegram: @medical_k

www.konkur.in

clinician and patient orient themselves, returning to it whenever nonmentalizing comes to dominate the interaction.

Finally, interventions are carefully matched to the mentalizing capacities of the patient. It is no good offering complex interventions that require considerable thought and appraisal to an individual functioning in psychic equivalence mode. At best, this serves to take over their mentalizing for them, rather than facilitating its rekindling. As stated earlier, nonmentalizing in the patient cannot be recovered by mentalizing in the clinician, but only by reactivating mentalizing in the patient. This is achieved through a series of steps, which underpin the trajectory of every MBT session and may recur several times within each session.

Trajectory of MBT Session and Interventions

Empathic Validation. The initial step in a session is listening to the patient's narrative. Listening to the patient's story allows the clinician to begin by empathically validating their experience. Empathic validation and establishing a shared affective platform held between patient and clinician increases the patient's experience that they are not alone and indicates that another mind can be useful to clarify mental states and increase a sense of agency. This is the first step to advancing the development of "we-ness" ability. The intervention needs to be skillfully implemented to instill a sense of being together with a shared focus. Increasing focus on affect and interpersonal interaction during a session and over time provides the context in which to explore ever more complex states of mind within an attachment context that would normally trigger loss of mentalizing.

Empathic validation requires the clinician to find something in the story that they can empathize with. This is not the same as behaving in a sympathetic manner or saying things that repeat the patient's story. Empathic validation seeks to engender in the patient a sense that the clinician really understands the patient, their internal state, and the issue they are talking about. This is the clinical equivalent of attachment-based contingent responsiveness.

Validation is an affectively based intervention with important cognitive components; the key component is the creation of a sense of alignment with the patient's internal emotional state. This is accomplished by demonstrating an appreciation of the experience and the consequent secondary emotions triggered by a powerful emotional reaction (e.g.,

Telegram: @medical_k

www.konkur.in

when the patient's fury with a partner engenders deep distress and anxiety). In contrast, a lack of appreciation of the patient's emotional experience and its impact on the patient's current state (noncontingent responsiveness on the part of the clinician) is likely to trigger nonmentalizing (e.g., pseudomentalizing) or generate avoidant or other insecure and disorganized attachment strategies. Once contingent responding has increased collaboration and reduced the patient's arousal, maintaining emotions at a manageable level, the clinician can consider sensitive but less contingent responses to try to stimulate mentalizing about the story the patient brings.

Clarification and Exploration. The second step is clarification and exploration (see case example, later). The "story" the patient brings is clarified. This is not clarification of facts about the narrative or events, although this must also take place. The clinician establishes the facts as quickly as possible. For example, if the patient speaks about an act of self-harm or a suicide attempt, a drunken brawl, or an emotional outburst, the clinician quickly elicits when it occurred, who was there, what were the circumstances, and so on. This will indicate the level of risk and provide other important information.

More than this, though, the MBT clinician wishes to contextualize events with mentalizing. Clarification establishes the reflection the patient has on the events—what was their "premorbid" state of mind, what were their hopes, what was their experience when they were waiting for their boyfriend to return home, what thoughts intruded into their mind, what feelings did they identify, and can they reflect on it differently now? This process of clarification, in the service of engaging mentalizing, links inextricably with affect identification and exploration, which is the third step.

Affects and Affect Identification. Affects and interpersonal relationships reciprocally interact and are core to the personality problems characteristic of BPD. Unmanageable emotions impinge on relationships, and relationships stimulate powerful feelings. Patients may not be able to identify their feelings accurately but experience them primarily as inchoate bodily experiences. Working with the patient to identify a range of feelings is part of the clarification and exploration component of MBT (see case example, later).

Telegram: @medical_k

www.konkur.in

Sometimes, emotions in specific contexts have to be normalized. Too often, patients feel that their experience is wrong; in effect, they invalidate their own internal perceptions and feel ashamed. It may be that their feeling is appropriate but excessive, or at other times inexplicably absent. All this becomes clear if the clinician systematically focuses on affects. Initially, the affects associated with the events are established, then any reflection on those feelings is clarified, followed by eliciting current concerns about the events.

Clarification of current affect in the session is included as the third step if the patient and clinician retain their capacity to jointly mentalize around the focus. This is more than asking the patient how they feel at the moment or how they "feel about" an experience they reported, although this may be an initial component. The process requires the identification of *current* affect *related to talking about events to the clinician in the session.*

This expansion from identifying affects in relation to events to affect experienced while talking to the clinician about the events is named the *affect focus* of the session. The patient may initially bring intense rage into the session in relation to an experience of rejection, which is gradually clarified as having been caused by characteristic inappropriate behaviors on the part of the patient. The affect focus turns out to be a sense of humiliation the patient experiences in once again failing to manage their own actions in a more effective manner. This is a subdominant theme that is then explored to increase the complexity of personal meaning and understanding. The aim throughout this process is to build a robust platform of multilayered mentalized experience jointly recognized and shared by the patient and clinician, which incorporates the complexity of mental states and moves the patient beyond a nonmentalizing, narrow oversimplification of their uncontextualized feelings.

The affect focus, that is, identification of the interpersonal interaction in the session and the associated affect, if accurate, heightens the focus on the clinician–patient interaction in the moment of the session. This often indicates that a patient's attachment strategies and relational patterns, or possibly those of the clinician, are being activated. Thus, it allows a move toward *mentalizing the relationship,* the final step of the intervention trajectory.

Presenting Alternative Perspectives. Before extending to incorporate the relationship with the clinician into the patient's narrative, the clinician

Telegram: @medical_k

www.konkur.in

endeavors to enhance the patient's mentalizing by broadening the patient's perspectives on an event. This follows naturally from clarification and the affect focus and entails elaborating the mental states of the participants in an event. However, it gradually moves the focus from emotion to cognition. The clinician explores alternative ways of looking an event, at first playfully but sometimes in a mildly challenging manner. If the affect focus helped to reestablish more balanced mentalizing, then considering additional possibilities of what may have happened, at the level of thoughts and feelings, helps further re-engage the patient's mentalizing processes.

Alternative perspectives may entail reconsiderations of entire scenarios from the point of view of the patient's hypotheses about the thoughts and feelings of others, or a re-evaluation of the putative sequence of the patient's reactions—reframing their version of events in the light of alternative thoughts and feelings which they may have also been experiencing. The aim of alternative perspectives is the gentle expansion of the patient's mentalizing, to move from the certainty of affect toward the doubt of cognition. In general, the move is also from situational (external determinants) to exploring putative internal states. If the patient's focus was exclusively on their own state of mind the alternative perspective may bring in the other, while if the focus was on all protagonists other than the patient, the alternative perspective can focus on the self. Overall, the clinician engenders a recognition that a pause for reflection and explicit mentalizing may be of value in addition to intuition and the certainty automatic mentalizing can bring.

Mentalizing the Relationship. The groundwork for mentalizing the relationship will have been done through the development of the formulation, which identifies the predominant attachment strategies of the patient.

Mentalizing the relationship in a session is conceptualized as a training ground for managing difficult feelings in interpersonal situations in daily life through maintaining mentalizing while within an emotional interaction. It is the process that fosters the development of a capacity for "we-ness."

The authors have identified a number of steps for the clinician to consider, which follow closely the three steps of technique described above. First, the clinician has to empathically validate the patient's perception of the clinician. If the patient says that they experience the

Telegram: @medical_k

www.konkur.in

clinician in a particular way, then the clinician needs to find part of that experience that they can validate. The clinician actively avoids invalidating the patient's experience.

Second, the clinician needs to work out their contribution to the patient's experience of the clinician. The clinician does this explicitly by thinking aloud about it and asking the patient to explain how they have come to that conclusion. This questioning must be authentic and genuinely curious and must not come from a perspective that implies that the patient's experience is inaccurate or a reemergence of the past distorting the present. Such an invalidating attitude will lead to therapeutic rupture because invalidation (a noncontingent response) will lead to increased arousal and a consequent reduction in mentalizing. Mentalizing the relationship can meaningfully take place only in the context of mentalizing.

Once the clinician has accepted their role in the relational process, the next step of more detailed exploration can occur. In this step, the aim is to generate a more complex understanding of the relationship, to see it from a different angle, and to see what its relevance is for the patient's life. It is not to engender insight in the sense of understanding the operation of the past in the present, although this may arise as part of the patient's broader understanding of their emotional experience.

Critically, the past is used only sparingly as an explanation of the present, in case considering the past leads to a nonmentalizing, reductionist "short-cut" that obscures rather than elaborates the patient's current experience. In MBT, the clinician is cautioned about offering historical interpretation in the context of nonmentalizing process. For the exploration of the therapeutic relationship to contribute to enhanced mentalizing, the clinician works toward increased complexity and the establishment of multiple mental models of relationships.

Mentalizing the *counter-relationship,* or the feeling in the clinician, is the counterweight to mentalizing the relationship. The feelings and mind state of the clinician are given considerable weight in MBT—not as representing the patient's projected feeling, but as a meaningful aspect of an interactive relationship, to be used to demonstrate how minds affect minds. MBT clinicians monitor their experience of the patient. Not knowing what to say to the patient may be the best indicator of the patient's inadequate mentalizing. The dominance of the pretend mode in the patient may be indicated by a sense of boredom, while teleologic mode may be indicated by a sense of confusion and anxiety. The interaction becomes the subject

Telegram: @medical_k

www.konkur.in

of useful concern, removing obstacles to mentalizing and enhancing accurate mentalizing of the relationship.

For example, if the clinician is frightened of a patient with ASPD, this is an important feeling in the clinician that interferes with treatment and dictates the form of the therapeutic relationship. The clinician finds a way of expressing their experience of the patient in a way that makes it palatable and recognizable as something worth exploring.

The authors recommend that this is done through a number of steps. First, the clinician works out exactly what their feeling is and what it relates to in the patient-clinician interaction. Second, the clinician considers the patient's likely response to an explicit statement of this current feeling state and states this before talking about the current feeling. Third, in the dialogue, the clinician identifies the experience as their own, marks it, and, finally, monitors the patient's reaction to the statement:

"It is possible that what I am going to say may make you feel I am telling you off or being critical but I assure you that is not the case (anticipating the response of the patient).

The problem is that when you sit forward like that and raise your voice, I start to feel anxious and under threat (identifying the behavioral evidence and focus of external mentalizing, presenting his own affect and the effect it has on him).

I realize that this may be me (marking the feeling) but it makes it difficult for me to concentrate on what you are talking about (additional effect on him, interfering with the relationship)."

From here the patient's reaction can be taken into account and the session can continue. But if the threatening attitude and angry presentation are something that permeates all the patient's relationships, then further exploration is essential.

In conclusion, the key to MBT is to:

1. Organize treatment around a collaboratively agreed formulation
2. Develop a focused narrative around the problems of the patient, especially interpersonal issues
3. Infuse the narrative with mentalizing process and prevent a collapse into nonmentalizing experience
4. Work with the patient to reinstate mentalizing when it is lost to prevent destructive behavior and personal distress. Mentalizing oneself with

Telegram: @medical_k

www.konkur.in

others is the basis of satisfactory social and personal relationships, which so often is the goal of people with psychiatric problems and yet seems to them so unreachable

CLINICAL ISSUES

Indications

MBT is effective in treatment of severe BPD. Patients in the early studies of the intervention (see Research and Evaluation, later) had made serious suicide attempts, been admitted to psychiatric hospital for risk, and/or had self-harmed. Both men and women were included in trials and patients showed high levels of comorbidity. Analysis of the data suggested that patients who showed comorbidity for a number of personality disorders, including ASPD, did preferentially better in MBT than comparison treatment. At a clinical level, patients with marked interpersonal problems who have a personality disorder rooted in mentalizing vulnerability and attachment problems may benefit from MBT.

Limitations

Patients treated with MBT show a reduction in life-threatening behaviors and distressing psychiatric symptoms at the end of treatment, require less mental health care, and demonstrate improved social and interpersonal functioning. Over 8-year follow-up of patients in an RCT, the number of patients meeting primary recovery criteria was significantly higher in patients treated with MBT compared with those receiving a well-structured control treatment. Participants treated with MBT showed better functional outcomes in terms of being more likely to be engaged in purposeful activity and reporting less use of professional support services and social care interventions than those in the control group. Nevertheless, many of the patients did not reach a level of normal social adaptation.

It should be noted that the evidence for mentalizing mediating therapeutic change in MBT is currently limited (see Research and Evaluation).

Complications

Psychotherapy can be harmful and MBT is probably no exception. However, MBT pays particular attention to ways in which patients may be

Telegram: @medical_k

www.konkur.in

harmed by treatment. On the basis that patients with BPD are uniquely sensitive to attachment process, and the stimulation of attachment reduces mentalizing, the MBT clinician focuses on levels of arousal in treatment sessions, constantly trying to balance arousal and mentalizing, ensuring that the therapeutic relationship is not a source of excessive attachment stress. Overstimulation of patients with avoidant attachment patterns is likely to trigger retreat and drop-out. Drop-out rates in MBT in clinical services in the United Kingdom are around 15% of people offered treatment, although in Scandinavia drop-out is as low as 2%. This suggests that the treatment overall is acceptable to people with BPD.

The aim of treatment is to increase the robustness of the patient's mentalizing capacity, and yet clinicians in many psychotherapeutic modalities may often tell patients "how they feel" or "what they are really saying." This undermines the mentalizing of the patient and so is avoided in MBT.

Contraindications

MBT is a generic treatment constructed to optimize access both by creating a low-demand treatment protocol and by facilitating access to training by a range of professionals. Individuals who have problems with mentalizing rooted in nonattachment contexts may not benefit from MBT; if they do, the mechanism of change should be assumed to be different from that in BPD. Individuals with relatively simple problems, such as phobias or uncomplicated depression, may do better with more direct approaches, such as cognitive-behavioral therapy. Even within a population of patients with BPD, patients with more complex presentations (multiple personality disorder diagnoses) are more likely to require MBT than those with a single BPD diagnosis, who may do as well in structured clinical management.

Telegram: @medical_k

www.konkur.in

A 24-year-old patient, Sharon, was referred following a number of suicide attempts. She self-harmed, engaged in frequent polydrug misuse, and described emotionally volatile and occasionally violent relationships with men. She had a 2-year-old daughter who had recently been removed by child protection services. The clinician was able to take a detailed history, which elicited a number of vulnerability factors. Sharon was taken into care at the age of 5 and had a number of foster placements. She experienced recurrent sexual abuse from a caregiver around the age of 8. Her behavior was described in social reports as “oversexualized” around the time of puberty, and she attended an adolescent unit from the age of 13 to 15 years. She left school at 16 years having not attended for the previous year. The formulation was developed, which included these vulnerability factors but also identified the interpersonal vulnerabilities that led to mentalizing failures. The clinician explored two relational events with her boyfriend in which she had been violent and two contexts in which she had tried to kill herself. Unsurprisingly, these events were interlinked.

FORMULATION AND NONMENTALIZING INTERACTIONAL PATTERNS

In the formulation of MBT, mentalizing vulnerability points are identified and placed in the context of attachment strategies. In this patient, there was evidence that she had an insecure attachment with marked ambivalence and some disorganization. She would seek reassurance or indicators of care from her boyfriend, but when he did not respond, she became desperate and increasingly demanding and clinging, eventually attacking him. She stated that if she could not “have him,” she would “prefer to die,” or alternatively, she would “trap him” forever by getting pregnant. This nonmentalizing interactional cycle of need, demand, rejection, coercion, and the associated nonmentalizing modes were jointly explored, written down, and shared with the patient. It is anticipated that the pattern will occur in relation to the clinician in a less intense way—the patient might seek some reassurance, for example, and the clinician may fail to respond contingently, triggering feelings of rejection. Identification and reduction of the nonmentalizing interactional process was an initial

Telegram: @medical_k

www.konkur.in

goal of treatment because the interactions occurred frequently and were an important area of vulnerability leading to suicide attempts.

Sharon reported that she had been in a fight with her boyfriend. She had telephoned her boyfriend to find out when he would be back from work because she was looking forward to seeing him and telling him that she loved him. He said that he was leaving soon and would be back within an hour. A few minutes later, a friend telephoned and, in their conversation, said that she had seen Sharon's boyfriend in a bar with a blonde woman only 30 minutes ago. When the boyfriend arrived home, Sharon asked why he had said that he was at work when she knew he was in a bar with a blonde woman. He said that he had called in for a drink on the way home. They had an argument during which Sharon attacked him and then, after smashing some crockery, cut herself.

CLARIFICATION AND ELABORATION AND AFFECT IDENTIFICATION

Clarification of mental states about this event suggested that Sharon initially felt that she was looking forward to seeing her boyfriend, which was why she phoned him. His response was "contingent" on her feeling for him—he said he would be home soon. When her friend reported having seen him in a bar, this feeling was replaced with doubt about his love for her and a sense of rejection. Rapidly, she started to have thoughts that he was having an affair with the blonde woman, and in the context of feeling a loss of being loved, this was experienced in psychic equivalence—"I am unlovable"—with some elements of hypermentalizing about his motives—"he was having an affair, and I am certain of it." This was the nonmentalizing cycle and associated modes identified in her formulation.

When Sharon's boyfriend arrived home, there was no doubt in her mind about what had happened. He was unable to persuade her it was not true. In nonmentalizing states, actions are the only meaningful way of communicating, and she was therefore left with being coercive to "make" him love her. But to do this, she tried to lock him in the house so he could not go out, and she demanded sex. He resented this, refused, and the violence occurred. At this point, her demand was driven by the teleologic belief that only his actions could prove his love for her.

Telegram: @medical_k

www.konkur.in

The task in MBT is now to rewind in time and identify how Sharon manages her initial excitement about seeing her boyfriend, the sudden collapse of these feelings, and her collapse into psychic equivalent thoughts about his infidelity. To do this, the clinician engages in the detailed delineation of her mental states while asking her to re-present them to herself to instill a sense of uncertainty: can she manage emotional turmoil between excitement and disappointment; can she question her certainty over her boyfriend's activities and motives; can she engage with him to establish a more robust way of managing the distrust in their relationship other than teleologic demand?

AFFECT SESSIONAL FOCUS AND MENTALIZING THE RELATIONSHIP

The clinician asked Sharon how she felt about her boyfriend now, and she said that she still felt that he did not care for her. She was miserable. But, in addition, she felt that she had created problems, which was "typical of me." This is the identification of the current affect in relation to the focus. But, as she was talking to the clinician, she said that she felt that the clinician was judging her and would give up on treating her as it had happened again. She was a failure. This is the identification of the current affect in the session and was quickly explored. At this point, Sharon became coercive to some degree, suggesting that the clinician could not stop seeing her, and to prevent it, she would take an overdose. It becomes possible at this point to mentalize the relationship. Sharon thinks that the clinician will not meet her needs and so automatically engages in a nonmentalizing interactional process. This needs to be discussed in the context of the clinician stating that it is not in his mind to stop seeing her in treatment (statement of clinician counter-relationship), so it is important to understand what is fueling her belief and questioning it. It is not for the clinician to interpret the repetition in the session of the interaction with the boyfriend but to define the emotional need that Sharon reacts to that makes her become coercive.

Goals of Treatment

The primary aims of MBT are to rekindle mentalizing when it is lost, to maintain it when it is present, and to increase the resilience of the

Telegram: @medical_k

www.konkur.in

individual's capacity to keep it going when it would otherwise be lost. But mentalizing is about something. So, the development and maintenance of mentalizing is initially focused on the core symptoms of BPD (or another condition), such as suicide attempts, self-harm, and other self-destructive behaviors and emotional instability. This is followed by emphasis on interpersonal problems because the key area of vulnerability to losing mentalizing in BPD is the interpersonal domain, especially when attachment processes are activated. So the clinician–patient relationship is a significant area of scrutiny. Patient and clinician increase attentiveness to mental states and interpersonal contexts in which they become disordered.

ETHICAL ISSUES

A key feature of MBT is the collaborative stance, which engages patients in a mutually agreed protocol, each phase of which focuses on achieving shared understanding between the patient and the clinician. It is not for the MBT clinician to impose cultural values and beliefs. In other words, it may be argued that MBT clinicians are less likely to encounter ethical issues than proponents of other therapeutic approaches in which collaboration is perhaps seen as a necessary condition but not the aim of the treatment.

However, MBT clinicians should be well aware that the nature of the clinical problems they are dealing with invariably and unavoidably creates ethical issues daily. Working with a person whose capacity to represent themselves in an agentive way is lacking, whose attachment system is disorganized, and who is extremely vulnerable to creating a dependent relationship, will present a consistent problem for the clinician to avoid exerting undue influence. MBT clinicians—like therapists working in other orientations—can prolong relationships beyond their useful timespan, citing the patient's need for their input as justification.

In particular, when patients pay for their treatment either themselves or through a third party, financial exploitation is a real and present risk. Beyond this, undue influence may manifest through the uncritical acceptance of the clinician's frame of reference: a nonmentalizing individual has no alternative and gratefully grabs hold of a powerful, coherent model when it is presented to them. The teleologic predisposition of patients sometimes leads clinicians to find themselves

Telegram: @medical_k

www.konkur.in

caught up in action-oriented attempts to address the patient's distress, offering more than they should, yet delivering less than they could.

RESEARCH AND EVALUATION

MBT for BPD

There have been several reviews of psychosocial interventions for BPD. DBT and MBT have the highest numbers of primary trials, with MBT having been investigated in seven RCTs. The reviews recognize the evidence base for MBT for BPD as generally inferior only to that for DBT, although not from a health-economic perspective. A recent Cochrane review concluded from a meta-analysis that MBT is more effective than treatment as usual (TAU) at reducing self-harm, suicidality, and depression. Encouragingly, a large qualitative study of patients' treatment goals established that the goals of MBT were closely allied with what patients hoped to gain from their therapies. A number of naturalistic studies have also tested the effectiveness of the MBT approach for BPD patients.

In a RCT of MBT for BPD in a partial hospital setting (MBT-PH), an 18-month program achieved significant and enduring changes in mood states and interpersonal functioning. Outcome measures included frequency of suicide attempts and acts of self-harm, number, and duration of inpatient admissions, service utilization, and self-report measures of depression, anxiety, general symptom distress, interpersonal function, and social adjustment. The benefits, relative to TAU, were large, with a number needed to treat approximately two; in addition, the benefits were observed to increase during the follow-up period of 18 months. Analysis of participants' healthcare use suggested that day hospital treatment for BPD was no more expensive than general psychiatric care and showed considerable cost savings after treatment.

A follow-up study of BPD patients 5 years after all treatment was completed and 8 years after initial entry into treatment, comparing patients treated with MBT and those receiving TAU, found that those who received MBT remained better than the TAU group. Superior levels of improvement were shown on levels of suicidality (23% in the MBT group vs. 74% in the TAU group), diagnostic status (13% vs. 87%), service use (2 years vs. 3.5 years), and other measurements such as the use of medication, global functioning, and vocational status.

Telegram: @medical_k

www.konkur.in

These early positive findings have been replicated by independent groups comparing MBT-PH with specialist treatment as usual (S-TAU), with MBT-PH being associated with higher acceptability to BPD patients compared with S-TAU, as reflected in significantly higher early drop-out rates of 34% in S-TAU versus 9% in MBT. A further study compared MBT-PH with MBT delivered as a less intensive outpatient treatment (MBT-IOP). MBT-PH and MBT-IOP both showed significant improvements of moderate to large effect sizes on all measures, but neither treatment was superior to the other on the primary outcome measure, despite the difference in treatment intensity. However, MBT-PH showed more rapid change and a tendency to be more effective on secondary outcomes, particularly in terms of relational functioning. Economic analysis revealed that MBT-PH, the more intensive and expensive treatment, had some advantage, albeit at additional cost, in effecting greater likelihood of remission.

Well-controlled single-blind trials of outpatient MBT have been conducted with adults with BPD and with adolescents presenting to clinical services with self-harm, the vast majority of whom met BPD criteria. In a study comparing MBT-IOP for adults with BPD with structured clinical management, MBT was found to be more effective on nearly all outcome measures, and the improvements were maintained at 5-year follow-up. A study on suicidal and self-harming adolescents found MBT to be superior to TAU in reducing self-harm, including suicidality, and depression. Importantly, in the adult trial, the control group received a manualized, highly efficacious treatment, namely structured clinical management; MBT was superior to this intervention, particularly in the long term.

A posthoc analysis of moderators found that the number of personality disorder diagnoses in addition to BPD was the key indicator of severity that predicted the need for the MBT approach, as structured clinical management appeared to have little benefit on most outcome measures among these patients. Furthermore, in the trial with an adolescent sample, improvements generated by MBT appear to have been mediated by improved levels of mentalizing, reduced attachment avoidance, and amelioration of participants' emergent BPD features; participants treated with MBT showed a recovery rate of 44%, compared with 17% of those who received TAU. Ongoing follow-ups of both these trials indicate that improvements in the MBT groups have been at least maintained, and in

Telegram: @medical_k

www.konkur.in

most cases, improvements continued after treatment termination and differences relative to the comparison group remain significant.

Further small studies on adolescents suggest that those who engage in an MBT group show improvement in borderline symptoms, depression, self-harm, peer attachment, parent attachment, mentalizing, and general psychopathology including social anxiety and emotion regulation. The mechanism of change may be through improved mentalizing. In one study enhanced trust in peers and parents in combination with improved mentalizing capacity was associated with greater decline in borderline symptoms. In another study, mentalizing emerged as a significant predictor of change over time in self-reported self-harm and hospital presentation for self-harm.

Additional independent studies provide further support for the efficacy of MBT in BPD in adults. An RCT from Denmark investigated the efficacy of MBT versus a less intensive, manualized supportive group therapy in patients diagnosed with BPD. Patients were randomly allocated to MBT (n = 58) or manualized supportive therapy (n = 27). Each intervention was delivered in combination with psychoeducation and medication. Both the combined MBT treatment and the less intensive supportive therapy brought about significant improvements in a range of psychological and interpersonal measures (e.g., general functioning, depression, and social functioning) and decreased the number of diagnostic criteria met for BPD; effect sizes were large (d = 0.5 to 2.1). The combined MBT was superior to the less intensive supportive group therapy on clinician-rated Global Assessment of Functioning.

An 18-month naturalistic follow-up found that treatment effects at termination were sustained at 18 months. Half of the patients in the MBT group met criteria for functional remission at follow-up, compared with less than one-fifth in the supportive therapy group, but three-quarters of both groups achieved diagnostic remission, and almost half of the patients had attained symptomatic remission. A limitation of this study is that the same clinicians delivered both interventions (and thus there was a high risk of spillover effects between the two treatments); incomplete data was a further significant limitation.

In a second study from Denmark, a cohort of patients treated with partial hospitalization followed by group MBT showed significant improvements after treatment (average length 2 years) on a range of measures, including Global Assessment of Functioning, hospitalizations,

Telegram: @medical_k

www.konkur.in

and vocational status, with further improvement at 2-year follow-up. In the New Zealand public health service, an RCT of MBT delivered by clinicians with brief training and some ongoing clinical supervision compared MBT with enhanced TAU. Both groups showed significant gains in reducing self-harm and suicide attempts, with little significant difference between groups at the end of treatment.

A quality improvement study examined the outcomes for BPD patients treated in an MBT program in a Norwegian specialist treatment unit compared with a former psychodynamic treatment program. This longitudinal comparison had a sample of 345 BPD patients, including 282 patients treated on the psychodynamic program and 64 who received MBT, who had comparable baseline severity and impairments of functioning on all measures. Outcome measures included Symptom Checklist-90 symptom distress, interpersonal problems, and global functioning assessed routinely throughout treatment, and suicidal/self-harming acts, hospital admissions, medication, and occupational status assessed at baseline and discharge.

The change in the program from traditional psychodynamic therapy to MBT led to a reduction in unplanned discharges (MBT had a low drop-out rate of 2%). Measured benefits from the change of program included greater improvements in symptom distress and interpersonal, global, and occupational functioning. Although the change was associated with the introduction of MBT, specific causal attributions are hard to establish in such a design. The same group reported that greater clinical severity was associated with poorer rates of improvement in psychodynamic psychotherapy but was not associated with significant differences in outcomes for patients in MBT. Differences in outcomes for patients in MBT and psychodynamic therapy increased significantly with greater severity of the disorder. This observation is consistent with earlier evidence that MBT is more effective than comparison interventions in patients with more severe symptoms.

One notable naturalistic study in the Netherlands investigated the effectiveness of an 18-month manualized program of MBT in 45 patients diagnosed with severe BPD. There was a high prevalence of comorbidity of DSM-IV Axis I and Axis II disorders. Results showed significant positive change in symptom distress, social and interpersonal functioning, and personality pathology and functioning; effect sizes were moderate to large (d = 0.7 to 1.7). The study also showed that the use of additional

Telegram: @medical_k

www.konkur.in

treatments and psychiatric inpatient admissions decreased significantly during and after treatment. The lack of a control group in this study limits the ability to draw conclusions about the efficacy of MBT.

In a related study, applied propensity score matching was used to determine the best matches for 29 MBT patients from within a larger (n = 175) group who received other specialized psychotherapeutic treatments. These other specialized treatments yielded improvement across domains, which was generally only moderate; in contrast, pre–posteffect sizes were consistently large for MBT, with Cohen's d for a reduction in psychiatric symptoms of −1.06 and −1.42 at 18 and 36 months, respectively, and ds ranging from 0.81 to 2.08 for improvement in domains of personality functioning. Given the nonrandomized study design and the variation in treatment dose received by participants, the between-condition difference in effects should be interpreted cautiously.

MBT has ameliorating effects on some of the neurocognitive problems of people with BPD, perhaps through enhancing social-cognitive skills by altering neural systems underpinning some aspects of neurocognition, such as executive function and attention, which support mentalizing ability. Patients with attentional and reasoning deficits showed increased sustained attention and better perceptual reasoning than controls after 6 months of treatment. Initial deficits in sustained attention among patients resolved after treatment. Patients also showed improved emotion regulation associated with better working memory capacity, and enhanced perceptual reasoning was accompanied by better interpersonal functioning.

MBT for Antisocial Personality Disorder (ASPD)

Research into treatment for ASPD up to 2009 is summarized in the United Kingdom's National Institute for Health and Clinical Excellence clinical guideline for ASPD, which confirmed that interventions for ASPD are poorly researched and that evidence on its treatment is scarce. The authors of the guideline concluded that the evidence for treatments for ASPD was extremely limited and did not support the development of any guidance on treatment recommendations. Two Cochrane reviews concluded that there was no consistent evidence for any intervention for ASPD and recommended that research to test interventions for the disorder is urgently needed.

Telegram: @medical_k

www.konkur.in

A feasibility study of MBT for ASPD reports findings from a small sample (*n* = 9) receiving group and individual MBT. Preliminary results on the Overt Aggression Scale suggested that the participants rated the severity of their aggression toward others and themselves as decreasing over the first 6.5 months of treatment; in contrast, their rating of irritability did not change. Psychiatric symptom severity on the Brief Symptom Inventory showed a reduction in the distress participants experienced in relation to their symptoms at a 6-month follow-up, with participants reporting the greatest decreases in distress resulting from symptoms of depression, anxiety, and hostility.

A number of trials on the effectiveness of MBT have not excluded patients with co-occurring ASPD. A separate analysis of individuals with comorbid ASPD revealed that they benefited significantly from MBT. Patients showed significant reductions in anger, hostility, paranoia, and frequency of self-harm and suicide attempts compared with controls, and there were significant improvements in negative mood, general psychiatric symptoms, interpersonal problems, and social adjustment.

32.15 Narrative Psychiatry

BRADLEY LEWIS, M.D., PH.D.

More than anything else psychiatrists do, they listen to stories. These stories so saturate the clinical encounter that it would be impossible to imagine a clinical encounter without them. In the very first meeting between psychiatrist and patient, the psychiatrist begins with an open-ended invitation to a story: “What brings you here?” or “What seems to be the problem?” Patients respond to these questions by telling psychiatrists about their life, their troubles, when the troubles began, what seems to have caused them, how they create difficulty, and what kinds of problem solving they have tried. Such stories may be rudimentary, they may be only partially worked out, and they may even be baffled and confused. The patient may even be perplexed enough to answer, “I don’t know why I came” or “I’m not really sure what’s wrong, my family sent me.” Nonetheless, the patient’s response to the psychiatrist’s initial questions always involves a story.

As the interview proceeds, going into greater detail about the person’s life and troubles, the psychiatrist and patient never leave the story frame. After the initial broad questions, focused questions aimed at particular symptoms also invite stories. Even finely-grained, highly medical-sounding questions like “Do you have any medical problems?” or “Does depression run in your family?” involve stories. Moreover, the clinical evaluation is only the beginning of the story-centered encounter between the psychiatrist and the patient. Follow-up interviews and meetings go deep into a clinical treatment process, including those that only involve medication checks once every so often and are also saturated with stories. “How have you been?” “What has happened since we last spoke?” “Are you having any side effects with this medication?” These questions all elicit stories from the patient.

One might ask what is the importance of these stories in clinical life? Until recently, little attention has been paid to the question of stories within clinical settings. A patient’s narrative of their troubles were seen as merely

Telegram: @medical_k

www.konkur.in

a vehicle to get across the facts. The “art” of clinical work was to abstract away the facts embedded in patient’s stories, but the stories themselves were secondary. In the last several years, however, the view of narrative as being merely functional has been thrown into question, and, increasingly, clinicians see stories as indispensable for understanding human phenomena. For these clinicians, stories are just as important as facts because it is the story that allows people to select, organize, and shape the facts that matter.

Narrative psychiatry emerges out of this increased interest in clinical stories. The two main tributaries that lead to narrative psychiatry come from the two different sides of psychiatry: “narrative medicine” on the one side and “narrative psychology and psychotherapy” on the other. Narrative psychiatrists are psychiatrists who combine the wisdom of these two domains.

Following the lead of narrative medicine, narrative psychiatrists recognize that psychiatric patients, like medical patients, come to clinics with intense stories to tell. Contemporary narrative medicine has developed from decades of work in bioethics and medical humanities devoted to humanizing the clinical encounter through a better understanding of patient stories. The term “narrative medicine” comes from Rita Charon, an internist and literary scholar, who used it to describe an approach to medicine that uses narrative approaches to augment scientific understandings of illness. Narrative medicine brings together insights from human-centered medical models, such as George Engel’s biopsychosocial model and Eric Cassel’s person-centered model, with research and insights from phenomenology, the humanities, and interpretive social sciences.

Narrative medicine uses these resources to better understand the illness experience, “to recognize, absorb, interpret, and be moved by the stories of illness.” As Charon argued, when clinician’s possess narrative competency, they can enter the clinical setting with a nuanced capacity for “attentive listening …, adopting alien perspectives, following the narrative thread of the story of another, being curious about other peoples motives and experiences, and tolerating the uncertainty of stories.” Charon further argued that doctors “*need* rigorous and disciplined training” in narrative reading and writing not just for their own sake (helping them to deal with the strains and traumas of clinical work), but also “*for the sake of their practice.*” Without such narrative competency, clinicians lack the ability to

Telegram: @medical_k

www.konkur.in

fully understand their client's experience of illness. For Charon and others in narrative medicine, narrative study is not a mere adornment to a doctor's medical training; it is a crucial and basic science that must be mastered for medical practice.

A major task of narrative medicine, and therefore narrative psychiatry, is to be a good listener and to connect empathically with the patient's story. A narrative psychiatrist, like a narrative physician, seeks to understand the patient first and foremost. This understanding brings patient and clinician together into a shared experience of the patient's world. This narrative understanding cannot be reduced to psychology, neuroscience, or sociology. Narrative understanding is much more than a causal explanation of problem A or problem B that the patient might have. It does not simply abstract from the person's situation, a categorical label that groups problems under a well-known abstract grid. Instead, narrative understanding tunes into the uniqueness of the individual and the unrepeatability of the person's experience and difficulties. Narrative understanding, in short, is a deep appreciation of the person as a whole—what it feels like for this person, in this particular context, going through these particular problems.

By tuning in to the person's story, first and foremost, as a goal in and of itself, narrative psychiatrists, like their narrative medicine colleagues, create an environment in which the person can be known and their difficulties can be appreciated. This step can be one of the most healing acts a clinician can perform. By allowing the person to be known, the clinician creates a bond that reduces the patient's isolation because the patient immediately becomes less alone with the problem. Whatever else may happen in the clinical encounter, this sense of togetherness will reduce the person's suffering. The patient now has a comrade, a foxhole partner, someone who is in it with them. This partnership may not change the extent of the person's troubles, but it changes immensely the experience of the situation. Although clinicians are not the only ones who can perform this role, a good clinician can sometimes be one of the few people in the person's world who can truly understand. Clinicians have extensive experience with similar experiences of human suffering, as well as the advantage of working in clinical settings in which many of the blocks to discussing shameful or embarrassing problems often are removed.

Telegram: @medical_k

www.konkur.in

In addition to following the lead of narrative medicine colleagues, narrative psychiatrists also follow the lead of contemporary colleagues in narrative psychology and psychotherapy. The history of narrative psychology and psychotherapy goes back to Sigmund Freud's early work at the inception of psychoanalysis. At that time, Freud lamented about how his case histories sounded more like narrative fiction than hard science. As Freud explained, "I have not always been a psychotherapist. Like other neuropathologists, I was trained to employ local diagnosis and electroprognosis, and it still strikes me as strange that the case histories I write should read like short stories and that, as one might say, they lack the serious stamp of science."

Despite this awareness of the role of story in his clinical work, however, Freud never embraced a narrative theory of psychoanalysis, and throughout his career, he remained attached to the natural science model he inherited from neurology.

Contemporary narrative psychology and psychotherapy's motivation for returning to the role of narrative comes partly from the broader turn to narrative in humanities and social science and partly from the history of psychotherapy since Freud. The last century of psychotherapy has been a century of strife, with one faction after another splitting off from psychoanalysis. Leading alternatives to psychoanalysis included behavioral, humanistic, family, cognitive, feminist, and interpersonal, just to name some. All of these splits are characterized by further splits within splits, which has fragmented the field of psychotherapy to the point that there are now more than 400 active approaches to psychotherapy. Narrative approaches emerge at this particular moment as part of an important trend away from further fragmentation and toward psychotherapy integration. Narrative approaches are invaluable for psychotherapy integration because they provide a metatheoretical orientation from which to understand and practice psychotherapy. As Lynne Angus and John McLeod pointed out in *The Handbook of Narrative and Psychotherapy,* narrative approaches allow psychotherapists to understand the common factors within psychotherapy and to appreciate the diversity of psychotherapeutic models without attempting to close these differences down. Thus, in many ways, the contemporary emergence of narrative approaches brings the history of psychotherapy back full circle. More than 100 years since Freud introduced "talking

Telegram: @medical_k

www.konkur.in

therapy," psychotherapy has returned to its early appreciation of the similarity between case histories and narrative stories.

Similar to narrative psychotherapists, narrative psychiatrists recognize that the stories people tell about themselves not only describe their lives, they also shape their lives. The stories people use to frame and organize their lives are not simply incidental to their identity; they are the primary tools people have for configuring and reconfiguring their identity. Narrative psychiatrists recognize that this shaping of identity through narrative is a major tool for recovery. When people come for help in a therapeutic situation, they not only want to be understood, they also want help making changes in their lives. Narrative psychiatrists collaboratively encourage and foster these changes by helping coauthor new stories of purpose and thriving. As SuEllen Hamkins puts it in *The Art of Narrative Psychiatry,* a narrative approach helps patients discover "untold but inspiring stories of resiliency and skill in resisting mental health challenges while dismantling aspects of presenting narratives that fuel problems. It examines what the doctor's kit of psychiatry has to offer in light of the values and preferences of the person seeking consultation, authorizing the patient as the arbiter of what are helpful and what is not." Working in this way, narrative psychiatrists understand that collaboratively reauthoring stories people tell about themselves is a powerful way to make changes toward recovery goals.

WHAT IS NARRATIVE?

Both narrative medicine and narrative approaches to psychotherapy are deeply informed by narrative theory. But how have writers and literary scholars tried to describe "narrative?" What are the important elements of narrative? How does narrative work in human life? Although these questions may sound straightforward, they are not so easy to answer. The literature on narrative theory is vast, and it has many tributaries. Historian and narrative theorist Hayden White has argued that to "raise the question of the nature of narrative is to invite reflection on the very nature of culture and, possibly, even on the very nature of humanity itself." For clinical work, therefore, it is important to select which aspects of narrative theory are most helpful.

Narrative physician and novelist Abraham Verghese provides a good place to start. Speaking to colleagues at the American Society of Internal

Telegram: @medical_k

www.konkur.in

Medicine, Verghese explains that "As physicians, most of us become involved in the stories of our patient's lives…we become players in these stories. Our actions change the narrative trajectory…and our patient's stories come to depend heavily on repetition of what we say." The inescapable implications for medicine are that:

> *Story* helps us link and make sense of events in our lives; we as physicians *create* stories as often as we record them …; and we are characters in [these] various stories, walking on and off the stage in tales that take place in our hospitals and clinics.

Verghese points to examples in which physicians reach narrative competence through years of attentive practice, but he finds a more direct route through combining medical practice with the "tools that the writer possesses," or what Verghese called the "storytelling craft." During Verghese's immersion into the craft of writing, he found that the pillars of narrative invariably involved the author's selection and organization of *metaphor, plot,* and *character.* Making selections from these narrative elements are "fundamental to good writing in the same way that internal medicine skills rest on understanding the mechanisms behind dyspnea, edema, polyuria, and other cardinal manifestations of disease."

Following Verghese's lead, narrative psychiatrists must, at a minimum, understand the narrative elements of metaphor, plot, character, and we can add to this list, point of view. The following sections use narrative theory, particularly the richly synthetic efforts of philosopher Paul Ricoeur, to develop these narrative elements. In addition, recent memoirs of mental illness diagnoses are explored to see how people use narrative elements to tell the story of mental health concerns.

Metaphor

The stories people tell are rich with metaphor. Consider this example from clinical life: "My boss looks at me lately like I am a piece of garbage. In his eyes, I am used up, something to discard and throw away. My whole interactions with him leave me feeling like shit. I feel utterly worthless, and my life is meaningless." This snippet of a clinical story has at least four metaphors. The person compares herself to garbage, shit, monetary value, and a literary text. Commonsense would indicate that these kinds of metaphors have little importance. Metaphors, most people believe, are embellishments and ornamentations to the content of a story, but they do little else. From this perspective, the person behind the snippet feels bad

Telegram: @medical_k

www.konkur.in

and believes her boss does not value her. End of meaning. The literal paraphrase is all you need.

For influential literary theorists, however, such as I. A. Richards, a number of philosophers, particularly Max Black, Mary Hesse, Paul Ricoeur, and Mark Johnson, and increasingly for cognitive scientists like George Lakoff, metaphor has a much larger function than simple ornamentation. In their book *Metaphors We Live By,* Lakoff and Johnson put it most succinctly: “metaphor is not just a matter of language, that is, of mere words…On the contrary, human thought processes are largely metaphorical.” Lakoff and Johnson argue that metaphor is a pervasive aspect of human life, not just in the words that are used, but also in the very concepts: “Our ordinary conceptual system, in terms of which we both think and act, is fundamentally metaphorical in nature.” By shaping concepts, metaphor structures the way in which the world is perceived, what is experienced, how people relate to other people, and the choices one makes.

Metaphor performs this function by allowing one to understand and experience one thing in terms of something else. Hesse uses the example, borrowed from Black, of “man is a wolf.” Hesse explains that the metaphor works because it transfers ideas and associations from one term to the other. The metaphor selects, accentuates, and backgrounds aspects of two systems of ideas so that they come to be seen as similar: “Men are seen to be more like wolves after the wolf metaphor is used, and wolves seem to be more human.” Hesse goes on, “Nature becomes more like a machine in the mechanical philosophy, and actual, concrete machines themselves are seen as stripped down to their essential qualities of mass in motion.” In short, metaphor allows the two terms, or more precisely the two systems of terms, to interact and adapt to one another.

Understanding metaphor in this way connects to broader work in continental linguistic philosophy, and that work, as a whole, shifts standard ideas about truth and objectivity. It allows one to sidestep the usual binary traps between relativism (anything goes) and realism (there is only one correct or true way to describe the world). When the role of language and metaphor as a mediator between concepts and the world is understood, it no longer makes sense to think in these highly modernist either/or terms. Rather than using a rigid binary splitting between true and false, people can think instead in a postmodern language of semiotic

Telegram: @medical_k

www.konkur.in

realism and pluridimensional consequences. Or, as Paul Ricoeur puts it, people can let their notions of universal truth (or single objective truth) give way to ideas about “metaphorical truths.”

The multiple metaphors that shape one’s concepts and perception allow one to see and experience the world in a particular way and from particular perspectives. Ricoeur calls these particular ways “metaphorical truths” to emphasize that the metaphorical process does allow one to understand something real about the world. That “reality” is not absolute, and it is always in tension with other ways of understanding something equally real about the world. However, these other ways of understanding are not available to unless people inhabit new or alternative metaphors for perception and description. For Ricoeur, this means that the “seeing as” of metaphor generally also means a “being as” of lived experience.

Plot

The plot works like a metaphor in that it also orders one’s experience and provides a form to the narratives. Plot, or the process of emplotment, adds to metaphor two key dimensions: (1) it brings together what would otherwise be separate and heterogeneous elements, and (2) it organizes one’s understanding and experience or time, or what could be called temporal perception.

The critical function of plot for narrative is that plot creates a narrative synthesis between multiple individual events and brings them together into a single story. It allows an intelligible connection to be made between them. Remarkably, plot can create a synthesis between events and elements that are surprisingly incongruous or heterogeneous—events that do not seem to fit together. In any one story, vastly incommensurable elements can all be brought together through the process of emplotment. Consider this list of diverse elements that might come up in even a small segment of clinical work: human desires, human rationality, human purpose, human agency, unconscious motives, unintended circumstances, unplanned accidents, other peoples’ desires and rationality, their unconscious motives, material force, natural laws, divine intervention, discoveries, nightmares, historical chance, social prejudice, economic downturns, failures of communication, contemporary styles and fashions, the effects of collaboration and conflict, grassroots organizing, spiritual conversion, the weather, technologic capacity, and cell phones

Telegram: @medical_k

www.konkur.in

(just to name a few). Without a plot, there is no way to make sense of such a diversity of phenomena.

Plot also configures these multiple elements into a temporal order. This temporal order is of two sorts. First, each plot is composed of a discrete series of incidents, of theoretically infinite *nows.* Second, each plot takes these infinite nows, proceeding one after another in succession, and organizes them into a humanly manageable experience. As Ricoeur points out, without plot, clock time is only a series of nows. The aporia, or gap, between clock time and the experience of "human time" comes from a well-known paradox: "the future is not yet, the past is no longer, and the present does not remain." This paradox means that clock time cannot be directly experienced. Although humans have a sense of time, when they are asked to describe it, they are baffled.

Ricoeur finds a phenomenologic solution to the paradox of human time in St. Augustine's "thesis of the threefold present." Augustine argued that present, past, and future can all exist simultaneously in the human mind through a coming together of a plural, or threefold, present: the present moment accompanied by *memory* and *expectation.* Memory in this formula recalls the past, and expectation, in an analogous way, looks toward the future. The present, in other words, contains one's memory of the past and one's expectation of future events. For Ricoeur, the threefold present of time highlights a parallel between the experience of time and the structure of plot. Plot, like human time, is organized in a temporal order of beginning, middle, and end. Through plots, people configure their confused, unformed, and otherwise mute temporal experience.

Ricoeur sees this relation between time and plot as a two-way phenomenon: time becomes human time when it is organized by plot, and conversely, plot is meaningful because it portrays the features of temporal experience. Ricoeur admits that his conclusion is "undeniably circular," but he argues that this circularity is not in itself a problem: The circle of plot and time, he explains, is "not a vicious, but a healthy circle." Emplotment, from this perspective, can be seen as a kind of prosthetic device. It does not solve the riddle of time so much as it allows one to keep going without a solution. The riddle of human time, in other words, leaves humans with an inconclusive rumination to which the process of emplotment alone can respond: "Emplotment… replies to the speculative aporia [of time] with a poetic making of something capable, certainly, of clarifying the aporia …, but not of resolving it theoretically."

www.konkur.in

Character

In narrative theory, the concept of character connects directly to contemporary controversy surrounding the related and more basic concept of personal identity. The controversy around identity may be understood as a tension between essentialist and nonessentialist approaches. Essentialist notions of identity indicate that humans have a fixed personality, perhaps biologically stamped, that is, authentically belongs to one's self and that is at the core of one's being. This "true self" or "core self" may be distorted or covered over, but it is nonetheless there for the discovery if people apply themselves patiently and persistently to the task. Nonessentialist critiques, however, have deconstructed this ideal of identity and its notion of an integral, originary, and unified self. This critique has been comprehensively advanced by influential philosophers like Roland Barthes, Jacques Derrida, and Michel Foucault and by psychoanalytic writers working in the tradition of Jacques Lacan politically inflected through cultural studies and feminism. As a group, these writers have deconstructed the essentialist ideal of identity and its similar notions of an integral, originary, and unified self.

One of the most productive ways to navigate the tension between essentialist and nonessentialist understandings of identity is to draw a comparison between identity (in life) and character (in fiction). Paul Ricoeur calls this approach to identity "narrative identity," and the basic idea has recently been developed into a school of psychology known as "narrative psychology." As Ricoeur puts it, "fiction, in particular narrative fiction, is an irreducible dimension of self-understanding…fiction is only completed in life, and life can be understood only through the stories that we tell about it."

Self-understanding, on this account, is an interpretive event, and narrative is the privileged form for this interpretation: "a life story [is] a fictional history or, if one prefers, a historical fiction, interweaving the historiographic style of biographies with the novelistic style of imaginary autobiographies." Literary theorist Peter Brooks sums up this idea beautifully in his book *Reading for the Plot: Design and Intention in Narrative:*

> Our lives are ceaselessly intertwined with narrative, with the stories that we tell and hear told, those we dream or imagine or would like to tell, all of which are reworked in that story of our own interrupted monologue. We live immersed in the narrative, recounting and reassessing the meaning of our past actions, anticipating the outcome of

Telegram: @medical_k

www.konkur.in

our future projects, and situating ourselves at the intersection of several stories not yet completed.

Narrative approaches to identity allow one to navigate the tension between essentialist and nonessentialist identities because narrative identity allows for a kind of continuity over time, and relative stability of self, without implying a substantial or essentialist core to this stability. People's interpretations of themselves use the cultural stories with which they are surrounded to tell a story of self that escapes the two poles of random change and absolute identity. In this way, a narrative identity is also an intersectional cultural identification. People's identifications may seem original, but they are narrated with the resources of history, language, and culture.

As cultural theorist Stuart Hall puts it, identity is a "process of becoming rather than being: Not 'who we are' or 'where we came from,' so much as what we might become, how we have been represented and how that bears on how we might represent ourselves." Culturally narrated identity stories, Hall argues, involve "not the so-called return to roots, but a coming-to-terms with our 'routes.'" They involve a deep appreciation of what routes have been taken, the effects of those routes, and what new routes might be chosen ahead. This coming to terms with routes, although it involves the use of inessential cultural narratives, in no way undermines the personal or political efficacy and value of identity. Nor does it undermine a genuine sense of belonging that can come from a well-narrated self.

First-Person Narratives

Bringing this theory to psychiatry, the importance of understanding the elements of narrative can be highlighted by looking at first-person memoirs of mental illness. As Hillary Clark, a scholar of mental illness memoirs puts it: "One cannot feel well one day, numb and oppressed the next, suicidal after a few months have elapsed…without seeking a narrative explanation—the cycle of bipolar disorder, for instance, or the Christian narrative of sin, repentance, and redemption—in order to make sense of it all, to trace a single self through all these changes." Clark finds that studying personal narratives are valuable because they "give voice to the ill, the traumatized, and the disabled," and they restore insights and wisdom they have achieved—wisdom that can be lost by medical

Telegram: @medical_k

www.konkur.in

research and clinical case studies that risk turning people into statistics and diagnostic labels.

Memoirs are also helpful because they show how models of mental illness work, like the narrative element of metaphor in the process of creating illness stories. Clinical models may be understood as containing root metaphors developed over time through a research and practice community. In ordinary writing or conversation, people generally use metaphors to provide a quick glimpse: “This hotel is a palace.” But, in a clinical model, research communities (e.g., biomedical, psychoanalytic, cognitive behavioral, family, social/political, art therapy, spiritual, or pastoral counseling) develop metaphors into systematic models that frame their work and that explain the world through a metaphorical redescription. The metaphor, “Joe is a pig,” redescribes Joe in a new way and allows for something new to be perceived about him. So too, the disease model of mental illness—“mental illness is a disease”—redescribes mental difference and allows something new about it to be perceived. Philosophical psychiatrists Bill Fulford and Tony Colombo use these insights to develop the following definition of psychiatric models: “[Psychiatric] models…are the conceptual frameworks, or sets of ideas, by which, in any given area, people structure and make sense of the world around them.”

Memoirs reveal that the root metaphors, which organize psychiatric clinical models, do not stay in the clinics; they seep into the culture and become cultural resources that join with the larger pool of mental models as well as the other narrative elements for organizing self-stories. In times of trouble, people look through the metaphorical structures of mental models to perceive, select, and plot aspects of their lives that they believe to be important. These culturally located self-stories and the priorities within those stories combine with other cultural resources to scaffold narrative identity and provide a compass for living. They tell where people have been and where they are now, and they provide a trajectory into the future. Studying memoirs of mental illness, a wealth of first-person stories can be found that help one to see how people plot the models and metaphors of mental difference into their narrative identity and their stories of recovery.

Lesley Dormen, in her memoir “Planet No,” emphasizes themes of loss and depression through a metaphor of unresolved grief common in psychoanalytic models. Dormen explains that she initially spiraled into

Telegram: @medical_k

www.konkur.in

depression by two losses in her life: “An architect I’d loved for under a year left me for a woman he met in a supermarket parking lot. And my best friend, Tessa, a woman as central to my understanding of myself as my brown eyes and small feet, disappeared into marriage and withdrew from our friendship completely.” Dormen used psychotherapy to explore these losses and came to realize that they were compounded by earlier losses and traumas from her childhood. She lost her father after her parents divorced when she was 6 years old, she was sexually abused by her stepfather, and she had a painful emotional relationship with her mother. Dormen felt so isolated and rejected by these experiences that when her therapist asked her, “if [you] were a girl in a story, how would [you] see yourself?” Dormen answered: “Like an orphan.” Building on this insight, she eventually came to understand that her many ungrieved losses amplified one another, and these unresolved feelings were repeated in the present life. As an adult, she relived her past experiences of solitary isolation and failure as an unmarried woman in New York, feeling the pressure to be coupled like “normal and successful” people.

Psychoanalytic therapy and self-reflection helped Dormen to understand that her stepfather’s sexual abuse was the central “curve in [her] depression story. His touch had caused the spine of the story to veer off into a new direction, had reconfigured the terms of my loves and longings.” Most pernicious for her ongoing development, the abuse left her confused about her desires, and this confusion left her “frozen in a girlhood made curiously old.” The dense and painful emotional conflicts that grew up around the sexual abuse knotted together shame, illicit sexual pleasure, heartbreaking loss, pity, betrayal, guilt, duplicity, and an aching distance between her mother and herself. These emotional knots were so tight that she could not begin to open them or untie the feelings, but at the same time she could not forget them. She found herself constantly and repeatedly returning to them “with the vague uneasiness that was a familiar part of [her] internal landscape.”

Slowly and often painfully, therapy helped her move past these knots in her character that seemed to rope her into depression and despair. She was able to separate herself from this history: “Something happened—something that was separate from me. There was a me that existed before the something and a me that existed after. Before and after were separate, not the same.” No longer tied together in knots, “it was possible to stand outside those events, to observe them and draw a conclusion

Telegram: @medical_k

www.konkur.in

about them. It was possible not to just be them." And, not only that, it became possible to move past the grief, to feel joy, and to make new connections: "I fell in love with New York, with the giddy green of the first spring after the worst of the depression lifted, with new friends, travel, and wonderful books. I looked around my apartment and saw that there was pleasure in things, in their colors and shapes, and that one did not actually need a marriage certificate to buy good pots." Dormen's memoir suggests that she came to understand her troubles through the metaphors of psychoanalysis, the plot of psychotherapeutic change, and the narrative identity of someone who used psychotherapy for recovery and transformation.

In contrast to Dormen's psychoanalytically inflected story, William Styron's memoir, *Darkness Visible,* is paradigmatic of the disease model as a narrative template. Styron describes himself as "laid low by the disease," a "major illness" of "horrible intensity," which came on him like a "brainstorm…a veritable howling tempest in the brain, which is indeed what clinical depression resembles like nothing else." This connection between depression and bad weather perfectly captures the disease model of depression as lying outside the frame of human goals, desires, losses, and disappointments. Like the weather, depression comes from the material world of inhuman forces, from physical and chemical interactions. For a strong disease model advocate like Styron, it makes no more sense to give human meaning to depression than to tell an atheist that thunder is caused by God's anger toward us. Styron explains how he sees it: "I shall never learn what 'caused' my depression, as no one will ever learn about their own…so complex are the intermingling factors of abnormal chemistry, behavior and genetics."

Styron's memoir was one of the first and most influential to adopt such a narrative frame. He relies on biologic metaphors for depression that perfectly match the disease model in psychiatry as well as an avalanche of pharmaceutical marketing devoted to promoting antidepressant medications. Depression, Styron writes, "results from an aberration of biochemical process. [It] is chemically induced amid the neurotransmitters of the brain…a depletion of the chemicals norepinephrine and serotonin." This "upheaval in the brain tissues" causes the mind "to feel aggrieved, stricken," and it creates "muddied thought processes" like the "distress of an organ in convulsion."

Telegram: @medical_k

www.konkur.in

Styron is far from alone in his approach, and the disease metaphor runs through many other memoirs. For example, in a collection of Depression memoirs, *Unholy Ghost: Writers on Depression,* it shows up in several examples. Virginia Hefferman laments the "substandard physiology," which creates her depression. Chase Twitchell moves past the phrase, "chemical imbalance," to chime in with a more updated disease model explanation: "What happens in depression, for reasons that are still unknown is that the limbic-diencephalic system malfunctions." And similarly, Russell Banks fears that his wife's "malfunctioning limbic diencephalic systems" has created a depression so severe it may result in her suicide. All of these memoirs show the metaphors of biology shaping the plots of recovery and the narrative identity of the people involved.

In contrast to biopsychiatry or psychoanalysis, David Budbill's memoir, "The Uses of Depression: The Way Around is Through," provides a good example of alternative models and metaphors. He approaches painful periods of depression through the less common but still vital models of spirituality and creativity. Because of what he calls his "rebellious, contrary" personality, none of the mainstream approaches is suitable for him, and he decides to push past the mainstream to develop his "own way of dealing with and using depression" that he calls his "give in" method: "I discovered that the only way around my periods of depression is directly through them; in other words, the sooner I can resign myself to the Angel of Depression, the sooner she will be done with me and leave me alone."

Drawing from the narrative frames of Zen Buddhism and creative writing, Budbill discovers that if he lets go of his critique of depression and allows himself to be with the intensity of the feelings, the depressive episodes are not all negative. Indeed, depression can be experienced as generative (or positive) as well. Budbill finds that one of its most important positive dimensions is that it slows him down. Depression forces him to enter a "negative space" where he can neither work nor produce; instead, he tunes into a very different experience—"empty, open, quiet, passive, receptive, dark." These slothful, withdrawn periods function as a kind of dormancy where he can store up energy for times when the Angel of Depression lets him go. During such times, he can better hear his muse, and this "receptacle" period later emerges in his poetry. For Budbill, the metaphorical frames of spirituality and creative writing helped him cultivate a narrative identity of spiritual seeker and artist whose experiences show sensitivity rather than pathology. The metaphor of

Telegram: @medical_k

www.konkur.in

sensitivity can be seen to scaffold a recovery plot that involves tuning into his depression experience as a muse and a generator of wisdom rather than a clinical plot that works to remove or transform the experience.

Joshua Wolf Shenk gives a good sense in his memoir how a self-reflective awareness of the many models and metaphors of mental illness can be a tool of coping. Responding to his depressive experiences by researching the history of depression and the role of metaphor in shaping what is known about depression, Shenk concludes that "what we call 'depression,' like the mythical black bile, is a chimera…It is cobbled together of so many different parts, causes, experiences, and affects as to render the word ineffectual and perhaps even noxious to a full, true narrative." Even so, the pain and suffering of depression is anything but a chimera, and Shenk understands the inevitable need to "abbreviate and simplify" in trying to understand it. He finds "no way around words like 'depression' and 'melancholy'…but it is one thing to use shorthand while straining against the limits of language. It is quite another to mistake such brevities for the face of suffering." For Shenk, simplified phrases like "biochemical malfunctions" and "biological brain diseases" favored by public health campaigns, well-intentioned clinicians, and pharmaceutical companies can mystify as much as they inform. "When we funnel a sea of human experience into the linguistic equivalent of a laboratory beaker, when we discuss suffering in simple terms of broken or fixed, mad and sane, depressed and 'treated successfully,' we choke the long streams of breath needed to tell of a life in whole."

This awareness allowed Shenk to consciously seek an array of different approaches to his depression. He gave medications a try (although found none that were helpful) and sought solace and guidance in several hundred afternoons of psychotherapy. He worked through the pain of his parents' divorce when he was seven—"the slow leakage of affection and kindness from my parent's marriage, the grim entrance of resentment, confusion, and anger," and he overcame the automatic tendency from his family life that "forbade expressing these emotions." All of this work went into the larger task of creating a life story that put his depression in perspective: "to find my story by living it, following moments of emotional clarity through life's maze. I look for help in therapy, [but also] in relationships, and faith in its broadest sense—faith in the gardener, the faith of the lover, the faith of the writer. The faith that I can experience

Telegram: @medical_k

www.konkur.in

what is real about the world, that I can hurt plainly, love ravenously, feel purely, and be strong enough to go on."

The story of the Icarus Project, a consumer-oriented mad pride group active from 2002 to 2020, provides another instructive example of how people can bring conscious awareness of the diversity of narrative options into the process of recovery. The Icarus Project was initiated by Sascha DuBrul and Ashley McNamara—two arts and humanities-educated college students who were given diagnoses of "Bipolar Disorder" in their 20s and who found themselves struggling as much with their psychiatric treatment as with their emotional intensities. DuBrul and McNamara, similar to many others in consumer activist groups, felt that the core of the problem with the psychiatric perspectives they encountered was an overemphasis on scientific models of "disease" and "treatment." DuBrul and McNamara did not respond against these models with an antipsychiatry perspective or dismiss psychiatric disease models outright, but they felt this way of telling the story of their difficulties missed something crucial. They agreed that their psychic differences could cause them tremendous difficulties similar to the way that medical illness can do, but they also found it a mistake to over-emphasize a model of pathology and story of broken brains.

Instead of accepting or rejecting the prevailing biologic narrative, DuBrul and McNamara set out to create a grassroots alternative community for healing and recovery that was open to the many stories of psychic differences. As McNamara explains, "We began The Icarus Project as a way of creating space for people to share their trajectories through this under-charted world of blackness and brilliance and the million shades of gray that the medical establishment has no idea how to describe." Throughout this process, Icarus Project organizing has been led by an insightful narrative organized around the story of the boy Icarus:

> Defining ourselves outside convention we see our condition as a *dangerous gift* to be cultivated and taken care of rather than [simply] a disease or disorder needing to be 'cured.' With this double-edged blessing we have the ability to fly to places of great vision and creativity, but like the boy Icarus, we also have the potential to fly dangerously close to the sun—into realms of delusion and psychosis—and crash in a blaze of fire and confusion. At our heights we may find ourselves capable of creating music, art, words, and inventions which touch people's souls and change the course of history.

DuBrul and McNamara go on to acknowledge the risks in using the Icarus story and the possible perils of narrating their emotional difficulties

Telegram: @medical_k

www.konkur.in

as dangerous gifts. However, in spite of these risks, they also recognize how metaphors of mental and biologic pathology and metaphors of creative, political, and spiritual sensitivity can be as close as a turn of the kaleidoscope. They recognize how stories centered on pathology can turn into stories of creativity and that this narrative flexibility can create "tools of inspiration and hope in this repressed and damaged society." As they put it, "We understand that we are members of a group that has been misunderstood and persecuted throughout history, but has also been responsible for some of its most brilliant creations. And we are proud."

The Icarus Project is similar to Shenk in that it consciously creates integrated narratives of psychic troubles that are open to pathologic metaphors as well as creative, spiritual, and political metaphors. The difference is that Shenk is working on his story alone, and the Icarus project uses a mutual aid community. The goals for both, as the Icarus project puts it, are to recognize the dangers and pitfalls of mental difficulties, to celebrate and tap into the "potential that lies between brilliance and madness," to put in the necessary effort to stay balanced and grounded, and to plot recovery stories that lead to full and meaningful lives (which might include stories of psychiatric medications, psychotherapy, artistic practice, activism, or spirituality). By foregrounding the narrative process of recovery, the Icarus Project aims to separate mental health issues "from the reductionist framework offered by the current mental health establishment" and in doing so, learn "from each others' mistakes and victories, stories and art, and create a new culture and language that resonates with our actual experiences of 'disorder.'"

NARRATIVE PSYCHIATRY

The deep implication of narrative theory and memoirs of mental illness for psychiatric practice is that there are many ways to tell the story of mental difference and suffering—not just one right way and many other wrong ways. To be helpful for people with the tremendous diversity of values and life-style preferences seen in memoirs, psychiatrists cannot be limited to one or two storytelling options. Psychiatrists must be comfortable using a range of metaphors and models to help people plot their recovery stories and narrative identities. To see how this works in practice, it is helpful to develop a character from literary fiction as a "case example" for a narrative psychiatry approach.

Telegram: @medical_k

www.konkur.in

Narrative psychiatrists find literary fiction an invaluable resource for "case examples" because literary examples, as a rule, provide much richer contextual data than clinical case studies. All too often clinical case studies tell a story that has been tightly organized along a particular narrative frame. Literary examples do this as well, but the framing is generally much less heavy handed and much more open to alternative frames and perspectives. That said, literary examples usually require additional imaginative work to make them suitable as clinical case histories.

To see how this works, consider Marina, a character in Claire Messud's 2007 novel *Emperor's Children.* Marina is a single woman, in her early 30s, lives with her parents, and is unemployed. She struggles throughout the novel with symptoms of depression and anxiety. To get to know Marina's story, start with a scene where she and her college friend Danielle are meeting for dinner. The dinner is at Marina's house, but Danielle arrives first, which leaves her spending several minutes alone with Marina's parents. Being alone with Marina's parents makes Danielle feel awkward and uncomfortable. Here's the passage:

> Danielle…felt like a teenager, as she used to feel in the kitchen of her parents' house in Columbus, before the divorce of course, and she was suddenly, powerfully, aware of the profound oddity of Marina's present life. A life arrested at, or at least returned to, childhood. Danielle couldn't imagine eating nightly with her parents, not only because they now lived in different states and didn't speak to each other, but because she was entering the fourth decade of life and hadn't been through the wearying rigmarole of family life for anything more than an almost supportable day since she was seventeen and had gone off to college.

In this passage, Danielle uses the metaphor of childhood to organize her understanding of Marina's life. Through the childhood metaphor, Danielle perceives Marina's adult life as "arrested, or at least returned to, childhood." If Danielle were to tell the story of Marina's life using this childhood metaphor, she might very well select events from Marina's past that led up to this moment. Perhaps she would recall a difficulty Marina had in committing to relationships, or a series of immature reactions to authority figures, or perhaps several examples of her being dreamy and irresponsible. These diverse elements would come together in a plot that leads to the present moment of Marina as trapped in childhood. The story would not only make sense of the past and the present and provide a narrative identity for Marina, but it would also provide clear direction for

Telegram: @medical_k

www.konkur.in

the future. In this narrative frame, Marina must "grow up." She must leave her parents and home, get a job, get married, and have children (or at least make steps in these directions).

This example highlights the importance of "point of view." Narratives tell a story from a particular perspective. Even if an author uses the omniscient point of view, that is still not a story from nowhere; it remains a story told by an author who has a particular take on the events that they select and frames. In the selection above from *Emperor's Children,* readers learn about Marina's life from Danielle's point of view. This passage does not tell the reader whether Marina would see herself as stuck in childhood; it only tells the reader that Danielle sees her this way.

A little further on in the story, readers learn that Marina does feel similarly about herself. Indeed, the perspective of herself as childish and immature has left her deeply unhappy and anxious about her life and even about her worth as a person. Not only this, but as the novel proceeds, readers see Marina's deep discontent with her "childish" self-perception leading her into a poorly thought-out romance and decision to marry an older man, a magazine editor, after they had been going out for a few weeks. In the process of this marriage, Marina gains in quick succession not only a husband but also a job (as she joins the editorial staff of her new husband's magazine). This rapid marriage and entrance into the job market effectively disrupt the childhood metaphor (Marina has now moved into "adulthood"), but, unfortunately, Marina's judgments turn out to have been potentially premature, as the magazine quickly fails and the relationship falters. By the end of the novel, it is not known whether Marina's marriage will work, but Messud leaves her readers feeling uncertain and doubtful.

To use this story as a literary "case example," the additional narrative work involves imagining Marina coming to see a psychiatrist at or near a moment of crisis. A common plot structure in narrative fiction involves what theorists call the Freitag triangle. In this plot structure, the story and its characters move from increasing tension and conflict to climactic crisis and then finally to resolution. If it is a novel or a complicated short story, the plot is often composed of multiple Freitag triangles that may or may not come together into an overarching Freitag triangle. In using literary material as case examples, it is helpful to imagine that a character in the story comes to see an imaginary clinician just at or near this point of climactic crisis. For example, imagine that Marina came to see a narrative

Telegram: @medical_k

www.konkur.in

psychiatrist for help when she was at the height of her crisis. This would be when she was in the middle of her most intense anxiety and feelings of inadequacy, and before these feelings were resolved (at least temporarily) by marrying the magazine editor and getting a job.

How would the narrative psychiatrist work with Marina in this situation? Like with narrative medicine and other person-centered approaches, the narrative psychiatrist's first and in many ways foremost task in helping Marina will be in getting to know her and developing a rich appreciation of her story. This empathic connection helps Marina become much less alone with her problems. She now has a nonjudgmental partner with whom to share them and to relate them. Psychiatrist Robert Coles captured this deeply person-centered dimension of narrative psychiatry in his book *The Mind's Fate: A Psychiatrists Looks at His Profession.* Coles sees the person-centered core of narrative psychiatry as the "*ultimate mission* of those who are doctors of the mind." To be a psychiatrist is to be an "attentive listener first" and to be able to make sense of the "inside cry for a knowing assistance that is at the heart of a person's decision to visit a physician." This kind of attentive listening remains central to psychiatry regardless of evolving science and research into mind and brain because:

> Human beings are creatures of awareness, of language, of long and articulated memory—and also, creatures whose special skills and triumphs live side by side with a special capacity for tragedy. Losses, vulnerabilities, weak spots and soft spots, one's ultimate destiny of disappearance from this planet are known to humans, but they are not to all other forms of life on this earth. Through words, whether spoken to others or silently put to one's self, humans constantly struggle to make sense of things, even as they try (if they can) to prepare themselves for the worst: hunker or huddle down, reach out, whistle in the dark, while trembling mightily within themselves. Not rarely, at such moments, people have learned in this century to seek the counsel of psychiatrists, men and women presumed to understand one's many possible predicaments, one's wild or loony sides, one's lapses into incoherence or rage, into lusts and times of darkness that threaten one's reliability, one's stability, one's very own life (or the lives' of others).

For Coles, psychiatrists must understand that to be sought out at these moments, to be asked to "attend such a cry" is an honor, a privilege, and the "ultimate bedrock" of psychiatry's professional competence.

This empathic core, however, will only be part of the interaction between Marina and the narrative psychiatrist. In addition, Marina will likely wish that the psychiatrist recommend interventions and treatment options to help her move beyond her current crisis and conflict. Narrative psychiatrists are closely guided in this process of care planning by the

Telegram: @medical_k

www.konkur.in

bioethical principles of *respect for autonomy* and *informed consent.* Bioethicists Tom Beauchamp and James Childress explain that respect for autonomy acknowledges the moral right of every individual to choose and follow their own plan of life and actions. Informed consent is the practical application of the respect for autonomy. Following Beauchamp and Childress, narrative psychiatrists agree with Johnson et al.'s description of informed consent in their *Clinical Ethics:*

> Informed consent constitutes a central feature of an encounter between physicians and patients, characterized by mutual participation, good communication, mutual respect, and shared decision making. Informed consent requires a dialogue between physician and patient leading to agreement about the course of medical care. After initial consent to treatment has occurred, and ongoing dialogue between patient and physician, concerning the patient's continuing medical needs, reinforces the original consent. A properly negotiated informed consent benefits both the physician and the patient—a therapeutic alliance is forged in which the physician's work is facilitated because the patient has realistic expectations about results of the treatment, is prepared for possible complications, and is more likely to be a willing collaborator in the treatment.

Following this approach to informed consent, the narrative psychiatrist initiates a collaborative process of selecting strategies for change by giving a background on the array of treatment options available and explaining the benefits and risks of these options. Narrative psychiatry is not unique in this way, however narrative psychiatry does share bioethicists concern that despite a vast literature in bioethics that physicians in general and psychiatrists in particular are often deficient in observing the practice and spirit of informed consent. Narrative psychiatry, by contrast, puts this form of ethical alliance building and collaborative planning at the center of care. Narrative psychiatrist SuEllen Hamkins describes this stage of treatment as exploring with the patient the "doctor's tool kit of psychiatry." As she puts it, "when we have a collaborative therapeutic stance, we can look side by side without our patients at the wealth of treatment options that might be helpful and weigh the pros and cons together."

In the case of Marina, because her problems are relatively mild, the narrative psychiatrist would suggest psychotherapy. However, which psychotherapy should Marina choose? The standards of care consist of a tremendous variety of options. The collection *Current Psychotherapies* features 14 different approaches, and *Theories of Counseling and Psychotherapy* focuses on 20 different options. Both of these texts cover psychoanalysis, cognitive therapies, and humanistic therapies, and the

Telegram: @medical_k

www.konkur.in

latter includes additional options of feminist therapies, narrative psychotherapy, expressive arts therapies, transcultural therapies, and neuropsychotherapy. But there are still many other possibilities. Neither text mentions alternative approaches to psychic troubles, such as pastoral counseling, acupuncture, yoga, peer support, and mad pride activism. Although these last options are not psychotherapy by definition, they do represent viable approaches to psychic difficulties that Marina might find helpful. Taking this tremendous variability of psychotherapies and other treatment options into account leaves the narrative psychiatrist with two problems. How to make sense of this diversity, and how to present these options to Marina in a way consistent with autonomy and informed consent?

Fortunately, one of the most helpful aspects of narrative theory for psychiatry is that it provides an overarching, or metatheoretical, rationale for understanding how these many psychotherapies work. From a narrative perspective, all therapies involve a process of storytelling and story retelling. No matter which style of psychotherapy one uses, the process of therapy involves an initial presentation of problems that the client is unable to resolve. The client and therapist work together to bring additional perspectives to these problems, allowing the client to understand them in a new way. These additional perspectives vary greatly depending on which style and therapeutic point of view are used. It matters whether the therapy is psychodynamic, cognitive, humanistic, feminist, spiritual, or expressive. But from the vantage point of narrative theory, what these different approaches all have in common is that they rework, or "re-author," the patient's initial story into a new story. This new story allows new degrees of flexibility for understanding the past and provides new strategies for moving into the future.

Having a metatheoretical narrative understanding of the variety of psychotherapy options helps make sense of perhaps the most important empirical psychiatric finding to date—an array of alternative approaches to psychotherapy are all *equally effective.* This finding is known lovingly in the therapeutic research community as the "Dodo effect." The appellation comes from a line in *Alice in Wonderland:* "At last, Dodo said, everyone has won, and all must have prizes." Although this finding is controversial and has been only partially integrated into clinical practice, empirical studies confirm with remarkable consistency that the positive effects of therapy (of which there are many) are not due to the specific interventions

Telegram: @medical_k

www.konkur.in

of the therapist. The benefits of therapy come instead from “common factors” of the therapeutic setting. These studies suggest that the process of setting up a strong therapeutic alliance with a quality therapist is much more important than the content of the specific models and theories from which the therapist works.

The Dodo effect suggests that a variety of theoretical models can be used to understand, cope with, and ameliorate painful emotional states. The Dodo effect does not mean that any old interpretation will do. Therapy does not work if the therapist says things completely out of context, such as “your sadness is because the cow jumped over the moon.” On the contrary, for psychotherapy to be effective and for the alliance to be strong, the therapist and the client must have a sense of belief and confidence in the interpretive frame being used. In the words of Saul Rosenzweig, who first coined the term Dodo effect, “Whether the therapist talks in terms of psychoanalysis or Christian Science is…relatively unimportant as compared with the formal consistency with which the doctrine employed is adhered to, for by virtue of this consistency the patient receives a schema for achieving some sort and degree of personality organization.”

When the narrative psychiatrist applies these insights to Marina’s situation, it suggests that an array of psychotherapy approaches might be helpful for Marina. Any number of different interpretations of Marina’s situation could be developed and worked through in a therapeutic relationship with a well-meaning quality practitioner. If that were to happen, there is a very good chance that an array of different insights and narrative structures could effectively help Marina understand her anxiety and feelings of inadequacy. If the insights and narrative frames were not imposed on Marina but were ones in which she participated in creating and to whose meaning she felt strongly connected, the therapy would “work” by encouraging modifications in Marina’s assumptive worlds. These modifications would transform the meanings of her painful feelings to more favorable ones and free her up for alternative forms of coping.

A narrative psychiatrist working with Marina would have all of this in the back of their mind as they began the process of making psychotherapeutic recommendations. Following the basic ethical principles of autonomy and informed consent, even in the fine-grained choices between types of psychotherapy options, the psychiatrist would give Marina background on the array of psychotherapies so that Marina

Telegram: @medical_k

www.konkur.in

could make informed choices about which therapy to choose. Most narrative psychiatrists would explain to Marina that they practice a narrative approach that collaboratively selects options and resources from a variety of treatment approaches as they seem appropriate for the therapeutic process. This means that narrative psychiatry tends to use an integrative form of psychotherapy that works through collaborate eclecticism. The strategic and collaborative frame for selecting from a range of different therapeutic approaches is guided by the narrative goal of creating preferred identities of meaning and thriving. Eclectic openness is consistent with narrative psychiatry because it appreciates that not only are a variety of therapeutic models valuable for people, but also a variety of therapeutic insights and strategies can be woven together to form a hybrid narrative of a person's past, present, and future that can be helpful. These insights may come from psychoanalysis or cognitive–behavioral, feminist, or creative arts perspectives, to name a few. Eclectic therapists are not constrained by loyalty to one point of view over another and, therefore, can borrow and mix from a variety of schools.

If this form of therapy did not sound helpful to Marina, or if she had preferences for a more specific form of treatment beyond what the narrative psychiatrist felt comfortable with, then the psychiatrist would work with her to find a suitable referral. If there was a match between what Marina would like to try and the narrative psychiatrist's collaborative, eclectic approach, then they could continue working together. It is important to point out that although there are overlaps, a narrative approach to the many different psychotherapies is different from a specific narrative psychotherapy approach. A "branded" narrative psychotherapy approach would not have particular pride of place in the therapeutic process. Narrative psychotherapy as a particular form of psychotherapy, in other words, would be one approach among others, which Marina and the narrative psychiatrist might eclectically choose from in developing her preferred recovery stories.

However, for the sake of this overview of narrative psychiatry, it is useful to consider what narrative psychotherapy approaches might look like for Marina. Narrative psychotherapy is a form of psychotherapy that is in some ways similar to psychodynamic or insight-oriented psychotherapy and in other ways similar to humanistic and existential psychotherapy. The key idea is that clients come to therapy with what narrative psychotherapists Michael White and David Epston call "problem-saturated

Telegram: @medical_k

www.konkur.in

stories." The process of therapy deconstructs this presenting story by carefully and lovingly pulling it apart. In this example, Marina and the narrative psychiatrist would look together for gaps and breaks in her story, for inconsistencies, for left-out information, for overly emphasized events, and for metaphors and linguistic distinctions that ground the assumptions of the story. Finding these kinds of gaps and inessential authorial choices would help to establish that Marina's presenting story is not an absolute necessity and that other stories could be told. Marina and the therapist would then work together to find a new story that would help Marina reauthor her past and present and expand her future options in desirable ways.

This process is similar to the process of other psychotherapy approaches, except that it would be less likely than most to rely on therapeutic jargon and pretold story frames—such as are more common in psychoanalytic therapy, cognitive therapy, interpersonal therapy, or feminist therapy. Rather than using therapeutic jargon, narrative psychotherapy would try to stay with the language of everyday meaning and folk psychology. In addition, narrative psychotherapy, more than most other therapy options, tends to be very conscious of cultural power dynamics and the way in which people's problems often have to do with internalized hierarchies that they have adopted from mainstream culture.

In Marina's case, the metaphor of "childhood" provides a good example of the pain cultural power dynamics can play. Marina lives in an elite and still deeply patriarchal culture, where "autonomy" and "independence" are prioritized over "connection" and "interdependence." These cultural norms are loaded into the meaning of the "childhood" metaphor. If Marina lived in a different culture or if she thought through these values preferences in the context of therapy, she might feel very differently about her current life and what it means to live at home. In narrative therapy, Marina and the therapist would look for aspects of Marina's life—what narrative therapists call "unique outcomes"—that go against the grain of the childhood metaphor. They would look at the many ways in which Marina's life is very different from the life of a child and they would deconstruct the wisdom of a cultural insistence on norms of autonomy and independence. Are these value preferences absolute, do they necessarily lead to a contented life, and are there examples in which people have followed these goals and ended up discontented and demoralized? Indeed, as it turns out in the novel, Marina's friend Danielle—the very one who could not imagine being

Telegram: @medical_k

www.konkur.in

in Marina's situation—is far from happy in following a path of relentless independence and "maturity." By working through this kind of narrative reauthoring, Marina could use narrative psychotherapy to reach a new level of peace with her current life and a new degree of flexibility as she makes plans for the future.

In Marina's "case," as it has been imagined thus far, the main treatment strategy has been psychotherapy. But it is important to point out that the process of using narrative as a guiding frame for treatment planning also includes more intensive psychiatric treatments such as medications, hospitalizations, and involuntary commitments. To enter into these additional aspects of narrative psychiatry, make a further imaginative adjustment to Marina's case history. Imagine that Marina did not enter therapy in the early stages of her crisis but that she continued to suffer alone with her problems. Imagine that without a resolution for her crisis, her sense of inadequacy worsened to the point at which Marina became not only anxious but also deeply sad and tearful, with intense feelings of worthlessness and a profound sense of hopelessness that she could ever move forward with her life. Imagine that she loses interest in the things that she had previously enjoyed and starts spending most of her time in bed watching television. These feelings go on for weeks, and it gets to the point at which Marina is unable to sleep, her appetite becomes erratic, and she even begins to fantasize about suicide.

If Marina were to see the narrative psychiatrist at this moment of worsened crisis, she would now have a presenting problem that fits the *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition (DSM-5-TR), diagnosis of Major Depression, severe without psychosis. With this diagnosis, Marina would be considered by many to have a "clinical depression," which the standard of care narrates as a kind of "disease," not unlike diabetes or high blood pressure. How would the narrative psychiatrist respond in this situation? Would it differ significantly from the previous situation? The answer is yes and no. As before, the first task for the narrative psychiatrist would be to get to know Marina's story in all of its unique complexity.

The main difference in this new situation would be the added complication of Marina's suicidal ideas and the need to make an assessment of her danger to herself. If Marina met the standard of care criteria for hospitalization, then the narrative psychiatrist would collaboratively work toward that goal. If the standard of care for

Telegram: @medical_k

www.konkur.in

hospitalization was met, but the patient refused, and collaborative treatment planning broke down, the narrative psychiatrist would work toward involuntary commitment. This would, unfortunately, interrupt the collaborative process of meaning-making as the narrative psychiatrist would have to act unilaterally. But the larger narrative process of the treatment would not stop. During the hospitalization and afterward, Marina and the psychiatrist would continue to process the event. The eventual narrative meaning of the involuntary hospitalization would be open to ongoing storytelling. It may turn out that Marina comes to agree with that "danger to self" plotting of the story or it may turn out that the psychiatrist comes to restory the involuntary hospitalization as an overreaction and even a mistake.

If hospital care was not an issue, the outpatient process of assessment and treatment planning would be similar to before, except for the question of medication. After getting to know Marina, or even while this process was proceeding, the narrative psychiatrist would explain that in view of the severity of her depressive symptoms, many, if not most, psychiatrists would recommend medication treatment along with psychotherapy. The narrative psychiatrist would explain the risks and benefits of the medication options along with a basic review of the outcome studies for the medicine's effectiveness.

If Marina opted for medication and it was indicated in the standard of care, the narrative psychiatrist would be comfortable with this choice. Narrative psychiatry, in other words, does not change its basic storytelling approach when it comes to biologic explanations, disease models, or psychopharmacologic interventions for mental states. Narrative psychiatry does not resemble antipsychiatry approaches that understand disease models of mental illness as a myth. However, narrative psychiatry also does not essentialize biologic or disease models of explanation and treatment as somehow more real and substantial than other models. For the narrative psychiatrist, biologic models are not an exception to a general understanding of the ways in which metaphor and plot work to shape narrative identity because narrative psychiatry conceptualizes biologic models not as myths or mirrors of truth but as metaphors. Narrative psychiatry stands on the shoulders of work in the philosophy of science and science studies to draw out the similarities between scientific models and metaphors more broadly. It recognizes that scientific models also create a kind of "seeing as." First-person narratives of mental illness

Telegram: @medical_k

www.konkur.in

show that when people inhabit scientific frames, they come to experience "seeing as" in a deeply naturalized way, to the point at which "seeing as" becomes "being as," and people experience themselves as having some form of "broken brain." However, this process is not different from other uses of metaphor to structure experience—it is just another example of the role of metaphor and linguistic structures in the formation of narrative identifications.

Biologic models do pose a problem for informed consent. However, because of the degree, the biologic point of view is overhyped in the media and in the medical literature. Sociologist Nicolas Rose uses the term "neurochemical self," and anthropologist Emily Martin uses the phrase "pharmaceutical person" to describe the dramatic rise in neurochemically mediated self-identity. To become a neurochemical self, one does not have to become a fundamentally different kind of human. One only has to internalize the metaphorical structures of neuroscience and the practices of psychopharmacology and use these metaphors and practices to organize one's sense of self. Consider the example of Gary, a character from Jonathan Franzen's book *The Corrections:*

> Although in general Gary applauded the modern trend toward individual self-management of retirement funds and long-distance calling plans and private-schooling options, he was less than thrilled to be given responsibility for his own personal brain chemistry, especially when certain people in his life, notably his father, refused to take any such responsibility. But Gary was nothing if not conscientious. As he entered the darkroom, he estimated that his levels of Neurofactor 3 (i.e., serotonin: A very, very important factor) were posting seven-day or even thirty-day highs, that his Factor 2 and Factor 7 levels were likewise outperforming expectation, and that his Factor 1 had rebounded from an early-morning slump related to the glass of Armagnac he'd drunk at bedtime. He had a spring in his step, and agreeable awareness of his above-average height and his late summer suntan. His resentment of his wife, Caroline, was moderate and well contained. Declines led key advances in key indices of paranoia (e.g., his persistent suspicion that Caroline and his two older sons were mocking him), and his seasonally adjusted assessment of life's futility and brevity was consistent with the overall robustness of his mental economy. He was not the least clinically depressed.

Whatever else one might want to say about Gary, it is clear that the metaphors and plots of neuroscience have become a core part of his self-understanding. For another example, this time from nonfiction, consider this quote from neurophilosopher Patricia Churchland. The context is that she is describing her feelings to Paul Churchland (her neurophilosopher

Telegram: @medical_k

www.konkur.in

husband) after coming home from a particularly frustrating faculty meeting:

> Paul, don't speak to me, my serotonin levels have hit bottom, my brain is awash in glucocorticoids, my blood vessels are full of adrenaline, and if it weren't for my endogenous opiates, I'd have driven the car into a tree on the way home. My dopamine levels need lifting. Pour me a Chardonnay, and I'll be down in a minute.

Neurochemical selves, as these examples make clear, are selves like other selves. The only difference is that they have different metaphors, plots, and narrative identifications than nonneurochemical selves. Narrative psychiatrists have an ambivalent relationship with this rapidly emerging phenomenon. On one hand, narrative psychiatrists are open to this form of selfhood and they respect it as much as they would other forms of self. William Styron's memoir and the many similar ones show that people are clearly able to integrate the biologic model and neurochemical self-identity into their lives in a helpful way. On the other hand, narrative psychiatrists are also aware of the deeply problematic power dynamics of this emerging form of self and that there are many people who prefer to avoid biologic stories as much as possible.

Both Nicolas Rose and Emily Martin point to contemporary pharmaceutical practices as a major determinant of this new form of self-making. Since 1980, the pharmaceuticals have transformed themselves from research-driven companies to companies that operate more like Procter & Gamble, the maker of Tide. The pharmaceutical business plan of expanding markets through chronic, life style, conditions (such as arthritis, asthma, diabetes, mental illness) means that the industry has moved away from a focus on product per se and toward the creation of climate of opinion and desire surrounding the product.

Jan Leschley, the former CEO of Squibb pharmaceuticals, explains: "We realized we are an information company more than we are a pill company." For Leschley, the modern transnational drug company does not sell its products, the pills, as much as the information that surrounds their pills. Today's pharmaceutical industry has become an information industry, an industry of cultural shaping, more than a pill industry, and this cultural shaping very consciously includes the internal culture of psychiatric research, education, and practice. These powerful marketing strategies and tremendous promotion budgets that go with them means that pharmaceutically inspired neurochemical metaphors for self-making can often drown out other options.

All of this becomes grist for the mill, as psychoanalysts like to say, in the clinical setting. Narrative psychiatrists navigate their complicated

Telegram: @medical_k

www.konkur.in

relationship to pharmaceutical self-making by sharing with their clients their ambivalence during their discussion of these options. They let their clients know that there is considerable hype around these kinds of interventions, and they make a point to discuss the reality of side effect risks along with the ambiguity of most outcome studies for these medications. However, they also make the point that, for any one person, there is no way to know—except through a treatment trial—how much they might benefit or risk from a medication. Should the patient wish to undertake such a trial in the context of informed decision making, the narrative psychiatrist is happy to offer whatever assistance is possible. For narrative psychiatrists, these kinds of psychopharmacologic frames and strategies become part of an array of possible tools that can be woven together into an eclectic narrative of treatment, and the baggage of "big pharma" promotion dynamics does not necessarily rule out their usefulness for a particular person in a particular situation.

FUTURE DIRECTIONS

In summary, the time is right for a narrative turn in psychiatry. Recent work in narrative medicine, narrative psychology and psychotherapy, and narrative theory has opened the door for the development of narrative psychiatry. Narrative is particularly valuable for psychiatry at this moment in history because it helps self-correct from an overreliance on biologic models without falling into a morass of antipsychiatry and without throwing away the bioscience baby with the bathwater. Plus, the narrative ferment in the intellectual life surrounding psychiatry—the arts, humanities, social science, medicine, and psychotherapy—means there has never been better resources available for cultivating narrative psychiatry. Finally, narrative psychiatry is valuable for helping psychiatry tell its own story because key identity questions for psychiatry as a field and for individual psychiatrists are narrative questions. Everyone involved in psychiatry must ask themselves: where have they been, where are they now, and where will they go in the future? All of these questions are about narrative identity. For the field, these questions are about how to prioritize future research, education, and practice models. For individual psychiatrists, these questions are about determining who they want to be and how they want to practice. These kinds of narrative identity questions for the field

Telegram: @medical_k

www.konkur.in

and for individual psychiatrists are storytelling questions; they cannot be answered by science alone without the help of narrative meaning making.

None of this means the end to neuroscience, the biologic model, psychiatric medications, or emergent neuroplastic training practices such as mindfulness-based stress reduction. Just the opposite. The biologic model is now, and will remain, a critical tool for understanding and intervening in psychiatric troubles. This will only become truer as biology and neuroscience moves into a brave new world that maps out physical markers for mental states and mental processes. Taking a narrative turn in psychiatry does not mean abandoning the biologic model, or any other model. A narrative turn says all models and metaphors are valuable if they are used self-reflexively in dialogue with patients and in the service of recovery. Ultimately, it is the patient's choice which models and metaphors fit best with their goals and desires. The task of psychiatrists is to help navigate the process and the options. This kind of narrative self-reflexivity helps psychiatrists remember that their allegiance is to their patients—not their models and metaphors. Recovery is the goal, not loyalty to particular narrative templates.

Narrative theory also does not take away from empirical research. Indeed, empirical studies of neural mapping and neuroplasticity are rapidly articulating a neurologic basis for narrative theory itself. The work of neuroscientists and humanists Nancy Easterlin, Paul Armstrong, Michael Gazzaniga, Joseph LeDoux, Antonio Damasio, V.S. Ramachandran, Jeffery Gray, and Gerald Edelman support the emerging consensus in neuroscience that self-understanding takes a narrative form. Philosopher Leslie Paul Theile summarizes the biologic research that understands humans as storytelling animals this way: "Neural mapping is best understood as a narrative accounting of lived experience. It constitutes a silent, synaptic story. This narrative accounting is an "obsession" for humans in the sense that, phylogenetically and ontogenetically, it constitutes our being. From the evolutionary perspective of the species and the developmental perspective of the individual organism, brain mapping makes us who we are. Synaptic storylines inventory the individual's life, serve as its engine of development, and foster a sense of self." Or, as literary theorist Paul Armstrong puts it: "The ability to tell and follow stories requires cognitive capacities that are basic to the neurobiology of mental functioning."

Telegram: @medical_k

www.konkur.in

In other words, at the neurobiologic level, everyone can be understood as fabricated characters. The brain constructs a model of the external world though synaptic maps and it constructs a model of the self as actor in the world. This emergent convergence of neuroscience and narrative theory can be invaluable in helping psychiatry move beyond deeply problematic mind/brain and science/humanities binaries. After a century of psychiatric swings between mind-centered and brain-centered versions of itself, narrative provides a biocultural third-space opportunity for psychiatry to be true to both its biologic dimensions and its human meaning-making dimensions.

Empirical research of recovery is also adding to an understanding of narrative processes in psychiatry. In one such study, Damien Ridge and Sue Ziebland interviewed 38 men and women who had recovered from depression to discover the strategies they used to revitalize their lives following depression. Ridge and Ziebland found that the people they interviewed did not use any single approach. Instead, they selected a variety of “narrative tools,” such as talking therapy, medication, yoga, and complimentary therapies to regain mastery of their situation. Ridge explains: a “key finding…was that recovery tools considered effective by patients go hand in hand with telling a good story about recovering from depression.” The very process of assembling a range of tools for recovery helped create the stories that were effective. The people interviewed found that therapists were most helpful if they could function not as experts but as “recovery allies.” The most helpful health professionals were those who were empathic, good listeners, provided hope and encouragement, and who had a positive belief in the person going through the depression. A recovery ally of this type does not function in a “doctor knows best” capacity, but is someone who helps the person select the narratives and the recovery tools that feel most true to them.

Thus, when psychiatrists take a narrative turn, they do not throw out their other skills, knowledge, or research methods. The shift to narrative is, as much as anything else, an attitude shift and an opening out to additional sources of information. It starts by bringing to the foreground that the clinical encounter is a human encounter, and it follows by opening out to colleagues in the humanities, interpretive social sciences, and the arts to help to better understand this human encounter. In addition, narrative psychiatry joins with other contemporary efforts in psychiatry—such as in bioethics and the recovery movement—to make clinical

Telegram: @medical_k

www.konkur.in

encounters much more client focused and collaborative. Narrative psychiatry, at its core, recognizes that there are many ways to tell the story of one's life. The choice among these different options is a key way in which people create their identity. These choices should not be reduced to expert choices or scientific choices because they are always also personal and ethical choices. In the end, they are choices about what kind of life one wants to live.

For psychiatric practitioners, taking a narrative turn means joining with colleagues in narrative medicine and narrative psychotherapy to develop their own narrative competency. Narrative psychiatrists must understand the basics of narrative theory, and they must learn to read widely in a range of different contexts. They must come to appreciate the many stories of biopsychiatry, psychoanalysis, cognitive therapy, interpersonal therapy, family therapy, humanistic approaches, cross-cultural approaches, feminist approaches, mad pride and disability activist approaches, postmodern approaches, and spiritual approaches, just to name a few. Furthermore, they must come to understand the value of biography, memoir, and fiction for developing a repertoire of narrative frames and options. In the end, narrative competency in psychiatry means a tremendous familiarity with the many possible stories of psychic pain and psychic difference. The more stories clinicians know, the more likely they are to help their clients to find a narrative frame that works for them.

For clients and potential service users, a narrative understanding means that there is a range of possible therapists and healing solutions that might be helpful. An approach that is right for one person may not be right for another. There must be a fit between the person and the approach, and people should feel empowered to take seriously their intuitions and feelings. If the person getting help does not feel this fit, they are likely right. There may well be another approach that would work better with the person's proclivities. Like everything else, however, judgment is critical. Therapeutic experiences of all kinds can be frustrating, slow, and uncertain. How, for example, does one know when an approach misses their need and when it is something that will take time, patience, and perseverance to be helpful? From a narrative perspective, there can be no gold standard or simple answers. Only judgment, wisdom, and trial and error can decide.

32.16 Positive Psychology

NANSOOK PARK, PH.D.

Positive psychology is an umbrella term describing the scientific study of what makes life most worth living. The good life, that is the happy, healthy, productive, and meaningful life, entails more than the mere absence of disease, disorder, and problems. Traditional approaches in psychology largely focus on identifying problems and reducing them. However, it is limited in addressing how to build and sustain a good life, which requires additional skills and conditions. The field of positive psychology is the science and practice that has the potential to fill this need.

Research findings from positive psychology are intended to provide a more complete and balanced scientific understanding of the human experience. The new field of positive psychology calls for as much focus on strength as on weakness, as much interest in building the best things in life as in repairing the worst, and as much concern with making the lives of normal people fulfilling as with healing pathology.

Positive psychology does not replace business-as-usual psychology, which often focuses on people's problems and how to remedy them. Rather, positive psychology intends to complement and extend problem-focused psychology. The attention of positive psychologists is increasingly turning to deliberate interventions that promote the well-being of individuals and groups, and the same qualifications apply.

For decades, scientific psychology has neglected the study of what can go right with people and often has had little more to say about the good life than pop psychologists, inspirational speakers, and armchair gurus.

Telegram: @medical_k

www.konkur.in

More subtly, the underlying assumptions of psychology have shifted to embrace a disease model of human nature. Human beings are seen as flawed and fragile, victims of cruel environments or casualties of bad genetics, and if not in denial, then at best, in recovery. This worldview has even crept into the common culture, and some people have become self-identified victims, trying to survive but not flourish. Positive psychology proposes that it is time to correct this imbalance.

Positive psychology studies what goes right in life, from birth to death. It is concerned with an optimal experience, people being their best, and doing their best. Everyone's life has peaks and valleys, and positive psychology does not deny the low points. Its signature premise is more nuanced: what is good about life is as genuine as what is bad and therefore deserves equal attention from psychologists. Positive psychology assumes that life entails more than avoiding or undoing problems and that explanation of the good life must do more than reverse accounts of distress and dysfunction.

HISTORY OF POSITIVE PSYCHOLOGY

The most basic assumption that positive psychology urges is that human goodness and excellence are as authentic as disease and disorder. Positive psychologists argue that these topics are neither secondary nor derivative. There are many good examples of psychological research, past and present, that illustrate the fundamental premise of positive psychology, although only recently has there been explicit emphasis on their common concerns.

Accordingly, positive psychology has a very long past but only a short history. The long past of positive psychology stretches at least to the Athenian philosophers in the West and to Confucius and Lao-tzu in the East. In the writings of these great thinkers can be found the same questions posed by contemporary positive psychologists. What is the good life? Is virtue its own reward? What does it mean to be happy? Is it possible to pursue happiness directly, or is fulfillment a by-product of other pursuits? What roles are played by other people and society as a whole?

Early Ancestors

Within psychology, the premises of positive psychology were laid out long ago. More than 100 years ago, when psychology began as a formal

Telegram: @medical_k

www.konkur.in

discipline in Germany, it had a narrow focus on sensation and perception. Psychology soon spread. When it came to the United States, it was blended with American pragmatism by William James, John Dewey, and others to result in *functionalism,* which was concerned with the consequences—functions—of psychological states, traits, and processes. Inevitably, functionalism gave rise to a host of applied psychologies and out-of-the-laboratory endeavors with practical goals.

Among the early goals of applied psychology was to understand accomplishment and satisfaction in domains such as education, religion, work, and the family. The very first applied psychologists had the explicit intent to identify what was successful in these important areas of life and to apply this knowledge to make the lives of normal people more fulfilling.

The first psychological clinic in the United States was founded in 1896 by Lightner Witmer at the University of Pennsylvania. Witmer is credited with coining the term clinical psychology, a field which he defined as “the study of individuals, by observation or experimentation, with the intention of promoting change.” Many of the clients at Witmer’s clinic were school children with learning difficulties, and the goal of the clinical work was to make them better students. Sounding like a contemporary positive psychologist, Witmer argued that “The progress of psychology, as of every other science, will be determined by the amount of its contribution to the advancement of the human race.”

Had this original mission of psychology been sustained, there would be no positive psychology today, although all of its current concerns would be well-represented. However, events occurred that changed psychology. With the rise of behaviorism and the positivism that provided its philosophical basis, a strict distinction between fact and value emerged, with the fact being seen as the province of science and value as the province of philosophy. Many psychologists stopped studying things that mattered morally.

In the early 20th century, psychologists interested in individual differences, what is now called personality, divided their subject matter into character—which could be changed—and temperament—which could not. The moral flavor of character was seen as a critical feature. Gordon Allport, the major personality trait theorist in U.S. psychology at that time, was uncomfortable with the notion of character and actually banished the term from academic discourse concerning personality. Allport argued that character was the subject matter of philosophy and not psychology. The

Telegram: @medical_k

www.konkur.in

traits he urged psychologists to study were presumably objective entities stripped of moral significance and linked to “adjustment” but not endowed with inherent value.

Another turning point was the separation between basic psychology and applied psychology. Whereas the early functionalists made no such distinction, the next generation of psychologists in the United States began to draw a line between laboratory experiments investigating “basic” processes of perception, thought, and learning and field studies investigating outcomes of interest because of their substantive content. The former studies were regarded as more important, and the elite schools stopped recruiting applied psychologists to their departments. Applied work, of course, was continued by psychologists in schools of business, education, kinesiology, and elsewhere, but what they did was not part of the acknowledged mainstream.

As important as these events were, the biggest change in psychology was the result of an external event. The realities of World War II changed psychology and spurred the growth of clinical psychology, now the numerically dominant specialization within psychology. With an unprecedented proportion of the adult male population serving in the armed forces and experiencing the stresses of modern war, the need for acute clinical services outpaced what could be provided by available psychiatrists. Psychologists, heretofore involved in clinical work mainly in devising, administering, and interpreting psychological tests, were called upon to provide treatment. What resulted was a generation of basic psychologists who through necessity became practitioners.

The immediate aftermath of World War II saw no reduction in the need for clinical services. Accordingly, the new generation of scientist–practitioner psychologists consolidated, formalized, and eventually institutionalized an identity and a profession, encouraged and supported by the U.S. federal government. The National Institute of Mental Health (NIMH) was created to support research into disorders and their treatment, and stipends for graduate training programs in clinical psychology were part of the NIMH portfolio. The Veterans Administration (VA) provided clinical psychology internships for students in these programs.

The growth of clinical psychology as a profession has been phenomenal. The downside of the growth of clinical psychology is that its view of people has come to dominate much of psychology and even the

Telegram: @medical_k

www.konkur.in

common culture. What students learn is that people are victims—of unfortunate genetics, cruel environments, and their own cognitive shortcomings. This characterization applies not just to clinical psychology but to the entire discipline. For example, the field of social psychology began in the 1940s with Kurt Lewin's stirring call for *action research,* using psychology to solve social problems, but it has since become a field that documents repeatedly what people cannot know and cannot do.

This is the context in which Martin Seligman, a mainstream academic psychologist, called for psychology to reclaim its original mission and study the rest of the human condition. The field was named in 1998 as one of the initiatives of Martin Seligman in his role as president of the American Psychological Association. A trigger for positive psychology was Seligman's realization that psychology since World War II had focused much of its efforts on human problems and how to remedy them.

The yield of this focus on pathology has been considerable, but there has been a cost. Much of scientific psychology has neglected the study of what can go right with people and often has little to say about the psychological good life. More subtly, the underlying assumptions of psychology have shifted to embrace a disease model of human nature. People are seen as flawed and fragile, casualties of cruel environments or bad genetics. This world view has even crept into the common culture, where many people have become self-identified victims.

Positive psychology is not intended to replace business-as-usual psychology but rather to complement and extend it, by drawing on past work into the psychological good life as well as doing new work from the positive psychology perspective.

In one sense, positive psychology is nothing new, and William James, John Dewey, Lightner Witmer, and other psychologists from a century ago can be considered positive psychologists. Yet, the label "positive psychology" has considerable value in the here and now because it draws together what had been scattered lines of inquiry within psychology and allied social science—for example, investigations of life and work satisfaction, utopian visions of education like those of Alexander Sutherland Neill; primary prevention programs based on notions of wellness as pioneered by George Albee and Emory Cowen; work by Albert Bandura and others on human agency and efficacy; work by Mihalyi Csikszentmihalyi on creativity, flow, and optimal functioning; George Vaillant's longitudinal studies of the benefits of mature defense

Telegram: @medical_k

www.konkur.in

mechanisms; investigations of resilience; studies of giftedness; conceptions of intelligence as multiple; and assessments of the quality of life among medical and psychiatric patients that went beyond their symptoms and diseases.

Humanistic Psychology

Chief among the immediate ancestors of today's positive psychology is *humanistic psychology* as popularized by Carl Rogers and Abraham Maslow (who actually used the phrase "positive psychology" to describe his own approach). Humanistic psychology is one of psychology's venerable perspectives, popular in the 1960s and 1970s and still with adherents today. *Humanism* is the doctrine that the needs and values of human beings take precedence over material things, and further, that people cannot be understood simply as part of the material world. Humanists argue that scientific psychologists miss what is most important about people by focusing on the supposed causes of behavior, as if people were simply billiard balls, doing poorly or well depending on what other billiard balls happen to have ricocheted into them.

Both Rogers and Maslow emphasized that people strive to make the most of their potential in a process called *self-actualization.* Self-actualization can be thwarted by various conditions, but if these conditions are changed, then the potential within each individual will necessarily unfold.

This is a very different way of thinking about human nature than that embodied in psychoanalysis or behaviorism, dominant perspectives within psychology during the 20th century. Humanistic psychology stresses the goals for which people strive, their conscious awareness of this striving, the importance of their own choices, and their rationality. The attention of psychology is thereby directed away from mechanical causes and toward fundamental questions about existence and meaning.

In a 2000 discussion of positive psychology, Martin Seligman and Mihalyi Csikszentmihalyi tersely distanced the new field from humanistic psychology. They made two arguments. First, contemporary positive psychology regards both the good and the bad about life as genuine, whereas humanists often—but not always—assume that people are inherently good. Second, positive psychology is strongly committed to the scientific method, whereas humanists often—but again, not always—are skeptical of science and its ability to shed light on what really matters.

Telegram: @medical_k

www.konkur.in

As points of relative and occasional contrast, these arguments are reasonable, and they highlight what is novel about positive psychology. Yet, as positive psychology has evolved and as positive psychologists have more carefully examined allied perspectives, positive psychology and humanistic psychology should be seen as close relatives.

Many humanists would agree that each person has the capacity for good and bad, just as positive psychology assumes. That “the good life is simply a matter of choice” seems to go too far, given the well-documented barriers to thriving posed by external circumstances like pestilence, poverty, and prejudice, but many positive psychologists nowadays acknowledge that notions of choice and will are indispensable ones. Finally, many humanistic psychologists, from decades ago to the present are as committed to science as any positive psychologist—although one can still question the success of humanistic psychology in creating a cumulative database.

Positive Mental Health

One more important historical precursor of positive psychology needs to be mentioned. In 1958, the U.S. Joint Commission on Mental Illness and Health was authorized by a unanimous resolution of Congress. The commission published a monograph series, and the first book in the series was *Current Concepts of Positive Mental Health* by social psychologist Marie Jahoda. Foreshadowing the arguments of positive psychology decades later, Jahoda argued that mental health was not simply the absence of mental illness, and further that psychological well-being needed to be understood in its own right.

Jahoda surveyed what previous thinkers—mainly clinicians—had to say about positive mental health and integrated their views. She proposed half a dozen underlying processes that produce the states and traits usually identified as psychologically healthy:

- Acceptance of oneself
- Accurate perception of reality
- Autonomy (freedom from social pressures)
- Environmental mastery
- Growth, development, becoming
- Integration of personality

Telegram: @medical_k

www.konkur.in

Note that she did not include happiness or satisfaction as part of her definition, believing that these were more properties of the situation than of the individual.

At the same time that Jahoda published her book, social psychologist William Scott surveyed the existing research literature on mental health, focusing on research definitions (measures) of well-being and empirically established correlates of these measures. Then as now, the majority of studies ostensibly looking at health were really studies of disorder. Scott could draw firm conclusions only about the factors that characterized the lack of pathology. Good social relationships were the most common correlate. Scott cited a personal communication from Jahoda in which she described her own attempts to develop measures of several of her criteria for mental health (i.e., accurate perception of reality and environmental mastery) as less than satisfactory, which may explain why her ideas did not stimulate further work for decades.

More recently, Carol Ryff and her colleagues repeated Jahoda's analysis by surveying and integrating what different theorists, again mostly clinicians, said about the psychological components of being and doing well—striving and thriving, as it were. They identified six points of convergence across discussions of psychological well-being, which agree substantially with those specified decades earlier by Jahoda:

- Autonomy
- Environmental mastery
- Personal growth
- Positive relations with others
- Purpose in life
- Self-acceptance

Notable about Ryff's work is that she and her colleagues have solved the measurement problem and have created reliable and valid self-report surveys of these components of psychological well-being. Using these measures, they have explored the links between psychological well-being and physical health, finding positive associations and implicating the left prefrontal cortex—believed to aid in the organization of goal-directed activity—in these associations.

Building on Jahoda's earlier work, contemporary positive psychologists suggest that doing well (mental health) and doing poorly (mental illness) are not simple opposites. They argue that these are distinguishable

Telegram: @medical_k

www.konkur.in

dimensions in terms of which people can be described (Fig. 32.16–1). Complete mental health is defined by high levels of psychological well-being along with the absence of signs and symptoms of psychological disorder. Said in DSM IV terms, complete mental illness is described by one or more Axis I diagnoses and a low Axis V (global assessment of functioning) score.

Figure 32.16–1 represents how we think about intervention from a positive psychology perspective. It is based on one of the signature premises of positive psychology that well-being is not simply the absence of pathology. Both well-being and pathology are multidimensional, and their various components can and do coexist. The framework is shown in Figure 32.16–1. This framework depicts strengths and problems as in principle independent of one another.

Individuals can be placed in Figure 32.16–1 depending on their particular profiles of strengths and problems. In Quadrant 1 are strengths accompanied by problems. We like to describe individuals in Quadrant 1 as "dealing with it," meaning that they have and use strengths despite experiencing problems and challenges.

The fully functioning person is found in Quadrant 2: high strengths and low problems. Here we find health as defined by in the constitution of the World Health Organization (WHO): "A state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity."

Individuals in Quadrant 3 are the ones most frequently studied by clinical psychologists, poorly functioning individuals with psychiatric diagnoses or problems such as alienation, demoralization, and loneliness.

Quadrant 4 is both unremarkable and understudied, occupied by individuals with neither problems nor strengths, passing time quietly, complacent but not joyful. What may characterize Quadrant 4 is a history of insufficient challenge. Because life has been easy, strengths have not developed or have not needed to be displayed.

Traditional psychotherapy or consultation is usually concerned with solving problems, moving individuals from Quadrant 3 to Quadrant 4. Figure 32.16–1 suggests additional intervention goals. The ultimate goal of practitioners should be to move people and groups into Quadrant 2 and to keep them there. Depending on where individuals and groups start, different interventions are probably needed because change will entail different processes. In some cases, strengths need to be built from

Telegram: @medical_k

www.konkur.in

scratch, whereas in other cases, individuals and groups need to capitalize on existing strengths.

Even among individuals and groups already in Quadrant 2, their well-being can be further promoted. Promotion needs to be distinguished from prevention, the goal of which is to prevent problems by reducing risk factors. Prevention is of course important, but attention to risk factors alone is not sufficient because people who develop problems may lack obvious risk factors. The positive psychology perspective is that building or enhancing strengths may be an additional and broader strategy for intervention.

When first introduced by Seligman, positive psychology was described as focusing on complete mental health and its further enhancement, but the scheme suggested by positive psychologists sensibly expands positive psychology and provides a useful way to describe the range of therapeutic interventions. For example, what can be called *positive psychotherapy* attempts to move people with problems closer to the state of complete mental health. The goal of *promotion* is to increase the well-being of those without problems. *Maintenance* keeps healthy people healthy. Given that existing treatments for psychological problems rarely if ever "cure" people in the sense of precluding recurrence of problems, it is surprising how little attention has been paid to the matter of maintenance. Along these lines, positive psychology may provide new insights into the challenging task of *relapse prevention:* helping people whose problems have been resolved to stay healthy. *Traditional therapy* simply tries to mitigate someone's psychological problems.

Incomplete mental illness and incomplete mental health are common states, and positive psychology has potential value in helping people who can be so described, as well as learning lessons from them. Incomplete mental illness might be a suitable label for people like Abraham Lincoln or Winston Churchill, who functioned well despite recurrent depression; somehow, they had learned to "deal with" their problems. Incomplete mental health might be a suitable label for those who lead lives of quiet desperation or those who earn NOS (not otherwise specified) diagnoses, should they enter the mental health system.

FIGURE 32.16–1. Mental health and mental illness. These are dimensions. Quadrants are shown for the purpose of illustration only.

CONCERNS OF POSITIVE PSYCHOLOGY AND CRITICISMS

The framework of positive psychology provides a comprehensive scheme for describing and understanding the good life and how it can be attained and sustained, regardless of one's starting point. The concerns of the field can be divided into four related topics:

- Positive subjective experiences (happiness, gratification, fulfillment, growth, and flow)
- Positive individual traits (strengths of character like humor, love, gratitude, forgiveness, modesty, spirituality, optimism, kindness,

Telegram: @medical_k

www.konkur.in

creativity, courage, and wisdom; talents; interests; values; and meaning and purpose)
- Positive interpersonal relationships (friendship, marriage, and colleagueship)
- Positive institutions (families, schools, businesses, communities, and societies)

A theory is implied here: positive institutions enable the development of positive relationships, which enable the display of positive traits, which in turn enable positive subjective experiences.

The word “enable” avoids strict causal language. It is possible for people to be happy or content even in the absence of good character, and good character can operate against the interpersonal and institutional grain. However, people are at their best when institutions, relationships, traits, and experiences are in alignment. Doing well in life represents a coming together of all four domains.

As a new field, positive psychology raises questions. Despite the pervasiveness of a victim mentality, everyday people seem to know that the elimination or reduction of problems is not all that is involved in improving the human condition. In contrast, the scientific community is more skeptical. Contributing to skepticism are widespread assumptions within the social sciences about human nature as brittle and broken, notions more explicit among social scientists than the general public.

Positive psychology is also criticized in some quarters for a relentless emphasis on being positive, that is, happy and cheerful. This criticism of the field reflects a misunderstanding, because positive psychologists merely propose that what is positive about life is worth studying, in addition to what is negative. Happiness is one of many topics of interest to positive psychology, but so too are virtues like gratitude and forgiveness, generosity, wisdom, optimism, and resilience, meaning and purpose, engagement, and good relationships.

Positive psychologists do not deny the problems that people experience, and positive psychologists do not ignore the negative—stress and challenge—in their attempts to understand what it means to live well. As already emphasized, positive psychology intends, by expanding the topics of legitimate study, to complement business-as-usual psychology, not to replace it.

Indeed, what is most troubling in life can set the stage for what is most fulfilling. Consider that complex emotional experiences often blend the

Telegram: @medical_k

www.konkur.in

positive and negative, that optimism is most apparent when people confront setbacks and failures, that crisis reveals strengths of character, and that ongoing challenge is a prerequisite to experience flow in the moment and to achieve something important in a lifetime. Along these lines, many positive psychologists believe that identifying and using what one does well can be an effective way to address and resolve psychological problems.

In fairness to critics, positive psychology has become so popular that at least some people appropriate the label and present "positive psychology" as a simplified version of the power of positive thinking. All one can do here is assert that Pollyanna is not the poster child for positive psychology, that the fortunate in life—those who are happy—deserve no special congratulations, and that the unfortunate—those who are unhappy—deserve no special blame.

Positive psychology does not endorse wishful thinking, self-deception, or quick fixes. Rather, it uses the scientific method to understand and enhance well-being. The lesson of history is that patience is needed. Great thinkers for many centuries have pondered well-being, and progress in positive psychology will be slow and difficult.

EMPIRICAL FINDINGS

Positive psychology already has a canon of established findings worth considering. Here are some of the research findings that provide some insight into ways to build a happy, healthy, resilient, and thriving life.

In contrast to stereotypes that happy people are naïve, stupid, or in denial, empirical studies show that happiness and positive emotions are beneficial. The real worry should be about people who are unhappy and not satisfied with their life.

Most people are happy. When psychologists study self-reported happiness and life satisfaction, usually under the rubric of subjective well-being, they administer numerical rating scales. The consistent and perhaps surprising result is that most people in most circumstances most of the time score above the scale midpoint, whether they are multimillionaires in the United States or pavement dwellers in Calcutta. This conclusion holds across demographic characteristics like age, gender, ethnicity, and education, each of which has a surprisingly small association with avowed happiness.

Telegram: @medical_k

www.konkur.in

Happiness is causal not epiphenomenal. People who are successful in life's venues are of course happy, but the less obvious and more interesting finding from experimental and longitudinal research is that happiness actually foreshadows success in academic, vocational, and interpersonal realms.

For example, researchers analyzed pictures from the 1958 and 1960 yearbooks of a women's college. All but three of the young women were smiling, but the smiles varied. Some displayed what is termed a Duchenne smile: a genuine, full-faced expression of happiness indexed by the degree to which the muscles surrounding one's eyes are contracted. Others showed the forced grimace known as a flight-attendant smile. The researchers chose these particular pictures for analysis because the women in them were participants in a long-term study of important life events. Specifically, the researchers knew—decades after their yearbook photos—whether the women were married and if they were satisfied with their marriage. As it turns out, ratings of the Duchenne-ness of their yearbook smiles predicted both of these outcomes. Young women who expressed genuine positive emotions (happiness) in yearbook photos, and presumably in other areas of their lives, as middle-aged women had better marriages. The skeptic might wonder if these results reflect the operation of some confound like physical attractiveness. As it turns out, rated "prettiness" was independent of the Duchenne-ness rating and moreover did not predict who had an intact or satisfying marriage.

Happiness can be increased. The possibility of deliberately pursuing happiness is a relatively recent arrival on the historical scene, immortalized by Thomas Jefferson in the U.S. Declaration of Independence. Prior to this time, happiness was relegated to the afterlife or seen as a matter of luck. Even today, some psychologists are skeptical that happiness can be increased.

Several factors contribute to this skepticism. First is the well-documented fact that people adapt to pleasure. When they repeatedly encounter the same pleasure-producing stimulus, they experience increasingly less pleasure in response. Adaptation to pleasure is so common that theorists have proposed that people live on a *hedonic treadmill,* meaning that they continually adapt to improving circumstances to the point that they always return to a point of relative neutrality. Another reason for pessimism about the possibility of increasing happiness is its

Telegram: @medical_k

www.konkur.in

demonstrable heritability, which has led theorists to posit a genetically determined *happiness set-point,* above which one cannot rise.

Research challenges these arguments. Current thinking about the hedonic treadmill and the happiness set-point holds that these are at best loose metaphors and hardly biologic realities. Heritability does not mean unchangeable. Remember the finding that most people most of the time are happy, which means that the metaphorical treadmill is not set at neutral. Furthermore, longitudinal studies show that the metaphorical set-point can be altered by life events like marriage and unemployment.

Other studies show that happiness can be increased when people simply act differently. For example, researchers asked introverted and extraverted college students to keep a careful diary for 3 weeks of their activities and mood. Both introverts and extroverts were happiest when doing extraverted things, implying that anyone who behaves in an outgoing way will be happy as a consequence, whether or not this behavior comes naturally. Happiness results not from what one is predisposed to do but instead from what one actually does. Growing evidence shows the importance of individual circumstances, cognitions, and behaviors for happiness.

Along these lines, researchers have shown that people instructed to do the sorts of things that characterize happy people indeed become happier as a result:

- Being grateful (e.g., counting blessings on a regular basis)
- Expressing sincere gratitude (e.g., writing a gratitude letter or gratitude visit)
- Creating flow (e.g., seeking out activities at work or at leisure that challenge one's abilities)
- Giving service to others (e.g., performing volunteer work)
- Performing acts of kindness (e.g., doing small good deeds for others on a regular basis)
- Counting acts of kindness (e.g., recalling our prosocial behaviors on a regular basis)
- Practicing self-compassion (e.g., treating ourselves with compassion, not being too hard on ourselves)
- Being socially connected (e.g., building positive and deep relationships with others who matter)
- Engaging in a positive approach to life (e.g., finding the good in life, holding a positive future outlook)

Telegram: @medical_k

www.konkur.in

- Spending time in nature (e.g., hiking, taking a walk in the park, gardening, having more interactions with nature)
- Experiencing healthy and adaptive humor (e.g., having good laughs, watching comedy films or shows)
- Savoring good things that happen (e.g., sharing experiences and memories with others, building memories, getting observed in the moment, using all senses, congratulating the self)
- Identifying and using character strengths in novel ways (e.g., seeking out different ways to display one's humor, teamwork, or love of learning)
- Articulating one's hopes and wishes (e.g., writing about an envisioned and desired "possible self")

People are terrible at emotional forecasting. People of course know that a promotion at work will make them happy and that a divorce will make them sad, but research consistently shows that people cannot accurately estimate how long these emotional reactions will last. They consistently overestimate their duration and further seem not to learn from experience that they do so. Clinicians know that part of treating depression is addressing the convictions of clients that they will never feel any differently, when in fact most depressive episodes are self-limiting. Conversely, the positive psychology practitioner needs to convey the information that even the most exhilarating experiences and activities lose their magic, sometimes quickly.

Happiness leads to physical well-being. People who are happy recover more quickly from infectious disease and live longer than their peers. For example, in an experimental study, volunteers were exposed to the virus that causes the common cold. All participants became ill, but those who were happier had less severe symptoms and recovered more quickly. For another example, from the well-known longitudinal study of Catholic nuns, women who described positive emotions in essays they wrote in their early twenties were more likely to be alive decades later. Indeed, the happier nuns (those in the upper 25% of the essay writers) lived on average 10 years longer than their less happy counterparts (those in the bottom 25%). Positive psychology interventions that bolster happiness may be of considerable value in the applied fields of behavioral medicine and health psychology.

Positive emotions and negative emotions are distinct. Theorists who catalogue basic emotions usually include one or two positive ones—for

Telegram: @medical_k

www.konkur.in

example, joy and sometimes surprise or curiosity—but their focus is on the negative ones. Part of the reason for neglecting positive emotions is the problem-focused nature of psychology in general; “emotional” problems are after all a synonym for psychological disorders. However, there are important differences between positive emotions and negative emotions. They have separate bases in brain chemistry, and they can coexist. They also function differently. Negative emotions are associated with specific behavioral predispositions. Fear makes people want to run, and anger makes them want to attack. In contrast, positive emotions are not linked to such specific action tendencies. Positive emotions like joy may activate people, but in a much more vague and diffuse way.

Positive emotions broaden and build people’s psychological and behavioral repertoires. Negative emotions—fear, anxiety, or anger—alert people to danger. When one experiences a negative emotion, response options narrow, and the person acts with haste to avoid, escape, or undo whatever danger is signaled. In contrast, positive emotions signal safety and the inherent response to them is not to narrow options but to broaden and build upon them. Laboratory studies have shown that inducing positive moods among research participants (by showing them brief video clips) leads to enhanced performance on tasks requiring creativity and flexibility. Perhaps it is advantageous to experience positive emotions because they lead people to engage in activities that add to their behavioral and cognitive repertoires, building so-called psychological capital.

Positive emotions undo the physiological effects of negative emotions. For example, in one study, college students were given just 1 minute to prepare a brief speech on “why you are a good friend” that would—so they were told—be videotaped and evaluated by their peers. They did so while having their heart rate, peripheral vasoconstriction, and blood pressure (all indices of sympathetic nervous system activation) measured. Following this preparation time, research participants saw one of four different films; two produced positive emotions (joy or contentment), one produced feelings of sadness, and the last one was emotionally neutral. None of these films in and of itself had an effect on sympathetic arousal. However, following the speech preparation exercise, research participants who then saw either of the positive emotions films showed more rapid cardiovascular recovery (return to baseline) than those who saw the sad film or the neutral film.

Engagement matters. Flow is the term used to describe the psychological state that accompanies highly engaging activities. During flow, time passes quickly for the engaged individual. Attention is focused on the activity itself. The sense of the self as a social actor is lost. The aftermath of the flow experience is invigorating. Flow is not to be confused with sensual pleasure. Indeed, flow in the moment is nonemotional and arguably nonconscious. People describe flow as highly and intrinsically enjoyable, but this is an after-the-fact summary judgment, and joy is not immediately present during the activity itself. Flow can be described as the experience of working at full capacity, which is why the concept figures prominently in positive psychology.

Unlike many positive psychology concepts, flow has been extensively investigated, using an experience sampling method which asks research participants to carry a pager that goes off at random intervals. They are then asked to describe what they are doing and how they are feeling at the time. From studies of this sort, psychologists have learned that flow is most likely to occur when there is an optimal balance between skill and challenge. One need not be an expert in a domain to experience flow. All that matters is that the presented challenge meets one's skills, and vice versa.

Flow can be experienced in all sorts of activities, at work or play, but usually among those perceived as voluntary. For example, homework for most school children strikes a balance between challenge and skill, but because homework is regarded as coerced, it rarely produces the flow state. Indeed, flow is rarely experienced by youth during any school activity. The other common activities of adolescents in the United States—watching television or "hanging out" with friends—also fail to produce flow, because they fail to meet one or another of its enabling conditions. People differ greatly in the frequency with which they experience flow, for reasons not well understood, and young people who experience more flow during adolescence show long-term desirable consequences, such as achievement in creative domains. They may even have better physical health.

"Good days" have common features. Wishing someone a good day is a common conversational gambit, and positive psychologists have been able to describe what a good day entails. For most people, it is one in which they do things that make them feel autonomous, competent, and connected to others. Encouraging people to experience pleasant events

Telegram: @medical_k

www.konkur.in

has long been a staple of behavioral therapy for depression, and this research makes the intervention less a matter of trial-and-error.

A rosy view of matters is associated with physical, psychological, and social well-being. For example, optimism assessed early in life predicts health decades later and even whether someone is still alive. For another example, viewing one's spouse in a more positive way than do others—presumably an idealization—predicts a good and lasting marriage. Data showing that positive illusions like these are beneficial stand in sharp contrast to theoretical arguments mounted by typical clinical psychologists and psychiatrists that realism and accuracy are the hallmarks of health.

Positive expectations drive analgesic placebo effects through physiologic pathways. Specifically, dopamine—implicated in the experience of positive emotions—triggers the release of endorphins. Optimism and hope are not just in one's head but also in one's nervous system.

Most people are resilient. Stressful life events can take an enduring toll on well-being, and their consequences have been extensively studied. Usually not highlighted in research on post-traumatic stress disorder is that the majority of people exposed to life-threatening events do not experience lasting negative effects.

One of the effective strategies that contribute to resilience is the positive reframing of unfortunate situation or events. One example is the phenomenon of *downward social comparison* described by psychologist Shelley Taylor. Her research program began as an investigation of depression that followed in the wake of a diagnosis of breast cancer, a terrible and serious life event. However, Taylor had trouble identifying a sufficient number of cancer patients who were severely depressed. Instead, most were able to deal with the diagnosis by a process by thinking of someone who was faring more poorly than they were:

> I have breast cancer, but it could be worse…after all, I could be younger … the surgery required is a lumpectomy rather than a mastectomy, a single mastectomy rather than a double mastectomy … I can tolerate the side effects of chemotherapy better than most … I have a supportive family … and so on.

A previous generation of psychologists might have concluded that these women were in denial, but they were open-eyed, lucid, and sober. This study foreshadowed the premises of positive psychology by concluding

Telegram: @medical_k

www.konkur.in

that resilience and the cognitive work that sustains it were the rule rather than the exception.

In some cases, people may even show psychological growth following adversity, evidencing improved relationships with others, openness to new possibilities, greater appreciation of life, enhanced personal strength, and spiritual development. Interventions that specifically target these components of posttraumatic growth may help people recover from the effects of traumatic events.

Virtue is more than its own reward. Positive psychologists have begun to study the sorts of character strengths enumerated by philosophers and theologians over the centuries. Several findings are important. First is that notions of good character are not idiosyncratic or culturally bound. There is a strong consensus about the qualities of a “good” person. Second is that character strengths have demonstrable consequences. For example, the strengths of love, hope, curiosity, gratitude, and zest are robustly linked to greater life satisfaction and less depression. Perseverance foreshadows successful at school and at work. Hope and optimism predict good health and a long life. So too does generosity as indexed by altruistic acts.

Meaning and purpose matter. According to positive psychologists, a meaningful life is one in which people feel connected to something larger than themselves. Research consistently links the presence of meaning to well-being. Individuals with a sense of purpose report greater life satisfaction, more positive affect, higher levels of optimism, and better self-esteem. They are less likely to have psychological problems. However, the search for meaning is related to lower life satisfaction. It seems that although having meaning and purpose is beneficial, the process of finding life meaning may entail challenge and confusion. Research further shows that a life framed by meaning is more satisfying than a life centered on pleasure.

For example, researchers asked undergraduate students to keep an online diary for several weeks, noting the frequency they did pleasurable things or more meaningful things like helping others or simply listening to their problems, as well as how satisfied they were each day. The more people participated in meaningful activities, the happier they were. Pleasure, in contrast, was unrelated to satisfaction. In order to investigate the direction of these effects, the researchers looked at the sequencing of activities and satisfaction, finding that participants became happier after

Telegram: @medical_k

www.konkur.in

they did something good, suggesting that happiness does, in fact, result from meaningful activities and not vice versa.

Other people matter. Good relationships with other people are the single most important contributor to a satisfied life and may even be a necessary condition for happiness. Having a “best friend” at work is a strong predictor of work satisfaction and even productivity. A good relationship is one in which the amount of positive communication considerably outweighs the amount of negative communication.

Positive psychologists have taken a close look at the features of positive communication, describing four ways that a person can respond to someone else when he or she shares good news, including good events like a raise at work:

- Active–constructive responding—a positive and enthusiastic response: “That’s great; I am so proud of you; tell me more about it.”
- Active–destructive responding—a response that is critical or points out the potential downside: “Are they going to expect more of you now?”
- Passive–constructive responding—a muted response: “That’s nice, dear.”
- Passive–destructive—a response that conveys disinterest: “It rained all day here; what’s for dinner?”

Couples who use active-constructive responding have good relationships. The other responses, if they dominate, are associated with relationship troubles. Although this research has only been done in the context of romantic relations, it may well generalize to other relationships.

The important correlates of happiness are social in nature. In contrast to the modest demographic correlates of happiness and well-being, consider the following robust correlates:

- Number of friends
- Being married
- Being extraverted
- Being grateful
- Being religious/spiritual
- Pursuing leisure activities
- Employment (not income)

Telegram: @medical_k

www.konkur.in

In a study that compared happy people to very happy people, there was one striking difference: good relationships with other people. Of the very happy people in the sample, all had close relationships with others. Psychology research documents very few necessary or sufficient conditions, but these data suggest that good social relationships may be a necessary condition for extreme happiness.

Kindness and generosity to others matter. Studies consistently show that doing volunteer work, helping, and giving are associated with high life satisfaction and good health. The implication of these findings is that encouraging people who have experienced difficult events to turn their attention to others might be beneficial. Doing so changes how the givers think about themselves, in positive ways that make them happier and healthier. It is also conceivable that doing service for others, as well as the feeling of contributing to others and society, gives people life meaning, that is the sense that their life matters. In particular, when people experience adversity and uncontrollable events, they feel helpless and depressed.

Perhaps encouraging people to engage in prosocial or service activities would empower them and increase their sense of self-worthiness. The activities do not need to be organized volunteer activities. Even simple acts of kindness in the community, followed by reflection on them, as through journaling, could have therapeutic effectiveness. For example, in a study with Japanese college students, merely asking them to count the kind acts they performed during the day led to increased happiness and more kind behaviors.

Money makes an ever-diminishing contribution to happiness. People who are so poor that they cannot meet their basic needs of course are unhappy, but above extreme poverty, increased income has a surprisingly small relationship with life satisfaction. In fact, money was related to experiencing less daily sadness, but no more daily happiness. The relationship between money and happiness is more complex. What people do with money matters more for happiness. That is, spending money on experiences increased happiness, while spending money on buying things did not. Also, when people spent money on other people, they became happier regardless of the amount of money they spent. Money has also been shown to have a downside. People with larger amounts of money savored less positive experiences compared to their lower-income counterparts.

Telegram: @medical_k

www.konkur.in

Work matters. Despite the small contribution of income to well-being, whether or not someone is working is much more strongly related to happiness. People who are employed and engaged in what they do are happy, regardless of the status or compensation associated with their job. Happiness and engagement lead people to regard their work as a calling and to be more productive at whatever they do, take fewer sick days, and even postpone their retirement.

Eudaimonia trumps hedonism. According to Aristotle's notion of *eudaimonia*—being true to one's inner self (demon)—true happiness entails identifying one's virtues, cultivating them, and living in accordance with them. Contrast this notion with the equally venerable idea of *hedonism*—pursuing pleasure and avoiding pain—that is the foundation for *utilitarianism,* which in turn provides the underpinning of psychoanalysis and all but the most radical of the behaviorisms. Research shows that eudaimonia consistently trumps pleasure as a predictor of life satisfaction. Those who pursue eudaimonic goals and activities are more satisfied than those who pursue pleasure. This is not to say that hedonism is irrelevant to life satisfaction, just that all things being equal, hedonism contributes less to long-term happiness than does eudaimonia.

The "heart" matters more than the "head." As already mentioned, positive psychologists have begun to study character strengths—individual differences like curiosity, creativity, kindness, and teamwork. Measures have been devised and administered to people across the lifespan. Research consistently shows that strengths of the "heart" that connect people together—like love and gratitude—are much more strongly associated with well-being than are strengths of the "head" that are individual in nature like creativity, critical thinking, and aesthetic appreciation. Formal education of courses stresses the latter strengths, but if one goal of education is to encourage the good life, the research results suggest that the former strengths deserve attention as well.

Happiness, strengths of character, and good social relationships are buffers against the damaging effects of stressful life events. No one will go through life without problems and setbacks, but to the degree that people have more life satisfaction, greater character strengths, and better social support, they will experience fewer psychological or physical problems in the wake of difficulties and recover more quickly from them. These findings provide targets for primary prevention and may represent a unique contribution of the positive psychology perspective. Although all

Telegram: @medical_k

www.konkur.in

can agree that prevention of psychological problems is more efficient and humane than their treatment once they occur, understanding of prevention has lagged far behind what has been learned about the etiology of psychopathology. Perhaps researchers have been looking at the wrong things—risk factors rather than protective factors.

Positive institutions have common features. Over the last decade, research on positive institutions has been growing steadily. There is agreement that institutions that allow people to flourish—whether families, schools, workplaces, or even entire societies—share a core of common characteristics:

- Purpose—a shared vision of the moral goals of the institution, one reinforced by remembrances and celebrations
- Safety—protection against threats, danger, and exploitation
- Fairness—equitable rules governing reward and punishment and the means for consistently enforcing them
- Humanity—mutual care and concern
- Dignity—the treatment of all people in the institution as individuals, regardless of their position

POSITIVE PSYCHOLOGY AND CLINICAL WORK

The goal of interventions based on positive psychology was not only relieving problems but also helping people with or without problems to lead a fulfilling life. The therapeutic goals were not to move people from −5 to 0 (problem-free)—the presumed goal of conventional psychology—but rather break through the zero point.

Interventions based on positive psychology can help people to do more than help people doing well in life do even better. These interventions may also help people with psychological problems lead a more thriving life, moving them from −5 to +2 or beyond. The core of positive psychology interventions is the strength-based approach. Whatever the presenting complaints, people also bring into therapy assets and strengths that can be used to resolve their problems. A crucial task of any treatment is, therefore, to identify a client's strengths and resources and encourage their use, not just to solve problems but more generally to encourage flourishing. Such a balanced approach should build rapport and bolster client confidence. It would certainly make sense to clients.

Telegram: @medical_k

www.konkur.in

When asked how they can tell that treatment has been effective, individuals with DSM diagnoses of depressive disorder describe their own view of "remission" in positive psychology language, spontaneously mentioning that would be more optimistic and confident, would have more energy, and would function well. They did *not* mention merely the reduction of symptoms or a change in diagnostic status. That is, depressed people, want to be more than just relieved of negative symptoms from their therapy. They also want to attain certain positive aspects of life.

Positive psychology interventions may also help psychologically healthy people stay that way—keeping them in the right-hand quadrants of Figure 32.16–1—by expanding the targets of prevention programs beyond risk factors to include those that maintain and create resilience. For those who have recovered from psychological difficulties, positive psychology interventions may prevent relapse, keeping them in the right-hand quadrants of Figure 32.16–1. Finally, these interventions may encourage and sustain physical health.

Perhaps the most general contribution of positive psychology to clinical work is to provide a vision of psychological health. Even if therapeutic concern is with traditional diagnostic categories, positive psychology provides substantive goals for any therapy that go beyond symptom reduction or removal.

Positive Psychology's Vision of Psychological Health

In its 1948 constitution, WHO defined *health* as "a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity." In more recent years, this statement has been expanded to include the ability to lead a life that is socially and economically productive. This definition is an important declaration that health entails more than the absence of illness, but it is circular, inasmuch as "well-being" is a synonym for "health." Work by positive psychologists makes this definition more concrete and thus useful as a guide for research and intervention.

If one can extrapolate from the sorts of topics that have been studied, positive psychology assumes that people are doing well when they experience more positive feelings than negative feelings, are satisfied with their lives as they have been lived, have deep positive relationships, have identified what they do well and use these talents and strengths on an

Telegram: @medical_k

www.konkur.in

ongoing basis, are highly engaged in what they do, are contributing members of a social community, and have a sense of meaning and purpose in their lives. Physical health and safety of course provide an important context for psychological well-being. It is difficult to imagine a cultural group in which these components of the good life are not valued. Respect for human diversity need not entail extreme cultural relativism.

Note that this fuller characterization of health reflects the WHO definition and is drawn from research in all of the domains of concern to contemporary positive psychology. The relevant research cautions that health so defined is not unitary. No one can have it all, at least at the same time, given tradeoffs among the psychological states and traits that reflect doing well. Psychological health therefore needs to be described with a profile of features and not a single summary score. DSM describes hundreds of psychological problems, and there may be just as many different manifestations of the good life.

The positive psychology vision of optimal functioning can also be used to make sense of the psychological problems that people do have. Problems (from a positive psychology perspective) represent shortcomings with respect to one or more of the components of the psychological good life. For example, people may experience more negative affect than positive affect; they may be dissatisfied with their lives; they may be socially estranged; they may be bored, alienated, or nihilistic; and so on.

These ways of thinking about problems of course differ from the DSM vision of psychopathology in terms of a set of symptom-defined disorders that are either present or absent. The positive psychology vision regards so-called “symptoms” as the problem and further expects them to exist in degrees. These visions need not compete. Traditional DSM diagnostic categories are not independent of the components of well-being implied by a positive psychology perspective, and a positive psychology perspective explains why given DSM symptoms and diagnoses constitute problems in living by identifying the ways in which optimal personal and social functioning are compromised by the disorder and its symptoms.

For example, it can be difficult to say why depression *per se* is considered a disorder, especially in light of discussions about its occasional utility and its basis in the evolutionary history of the human species. Yet, if depression is examined further in terms of its association with such difficulties as disinterest, indifference, helplessness, isolation

Telegram: @medical_k

www.konkur.in

and loneliness, pessimism, and alienation, then one can readily understand when and why depression is a psychological problem. At least in principle, a person who is “depressed” only in the sense of being sad and subdued does not have a problem. This person might simply be solemn and cautious, and Prozac should not be prescribed to counteract what may really be strengths of character.

Positive psychology can be criticized for being value-infused. The offsetting virtue is that the values inherent in positive psychology are clearly stated. The real question is whether these values are idiosyncratic or culture-bound. At a certain level of abstraction, the vision of psychological well-being that emerges from positive psychology seems ubiquitous if not universal.

As a perspective on topics that deserve scientific study, positive psychology has no single theory. Like much of contemporary psychology, it instead relies on midrange theories that draw on a variety of larger perspectives, from evolutionary to behavioral to cognitive to sociocultural models, in order to make sense of specific phenomena. Different topics are explained with different theories. The eventual integration of psychology may be a worthy goal, but it has not yet been achieved.

Positive Psychology Assessment

Much of psychological assessment has been tilted toward identifying weaknesses, deficiencies, and problems. The positive psychology perspective is that problem-focused assessment should be expanded to include strengths, assets, and competence. For example, low life satisfaction can occur in the absence of psychopathology, and it is nonetheless related to psychological and social problems. Conversely, high life satisfaction is linked to good functioning even in the presence of symptoms. The absence of problems is not equal to health. Problems and strengths can coexist.

Positive psychologists have already developed an impressive set of measurement instruments that allow someone doing assessment to break through the zero point of deficiency measures. For example, the healthiest that one can score on a typical measure of depression is 0, but this lumps together people who are blasé with those who are filled with zest and joy. The distinction seems well worth making, and the self-report surveys and interviews developed by positive psychologists allow it.

Space does not permit a detailed presentation of positive psychology measures, but Table 32.16–1 provides some examples. For example, the Values in Action Inventory of Strengths (VIA-IS) is a comprehensive survey that measures an individual's character strengths, 24 positive traits like curiosity, social intelligence, hope, kindness, zest, and teamwork. Positive psychology interventions are often described as strengths-based, which means that the results of this survey can provide useful information for the therapist and the client in identifying the client's strengths and devising interventions.

Many of the popular positive self-report surveys are available online at no cost at www.authentichappiness.org. Upon completion of a survey, individual feedback is provided, which means that clients can be directed to this website and asked to keep a record of their scores.

Most of the existing positive psychology measures were developed for research purposes, and they are most valid when aggregated to yield conclusions about groups of people. They can also be used ipsatively to describe the psychological characteristics of an individual and how they stay the same or change over time, but the cautious use of these descriptions is a point of discussion and departure in treatment. They are not strong diagnostic tests, and none should be treated as if they are. They should not be used alone for important decisions. Prudence is necessary for its interpretation and use, especially in the clinical setting. Such prudence is appropriate for all psychological assessments, but it is worth emphasizing in the special case of positive psychology measures.

Positive Psychology Techniques

Positive psychologists have shown that a variety of brief interventions can, in the short term, increase well-being as measured by happiness, satisfaction, and fulfillment. In some cases, there is also evidence that they can alleviate depression. These interventions have an obvious role not only in remedying distress following experience with adversity but also

Telegram: @medical_k

www.konkur.in

in building resources that blunt the negative effects of adversity in the first place.

When people experience adversity, they could be overwhelmed to appreciate the good things in life. In an experimental study by Lauren Conklin and her colleagues, depressed people showed no difficulties in learning negative information but had trouble learning positive information. Depressed people may have trouble recognizing and remembering the good things in life. This suggests that therapists should consider helping clients to identify, appreciate, and celebrate positive aspects of their everyday life. Here are some promising positive psychology intervention techniques of potential value in prevention, promotion, and/or treatment interventions.

Savoring. Savoring is one's awareness of pleasure and one's deliberate attempt to make it last. One way to cultivate positive emotion is to maximize when good things happen in one's life. Fred Bryant and Joseph Veroff examined the effects of savoring good events and found that people who do so are more satisfied. They also identified simple strategies for savoring, such as sharing good events with others, either in the moment or after-the-fact; building memories of the good events (e.g., photographs, diaries, souvenirs); congratulating the self when good things happen; sharpening perceptions during the experience of good events, and becoming fully absorbed in pleasure and not thinking about other matters. Professionals could also help their clients to use more of these strategies to maximize even simple and routine life experiences such as eating or walking. People who habitually savor are happier and more optimistic, and less depressed than those who do not savor.

Counting Blessings. Across the lifespan, people who are grateful have higher life satisfaction. Gratitude can be added to someone's repertoire by deliberate intervention, and a number of studies by different research groups have shown the effectiveness of so doing for both children and adults by increasing life satisfaction and optimism and reducing depression. Participants are usually asked to write down at the end of the day things that went well during the day and for which they are grateful. Details of this intervention may vary across the number of things listed and the frequency of listing them. This exercise can be modified depending on the client's age and situation. To avoid making this exercise burdensome to some people, especially children, it could be done a few

Telegram: @medical_k

www.konkur.in

times a week and count one or two blessings instead of three blessings. Although more evidence is needed for the effect of different frequencies and the amount of blessings on the outcome across different age groups, a study reported the negative effect when this exercise becomes excessive and, as a result, a burden.

In our own work, we have asked participants to write down why each good thing happened, encouraging them to be more mindful:

Every night for 1 week, set aside 10 minutes before you go to bed. Use that time to write down three things that went really well on that day and why they went well. You may use a journal or your computer to write about the events, but it is important that you have a physical record of what you wrote. It is not enough to do this exercise in your head. The three things you list can be relatively small in importance or relatively large in importance. Next to each positive event in your list, answer the question, "Why did this good thing happen?"

Participants, specifically those who continue to do this exercise, reported more happiness and less depression. The effect was maintained even in a 6-month follow-up. The mechanisms for these effects have not been closely studied, but there are likely several of them. This exercise could help people to pay more attention to the positive aspects of ongoing life and appreciate life more and be more optimistic and experience more positive emotions.

Strengths-Based Approach: Identifying and Using Strengths of Character in Novel Ways. Our multidimensional character strengths measures can be scored within the person (e.g., rank ordered)—to identify an individual's "signature strengths" relative to their other strengths. Everybody has strengths regardless of where they may stand relative to others. This strengths-based approach is particularly useful for working with people with a history of disability, low achievement, or low self-esteem. They often have a hard time finding anything they are good at. However, if the strengths *within* a person are compared, those strengths that are stronger than others can be identified. Subsequently, professionals can help them to use these strengths in their lives.

After clients identify top character strengths using online questionnaires (VIA-IS), they are encouraged to use them in novel ways in their daily life:

Every day for the next 7 days, use one of your top five strengths in a way that you have not before. You might use your strength in a new

Telegram: @medical_k

www.konkur.in

setting or with a new person. It's your choice.

Our research found that this exercise reduces depression and increases happiness and that the effect is evident even at a 6-month follow-up, so long as people continue to do the exercise.

Once individuals build their confidence by using their signature strengths, they can be taught how to use these strengths to work on weaknesses or less-developed strengths. If discussions and interventions start with the strengths of clients—things at which they are good—this can build rapport and increase motivation.

Research support is still accumulating. Enough outcome studies have been conducted to conclude that strengths-based approaches to change are more than just promising. Not known in most cases is how these expanded therapies fare in direct comparison to traditional treatments for problems and what are the mechanisms involved. Perhaps, attention to both strengths and weaknesses is critical and that no useful purpose is served by regarding these as mutually exclusive therapeutic goals.

See Table 32.16–2 for other examples.

Outcome research shows that a variety of psychotherapies are effective in alleviating problems, and usually equally so, despite the different forms they take. One interpretation of the equal effectiveness of different therapies is that nonspecific factors common to all treatments are responsible. Perhaps the sorts of strategies being studied by positive psychologists reflect these common factors and give names to them. Strategies like instilling hope and building strengths may be critical to the effectiveness of any therapy.

Telegram: @medical_k

www.konkur.in

Table 32.16–2.
Positive Psychology Techniques and Interventions

Exercises to increase positive feelings
Performing acts of kindness
Savoring
Writing a gratitude letter
Walking in nature
Exercises to decrease negative feelings
Turning one's head to see the positive
Positive reframing
Self-compassion
Exercises to increase life satisfaction
Counting one's blessings
Exercises to develop talents and strengths
Using talents and/or signature strengths of character in novel ways
Exercises to increase engagement
Finding a challenging hobby
Exercises to increase social connectedness
Being a good teammate
Active–constructive responding
Exercises to increase meaning and purpose
Performing secret good deeds
Writing one's own legacy
Working for a valued institution

Some qualifications are in order if these techniques are used in the context of treatment. First, they are not therapies *per se* but simply exercises to be deployed as part of an overall treatment program. The therapist must ascertain a client's readiness to change in the particular ways requested in the exercise, as well as the client's capacity to make the change. Like any psychotherapeutic procedure, these techniques cannot be imposed on the unwilling or the unable.

Second, none of these techniques is akin to a crash diet or an antibiotic. To the degree that they have lasting effects, it is because clients integrate them into their regular behavioral routines. Counting blessings for a week will make a person happier for that week, but only if the person becomes

Telegram: @medical_k

www.konkur.in

habitually grateful will there be a more enduring effect. Research finds—not surprisingly—that the people who showed lasting benefits were those who continued to use the exercise.

Third, these exercises are typically presented as one-size-fits-all, but there is no reason to think that they are equally useful for all clients. Nothing is known about the match of an exercise with a client's particular presenting problems or goals or with a client's age, gender, social class, or ethnicity.

Fourth, little is known about the parameters of these interventions. For example, how many blessings should one count, and how frequently should this be done? With college students, counting blessings three times a week may be more effective in increasing happiness than counting them more frequently. Is this a general phenomenon or one specific to young adults attending college?

Fifth, all interventions run the risk of unintended harm, and while positive psychologists would like to believe that their techniques avoid iatrogenic effects, this assertion cannot be made with thorough confidence. For example, although optimism is related to mental and physical health, it would be simplistic and potentially hazardous to tell clients that positive expectations will solve all their difficulties. Along these lines, if a positive psychology intervention overemphasizes a client's choice and responsibility, considerable damage could be done in cases of abuse and victimization, where self-blame needs to be undone and certainly not encouraged. Interventions based on positive psychology should not preclude the use of existing therapeutic strategies when these are indicated.

Positive Psychotherapies

Positive psychotherapies are beginning to appear: therapeutic interventions based on the theories and findings of positive psychology. What distinguishes these emerging positive psychotherapies from conventional treatments is that their stated goal is not just symptom reduction or relief but also enhanced happiness, life satisfaction, fulfillment, productivity, and the like—one or more components of positive psychology's vision of the good life. These new therapies target people with psychological problems as well as those without (see Fig. 32.16–1). In the latter case, positive psychotherapies make contact with life coaching.

Telegram: @medical_k

www.konkur.in

However, there is a danger in the label because it may give the misleading impression that an altogether different approach to treatment has been created. Almost all treatments labeled as positive psychotherapy are derived from well-established cognitive-behavioral approaches. The authors prefer to describe these interventions as *informed* by positive psychology and stress the continuity between them and existing approaches.

In identifying positive psychotherapies, the definition is crucial but difficult. As noted, positive psychotherapies have the goal of helping people thrive. They attempt more than the solution, eradication, or mitigation of problems. The possible field of positive psychotherapies is so broad that it needs narrowing, and somewhat arbitrarily, the focus here is on approaches characterized by an explicit *therapeutic alliance* between the positive psychologist and the client. This feature goes by many names and has been variously defined, but its recurring themes include collaboration between therapist and client, an affective bond between them, and agreement on the goals and tasks of the intervention. Asking people to write about their goals or to perform acts of kindness, despite beneficial consequences, may or may not be instances of positive psychotherapy; what matters is the relational context of the request.

This more narrow definition of positive psychotherapy is met by several approaches, most of which are recent. These are described in the next section. In most cases, there is only limited evidence for their effectiveness. This is not to say that the evidence argues against their use but simply that not enough research has been done. The good news is that most of these positive psychotherapies have been devised by research-minded psychologists, who are in the process of putting their ideas to the empirical test.

The further good news is that there are decades of available lessons from the psychotherapy outcome research literature to guide the evaluation efforts of positive therapists. The need for well-characterized samples, plausible comparison groups, random assignment, treatment manuals, objective outcome measures, effect size estimates, long-term follow-ups, and analyses of the process is recognized. All are readily applicable to the investigation of positive psychotherapy effectiveness.

In the meantime, investigation of the effectiveness of conventional therapies will continue, and it would be desirable for researchers to add positive psychology measures to their assessment batteries. These

Telegram: @medical_k

www.konkur.in

measures include a number that is brief yet well-validated. Although the inclusion of these measures would not transform conventional therapies into positive ones, they would provide important information for practitioners of all stripes. Do therapies that effectively treat anxiety or depression return clients to a typical level of life satisfaction or still leave them short? Might they, in some cases, lead to actual flourishing? Are the individual differences of concern to positive psychology moderators or mediators of traditional therapy effectiveness? One simply does not know, but these are easily answered questions given the availability of appropriate assessment techniques.

Positive Psychotherapy Examples. Here are descriptions of some of interventions that can be considered positive psychotherapies and—if the information is available—what is known about their effectiveness. As noted, positive psychology is a perspective, and no single theory underlies this perspective. When positive psychologists propose full-blown approaches to psychotherapy consistent with the premises of positive psychology, they turn to existing therapies for the overall model of treatment.

1. Decades ago, Michael Fordyce developed a *Personal Happiness Program* and showed it to be effective in boosting the long-term satisfaction of college students. Fordyce surveyed the research literature on happiness and identified predictors presumably under the short-term control of ordinary people—for example, keeping busy, socializing with others, doing meaningful work, and making the pursuit of happiness a priority. This information was conveyed to individuals along with suggestions to carry out 14 different behavioral and cognitive exercises over the course of a semester. In seven studies that included no-treatment comparison groups, Fordyce found that self-reported happiness increased and feelings of depression decreased. Follow-up was as long as 18 months. Fordyce believed that mere exposure to what he called “happiness principles” drove these effects, but one can suspect that the exercises were crucial, as well as their encouragement of positive emotions.
2. Already described were investigations of specific *positive psychology techniques* like counting one’s blessings and using signature strengths in novel ways. These studies were part of a deliberate program to develop and evaluate a positive psychotherapy. Much like Fordyce,

Telegram: @medical_k

www.konkur.in

Seligman and his colleagues surveyed the scientific and popular literature for interventions purporting to increase happiness. More than 100 of these were identified, of which 40 were able to be manualized. Ongoing work is systematically testing the effects of these manualized interventions in randomized trials against a plausible placebo control (asking individuals to write about their early memories). The Internet is used to recruit participants, deliver the intervention, and collect data. So-called cybertherapy is obviously new and invites skepticism, but the only way to evaluate what promises to be a cost-effective strategy for helping people is to do the relevant outcome studies. Two of the interventions so far evaluated—counting one's blessings and using signature strengths in novel ways—increase happiness and decrease depression through 6 months of follow-up, with effect sizes as large as those of conventional psychotherapy. A third intervention—writing and delivering a letter of gratitude to another person—had a very large effect on happiness and depression, but only for 1 month. Two other interventions—writing an essay about "you at your best" and identifying one's signature strengths (without the instruction to use them in novel ways)—did not affect well-being. As noted, research is ongoing, and it will be just as important to learn what does not work as to determine what does.

3. The *positive psychotherapy* sketched by Martin Seligman, Tayyab Rashid, and Acacia Park packages together different positive psychology techniques and uses them sequentially in one-to-one therapy with depressed clients (see Table 32.16–3). Out-of-session homework assignments are given, and their results are the focus of discussion in treatment. Pilot data suggest that this form of treatment reduces depression and increases life satisfaction. However, more research is needed to determine the critical techniques for therapeutic outcomes, how each technique contributes to its result, and whether the order in which different techniques are given matters.

www.konkur.in

Table 32.16–3.
Idealized Sequence of Positive Psychotherapy Sessions

1. Orientation to therapy
2. Identifying strengths of character and approaches to happiness (pleasure, engagement, and meaning)
3. Using signature strengths of character in novel ways
4. Positive emotions in the past (reminiscence)
5. Undoing negative emotions in the past (forgiveness)
6. Gratitude
7. Taking stock
8. Meaning
9. Optimism and hope
10. Love and attachment
11. Family
12. Savoring
13. Giving to others
14. Integration: the full life

4. *Mindfulness-based cognitive therapy* (MBCT) combines techniques of cognitive therapy with the Buddhist practice of mindfulness meditation, which encourages people to be more aware of what they are thinking, to live in the moment, and to refrain from evaluating judgments about their own thoughts. Whereas typical cognitive therapy tries to change the content of thought, MBCT emphasizes nonjudgmental awareness. MBCT grew out of stress-reduction strategies developed by Jon Kabat-Zinn to help people with physical problems like chronic pain and hypertension. Zindel Segal, John Teasdale, and Mark Williams adapted these strategies to help individuals with recurring depression. MBCT entails weekly group sessions and homework assignments. Outcome studies show the effectiveness of MBCT in decreasing depression and anxiety. MBCT may also be more effective than conventional pharmacologic or psychotherapy treatment in reducing relapse rate. MBCT also improves the quality of life among medical patients, which makes it an instance of positive psychotherapy.
5. The *Penn Resiliency Program* (PRP) was developed by Jane Gillham and Karen Reivich to prevent depression by teaching children cognitive–behavioral skills before the development of problems. Its most-studied version is a 12-session program designed for group

Telegram: @medical_k

www.konkur.in

administration to middle-school students. PRP contains two main components, one cognitive and the other based on social problem-solving techniques. In the cognitive component, core cognitive techniques are translated, through the use of cartoons and skits, into a language that adolescents can understand and apply to their own lives. In the social problem-solving component, students learn skills that help them better interact with this world: assertiveness, negotiation, relaxation, avoidance of procrastination, social skills, decision making, and problem solving. PRP has been successfully evaluated in school and managed care settings in both the United States and China. Results indicated that prevention participants report fewer depressive symptoms and are less likely to report symptoms in the moderate to severe range through 2 years of follow-up. Researchers are in the process of investigating the effects of PRP on life satisfaction, which means that it can be construed as a positive psychotherapy.

6. *Action and commitment therapy* (ACT), developed by Steven C. Hayes and colleagues, has not been explicitly discussed by its originators as a positive psychotherapy, although its goals are unambiguously positive: to reduce the psychological suffering of clients and to help them live a life of value. ACT is a short-term structured therapy that has been used with individuals and groups with a variety of psychological and medical problems. It provides exercises and assignments that encourage an individual to accept psychological pain as normal and indeed important but also to avoid increasing it unnecessarily. ACT takes issue with the premise of typical cognitive therapies that the direct targeting of problematic ways of thinking is helpful. Indeed, the proponents of ACT argue that too much attention to thinking is counterproductive and may even exacerbate problems. ACT distinguishes between language and experience and teaches clients mindfulness techniques that identify experience without the entanglement of language. Cognitive defusion is the term used for learning to regard thoughts as mere thoughts. ACT also helps clients to identify their core values, commit to them, and to take action to live in accordance with them. ACT has a Buddhist flavor acknowledged by its originator, but this therapy was derived from behavior therapy and an explicit psychological theory of thought and language. Of all the positive psychotherapies discussed here, ACT has been among the most frequently tested, and it is as effective in reducing psychological problems as conventional cognitive–behavioral therapies. Most

Telegram: @medical_k

www.konkur.in

outcome research to date has used pathology measures, although some studies have also used the well-being measures of interest to positive psychology.

7. C. Rick Snyder's *hope therapy* uses cognitive–behavioral techniques to increase hope through a process of setting and monitoring explicit goals. It consists of formal and informal strategies for building and enhancing hope among children and adults. Versions of hope therapy exist for individuals and groups, and several studies demonstrate that by enhancing hope, hope therapy increases well-being and decreases symptoms of depression and anxiety.
8. *Well-being therapy* was developed by Giovanni Fava and is based on Ryff's model of psychological well-being. As described earlier, Ryff's model distinguishes several components of doing well and overlaps considerably with the positive psychology vision of psychological health. Well-being therapy is a short-term individual treatment that takes a thoroughly cognitive approach. In early sessions, clients are asked to identify and situate episodes of doing well. Then they are asked to keep a diary or journal about such episodes and to identify the thoughts and beliefs that interrupt them. Finally, they are taught to challenge and test these beliefs. Special attention is paid to the components of well-being that are frequently impaired, which makes well-being therapy more remedial than other positive psychotherapies. Well-being therapy is effective in reducing anxiety and depression, and it enhances well-being.
9. *Positive behavioral support* is a form of behavior therapy that focuses on the environment and specifically on problem contexts, defined as counterproductive and unfair situations that produce or exacerbate difficulties for people. Originally devised by Jacki Anderson, Edward Carr, Glen Dunlap, Robert Horner, Robert Koegel, Wayne Sailor, and Ann Turnbull to help people with disabilities, positive behavioral support has more general applicability. It attempts to impart to clients skills, coping strategies, and the motivation to change. It also enlists the support of family members and other key figures in the person's life. Positive behavioral support becomes an instance of positive psychotherapy when it expands its attention from what produces problems to what promotes happiness and life satisfaction. Like positive psychology per se, positive behavioral support is based on the premise that happiness is not simply the absence of conditions that produce problems.

Telegram: @medical_k

www.konkur.in

10. *Quality-of-life therapy* was developed by Michael Frisch, who presented it as an instance of cognitive therapy. Its goal is to increase one's quality of life (happiness) by using the sorts of techniques developed by Aaron Beck and colleagues to decrease depression. Like other positive psychotherapies, quality-of-life therapy assumes that there are multiple routes to the good life, and it describes specific techniques for achieving these, from changing one's objective situation to revising one's standards for defining personal success. Quality-of-life therapy can be used with individual clients or groups. Different versions of quality-of-life therapy have been created for clinical versus nonclinical clients, and evidence is starting to accumulate that quality-of-life therapy is successful in its intended goal of increasing life satisfaction.

Taking Stock. The unique and explicit goal of emerging positive psychotherapies is to enhance well-being and promote the good life among those with obvious psychological problems as well as those without. They are also similar to more established therapies. Positive psychotherapies are short-term structured interventions for individuals or small groups. Most can be placed in the cognitive–behavioral realm, although their techniques could be integrated easily into other treatment models. Most positive psychotherapies entail out-of-session exercises and homework assignments, the results of which are discussed in sessions. A number of positive psychotherapies ask clients to keep journals, and many of these therapies rely on ongoing assessment.

Like other cognitive–behavioral interventions, positive psychotherapies take issue with assumptions of the medical model that people in treatment are ill and that their problems are best described as discrete (present-or-absent) entities *à la* DSM. According to positive psychology, people's weaknesses and strengths exist in degrees.

As emphasized, research support is still accumulating. Enough outcome studies have been conducted to conclude that positive psychotherapies are more than just promising, with effect sizes in the small to moderate range typical of psychological interventions. Not known in most cases is how positive psychotherapies fare in direct comparison to conventional treatments for anxiety or depression. As already mentioned, the boundary conditions of effective positive psychotherapy are unknown.

In the past, it was thought that positive psychology interventions were inherently light-handed, meaning that they are met with little resistance

Telegram: @medical_k

www.konkur.in

and that they are self-sustaining. Why would someone *not* want to be happier and more fulfilled, especially given the additional—presumably rewarding—benefits of so being?

Current thinking is that positive interventions can challenge both the client and the therapist. People do not always do the right or good (i.e., happy) thing, even when they know perfectly well what is to be done. Challenging one's skills is more exhilarating than watching television. Spending time with close friends is more fulfilling than surfing the Internet. Doing volunteer work pays more dividends than reading the tabloids. Living in accord with explicit values is more satisfying than constant compromising. So why do people live as they do?

This question is among the most crucial for positive psychologists to answer, especially as they develop and deploy positive psychotherapies. The not-so-good life has considerable inertia. In the case of happiness, theorists have made sense of this inertia by positing a hedonic set-point. This set-point may reflect genetic constraints, cognitive styles like defensive pessimism, or habits sustained by given environments. Although recent research shows that the hedonic set-point can be changed by major life events, nothing suggests that change for the better is typical or easy.

CONCLUSIONS

Positive psychology goes beyond a focus on problems and their absence to reflect health and well-being. Positive psychology focuses on identifying and capitalizing on strengths and capacities. Evidence is accumulating that positive constructs such as positive emotions, good relationships, meaning and purpose, character strengths, and services for others play important roles in health and well-being, not only as broad protective factors, preventing or mitigating pathology and problems, but also as enabling conditions that promote thriving and flourishing life.

The good life can be taught and learned, but it requires hard work. Psychologists, at least in the United States, have long believed that the human condition can be improved by the intelligent application of what they have learned. Positive psychologists are no exception, and many have turned their attention to interventions that make people more happy, hopeful, virtuous, productive, and socially involved. In some cases, these applications are running in front of data that would support them, but in

Telegram: @medical_k

www.konkur.in

other cases, outcome research has been done. Even the most compelling research is not based on a follow-up that extends beyond a few years, and the research participants are usually motivated and willing volunteers. How well these interventions will generalize—across diverse people and over time—is, therefore, a research topic of high priority.

It is difficult to predict the future of positive psychotherapies except to say that their success will hinge on the relevant research. Although many therapy techniques informed by positive psychology seem promising, so far, only a few of them have been tested rigorously. More work needs to be done.

One point of view is that a thoroughly successful positive psychology will result in the fading away of the perspective, leaving a balanced psychology, one that recognizes the positive and the negative and of course their interplay. As emphasized, positive psychology does not deny the negative, and it may well be that what is most troubling in life can set the stage for what is most fulfilling. Complex emotional experiences often blend the positive and negative; optimism is most apparent when people confront setbacks and failures; crisis reveals strengths of character; ongoing challenge is a prerequisite to experience flow in the moment and to achieve something important in a lifetime; relationship success is foreshadowed not by the absence of problems but by how people resolve those that arise.

All people want to live happy and fulfilling lives. It is a fundamental human desire and right. Positive psychology provides a valuable perspective on the good life as well as strategies for assessment, treatment, prevention, maintenance, and promotion. Positive psychology expands the view of psychological health beyond the absence of symptoms and disorders and provides hope that a healthy, fulfilled, and productive life is possible for all.

32.17 Acceptance and Commitment Therapy

Courtney Barry, Psy.D., M.S., Zabrina Ebert, D.O., and Joanna Petrides, M.B.S., Psy.D.

Acceptance and Commitment Therapy (ACT) is a therapeutic orientation rooted in behaviorism, functional contextualism, and relational frame theory (RFT). According to Hayes, the focus of ACT is to increase psychological flexibility through the utilization of various processes, including acceptance, cognitive defusion, and mindfulness. Within these processes, experiential exercises and metaphors are used to help one identify and engage in a healthy way with one's thoughts, feelings, and sensations. The ultimate goal is to assist in guiding one to be more in line with their values and to allow them to make value-driven behavioral changes, even when experiencing difficult thoughts or emotions. It is important to note that ACT is one of the "third wave" behavioral therapies, which focuses more on how context influences behaviors rather than eliminating behaviors completely.

FUNCTIONAL CONTEXTUALISM

Functional contextualism looks to understand one's thoughts, behaviors, emotions, and memories within a specific context to better recognize the functions they serve, the meaning they carry, and the effect they have on a person (moving toward or away from their values). This understanding ultimately allows for increased prediction and influence of behaviors toward one's values to create a more meaningful life. For example, a pen that ran out of ink may not serve its purpose in the context of writing. However, in a different context, such as using it to point to something, the pen may serve its function. In a clinical setting, a thought, emotion, or behavior may not be problematic. However, it provides insight into how thought, emotion, or behavior affects an individual in moving toward their values. ACT postulates that functional contextualism allows the clinician to see the individual as an individual and not as "damaged." This ultimately

Telegram: @medical_k

www.konkur.in

permits the clinician to change how an individual relates to their thoughts, feelings, and behaviors. When individuals become more aware of how their thought, feeling, or behavior works in the context of their life, they can make choices in relation to their values leading to more satisfying outcomes.

RELATIONAL FRAME THEORY

RFT is another approach that comprises the foundation of ACT. RFT builds on being able to identify language and derive relationships. At a young age, children learn what certain objects are and begin to label those objects with words. For instance, a child sees a picture of a dog in a book, and an adult tells the child, “That is a dog.” The child has learned the picture of a dog carries the sound D-O-G. When asked to point to a picture of a dog, the child points correctly and also makes the sound D-O-G. The child now derives relations based on what they learned. As children grow, they develop more relations based on their experiences and derive others. They connect the relations between events, as well as connect different functions to the events, which is RFT. In a clinical example, experiencing anxiety in one event and relating it to different events in one’s life evokes more anxiety across other events. It is important to understand how relationships between language and cognition have significant impacts on our lives despite simply being words.

EMPIRICAL EVIDENCE

Empirical evidence supports the effectiveness of ACT within a wide variety of contexts and conditions. ACT has been validated for various health and psychiatric disorders, including but not limited to chronic pain, depression, anxiety, stress, weight loss management, substance use, psychosis, quality of life, and smoking cessation. It has been shown to be effective in increasing psychological flexibility, thus, reducing depressive or anxious symptoms, which can be sustained for months following the intervention. In terms of patient populations, effectiveness has been supported in children, adolescents, adults, and individuals with cancer. ACT can be utilized in a wide variety of settings, such as inpatient, outpatient, group, and individual. Furthermore, ACT has been utilized with demonstrated

Telegram: @medical_k

www.konkur.in

effectiveness in various methods of delivery, including in-person as well as web-based and smartphone applications.

PROCESSES

The ultimate goal of ACT is to increase a person's ability to connect with the present moment and to persist in or change behaviors toward bringing them closer to their values. This process is known as psychological flexibility and is gained through the utilization of the six core processes discussed below. ACT uses a hexaflex (Fig. 32.17–1) to illustrate the six core processes. Each is interconnected, and together, they come together to increase an individual's psychological flexibility. The processes can be highlighted using certain skills and metaphors, as highlighted in Table 32.17–1. It must be noted that these processes are not intended to be used as methods of avoidance but rather as positive skills.

FIGURE 32.17–1. ACT hexaflex. (Copyright Steven C. Hayes, Ph.D., used with permission.)

Telegram: @medical_k

www.konkur.in

Acceptance

Acceptance is the process in which a person learns to actively embrace internal experiences without working to avoid or change them. In other words, acceptance allows a person to engage with thoughts and feelings as they are, regardless of whether they are pleasant or painful. Because it is defined as an act, a person must be willing to engage in acceptance through action, which ultimately requires a decision to embrace acceptance. It is important to emphasize that acceptance and willingness are not the same as wanting. For example, a person does not have to want their physical/emotional pain to be present, but they must work toward accepting their pain will continue to exist as they engage in actions to live life more fully and with less pain. This process ultimately allows a person to move toward their values without engaging in experiential avoidance.

Cognitive Defusion

Cognitive defusion is a process in which a person works to alter their interactions with their own thoughts. Rather than working to alter the content, function, or frequency of distressing thoughts, a person learns to observe thoughts from a more neutral position. In essence, a person learns to notice thoughts passively over getting caught up in them and believing the content. The final result is a person decreases “buying-in” to their thoughts, leading to a reduction in emotional response and, ultimately, being able to more readily move on from the thought itself. Because thoughts often drive behavior, cognitive defusion is an important step to behavioral change. As an example, a person may continually have self-deprecating thoughts such as “I am a bad person” or “I am no good” and think because they had the thought, it must be true. Through cognitive defusion, a person learns to view the thought as just a thought without reacting behaviorally to address the thought or attaching their identity to what the thought is saying. By doing so, individuals let thoughts flow through their minds with no further examination and without assigning meaning, thus, allowing their life to continue.

Telegram: @medical_k

www.konkur.in

Table 32.17–1.
ACT Processes and Examples

Telegram: @medical_k

www.konkur.in

Process	Brief Definition	Theoretical Clinical Examples (All case examples are fictional)
Acceptance	Actively embracing internal experiences without working to avoid or change them.	A young adult with a history of PTSD on escitalopram and prazosin presenting with continued anxiousness related to having previously experienced a traumatic event. Feels medications are helpful but unable to move past the frustration that this happened to him. *Brief Intervention:* Can focus on ideas of acceptance by addressing the idea that willingness to accept trauma in order to live more fully is not the same thing as having wanted trauma to happen.
Cognitive Defusion	Rather than working to alter the content, function, or frequency of distressing thoughts, a person learns to observe thoughts from a more neutral position, i.e., a thought is just a thought until one assigns meaning to it.	An adult patient with a history of MDD with psychotic features on fluoxetine presenting with distress secondary to having negative thoughts about others. Expresses the belief that this must mean hallucinations have returned because there is no way they could think negative thoughts about others. Does note these thoughts to be internal and in their own voice. No other psychotic or mood symptoms noted. *Brief Intervention:* Discussion surrounding the idea that a thought can be just a thought and doesn't necessarily have to have

Telegram: @medical_k

www.konkur.in

		a deeper meaning can increase the resolution of distress.
Being Present	Working toward living in the here and now to promote increased awareness of oneself, others, and experiences.	An adolescent with a history of social anxiety disorder presents with decreased social interaction in the context of being hyper-focused on past social interactions. *Brief Intervention:* Exploration of various mindfulness techniques can improve contact with the present moment and minimize the over-evaluation of past interactions.
Self-as-Context	Aims to have a person identify themselves as the observer; a person is the one observing what is happening, not the observation itself.	An adult patient with a history of OCD on clomipramine presented with a worsening mood secondary to ruminating thoughts. Expresses distress with an inability to silence their thoughts and feels their thoughts define them as a person. *Brief Intervention:* Have a patient listen to their thoughts and then discuss with them how they were able to observe their thoughts. They were, in fact, the outside perspective.
Values	Identification of the person one wants to be, what one wants to stand for, and what will ultimately make life both fulfilling and meaningful.	A geriatric patient with a history of depression, unspecified, on venlafaxine presents with family with concerns of anhedonia and low energy. When discussing with the patient, they express feeling useless and without purpose since they retired a few years ago. Prior to retirement, they felt

Telegram: @medical_k

www.konkur.in

		they had been doing well on their medication regimen. *Brief Intervention:* Discussions about the different stages of life and the idea that despite this change, there is still room to work toward values to provide purpose and meaning that can improve the sense of satisfaction and fulfillment.
Committed Action	Commitment to making a change. Guided by identified values and accomplished through identification of goals.	A child patient with no past psychiatric history presents for evaluation of insomnia. Various behavioral barriers to proper sleep, including screen time before bed, varying bedtimes, etc., were noted. No acute mood or anxious symptoms were elicited. *Brief Intervention:* Create an action plan for proper sleep hygiene, including the identification of an ultimate goal (better sleep) and numerous small goals (reduce screen time, have a consistent bedtime, etc.) to reach the ultimate goal.

Being Present

Preoccupation with the past and/or future is a common pattern in many people. This preoccupation usually results in a judgmental evaluation of themselves, their environment, and their actions, as well as a disconnection from relationships and events. All too often, it is common to dwell on the past or be consumed with worries about the future. When engaging in the processes of being present, a person works toward living in the here and now to promote increased awareness of themselves, others, and experiences. This ultimately allows them to more readily

Telegram: @medical_k

www.konkur.in

utilize behaviors consistent with their values and achieve increased fulfillment from the present context. Commonly, this process is achieved through the use of mindfulness exercises ranging widely from breathing techniques to meditation and even mindful use of one's senses.

Self-as-Context

One's sense of self is often grounded in self-as-content, which is based in language. Self-as-content is the label one assigns to the self to define who someone is. For example, a person may define themselves based on their position in their family (parent, child, etc.), profession (businessperson, health care provider, athlete, etc.), the circles they exist within (religiously, economically), and even based on who they are not (the opposing groups). Self-as-context, on the other hand, aims to have a person remove language from the algorithm altogether and identify themselves as the observer. In other words, a person is the one observing what is happening, not the observation itself. For example, a person may experience various thoughts about themselves, including "I am successful" or "I am a daughter," and believe this is who they are. However, in actuality, they are the ones having the thoughts and not being the thought themselves. Therefore the language becomes "I'm having the thought 'I am successful.'"

Values

ACT embodies the importance of a person identifying who they truly want to be, what they want to stand for, and what will ultimately make their life both fulfilling and meaningful. In simpler terms, a person must identify their values. Given the nature of the definition, values are individualized and cannot be assumed based on one's culture, religion, or other identifying groups. Values provide a person with a sense of direction and will guide decision-making and behaviors taken when clearly defined. It is important to note that values are not tangible, and they cannot be finite; they are an ongoing influence on what motivates someone to engage in the way they do. The other ACT processes (especially acceptance, cognitive defusion, being present, and self-as-context) work to increase value-driven behaviors and actions.

Committed Action

Telegram: @medical_k

www.konkur.in

After identifying values, one must commit to the behavioral changes that align with those values. Phrased another way, values guide the behavior change, and committed action is practical steps taken toward making a change. While values and goals are different (goals can be checked off when accomplished, whereas values are ongoing), goals can help a person move toward their values. The utilization of SMART goals, in particular, can be of great use to a person as it helps them narrow down how exactly to initiate a change. The SMART mnemonic stands for Specific, Measurable, Attainable, Relevant, and Time-based. With each accomplishment of a SMART goal, another can be created, thus, always driving a person closer to their values.

The changing of behaviors is not automatic and by continuing to utilize the processes above, the individual can move toward a value-driven life.

32.18 Hallucinogen-Assisted Psychotherapy

ERIKA STEINBRENNER, M.D.

DEFINITION

This section provides an overview of the known literature on the clinical use of hallucinogens as adjuncts to psychotherapy. Most research relates specifically to psychedelics or *serotonergic* hallucinogens (i.e., those hallucinogens that exert consciousness-altering effects primarily through agonist or partial agonist activity at serotonin 2A [5-HT_{2A}] receptors).

Telegram: @medical_k

www.konkur.in

Ketamine has often been classified as a psychedelic, although it is chemically distinct and profoundly different. It will be addressed at the end of this section.

The past decade has seen a resurgence of interest in the clinical applications of psychedelics such as psilocybin, lysergic acid diethylamide (LSD), and 3,4-methylenedioxymethamphetamine (MDMA). Although psychedelics have been used by humans for millennia, known to science for over a century, and subjected to extensive basic research for years, the rigorous study of their clinical use as adjuncts to psychotherapy is in its infancy. Results from clinical trials have been auspicious, although additional research is needed. If the data ultimately support treatment efficacy, psychedelic-assisted psychotherapy would genuinely constitute a novel treatment paradigm in psychiatry. Many believe we are on the verge of a paradigm shift that will fundamentally change the field of mental health. A push is underway to legalize these substances, and leading researchers are gathering evidence of their safety and efficacy in various patient populations.

PSYCHOPHARMACOLOGY

Hallucinogens are a highly diverse group of substances that can alter and distort perception, thought, and mood. Hallucinogens are categorized by their chemical structure and include tryptamines, phenethylamines, dissociative anesthetics like ketamine and phencyclidine (PCP) (which interact with the glutamate system), anticholinergic hallucinogens, and cannabinoids. In addition, there are also several unclassified hallucinogens, such as kava kava, kratom, nutmeg, and Salvia. Psychedelics refer specifically to two classes: variations on the structure of tryptamine (i.e., psilocybin, LSD, *N,N*-dimethyltryptamine [DMT], ibogaine) and substituted phenethylamines (i.e., mescaline and MDMA). What they share is a common mechanism of hallucinogenic action: agonism or partial agonism at the 5-HT_{2A} receptor. Psilocybin, DMT, LSD, and mescaline are considered the “classic psychedelics.” Each psychedelic has unique properties and understanding the basics of each is vital for potential therapeutic use.

Psilocybin

Telegram: @medical_k

www.konkur.in

Psilocybin is a psychoactive substance found in over 200 species of mushrooms. Psilocybin is a prodrug and is rapidly dephosphorylated to the psychoactive metabolite psilocin in the intestinal mucosa and liver. The concentration of psilocybin and psilocin varies significantly between mushroom species. Effects first become apparent after approximately 20 to 45 minutes, peak between 60 and 90 minutes, then gradually come in progressively less intense waves for a total of about 6 hours. In terms of comparative potency, psilocybin is approximately 45 times less potent than LSD and 66 times more potent than mescaline.

LSD

LSD is a synthetic substance first synthesized in 1938 by Albert Hofmann. The onset of effects occurs around 30 minutes, with peak effects generally reached in 2 to 3 hours. Peak effects generally hold for another 2 to 3 hours and slowly dissipate for up to about 12 hours.

DMT

DMT is a psychoactive compound found naturally in a variety of plants and animals and endogenously produced in humans. When consumed orally, DMT is rapidly metabolized by the enzyme monoamine oxidase A (MAO-A) in the GI tract, thus making it inactive. Therefore, it is typically smoked or vaporized. This form of ingestion produces a potent hallucinogenic state, considered one of the most intense psychedelic experiences in existence. DMT is exceptionally fast-acting when consumed via inhalation, with peak subjective experiences occurring around 2 minutes after inhalation and completely resolving within 15 to 20 minutes. Due to its endogenous production in humans, DMT has been theorized to be associated with several nonordinary states of consciousness (i.e., dreaming, spiritual experiences, encounters with nonhuman intelligence, out-of-body experiences, near-death experiences).

Ayahuasca

Ayahuasca is a very complex brew in which plants containing DMT are combined with plants containing MAO-I's (β-carboline alkaloids), which increase the oral bioavailability of DMT. Besides protecting DMT from degradation, the β-carboline alkaloids also have their own psychoactive

Telegram: @medical_k

www.konkur.in

properties. Ayahuasca's effects begin to be felt between 20 to 40 minutes after ingestion, peak between 1 to 2 hours, and subside gradually within about 6 hours.

Ibogaine

Ibogaine is a natural compound derived from the root bark of a West African shrub, *Tabernanthe iboga Baill.* Ibogaine is pharmacologically distinct from the classic psychedelics: it simultaneously interacts with several neurotransmitter systems, with the highest affinity for the σ-2 receptor. It is commonly used in several other countries for opioid detoxification, although the mechanism of action for its efficacy in this setting is unknown as clinical observations suggest it is not acting as a mu-opioid agonist. The ibogaine experience is extremely long, lasting anywhere from 18 to 30 hours.

Mescaline

Mescaline is a psychoactive compound found in several species of cactus, most notably peyote. Mescaline binds the 5-HT_{2A} receptor at a much lower affinity than LSD, perhaps explaining the much higher doses needed for mescaline to have similar effects. Mescaline does not readily cross the blood–brain barrier, contributing to its low potency and substantial physical side effects, especially nausea and vomiting. These adverse effects are posited to account for the eclipse of mescaline research by LSD in the 1950s. Effects are generally felt within 45 to 90 minutes of consumption, peak at 3 to 6 hours, and last for 10 to 12 hours.

MDMA

3,4-Methylenedioxymethamphetamine (MDMA) is often referred to as a psychedelic, but it is quite different in many ways from classic psychedelics such as LSD or psilocybin; it produces mood elevation and an increased sense of empathy but the ego remains relatively intact. Therefore, it has been proposed that MDMA is actually an entactogen or empathogen, a distinct class of drugs. For organization and clarity, MDMA will be addressed in a separate section from the classic psychedelics.

SUBJECTIVE EFFECTS

Telegram: @medical_k

www.konkur.in

The range of possible subjective experiences under classic psychedelics is extensive and impossible to characterize fully. Effects occur along a dose-dependent range and vary between psychedelic substances. An individual's experience is also unique from one experience to another and is highly influenced by the extra pharmacologic factors of *set* (psychological frame of mind, intention) and *setting* (environment in which use takes place). Very broadly, experiences can be generalized along several dimensions: (1) perceptual distortions (i.e., visual and auditory illusions or hallucinations, synesthesia), (2) shifts in cognition (i.e., tangential thought processes, dissociative phenomena), (3) mood fluctuations (i.e., euphoria, sadness, anger), (4) the dysphoric effects of ego dissolution (i.e., anxiety, panic, fear of losing control), and (5) mystical experiences (dissolution from self, oneness with the universe, transcendence of space and time).

PROPOSED MECHANISM OF PSYCHEDELICS

Psychedelic drugs are fundamentally different from all other psychotropic medications. They are not inherently therapeutic themselves; rather, the benefits accrued by users are dependent on the integration of enduring memories and insights of the particular states of consciousness that were experienced during the period of drug action. That is why those who encounter profound states of mind typically express little interest in repetitive ingestions in the near future.

Although neuroimaging studies have begun to characterize the acute effects of psychedelics on brain function, how these changes neurobiologically mediate therapeutic benefit remains poorly understood. One of the most consistent observations on imaging is the disintegration of normal brain network communications after ingestion of a psychedelic substance. One key network that is disrupted is the default mode network (DMN), which is involved in introspection and sense of self; in many ways it represents the seat of what Freud called "the ego." The DMN becomes more chaotic and statistically random, and thoughts, perceptions, and memories typically inaccessible to awareness have a much higher probability of activation. During a psychedelic experience, the segregation between the DMN and related cortical networks is also lost, and new between-network communication patterns are formed. Thus, psychedelics lead to an overall brain dynamic characterized by a less-constrained

Telegram: @medical_k

www.konkur.in

consciousness, an increased degree of entropy, and the opportunity to experience a broader spectrum of cognitive insights and emotional breakthroughs.

A common characteristic of a lot of mental health disorders is that they can be defined by an entrenchment into a rigid and “stuck” way of thinking and behaving (i.e., a negative cognitive bias in depression, excessive rumination about some type of threat in anxieties, excessive control, and specificity of whatever the object of relief is in addiction, repeated behaviors in obsessive-compulsive disorder (OCD), repeating thoughts and ways of looking at oneself in eating disorders). It may be that psychedelics temporarily “shake up” the system and relax these overweighted habits of mind and behavior, which then provides the opportunity for recalibration into a healthier form once things resettle.

At cellular levels, psychedelics have been found to enhance processes associated with neuroplasticity, such as the growth of dendritic spines. They increase the expression of genes associated with brain-derived neurotrophic factor (BDNF) and other mediators of synaptic plasticity. Additionally, research has discovered that psychedelics possess incredibly potent anti-inflammatory properties at very low, sub-behavioral doses, although whether this ability contributes to its mental health effects is not yet known.

HISTORY

Early Academic Research With Psychedelics

Indigenous cultures have used psychedelics for religious and healing purposes for more than 10,000 years. However, Western scientific study of hallucinogens dates to the late 1800s when Arthur Heffter isolated mescaline. Initial interest focused on the possibility that mescaline could produce insight into the basis of psychotic disorders and serve as an experimental model for schizophrenia. In 1943, Albert Hofmann discovered the psychoactive effects of LSD when he accidentally ingested traces of an ergot derivative he had synthesized. The therapeutic potential of LSD was quickly recognized; it was marketed under the name Delysid and made widely available to psychiatrists worldwide, mainly as an adjunct for psychotherapy. Between 1950 and 1965, some 40,000 patients had been prescribed one form or another of LSD-assisted

Telegram: @medical_k

www.konkur.in

therapy as a treatment for neurosis and mood disorders, alcoholism and other addictions, and psychosis (schizophrenia).

Research investigating psychedelics grew as well. By 1961, over 1,000 scientific papers on psychedelics (mostly LSD) had been published. Results strongly suggested therapeutic benefits for psychedelic-assisted psychotherapy, with data strongest for alcohol use disorder and cancer-related psychological and existential distress. Unfortunately, early investigators did not employ rigorous clinical methods such as randomized trials, specified outcome measures, and controlled treatment settings, and thus these studies did not provide definitive results. Even so, the preliminary findings seemed to warrant further research into the therapeutic benefits of psychedelic drugs.

However, clinical research on psychedelics came to a halt in the early 1970s, in large part due to sociopolitical issues. LSD, with its ability to completely reframe one's relationship to reality (at least temporarily), contributed to the emergence of a counter-culture in which one was not only permitted but expected to question every aspect of social norms, from politics to religion to morality. In one of the most famous slogans of the 1960s, Timothy Leary popularized LSD as a way to "turn on, tune in, drop out." This was occurring against the backdrop of the Vietnam War and growing opposition to the perceived military–corporate control of society in general. The backlash was fierce. The Controlled Substances Act of 1970 placed LSD, psilocybin, and related compounds in Schedule I, and human research was not allowed to continue. The United States applied political and economic pressure on other U.N. members so that a global ban was fully in effect by 1971. LSD, despite more than two decades of scientific investigation pointing to an array of likely therapeutic benefits, was stigmatized as the most dangerous drug in the world. Decades of positive work with psychedelics were effectively discounted.

Reemergence of Research Using Psychedelics

After a hiatus of two decades, human research on psychedelics resumed in the early 1990s with Rick Strassman's exploration of the subjective and physiologic effects of intravenous DMT on normal volunteers. Researchers began conducting basic science studies, and a considerable body of work has characterized the acute effects of classic psychedelics on physiology, cognition, emotion, and brain function. In turn, this led to a renewed interest in psychedelics' potential therapeutic value for mental

Telegram: @medical_k

www.konkur.in

health. Clinical trials have resumed, investigating the effects of psychedelics (primarily psilocybin) in the treatment of a number of psychiatric illnesses and addictive disorders. The studies that have been completed thus far are primarily open-label or randomized controlled trials (RCTs) with small sample sizes, but the results have been extremely promising. The FDA granted breakthrough therapy designation to psilocybin for treatment-resistant depression twice: in 2018 (COMPASS Pathways) and 2019 (Usona Institute). A breakthrough therapy designation is meant to accelerate the typically sluggish process of research and development for drugs that treat a serious condition and for which preliminary clinical evidence indicates may demonstrate substantial improvement over available therapies. At the time of writing, there are over 200 ongoing or planned research studies involving psychedelics. Suffice it to say we are just beginning to explore the potential possibilities and uses for psychedelics.

PRINCIPLES AND GOALS OF THERAPY

Two models of therapy were used in the 1950s through the early 1970s: psycholytic and psychedelic therapy. Although both combined administration of hallucinogens with psychotherapy to achieve therapeutic change, they emphasized different processes in bringing about these changes.

Psycholytic Therapy

In the psycholytic method, low-to-moderate doses of hallucinogens are administered on multiple occasions to facilitate therapy based on traditional psychoanalytic principles (helping the patient become aware of unconscious desires, emotions, attachments, self-representations, and intrapsychic conflicts).

Psychedelic Therapy

Psychedelic therapy was developed based on the observation of sudden and dramatic clinical improvements associated with high-dose hallucinogen administration. Quantum shifts in perception and cognition were noted in patients who typically experienced “peak” experiences marked by highly salient spiritual, religious, or mystical phenomena. One of the main goals of psychedelic therapy is to create an optimal treatment

Telegram: @medical_k

www.konkur.in

environment during the preparatory psychotherapy and in the dosing session to foster such “peak” experiences. Contemporary research in the 21st century has used a variant of the psychedelic approach. Although the details of the protocol used in clinical trials have varied, several core principles are shared.

Preparatory Sessions. There are typically several preparatory sessions where participants discuss their intentions, expectations, and concerns and talk about meaningful aspects of their lives. These sessions serve a twofold purpose: First, the discussion helps build trust and rapport with the facilitators and reduces the likelihood of paranoia during the trip. Secondly, related personal material may emerge under the effects of psychedelics; by knowing details about the participant, facilitators can better understand the participant’s experience and how best to provide support should difficult emotions arise.

Dosing Sessions. During a psychedelic session, participants are typically invited to lie down with eyeshades and listen to carefully selected music through headphones. The most common issue in psychedelic sessions is resistance to the emerging unconscious material and an unwillingness to “go with the experience.” For this reason, conversation between participants and facilitators is best kept to a minimum, especially during the early, most intense hours. Therapeutic activity is primarily oriented toward assisting the participant in focusing attention inward and facing and fully experiencing whatever emerges without avoiding anything. Facilitators periodically check in with the participant and offer support and reassurance if fear or distressing emotions arise, but mostly the journey is uninterrupted. Occasionally, therapeutic touch is appropriate and can provide stability and connection. Length of sessions varies depending on substance (i.e., typically 4 to 6 hours for psilocybin).

Integration Sessions. Integration sessions follow in the days or weeks after a psychedelic session and are a time for participants to process their experience and sort out new insights and discoveries. Old maladaptive defenses are discarded, and new ways of experiencing, looking at, or reacting to events are explored. These integration sessions are a crucial component for optimizing benefits from the psychedelic experience.

Telegram: @medical_k

www.konkur.in

CLINICAL ISSUES

Indications

Psychedelic-assisted psychotherapy has historically been applied to a wide variety of psychiatric conditions. In the past decade since contemporary research has resumed, the most studied indications (and the ones with the most robust data from Phase II trials) are the use of psychedelic-assisted therapy for cancer-related distress and treatment-resistant depression. There is also encouraging research for its use in addiction and OCD, and trials are exploring its potential for several other indications (see Clinical Research section).

Limitations

There are several limitations to providing psychedelic-assisted psychotherapy. First and foremost, all psychedelics are currently Schedule I drugs and illegal in most states; thus they are largely not available for clinical use. If psychedelics are rescheduled and available as adjuncts to psychotherapy, there are several other obstacles to their broad use among mental health practitioners. The long duration of psychoactive effects (i.e., approximately 6 hours for psilocybin) necessitates daylong treatment sessions, which increases the clinical and infrastructure resources required and would thus likely result in high costs associated with treatment. Additionally, it has been shown that chronic use of SSRIs and other medications that bind the 5-HT_{2A} receptor (i.e., tricyclics, buspirone, and antipsychotics [chlorpromazine, risperidone]) reduce the subjective effects of psychedelics by 40% to 99%. Therefore, treating medication-heavy patients with psychedelics will be especially challenging, and a period of destabilization from medication discontinuation will likely be required before receiving psychedelic treatment.

Complications

Physiologic Toxicity. The safety of classic psychedelics (particularly psilocybin) in clinical research settings has been well-documented. In general, classic psychedelics possess remarkably low physiologic toxicity and are not associated with end-organ damage, carcinogenicity, teratogenicity, lasting neuropsychological deficits, or overdose fatalities.

Telegram: @medical_k

www.konkur.in

They do produce sympathomimetic effects and can moderately increase pulse and blood pressure, although this has not been associated with cardiac, neurologic, or other organ damage. They do not result in overdose deaths after reasonable dosages. Classic psychedelics are not typically considered drugs of addiction, as they are not capable of producing sufficient reinforcing effects to produce addiction.

Psychological Toxicity. Acute, adverse psychological experiences ("bad trips") are the most significant concern in psychedelic administration and typically include anxiety, panic, dysphoria, paranoia, agitation, and fear of losing one's mind. These unpleasant experiences are more likely to occur in recreational settings involving poorly prepared individuals and those who have psychological risk factors (i.e., severe mental illness, recent trauma). Despite such adverse reactions, users usually retain insight into the fact that their symptoms are related to drug ingestion, and they typically respond to verbal reassurance. Classic hallucinogens can acutely engender frank psychosis marked by hallucinations, thought disorders, and delusions, although this is rare in individuals without underlying psychotic spectrum illness. Hallucinogen-persisting perception disorder (HPPD) is an uncommon condition that can occur sometime after the cessation of a psychedelic or other hallucinogen. It is more likely to occur in individuals who chronically use hallucinogens or who concurrently use several substances (i.e., cannabis, MDMA, alcohol).

Contraindications

Given the known link between psychedelics and their ability to initiate or exacerbate psychosis in patients with underlying psychotic spectrum illness, they are contraindicated in anyone with a significant history of psychosis, whether it be from a primary psychotic spectrum illness (i.e., schizophrenia, schizoaffective disorder), affective psychotic illnesses (i.e., Bipolar I disorder with psychotic features, major depression with psychotic features), or severe personality disorders associated with psychosis. Furthermore, they are contraindicated in patients at high risk for psychosis (i.e., strong family history of psychosis). All contemporary research trials have excluded participants with bipolar disorder, given the risk of triggering mania; however, a current study is investigating the safety and efficacy of psilocybin for Bipolar II depression.

Telegram: @medical_k

www.konkur.in

CLINICAL RESEARCH

Use of Psychedelics for Treatment-Resistant Depression

Psilocybin. The use of psilocybin-assisted therapy for major depressive disorder (MDD) has been one of the largest areas of recent research. Several trials have been published in the last few years with encouraging results. Two consecutive psilocybin-assisted therapy sessions (spaced 1 to 3 weeks apart) were shown to significantly decrease depressive symptoms in an open-label setting or when compared to a waiting list group. Three randomized, placebo-controlled trials have investigated the effects of a single psilocybin-assisted therapy session (along with preparatory and integration sessions) in MDD. In these trials (one with inactive and two with active controls), psilocybin-assisted therapy produced rapid and significant decreases in depression symptomatology. Effects persisted to study endpoints, although notably these follow-up periods were limited (21 to 43 days). There was some variability in study design between the trials, but all contained a moderate dose of psilocybin and psychological support during the psilocybin intervention.

Psilocybin-assisted therapy has also shown noninferiority to a commonly prescribed antidepressant. In a study by Carhart-Harris, 59 patients were randomized to receive either two separate doses of psilocybin (25 mg; 3 weeks apart) + daily placebo (psilocybin group) or two separate control doses of psilocybin (1 mg; 3 weeks apart) + daily escitalopram (escitalopram group). All patients participated in a preparatory session and integration sessions following the two dose days. Results indicated that psilocybin-assisted therapy was as effective as escitalopram in reducing depressive symptoms at the 6-week endpoint. Of note, psilocybin-assisted therapy outperformed escitalopram on a number of secondary endpoints, including measures of well-being, anhedonia, work and social functioning, and suicidality. At the time of writing, there are multiple additional trials underway, including the first Phase III trial investigating psilocybin-assisted therapy for MDD.

Ayahuasca. Contemporary clinical trials with ayahuasca suggest an antidepressant effect, particularly in the subacute period. An open-label, within-subject trial investigated the effects of a single dose of ayahuasca

Telegram: @medical_k

www.konkur.in

on six subjects with varying degrees of depression. Ayahuasca was well-tolerated by all participants, and there were significant reductions in depressive symptoms at 21 days. The same team conducted another study in a larger sample (*N* = 17) and found that the results held. The first double-blind RCT for ayahuasca was published in 2018. Twenty-nine patients with treatment-resistant depression received a single dose of either ayahuasca or a placebo. Significant antidepressant effects were observed at all-time points following administration compared to baseline (1, 2, and 7 days after dosing). Notably, the effect size increased with time (from postdose day 1 to day 7).

DMT. There is much interest in whether DMT could be useful for treating mental health problems, given that it has a quick onset and short duration of action, which may provide a more cost-effective approach to treatment. There are currently no published studies investigating DMT for clinical use. Preliminary trials are underway in several academic medical centers investigating the safety and efficacy of specific doses of intravenous DMT in humans, as well as for the treatment of depression.

LSD. LSD was extensively investigated in humans in the 1950s and 1960s and demonstrated promise for attenuating depressive symptoms, but no contemporary studies have been conducted on this subject. A Phase II trial investigating the efficacy of LSD for patients with major depression is in progress.

Use of Psychedelics for Psychological and Existential Distress in Patients With Life-Threatening Illness

LSD. The first clinical study of LSD since the 1970s was conducted in 2014. This randomized, double-blind, placebo-controlled trial with a crossover design (2 months) included 12 participants with life-threatening medical disorders. Participants received two treatment sessions (2 to 3 weeks apart) with either LSD or active control in conjunction with psychotherapy. The experimental group had significant short-term (2-month follow-up) reductions in anxiety compared to the control group. A follow-up study found sustained reductions in anxiety at 12 months, and no reports of any adverse psychological or medical sequelae. A recent trial (*n* = 42) corroborated and expanded on those findings. Using a similar design, it found that two LSD-assisted treatment sessions (2 weeks apart)

Telegram: @medical_k

www.konkur.in

significantly reduced anxiety in patients both with and without life-threatening diseases for up to 16 weeks.

Psilocybin. Three contemporary research studies have been published investigating psilocybin to treat cancer-related psychiatric distress. A double-blind, randomized, placebo-controlled trial at UCLA (*N* = 12) suggested an acute and short-term sustained antidepressant and anxiolytic effect associated with a single low dose of psilocybin versus active placebo (niacin). Two other trials at the NYU Langone Medical Center (NYU) and Johns Hopkins University Medical Center used a similar treatment model, although varied on the dose of psilocybin and the comparator. Both studies had significant reductions in anxiety and depression at short-term follow-up.

A long-term follow-up of patients from the NYU study found that reductions in anxiety, depression, hopelessness, demoralization, and death anxiety were sustained at 3.2 and 4.5 years after the original psilocybin dosing date. At the second (4.5 years) follow-up, approximately 60% to 80% of participants met the criteria for clinically significant antidepressant or anxiolytic responses. Participants overwhelmingly (71% to 100%) attributed positive life changes to the psilocybin-assisted therapy experience and rated it among the most personally meaningful and spiritually significant experiences of their lives. A Phase II trial investigating psilocybin for depression in cancer patients is currently being performed.

Use of Psychedelics in the Treatment of Addiction

Alcohol Use Disorder

LSD. The use of LSD in treating alcohol addiction was studied extensively from the 1950s through the early 1970s. Uncontrolled trials had variable but generally encouraging results. A recent meta-analysis looking at the six published randomized trials of LSD for alcohol dependence (1943–2010) revealed consistent and clinically meaningful effects of LSD over control treatment. LSD was administered in a single high-dose session in all the studies, in doses ranging from about 210 to 800 mcg. At the first posttreatment follow-up, LSD-treated patients were more likely to show significant improvement in drinking outcomes. Treatment effects remained significant at 6 months. The effect of LSD

Telegram: @medical_k

www.konkur.in

treatment was homogeneous across the six studies, despite significant variability in the psychotherapeutic components of treatment and the control treatments employed. These promising findings strongly support renewed clinical investigation of LSD for the treatment of alcohol use disorder.

PSILOCYBIN. The first double-blind study investigating psilocybin-assisted therapy for alcohol use disorder was recently completed, and demonstrated positive results. Ninety-five participants engaged in 12 weeks of manualized therapy, and were randomly assigned to receive high-dose psilocybin or active placebo (diphenhydramine) during 2-day-long medication sessions at weeks 4 and 8. The therapy included motivational interviewing, cognitive behavioral therapy, and material for managing and integrating the psychoactive effects of the study medication. Results found that the psilocybin group had significantly reduced number of heavy drinking days in the 32-week follow-up period (10% vs. 24% in the placebo group). This supports findings from an earlier open-label pilot study. At the time of writing, six other trials investigating psilocybin for alcohol addiction are in progress.

IBOGAINE. There have not been any published studies on ibogaine in the treatment of alcohol use disorder. However, a Phase II trial investigating ibogaine in the treatment of alcohol addiction is in progress.

Tobacco Use Disorder. The first investigation of psilocybin for the treatment of tobacco use disorder has reported remarkably positive outcomes. In this open-label study, 15 nicotine-dependent smokers received psilocybin in moderate to high doses over 2 or 3 sessions during a 15-week course of manualized CBT therapy. At the 6-month follow-up, 80% of participants were abstinent based on self-report and verified by biologic measures (urinary cotinine and breath carbon monoxide). This success rate far exceeds those previously seen in clinical trials of any currently available pharmacotherapies for tobacco addiction. Smoking outcomes were significantly correlated with measures of mystical experience during psilocybin sessions, as well as the spiritual significance and personal meaning attributed to the sessions. Based on these very encouraging results, a comparative efficacy trial (psilocybin vs. nicotine replacement) is being performed.

Telegram: @medical_k

www.konkur.in

Opioid Use Disorder. Ibogaine was first promoted in the West as having antiaddictive properties in 1962 by Howard Lotsof, who was a heroin addict himself. Uncontrolled data from hundreds of patients suggest that ibogaine is effective in both acute detoxification as well as treatment for opioid addiction. Clinical trials to validate its therapeutic use have begun: a Phase II trial is currently investigating ibogaine's efficacy for methadone detoxification. Phase I trials for noribogaine, as well as an ibogaine analog, are also underway.

Cocaine Use Disorder. There is much hope that psychedelics could be effective for cocaine addiction, given the considerable prevalence of this condition and the limited pharmacotherapies that are currently available. The first clinical trial investigating psilocybin for cocaine use disorder is currently being conducted at the University of Alabama School of Medicine.

Use of Psychedelics in the Treatment of OCD

Only one published study has evaluated the use of psilocybin for OCD. Nine subjects were given up to 4 different doses in a modified escalating blinded protocol. A subthreshold dose was given randomly after the first dosage as a blind. Testing days were separated by at least 1 week. Psilocybin was well-tolerated by all participants, and marked decreases in OCD symptoms of differing degrees were observed in all subjects during one or more of the experimental sessions (23% to 100% decrease in YBOCS score). Research is continuing: at the time of writing, there are three studies investigating psilocybin for OCD.

Other Potential Indications

There are currently registered trials looking at the use of psilocybin for anorexia nervosa, body dysmorphic disorder, and depression in early Alzheimer disease. Clinical trials investigating psilocybin for opioid use disorder are also beginning or planned at multiple academic medical centers. While we await more definitive results of psilocybin's potential for cocaine, tobacco, and opioid use addictions, the possibility of an approach with cross-addiction generality is looking more realistic. Psychedelics could also potentially be explored to treat other drugs of abuse (i.e., methamphetamines, tetrahydrocannabinol [THC]) or behavioral addictions (i.e., gambling, overeating, and sex).

Telegram: @medical_k

www.konkur.in

Given the anti-inflammatory and neurotrophic properties of psychedelics, a Phase I study has been completed on a low-dose LSD formulation for the treatment of neurodegenerative diseases; a second Phase I study on the same molecule has been announced.

MDMA

Psychopharmacology

MDMA's primary mechanism of action is indirect—it stimulates the release and inhibits the reuptake of serotonin, dopamine, and norepinephrine. Its most potent effects are on serotonin, and it has an affinity for 5-HT_{2A} receptors. It also stimulates the release of hormones, including oxytocin, vasopressin, and cortisol.

Subjective Effects

MDMA facilitates states of positive mood, increased responsiveness to emotions, a heightened openness, and a sense of closeness to other people. Notably, it does not cause alterations in perception or sense of self commonly seen with classic hallucinogens.

Proposed Mechanism of MDMA-Assisted Psychotherapy

Slightly different mechanisms may be involved in the healing with MDMA than appear to be the case with classic hallucinogens. While the specific neurobiologic mechanisms underlying MDMA's efficacy for treating PTSD are poorly understood, they appear to be related to the alteration of emotional memory. MDMA can mitigate the fear response and decrease defense mechanisms without blocking access to memories or preventing a deep and authentic experience of emotion. This facilitates trauma processing, allowing participants to stay emotionally engaged while revisiting traumatic experiences without being overwhelmed by anxiety or other painful emotions. Emotional memory reconsolidation subsequently decreases or eliminates chronic hyperarousal and stress reactions to triggers. MDMA can also promote a sense of empathic rapport with the therapists, facilitating a corrective experience of secure attachment. Often a clearer perspective emerges that the trauma was a past event and a strengthened awareness of the support and safety that exist in the present. MDMA's use for other indications is thought to flow from this

Telegram: @medical_k

www.konkur.in

same principle: MDMA is a catalyst that enhances intra- and interpersonal growth without the typical interference of defensive conditioning.

History

MDMA was developed by Merck Pharmaceuticals in 1912. Researchers began investigating its potential to create controllable altered states of consciousness in the 1970s. Informal investigations found it was helpful for treating a wide range of conditions (PTSD, phobias, psychosomatic disorders, depression, suicidality, drug addiction, relationship difficulties, and the psychological distress of terminal illness), and it became the new drug of choice for therapists seeking a legal approach to psychedelic-assisted psychotherapy. However, despite the reported therapeutic potential, MDMA was officially categorized as a Schedule I drug in 1985. An expert committee of the World Health Organization (WHO) recommended the international prohibition of MDMA as an adjunct to psychotherapy. The committee, however, was not opposed to the further study of MDMA. In 1986, the Multidisciplinary Association for Psychedelic Studies (MAPS) was founded, and for more than 30 years promoted research into MDMA. Between 1994 and 2018, nine Phase II clinical trials of MDMA-assisted psychotherapy were completed at seven different sites in four different countries. Six of these trials treated individuals with PTSD and are the basis upon which the FDA ultimately granted breakthrough therapy designation for MDMA-assisted psychotherapy in 2017.

Principles and Goals of Therapy

Similar to psychedelic-assisted therapy with classic psychedelics, the design of MDMA-assisted therapy involves preparatory sessions before the dosing session and integration sessions following it. However, a core difference between classic psychedelic-assisted therapy and MDMA-assisted therapy is the therapists' interaction with participants during the dosing experience. Whereas participants are largely left undisturbed during a dosing session with a classic psychedelic, interaction with therapists is a vital part of sessions with MDMA. The therapeutic method that has been used in clinical trials for PTSD is described in detail in the MAPS MDMA-Assisted Psychotherapy Training Manual. Key concepts include (1) a nondirective approach based on empathetic presence and listening, (2) encouragement that the participant trusts their own inner healing intelligence, and (3) intervention in the form of guidance or

Telegram: @medical_k

www.konkur.in

redirection when appropriate to help facilitate the processing of trauma. In clinical trials, therapy has been delivered by two cotherapists (usually a male and a female), and sessions lasted 8 hours. Typically, patients receive two or three dosing sessions within a 12-week period with multiple integration sessions throughout.

Clinical Issues

Indications. The majority of research has focused on the use of MDMA-assisted therapy for PTSD. However, there have also been exploratory studies for three other indications: social anxiety in autistic adults, anxiety associated with a life-threatening illness, and cognitive-behavioral conjoint therapy. These have all produced promising results calling for further studies in the future. There are also trials underway investigating several other conditions (see Clinical Research section).

Limitations. MDMA is currently still a Schedule I drug, which limits its use to research trials. Similar to psychedelics, chronic use of SSRIs blunts the effects of MDMA. Given that SSRIs are commonly prescribed for PTSD, consideration must be given to managing potential destabilization during a period of tapering off.

Complications—Physiologic Toxicity. MDMA appears to be physiologically safe when administered in a clinical setting to healthy individuals. MDMA produces sympathomimetic effects, including elevation in blood pressure and heart rate, primarily due to norepinephrine release. Elevation in systolic blood pressure above 160 mm Hg and heart rate exceeding 110 beats per minute occurred in research participants but was self-limiting. Due to adequately conducted medical screening, there have been no adverse cardiovascular events to date in any clinical trial. Hepatotoxicity has rarely been reported in people using Ecstasy in unsupervised and nonmedical conditions. No cases of liver disease or hepatotoxicity have occurred in clinical trials with MDMA.

Contraindications. Given the risk of hypertensive crisis, concurrent use of MAOIs is contraindicated. In the recent Phase III trial by MAPS, exclusion criteria included participants with primary psychotic disorder, Bipolar I disorder, eating disorders with active purging, MDD with psychotic features, personality disorders, current alcohol, and substance

Telegram: @medical_k

www.konkur.in

use disorders, pregnancy or lactation, as well as any medical condition that could make receiving a sympathomimetic drug harmful due to increased blood pressure and heart rate, including uncontrolled hypertension, history of arrhythmia, or marked baseline prolongation of QTc interval.

Clinical Research

MDMA-Assisted Therapy for PTSD. The only completed Phase III trials on a psychedelic molecule involve MDMA-assisted therapy for PTSD. The first landmark study was a randomized, placebo-controlled trial of 90 adults with severe, chronic PTSD. Notably, the study included people with common comorbidities such as dissociation, depression, a history of alcohol and substance use disorders, and childhood trauma. Participants were randomized to receive three 8-hour sessions of manualized therapy with either MDMA or placebo, combined with three preparatory and nine integrative therapy sessions. Results showed that three doses of MDMA given in conjunction with therapy over the course of 18 weeks resulted in a significant improvement in PTSD symptoms and functional impairment. After three MDMA-assisted therapy sessions, 67% of participants with PTSD no longer met the criteria for the diagnosis, and 88% experienced a significant reduction in symptoms. The results from this trial demonstrated greater efficacy for PTSD than any other psychotherapy or medication. Of importance, MDMA did not increase the occurrence of suicidality during the study. A pivotal second Phase III trial (n = 104) with similar design was recently completed and also demonstrated robust findings of reduced PTSD symptom severity and decreased functional impairment. It is anticipated that MDMA-assisted therapy for PTSD will likely be approved by the FDA in the near future. The FDA approved an expanded access program in which 50 patients will receive the treatment ahead of official approval.

MDMA-Assisted Therapy for Social Anxiety in Autistic Adults. A pilot study at UCLA demonstrated rapid and durable improvement in social anxiety symptoms in autistic adults following two 8-hour MDMA-assisted sessions of mindfulness-based therapy that were spaced 1 month apart. Results held at follow-up 6 months after the second session.

Telegram: @medical_k

www.konkur.in

MDMA-Assisted Therapy for Anxiety Associated With Life-Threatening Illness. A recently completed pilot study randomized 18 participants with anxiety from a life-threatening illness to receive either MDMA or a placebo during two 8-hour psychotherapy sessions. One month following the second experimental session, the MDMA group showed a greater decrease in anxiety symptoms than the placebo group, with group differences trending toward significance.

MDMA-Assisted Cognitive-Behavioral Conjoint Therapy (CBCT). Before MDMA was scheduled in 1985, it was used in couples therapy. It reportedly benefited couples in this context by fostering a deeper connection, enhanced communication, and the ability to receive criticism and work through problems more easily. An open-label treatment development study was recently completed. Six couples were treated with two sessions of MDMA-assisted psychotherapy within a compressed course of CBCT lasting 6 weeks. The study was not designed to separate the effects of MDMA from the effects of CBCT, and there was no control group. However, researchers' impression was that MDMA helped the couples overcome obstacles to communication and mutual empathy, and CBCT provided valuable skills and structure for integrating the MDMA experiences and maintaining the gains over time. Controlled studies are planned based on these promising results.

Other Possible Indications. There are currently registered trials underway investigating MDMA-assisted therapy for alcohol use disorder and eating disorders. Child and adolescent psychiatry is another area that deserves to be explored, as MDMA-assisted therapy offers the potential to address trauma, abuse, and family dynamics issues decades before they lead to poverty, addiction, or chronic mental illness.

KETAMINE

Difference From Psychedelics

As mentioned at the beginning of this section, although ketamine is a hallucinogen, it is not technically a psychedelic, as it does not bind to the 5-HT_{2A} receptor. This makes it profoundly different from psychedelic hallucinogens, both in terms of its effects as well as the way it can be utilized in mental health settings.

Telegram: @medical_k

www.konkur.in

A critical difference between ketamine and psychedelics is the limited duration of ketamine's positive effects. Repeated treatments with ketamine are often necessary, if not the norm. The standard treatment model for ketamine currently in use also does not require the combination of ketamine with psychotherapy. Some ketamine clinics offer ketamine-assisted therapy (KAP), but that is the exception. As such, ketamine is intended to be used as an antidepressant drug that is continued indefinitely in contrast to psychedelic medicines that seek transformational change in a setting that includes preparation for and integration of insights from the psychedelic experience.

Ketamine is also a Schedule III drug, whereas all psychedelics are classified as Schedule I. This allows all physicians, nurse practitioners, and physician assistants who have DEA licenses to prescribe ketamine (although there is a large diversity of clinical practices). The remainder of this section will highlight other notable differences between ketamine and psychedelics.

Psychopharmacology

Ketamine acts primarily as a noncompetitive *N*-methyl-D-aspartate (NMDA) receptor antagonist. It is also active at a number of other neuroreceptors in the brain, including opioid, dopamine, and muscarinic and nicotinic acetylcholine receptors; however, the contribution of these possible targets for ketamine's myriad effects remains mysterious and controversial. Ketamine can be administered by a variety of routes, including intravenous (IV), intramuscular (IM), intranasal (IN), sublingual, and oral. The bioavailability of ketamine is approximately 90% when given IV or IM, compared with 25% to 50% intranasally, 30% sublingually, and 16% orally. The majority of clinical research and practice to date has used IV administration, although an IN formulation of one of its enantiomers (esketamine) was recently FDA-approved for treatment-resistant depression and acute suicidality.

Subjective Effects

The subjective experiences induced by ketamine have similarities to those produced by psychedelics but tend to be much gentler. Like psychedelics, ketamine can bring people into nonordinary states of consciousness that have the potential to disrupt rigid and maladaptive mental structures. However, whereas psychedelics can evoke challenging states of mind,

Telegram: @medical_k

www.konkur.in

ketamine more reliably induces a dose-dependent dissociation and gentle "lifting" of existential burden. The anxiety or fear reactions often produced by psychedelics seem to be attenuated or even absent. Moreover, while a ketamine experience can still be quite powerful, the intensity of the experience is significantly determined by the dose and rate of delivery. This allows clinicians a high degree of control over the treatment (especially when administered IV).

Proposed Mechanism

Similar to all antidepressant drugs, the mechanism by which ketamine exerts its antidepressant effect is a mystery. It is known that ketamine acts as a partial NMDA antagonist. Ketamine appears to affect glutaminergic function and initiate a number of cellular effects on neuron signaling pathways, resulting in new synaptogenesis and elevated levels of BDNF. This neural plasticity is hypothesized to be the basis for the antidepressant response.

Principles and Goals of Therapy

Over the past several years, ketamine has come into use in mental health as an IV medication intervention without a psychotherapeutic component. Ketamine's potential to provide a legally available form of hallucinogen-assisted therapy has mainly been ignored by researchers in academic psychiatry. However, many psychiatrists are starting to use ketamine (administered IV, IM, or sublingually) in combination with psychotherapy or partnering with therapists who provide psychotherapy. There have been reports that KAP, following treatment models that combine elements of psycholytic and psychedelic methods, may enhance treatment outcomes for patients by fostering greater access to the unconscious. Nonetheless, in general, models of psychotherapy with ketamine have not been formally researched.

Clinical Issues

Indications. Esketamine (an IN form of the s-enantiomer) is FDA approved for treatment-resistant depression and acute suicidal ideation or behavior. Ketamine itself (IV, IM, sublingual, oral) is not FDA-approved for any mental health condition but is routinely used off-label for depression and mood disorders.

Telegram: @medical_k

www.konkur.in

Limitations. As previously discussed, ketamine has a limited duration of positive effect and thus is currently utilized as a medication treatment that could continue indefinitely. Although KAP holds a lot of promise, there has been very little research on this model yet. Ketamine can also be expensive for patients: only esketamine has FDA-approved indications covered by insurance, so ketamine currently exists mainly as a self-pay treatment.

Complications—Physiologic Toxicity. In a meta-analysis of 60 studies of the standard ketamine model for the treatment of depression, the most common acute side effects were headache, dizziness, elevated blood pressure, and blurred vision, with most effects resolving shortly after the procedure. Longer-term side effects of patients using ketamine under medical supervision remain mostly unstudied. Evidence from heavy recreational users of ketamine (at doses and frequency much higher than is used to treat psychiatric illness) includes significant urologic pathology, hepatotoxicity, and cognitive deficits. Ketamine is not thought to be a physically addictive substance, as it does not produce physical withdrawal symptoms. However, there have been a few reports of iatrogenic abuse or addiction stemming from ketamine-assisted treatments, and clinicians are warned to inquire about a history of substance dependence in those seeking ketamine therapy.

Contraindications. Ketamine is contraindicated for anyone with active psychosis or mania. It is also contraindicated in patients with underlying conditions in which increased blood pressure would pose a risk of complications (i.e., aortic dissection, uncontrolled hypertension, myocardial infarction, or aneurysms). It is not currently recommended for use during obstetrics, pregnancy, or breastfeeding, as it is unknown if this medication passes into breast milk. Unlike psychedelics, since ketamine does not rely on serotonin as part of its mechanism of action, patients can remain on SSRIs while undergoing ketamine treatment or start ketamine treatment during the process of tapering off serotonergic medications.

Clinical Research

There has been little published research in the newly emerging field of office-based KAP. A recent complication of demographic and clinical outcome data of 235 patients treated with KAP in three psychiatry

Telegram: @medical_k

www.konkur.in

practices (using sublingual or IM routes of administration) showed a significant reduction in both depression and anxiety. Scores dropped an average of 11.24 points on the Beck Depression Inventory and 5.5 points on the Hamilton Anxiety Rating Scale. The most considerable improvement was seen in patients with more severe symptoms. Although this data is preliminary, it suggests that office-based KAP could be a safe and helpful treatment for a number of psychiatric disorders. Nonetheless, further studies are needed to evaluate the parameters and efficacy of KAP.

CONCLUSION

The efficacy of psychedelic-assisted therapy is self-evident. Modern medicine has already started to consider what value these molecules may have in treating certain populations and conditions (i.e., patients with significant trauma, depression, or substance use disorders), particularly given the limited efficacy of existing treatments. In addition, research is offering the prospect of a much-needed paradigm shift in psychiatry, which bridges the gap between psychopharmacology and psychotherapy. Psychedelics are starting to open our eyes to a deeper understanding of the nature of the psyche and show us how to more effectively access the potential of each individual for psychological healing and growth. A general conclusion drawn from nearly seven decades of clinical research is that psychedelic-assisted treatments activate endogenous self-healing processes.

As a result of diligent and rigorous research by a growing number of investigators, it now appears assured that both psilocybin and MDMA will achieve regulatory approval for clinical use within the next 3 to 5 years. This will pose a challenge to the current economic models of health care, which will need to develop a production and distribution infrastructure as well as a cost-effective treatment model to achieve widespread clinical usage.

Ketamine, despite having a different mechanism than psychedelics, also holds promise as an additional tool in the growing field of consciousness medicine. There are multiple unanswered questions about the potential role of KAP in psychiatry, including how to best optimize the dose, route, frequency, and role of adjunctive psychotherapy. What is clear is that treatment needs to be individualized while these best

Telegram: @medical_k

www.konkur.in

practices are investigated. Also, it should be noted that ketamine and psychedelics appear complementary and not in opposition. Due to different mechanisms of action and effects, they may be better suited for different uses or have value at different points in a patient's recovery. While psychedelics will likely become more widely available in the near future, ketamine is likely to have a durable role due to its unique capacity for transient mind–body dissociation, established safety, and its rapid efficacy as a short-term antidepressant and antisuicidal agent.

We are at the dawn of a transformative and exciting era of development in mental health.

32.19 Hypnosis

Allan David Axelrad, M.D., Daniel P. Brown, Ph.D., and Harold J. Wain, Ph.D.

Why and what is it about hypnosis that, for centuries, it has procured myths and the imagination of not only the medical community but the lay public as well? Is it a treatment, a state, or a trait? Where and how can it be used effectively? Myths and misconceptions are abundant. There is a myriad of perceptions among clinicians and the lay public. Even the term hypnosis can be misleading, coming as it does from the Greek root *hypnos* (meaning "sleep"). Hypnosis is not sleep. It is more likely a complex process that requires alert, focused, and receptive attention. Many also accept the myth that the clinician projects the hypnotic trance onto the patient or has the power to influence the patient. In reality, it is the patient who has the hypnotic gift, and the clinician's role is to assess the patient's capacity to capitalize on their assets and to help them to discover and use them effectively. Patient motivation, personality style, and biologic predisposition may contribute to the manifestation of this talent.

The lay public and many clinicians have frequently witnessed hypnosis as a form of entertainment. Though this has kept the intrigue of hypnosis alive, it has also contributed to a possible lack of appreciation or a diminished impact of its possible clinical utility. However, for the trained clinician, hypnosis can be a remarkably effective tool in helping with pain, surgery, stress habits, anxiety disorders, somatic symptom and related disorders, dissociative disorders, trauma- and stressor-related disorders, as well as many medical issues and unexplained symptoms. For experienced clinicians, hypnosis is not always a treatment of a syndrome but is a treatment of the individual patient as long as the clinician is comfortable and experienced using the intervention. With its effect on a myriad of medical and psychiatric conditions that range from PTSD to surgery, hypnosis can be facilitative for researchers to track both biologic

Telegram: @medical_k

www.konkur.in

and psychological variables. The milieu of hypnosis can also be an exceptional research milieu to explore mind–body interactions.

HISTORY

Early Chinese and Egyptian writings, as well as discussions in the Hebrew Bible and New Testament, seem to refer to hypnotic phenomena, trance states, and spontaneous dissociation being used for medical intervention. Franz Anton Mesmer was perhaps the first to describe the significance of this phenomenon. He postulated that magnetic energy or an invisible fluid could be provided by a clinician or an object to correct imbalances and restore health to an individual with an illness. Mesmer's style was dramatic and included physical passes over the body of the patient by using his own magnetic field in an attempt to restore equilibrium to the patient's "fluid." Many times his patients appeared to have experienced nonepileptiform seizures on their road to recovery.

His theories were highly controversial and, although anecdotally successful, attracted negative attention. In 1784, the French government convened a panel of experts that included Benjamin Franklin, the chemist Antoine Laurent Lavoisier, and Joseph-Ignace Guillotin to meet in Paris. They concluded that the phenomenon was nothing but "heated imagination." As a result, Mesmer's influence in France declined, although history credits him with beginning contemporary medical hypnosis.

In the 1840s, James Braid, an English physician and surgeon, described phenomena similar to those that Mesmer had noted. He reported that he could produce trance states using eye fixation and eye closure. In 1847, Braid rejected magnetic theory and created a psychological concept that he called monoideism, by which he meant mental concentration on a single dominant idea. In this state, subjects were highly suggestible and could focus their attention on specific ideas that would influence behavior.

In 1846, James Esdaile, a Scottish physician serving in India, described in his book *Mesmerism in India, and Its Practical Application in Surgery and Medicine,* the use of such techniques as the only anesthetic in more than 300 major surgical procedures. During the mid-19th century, John Elliotson, a noted professor of medicine and an editor of *Lancet,* became a strong supporter of hypnosis. Because hypnosis was still rejected by many physicians at the time, Elliotson fell out of favor with his colleagues

Telegram: @medical_k

www.konkur.in

and was forced to resign from the journal. Later many others became impressed with the effect and results of hypnosis and began studying the technique.

By 1880, the noted French neurologist Jean-Martin Charcot at the Salpêtrière in Paris considered the hypnotic state a neurophysiologic phenomenon and a sign of mental illness. Some prominent physicians, such as Pierre Janet, supported this position about hypnosis, but others, such as Hippolyte Bernheim, believed that hypnosis was a function of the normal brain. Bernheim emphasized the role of suggestibility in hypnosis over pathologic theories. Sigmund Freud studied hypnosis with Charcot, and it was central to his classic work on hysteria with Joseph Breuer. The latter facilitated a shift in hypnotic treatments by recognizing the value of abreaction under hypnosis. Of interest, Freud noted in his autobiography his setting aside the use of formal hypnosis and focusing on the concept of transference. When a patient threw her arms around his neck during a hypnotic trance, he related that “I was modest enough not to attribute the event to my own irresistible personal attractions, and I felt that I had now grasped the nature of the mysterious element that was at work behind hypnotism.” To concentrate on the elements of transference, he had to exclude extraneous variables, and it was, therefore, necessary to abandon hypnotism. Along with the rise of behaviorism, Freud’s rejection of hypnosis contributed to its decline in the early 20th century. However, later Freud spoke of the need to blend “the pure gold of analysis plentifully with the copper of direct suggestion.”

After Freud discarded hypnosis, its influence continued to wax and wane. During World War I, Ernst Simmel, a German psychoanalyst, became interested in hypnosis for the treatment of “war neurosis.” He developed a technique for accessing repressed material, which he called hypnoanalysis. Other psychiatric pioneers, such as Sandor Ferenczi, Paul Schilder, Lawrence S. Kubie, Sydney Margolin, Merton Gill, Margaret Brennan, John Watkins, and Erika Fromm, contributed to the early development of a psychodynamic approach to clinical hypnosis. During World War II, hypnosis played a prominent role in the treatment of pain, combat fatigue, and neurosis through the work of John Watkins and John Spiegel. Some of the first research on memory recall and the control of physiologic activity with hypnosis were carried out at the U.S. Army School of Military Psychiatry. Despite Freud’s earlier perceived rejection of hypnosis, many researchers and clinicians helped to shape the modern

Telegram: @medical_k

www.konkur.in

period of scientific hypnosis. For example, Ivan Pavlov focused on a biologic perspective in the understanding of hypnosis. World War I brought more interest in treating “battle fatigue” and “shell shock.” Other researchers and clinicians, such as Clark Hull, Ernest and Josephine Hilgard, Andre Weitzenhoffer, Milton Erickson, Martin Orne, and Herbert and David Spiegel, all contributed to establishing the contemporary place of hypnosis. In 1955, the British Medical Society formally recognized hypnosis and recommended that it be taught in medical schools. In 1958, the American Medical Association (AMA) and the American Psychiatric Association officially recognized it as a safe and effective treatment. Three specific national societies were soon established, including the Society for Clinical and Experimental Hypnosis, the Society of Psychological Hypnosis (American Psychological Association [APA] Division 30), and the American Society of Clinical Hypnosis.

THE TRAIT OF HYPNOTIZABILITY

When Clark Hull first studied responses to direct ideomotor suggestions in the laboratory he found that responsiveness was not evenly distributed across subjects into a more suggestible and a more resistant group. In the 1950s and 1960s, Ernest R. Hilgard and Andre Weitzenhoffer developed standardized instruments to measure hypnotic responding. The Stanford Hypnotic Susceptibility Scale (SHSS) consists of a formal hypnotic induction ceremony, followed by 12 specific suggestions to alter ideomotor response or cognitive-perceptual experience, or posthypnotic behavior. Administration of these scales to large numbers of subjects led to the view that hypnotizability is distributed, with 10% to 20% of the general population being highly or very highly hypnotizable and the remainder of the population being mildly or moderately hypnotizable. Figure 32.19–1 illustrates the distribution of hypnotizability.

FIGURE 32.19–1. Distribution of hypnotizability resulting from administration of the Stanford Hypnotic Susceptibility Scale to a large number of subjects, reflecting that 10% to 20% of subjects are highly or very highly hypnotizable and the remainder of subjects are mildly or moderately hypnotizable.

The use of a variety of standardized instruments to assess hypnotizability over the last half century in large samples of subjects from different geographic areas representing various cultural and ethnic groups has consistently demonstrated individual differences in hypnotizability. The convention has been to divide hypnotic subjects into three groups:

1. High hypnotizables represent 8% to 10% of the general population. These are the virtuosos of hypnotic talent.
2. Moderate hypnotizables make up the bulk of hypnotic subjects—from 84% to 88%.
3. About 4% to 6% of the general population are low hypnotizable.

Telegram: @medical_k

www.konkur.in

A comparison of results obtained using different instruments to measure hypnotizability shows that the cut-off points distinguishing high, medium, and low hypnotizability do not always exactly correspond.

Accurate assessment of hypnotizability in children depends on adapting the hypnotic technique to the level of cognitive development of the child. Preschool children are less hypnotizable than school-age children. Nonetheless, their degree of hypnotic responding increases with brief, open-eye hallucinatory pretend play suggestions matched to the preoperational thinking and short attention span of that age group. Early school-age children respond best to action-oriented fantasy suggestions of longer duration, matched to the late preoperational thinking of that age group. Older school-age children (ages 9 to 12 years) respond well to closed-eye detailed fantasy suggestions and ideomotor suggestions, as well as to a wide range of suggestions for cognitive and perceptual changes, corresponding to the development of concrete operational thinking, along with a rich internal world of fantasy and affective states and stable attentional skills characteristic of that age group. Longitudinal studies of changes in hypnotizability in the same children over the course of child development consistently have shown that irrespective of the issue of matching the style of hypnotic suggestion to the developmental age of the child, there is a progressive increase in hypnotizability from younger to older childhood, with the degree of hypnotizability reaching a peak between 9 and 12 years of age, an age roughly corresponding to the development of concrete operational thinking. Because most children from 9 to 12 years old are highly hypnotizable, this age range has been considered to have peak hypnotizability. For most individuals, the degree of hypnotizability drops off by mid-adolescence, so the majority of older adolescents and adults fall within the medium range of hypnotizability.

Test–retest correlations (0.7 to 0.8) of standardized hypnotizability scales and/or repeated experiences associated with interpersonal trust, such as psychotherapy or participation in growth groups, can lead to very modest, stable increases in hypnotizability over time, at least in some individuals. Drastic alterations in consciousness, for example, induced by hallucinogenic drugs or prolonged sensory deprivation, lead to significant but temporary changes in hypnotizability, after which the degree of hypnotizability returns to baseline for most individuals. There is little evidence that any procedure leads to significant stable changes in the degree of hypnotizability for most adults. In other words, low- and

Telegram: @medical_k

www.konkur.in

medium-hypnotizable subjects are likely to remain within that range of hypnotizability and are unlikely to become hypnotic virtuosos under any circumstances.

The trait of hypnotizability is distributed across a wide range of personalities, and as research with a wide range of personality tests has indicated, there is no simple stereotype of the type of individual who is highly hypnotizable. With respect to the correlation of hypnotizability to single personality traits, measures of attachment style, attentional skills, absorption, dissociation, fantasy-proneness, and active imagination show a mild to modest, yet significant correlation with hypnotizability.

The correlation between hypnotizability and psychiatric diagnosis has yielded more promising results. Comparing patient groups with independently validated psychiatric diagnoses on standardized measures of hypnotizability has shown that as a group

- patients with anxiety disorders (generalized anxiety, panic, and OCDs), somatoform disorders (e.g., conversion), and irritable bowel syndrome (IBS) are slightly but significantly more hypnotizable;
- patients with PTSD are moderately more hypnotizable; and
- patients with dissociative identity disorder are much more hypnotizable than the general population.

These differences in the hypnotizability of various psychiatric groups have led to the belief that hypnosis may be a preferred treatment, at least for certain psychiatric conditions. Again, this is not to suggest that it is only the hypnotic intervention that accounts for the change; it is the strategy one utilizes with the milieu of hypnosis that accounts for the positive outcome.

The relationship between degree of hypnotizability and clinical efficacy has not been clearly established. Some clinicians select only high hypnotizables for hypnotherapy. However, the majority of clinicians who use hypnotic procedures offer hypnosis most often to medium and high hypnotizables and some of the low hypnotizables under the assumption that anywhere from a low-to-moderate to higher level of hypnotizability is sufficient for most clinical work. Some clinicians believe that establishing certain expectancies, as well as a therapeutic alliance, facilitates therapeutic change even in patients with low hypnotizability. The prevailing view is that the clinical applications of hypnosis are not

Telegram: @medical_k

www.konkur.in

restricted to highly hypnotizable individuals. Some clinicians suggest that intervention strategies can be based on levels of hypnotizability.

Research consistently supports the view that hypnotizability predicts clinical outcomes for a variety of DSM-5 diagnoses, somatic symptoms, and related disorders and/or DSM-IV Axis I psychiatric conditions and not others. Hypnotizability as a personality trait, irrespective of whether the clinical procedure is conducted in a waking or hypnotic state, predicts clinical outcomes for a variety of psychiatric conditions and medical conditions, such as in the treatment of anxiety disorders, conversion disorders, posttraumatic or dissociative disorders, bulimia, pain, headache, asthma, certain skin conditions, and functional gastrointestinal disorders, but does not predict the outcome for a variety of addictive behaviors, such as smoking, weight control, and alcohol/drug abuse.

The implication of this research on the distribution of hypnotizability is that hypnotic responding, at least for high hypnotizables, is a personality trait or talent. Such a view should dispel the stereotype that hypnosis somehow exemplifies the special power of the clinician to exert undue influence. Appreciating hypnosis as a talent or gift within the patient naturally leads to a more egalitarian, less hierarchical or power-oriented approach to hypnotherapy. In permissive hypnosis, the hypnotherapist provides the relational conditions to facilitate the patient's exploration of their hypnotic abilities and inner resources relevant to therapeutic change.

HYPNOSIS AND SUGGESTIBILITY

Clark Hull systematically studied the effects of direct suggestions on motor response and believed that responsiveness to ideomotor suggestion constituted the primary factor of overall hypnotic responding. Andre Weitzenhoffer studied the effects of suggestion as a form of external social influence through verbal communication. Weitzenhoffer noted that some individuals significantly increased their suggestibility after a hypnotic induction ceremony, and this was used to induce a trance state. This led to the view that trance induction caused a *condition of heightened suggestibility* so that the individual immediately following trance induction was significantly more responsive to subsequent suggestions than to suggestions given outside of the context of trance induction. Weitzenhoffer coined the term "classic suggestion effect" to illustrate how high-hypnotizable subjects following the induction of trance accepted

Telegram: @medical_k

www.konkur.in

subsequent suggestions involuntarily and with uncritical acceptance and deep conviction, even when the suggestions violated conventional logic or normal reality testing. The *heightened suggestibility model* of hypnosis has had an important influence on hypnosis research since the last half of the 20th century, in that most of the standardized instruments to assess hypnotizability are constructed around this assumption; namely, each instrument begins with a formal hypnotic induction ceremony, followed by a series of specific suggestions given in a standard format. Overall hypnotizability in these scales is assessed as a function of how many specific suggestions are accepted by the subject following the induction ceremony.

In a broader view, heightened suggestibility is best seen as one important dimension within the overall domain of hypnotic responsiveness, with a variety of state effects occurring at least partially independent from suggestion effects in certain hypnotic subjects. The state model of hypnosis assumes that a formal induction ceremony results both in a hypnotic state and an increase in responsiveness to suggestion. Subsequent suggestions serve to shape the nature of hypnotic experiences and behaviors.

THE DOMAIN OF HYPNOTIC EXPERIENCES AND BEHAVIOR

Ernest Hilgard's research on hypnotizability defined six main areas of hypnotic responding: ideomotor response, hypnotic imagery and dreaming, effects on memory, sensory and perceptual effects, cognitive-affective changes, and posthypnotic effects.

Ideomotor responsiveness refers both to the facilitation and the inhibition of motor response through specific suggestions, for example, to facilitate eye closure, postural sway, movement of outstretched hands together as if pulled by a magnet, and hand/arm levitation and lowering, and/or suggestions, for example, to inhibit the bending or lifting of an arm, the unlocking of clasped fingers, the opening of closed eyelids, or the verbalization of certain words. Ideomotor responsiveness accounts for the largest portion of the variance of overall hypnotic responding.

Some hypnotized subjects experience a richer quality and greater quantity of imagery in hypnosis. Imagery, as compared to cognitive

Telegram: @medical_k

www.konkur.in

information processing, may play a greater role in hypnotic over waking experiences.

The effects of hypnosis on memory are complex. Hypnotic suggestions may increase the recall, which is known as hypnotic hypermnesia, but not the recognition of personally meaningful material (semantic or procedure memories). The accuracy of recalled information varies according to whether the hypnotist created realistic or unrealistic expectancies about memory retrieval, which did or did not encourage guessing and/or did or did not suggest misinformation about the recall target.

Hypnotic analgesia is a well-established phenomenon, especially among high-hypnotizable subjects. A relatively small group of high-hypnotizable individuals are able to produce positive or negative hallucinations in response to specific hypnotic suggestions. A hypnotically suggested heat hallucination not only results in an intense subjective experience of heat that is virtually indistinguishable from actual heat in certain high hypnotizables but may also result in burn blisters. Hypnotic suggestions can also inhibit the perception of actual experiences (negative hallucination), such as failing to see an actual light or color, failing to see a hand on a watch, or selectively becoming deaf to certain words or sounds.

Hypnotic suggestions can also affect changes in meaning systems, affective experience, and self-representation. For example, hypnotic suggestions can produce temporary agnosias and aphasias. Direct suggestions to experience a discrete emotional state, for example, fear, result in not only the subjective experience of fear but also an increase in catecholamine and cortisol output. Hypnotic suggestions can directly alter self-representation, such as the suggestion to imagine oneself completely free of pain or the suggestion to no longer identify oneself as a smoker. It can also be used to create somatic symptoms as a defense or bridge while looking for the metaphorical meaning of the presenting symptom.

Certain suggestions given during a hypnotic state are designed to have an effect after the formal termination of the hypnotic session. These are called posthypnotic effects and include posthypnotic amnesia and other posthypnotic behavior. Posthypnotic suggestions are either cue-induced, that is, the experience or behavior occurs in response to a specific cue given previously during trance, or are graded, that is, the effect occurs progressively, such as the posthypnotic suggestion that the meaning of a hypnotic dream will become increasingly more clear over time.

www.konkur.in

DIMENSIONS AND PHENOMENA OF THE HYPNOTIC EXPERIENCE

Clinicians suggest that although hypnosis is an altered state, the capacity to experience the phenomenon varies among individuals according to their biologic substrata and cognitive and emotional styles. Most would agree there is both a general and individual specific capacities of hypnotic responding.

Ronald Shor identified eight dimensions of hypnotic experience, each of which varies according to the hypnotic subject: Fading of the individual's generalized reality orientation, nonconscious involvement, archaic involvement, drowsiness, relaxation, the vividness of imagery, absorption, and access to the unconscious. Peter Sheehan and Kevin McConkey concluded from their research that the subjective experience in hypnosis depends on specific expectancies, cognitive style, the nature of imagery, perception of the hypnotist, and reality awareness. The data revealed "patterns of individual differences in reported hypnotic experiences," and that hypnotic experiences are different across subjects, depending on that subject's cognitive style. Three cognitive styles were identified: concentrative, independent, and constructive. Ronald Pekala attempted to quantify the patterns of consciousness in a hypnotic trance and concluded that there were specific differences between low and high hypnotizables. Low hypnotizables scored lower on voluntary control, self-awareness, internal dialogue, rationality, and availability of memory. High hypnotizables scored significantly higher on measures of hypnosis as an altered state, absorption, and altered time sense. These data suggest that a high hypnotizable's experience of an altered state of consciousness or trance is fundamentally different from the state experienced by medium or low hypnotizables.

DEFINITION OF HYPNOSIS

Until recently, there did not appear to be a consensual definition of hypnosis. Earlier hypnosis was defined by any induction procedure followed by a series of suggestions. Most experts agree that hypnosis is associated with a set of unusual subject experiences and behaviors, and most agree with a limited *state definition* of hypnosis with respect to the redistribution of attention. The central issue of ongoing debate is whether

Telegram: @medical_k

www.konkur.in

hypnosis entails a discrete altered state of consciousness. The 2003 definition of hypnosis by the American Psychological Association (APA) failed to mention either self-hypnosis or hypnosis as an altered state of consciousness. In 2015, a new APA task force was able to reach a consensual definition. Hypnosis was defined as “A state of consciousness involving focused attention and reduced peripheral awareness characterized by an enhanced capacity for response to suggestion.” A hypnotic induction was defined as “A procedure designed to induce hypnosis.”

Sakari Kallio and Antti Revonsuo proposed a solution to the state/nonstate controversy. They convincingly argued that there might be two groups of hypnotizable individuals—a smaller group of highly hypnotizable individuals who have a propensity toward extreme changes in sensation, perception, and cognition, and for whom an altered state definition of hypnosis best applies, and a much larger group of mild to moderately hypnotizable individuals, whose state changes are less extreme and whose experiences are more a product of social context. Although both the state and sociocognitive theories of hypnosis partially explain overall hypnotic responding in both groups, the altered-state and trait models of hypnosis may explain a greater portion of the variance of the high-hypnotizable group, and the sociocognitive task-motivational and response-expectancy models may explain a greater portion of the variance of the medium-hypnotizable group. (A similar argument was made by Herbert and David Spiegel.) Kallio and Revonsuo’s proposal resurrects the problem discussed at great length by Ernest Hilgard, namely that hypnotic responding appears to be distributed into two groups.

Kallio and Revonsuo have expanded the idea that medium hypnotizables may respond more to social influence, whereas high hypnotizables may respond in a way that is at least partially independent of both social influence and hypnotic context.

HYPNOSIS AS REDISTRIBUTED ATTENTIVENESS

According to Amir Raz, “attention is an integral, defining aspect of hypnosis.” Hypnosis is seen as a condition of “atypical attention.” Limited state models emphasize hypnosis as a condition of altered or heightened attentiveness and the effects of altered attentiveness on hypnotic

Telegram: @medical_k

www.konkur.in

experience and behavior. The hypnotic state is associated with changes in at least three of the normal attentional systems: alerting, orienting, and executive control.

Relaxation suggestions commonly incorporated into a hypnotic induction alter waking alertfulness but do not cause sleep. David Spiegel viewed hypnosis as alert activation without arousal or vigilance, a type of alert consciousness lacking sympathetic arousal.

Hypnotic trance is also associated with a diminished generalized orientation to external reality and inward absorption but also with enhanced orienting to specific hypnotic suggestions while avoiding distraction. Hypnotic trance is also associated with changes in executive attentional processes, which results in (a) enhanced selective focus on suggested effects along with a reduced focus on peripheral cues or on parallel competing for attentional demands; (b) alteration in the allocation of divided attention; (c) alteration in error processing, such as the suspension of critical judgment and normal reality monitoring; and (d) alteration in response monitoring, as exemplified by the facilitation or inhibition of motor response, the shift in response criteria for reporting memory recall, or the suspension of belief with respect to suggested hallucinatory experiences.

In addition to these three frontal attention systems, the parietal lobes play an important role in levels of awareness, broadening or narrowing the field of consciousness, and shifting from local to global attention, and they may also play an important role in the hypnotic experience. The magnitude of these attentional shifts in a hypnotic state is significantly greater than in, for example, a waking absorbed state while reading a book, a deeply relaxed, nonhypnotic state, a state simulating hypnosis, or in whatever state is characteristic of low hypnotizables.

TRANCE CHARACTERISTICS

Another version of the state model uses “state” to imply a *discrete altered state of consciousness* or *trance,* uniquely different from the normal waking state and characterized by a set of unique *trance characteristics,* which include a fading of the generalized reality orientation, involuntarism; a suspension of normal critical judgment and reality monitoring (sometimes called trance logic); dissociation; and the capacity for altered cognitive-perceptual information processing. Some versions of the altered

Telegram: @medical_k

www.konkur.in

state model stress the relationship between the trance induced by a hypnotic induction and naturally occurring states outside of a hypnotic context, such as self-hypnosis, daydreaming, stares of absorption, and dissociative states.

Induction of trance is associated with a relative *reduction in generalized external reality orientation* and increased inward absorption. Hypnotized individuals are either less aware of, or aware of, but less responsive to, external stimuli than in the normal waking state.

A related component of hypnosis is *absorption*—a narrowing and intensification of attention resulting in complete focus. The shift into the hypnotic state is something like a psychological zoom lens that can shift toward highly focused attention. As attention becomes more intense and focused, awareness of orientation in time and space decreases.

The experience of *involuntariness* or automatic responding is considered a benchmark of high hypnotizability. For example, although it is clear that the hypnotized subject is using active imagination to experience the hands moving together in response to the suggestion that the hands are drawn together like magnets, the subject typically reports that the hands “seemed” to move together by themselves, as if top-down, voluntary executive control over the suggested response was suspended and it occurred in an automatic, nonvolitional manner. John Kihlstrom emphasized that perceived involuntariness does not necessarily imply suspension of volitional control during trance. Sociocognitive theorists have stressed that perceived involuntariness is not really involuntary but is a function of purposeful, goal-directed cognitive activity in response to hypnotic expectancies and the nature of the hypnotic interaction. Irrespective of differences in the explanations for involuntariness, most experts concur that perceived involuntariness is a central feature of hypnotic subjective experience.

Some high-hypnotizable subjects manifest a transient suspension of *critical judgment* during trance, which allows them more easily than in the walking state to believe in the actuality of suggested positive hallucinations, to deny the actual reality in suggested negative hallucinations, accept suggestions for reduced pain experience and hypnotic analgesia in the face of actual pain experience, accept suggestions that confuse imagination and actual perception, or accept the actuality of hypnotically suggested pseudomemories. However, the extent

Telegram: @medical_k

www.konkur.in

to which a suspension of critical judgment is a defining feature of trance remains largely untested.

Few studies exist that experimentally test suggestions to improve critical judgment during trance, except for a few studies that suggest warnings about possible inaccuracies in hypnotic recall, which tend to show lower memory error rates while not eliminating memory error altogether. Trance logic is often referred to as a strong belief about suggested experiences in hypnosis that is logically incongruous from the perspective of the normal waking state, such as the presence of a hypnotically hallucinated person. Sometimes hypnosis is associated with a suspension of normal waking initiative, planning, and goal-directed behavior so that the hypnotizable subject passively and uncritically responds to suggestions. However, some experts have emphasized hypnosis as an active cognitive, problem-solving endeavor. The common factor may be hypnotically altered action planning, either in the direction of less or more action planning, depending on the hypnotic context.

The hypnotic state has been characterized as a *dissociative state.* However, there are two fundamentally distinct uses of the term *dissociation:*

1. dissociation as shifts in a state characterized by a narrowing or expansion of the field of conscious awareness and
2. dissociation as the disintegration of the normally integrated operations of waking consciousness resulting in the dissociative compartmentalization of experience.

Dissociation as state shifts and changes in the field of conscious awareness, as exemplified by absorption, consistently accounts for a significant but small portion of the variance of overall hypnotic experience. *Dissociation as compartmentalized states* is more characteristic of high than less-hypnotizable subjects, such as the dissociation of the “part of the mind” experiencing hypnotic analgesia from the “hidden observer” part of the mind still registering actual pain experience or dissociation of the emergence of conflictual mental content during trance from the normal waking defensive operations against the emergence of this material.

High hypnotizability may represent a capacity for altered *cognitive-perceptual information processing.* The fading of the generalized reality orientation results in an overall reduction in the amount of information and information processing is relatively restricted to the verbal suggestions

Telegram: @medical_k

www.konkur.in

supplied by the hypnotist. Temporal or sequential (serial) information processing is characteristic of the normal waking state.

Evidence from two sources implies that information processing in the trance state favors parallel, simultaneous over serial, temporal processing: (1) disordered recall after removal or suggestions for posthypnotic amnesia and (2) increased ability to generate random numbers in the hypnotic state as compared to the waking state, wherein the spontaneously generated numbers tend to be patterned. As a consequence of altered information processing, suggested or spontaneous time distortion is a characteristic feature of high hypnotizability.

Advocates of the altered states-of-consciousness model of hypnosis, such as Charles Tart, view the trance state as a discrete state of consciousness with a set of special characteristics. From their perspective, the hypnotic induction ceremony constitutes a set of expectancies and specific suggestions designed to induce and ratify the special characteristics of the hypnotic state as markedly different from the normal waking state. The unique characteristics of the trance state are believed to correlate with heightened suggestibility on the one hand and the clinical efficacy of hypnosis on the other. Cardena and Terhune asked hypnotic subjects to report their deepest level of hypnosis as compared to a non-hypnotic resting condition. Those in the hypnotic conditions gave more reports of altered state experiences, body images, and time distortion and as being less rational or operating out of self-agency. Expectancies were significantly correlated with altered state reports of hypnosis.

SOCIAL INFLUENCE MODELS FOR HYPNOTIC RESPONDING

According to the *task motivational theory* of hypnosis, responsiveness to hypnotic suggestions does not require the induction of a hypnotic state but depends on the tasks set by the hypnotist, the manner in which these tasks are communicated, and the way in which the hypnotist shapes the attitudes, motivation, and efficacy expectancies of the hypnotic subject. Attitude pertains to whether hypnosis is seen by the subject as a desirable or feared state. Motivation pertains to the willingness of the subject to be

Telegram: @medical_k

www.konkur.in

hypnotized. Efficacy expectancies refer to the hypnotic subject's belief in their capacity to become hypnotized.

Theodore Barber's research demonstrated that most of the unusual subjective experiences and behaviors characteristic of high hypnotizables could be produced without a hypnotic trance induction if the subject were motivated to the hypnotic task. Although these experiments led to a greater appreciation of the relative contributions of attitudes, motivation, and efficacy expectancies to overall hypnotic responding, they did not refute the contribution of a trance trait state to overall hypnotic responding, at least for certain high hypnotizables.

More recently, social influence models of hypnotic responding have been revitalized in the form of a *response expectancy model.* Advocates emphasize the relative omission of expectancy effects in Andre Weitzenhoffer's suggestion model and Ernest Hilgard's state model. Response expectancies are defined by Irving Kirsch as "anticipations of automatic reactions to particular situations," such as automatic, nonvolitional behaviors or emotional states, and are especially relevant to the perception of internal states. According to sociocognitive models, response expectancies regarding hypnotic response are the consequence of culturally mediated a priori expectancies about hypnosis and/or specific information shaped by the interaction with the hypnotist. Response expectancies pertain to the prediction of the probability of successfully responding to a given hypnotic situation. Within a hypnotic context, hypnotic subjects learn to produce a given hypnotic response according to their cultural understanding of hypnotic role behavior and/or the specific expectancies shaped by the hypnotist. In other words, the hypnotic response is the outcome of social influence and the systematic shaping of hypnotic expectancies by the hypnotist. For example, suggestibility increased by only a small amount with a hypnotic induction when the procedure was labeled as "relaxation" but increased by a much larger amount when the procedure was labeled as "hypnosis." Although expectancy models of hypnosis are valuable in helping in the appreciation of the contribution of expectancy effects to overall hypnotic responding, these models have several limitations. The overall contributions of expectancy effects are sometimes overstated as if expectancy were "the final common pathway to hypnotic suggestibility." Although expectancy theory has helped in the appreciation of the relative contribution of social influence to overall hypnotic responding, it does not serve as a complete

Telegram: @medical_k

www.konkur.in

explanation for hypnotic responding, any more than placebo effects serve as a complete explanation for drug effects. Both expectancy effects and state-trait effects contribute to overall hypnotic responses.

THE STATE/NONSTATE CONTROVERSY

An ongoing debate continues between state theorists and sociocognitive theorists of hypnosis. State theorists have turned to psychophysiological and functional imaging studies of hypnotic responding to support limited- or altered-state theories of hypnosis and claim that sociocognitive theorist ignore the evidence from neuroscience. The evidence supports altered brain functioning during hypnotic responding, at least for high hypnotizables, and the hypnotic induction does activate or deactivate certain frontal attentional systems and other brain areas. A review of the neurobiologic evidence follows in the next subsection.

Sociocognitive theorists argue that trance characteristics and the altered state itself are a product of social influence and the shaping of response expectancies and that all of the experiences and behaviors characteristic of the domain of hypnosis can be produced through social influence without prior hypnotic induction or a trance state.

USING HYPNOTIC CHARACTERISTICS IN CLINICAL CONTEXT

Although the controversy over the definition and specifics of the theory remains, the clinical outcome of using hypnotic phenomena is undisputed. The effect of the clinical phenomena of hypnosis may rest on the biology of the patient, the presenting clinical problem, and the skills of the clinician. What follows are some of the hypnotic phenomena identified in the previous subsections that summarize strategies that can be used:

- *Catalepsy.* An involuntary tonicity of the muscles so that limbs remain where they are positioned with inhibition of fatigue. It is used for the assessment of responsivity to hypnosis, for trance ratification, to help with obtaining radiography, for induction of deepening and to facilitate anesthesia and analgesics.
- *Amnesia.* Inhibition or disruption of memory, which may be either spontaneous or suggested. Spontaneous amnesia suggests a deeper trance state. The duration of amnesia is unpredictable. Amnesia

Telegram: @medical_k

www.konkur.in

assists posthypnotic suggestions to occur by reducing conscious "spectatoring."

- *Dissociation.* A detachment from the immediate environment, similar to dreaming when one sees oneself doing something from outside of one's body. It is useful in promoting increased depth, in pain relief, and in facilitating "automatic writing" for purposes of unconscious hypnotic exploration.
- *Analgesia and anesthesia.* Experiencing analgesia is like turning down the dimmer switch on a light and is characterized by some milder grimace. Estimates are that 70% to 90% of subjects may develop at least some degree of analgesia, and perhaps 20% can develop complete anesthesia (even during surgery). This phenomenon is useful for managing pain, reducing inflammation and facilitating more rapid healing, and providing a method of trance ratification.
- *Hyperesthesia.* Increased sensitivity to touch.
- *Ideosensory activities.* This refers to the capacity of the brain to develop responses on any of the sensory modalities: auditory, visual, kinesthetic, olfactory, or gustatory.
- *Somnambulism.* This is one of the deepest levels of hypnosis and refers to being in a trance but with the eyes open. A patient may go into a trance, and the untrained clinician may not be aware of its significance.
- *Hallucinations.* A negative hallucination refers to not seeing or sensing a stimulus that is present. Negative hallucination for smell (anosmia) may be produced for a pungent odor in perhaps 25% to 35% of subjects. Having a positive hallucination is perceiving something that is not there. All five senses may be hallucinated. Taste and smell are the easiest to hallucinate, vision is the most difficult (only 3% were able to do this in Hilgard's research sample), and hearing is the second most difficult to hallucinate.
- *Hypermnesia.* Refers to increased capacity for memory recall.
- *Age regression*—(a) *Revivification* refers to a complete regression or reliving of a past event; voice and writing become child-like; (b) In *partial regression* to a past time or event, the patient retains some awareness of the hypnotist and the patient's adult identity and thus has the capacity to apply an adult perspective to the past experiences. This can be an instrumental means in facilitating psychotherapy, uncovering repressed or dissociative data, and working through poor object relations and attachments.

Telegram: @medical_k

www.konkur.in

- *Ideomotor activity and ideomotor exploration.* This refers to the involuntary capacity of muscles to respond instantaneously to thoughts, feelings, and ideas—for example, the experiencing of fingers or limbs floating and seeming to move by themselves. Ideomotor exploration is a method for rapid, unconscious exploration using involuntary finger signals. These signals may also be used to signal the therapist when internal processes have been completed (e.g., when numbness is present).
- *Age progression.* Pseudo-orientation in time to the future may seem like a fantasy or mental rehearsal about the future to some subjects, but to talented hypnotic subjects, it can feel quite real. Purposes include covert rehearsal and confidence building; the diagnostic determination of how the patient will react to a future situation; and, in some cases, the determination of what treatment “helped you recover.” In addition, for some depressive states, it also facilitates allowing the patient to foresee the possible future. This can be an invaluable approach in facilitating psychotherapy and working through poor object relations and affiliations.
- *Time distortion.* There are two possible aspects: (a) Time expansion, by which 2 minutes, say, can seem like 20 minutes, with a subjective sense of time going by very slowly. An everyday example would be waiting for a ride on a snowy day or waiting in a slow checkout line. (b) Time contraction, by which 10 minutes, say, can pass in what seems like 1 minute during a pleasurable activity or by suggestion. Purposes can range from sports activities to pain or migraine, to a past review of etiologic factors, to trance ratification to convince patients that they were in an altered state of consciousness. It can be used to expedite painful times while going through medical procedures, as well.
- *Depersonalization.* Through suggestion, an individual can temporarily forget their identity and view past traumatic experiences like an objective intelligence or may take on the identity of another person and identify with them.
- *Induced dreams.* Hypnosis may influence dream content at night, and “dreams” may be produced in a hypnotic state. Purposes include exploring and revealing causes and conflict, identifying solutions and insights, altering feelings, and recalling nocturnal dreams. In a hypnotic state, sleep ideation also may be “searched” in treating insomnia or physiologic disturbances (e.g., morning ulcer disturbance or premature labor).

NEUROBIOLOGY AND NEUROPSYCHOLOGY OF HYPNOSIS

A limitation in the physiologic studies of hypnosis is the failure to distinguish between the physiologic effects of the hypnotic state per se and the physiologic effects of specific hypnotic suggestions given within that state. Seemingly innocuous changes in the wording of specific suggestions, such as “you’re becoming more and more relaxed,” “focus your attention on,” “your breathing will become slower and slower,” or “allow a scene to come into your mind,” may produce substantial physiologic changes, so that without careful control of the wording of suggestions, the overall physiologic effects of hypnotic suggestions may seem to be a wash.

Electroencephalographic (EEG) studies of hypnosis have failed to reveal a clear-cut EEG signature of the hypnotic state. The hypnotic state consistently is associated with increased theta activity in high versus low hypnotizables, yet the type and location of theta activity may be more important in hypnotic responding than theta activity per se. Posterior theta activity is more a function of relaxation than hypnotic responding per se, but it might signify hypnotic responding if the overall hypnotic suggestions include engaging in progressive relaxation and passively allowing experiences to arise, whereas anterior theta may reflect the activation of attentional systems and active cognitive processing in response to specific hypnotic suggestions. Furthermore, the frequency of theta activity may indicate the presence of imaginative as compared to realistic responses in high versus low hypnotizables and increased attentional focus. Increased alpha activity has sometimes been associated with the hypnotic state in high hypnotizables, but these findings have been disputed.

Increased high-frequency gamma activity (40 Hz) is associated with focused arousal in high as compared to low hypnotizables with and without hypnotic induction. The eye roll sign in certain high hypnotizables is associated with left frontal and bilateral occipital activation. EEG findings clearly establish that hypnosis is not sleeping.

Thus, although no definitive overall EEG signature of hypnosis exists, specific EEG patterns are associated with various components of overall hypnotic responding, such as suggestions for eye roll, hypnotic relaxation, imaginative involvement, receptive attention, and intensely focused

Telegram: @medical_k

www.konkur.in

attention. Functional imagery studies such as positron emission tomography and MRI studies have consistently documented significant differences in the brain functioning of high and low hypnotizables so that high hypnotizability may constitute a unique brain state.

Induction of a hypnotic state may represent the alteration of brain functions operative in the regulation of consciousness. Helen Crawford and her associates argued that high as compared to low hypnotizables have more efficient executive control systems and supervisory attentional systems. Low hypnotizables do not activate these same brain-attentional systems. Nevertheless, it is also clear that the activation and deactivation of localized brain areas during hypnosis are strongly associated with the specific hypnotic task suggested. There may be no single brain activation/deactivation profile for hypnosis, but instead, a number of neurocognitive patterns, depending on the nature of the hypnotic induction and the specific suggestions, are given.

Various components of the hypnotic induction may also be associated with specific patterns of brain activation/deactivation as suggestions affect the alerting, orienting, and executive attentional networks accordingly. Amire Raz provided fMRI images of the three attentional networks activated in hypnosis.

Hypnotic relaxation was associated with lower levels of activation of the mesencephalic tegmentum of the brainstem, the thalamus, and the anterior cingulate cortex (ACC), comparable to changes produced by waking decreased vigilance or sleepiness, whereas hypnotic absorbed attention was associated with higher levels of activation in the brainstem, thalamus, and rostral ACC. The overall hypnotic induction resulted in lower levels of activation of the parietal areas consistent with an overall reduction in the field of conscious awareness, temporal and spatial distortion, and disorientation of self. According to John Gruzelier, the traditional induction is not a haphazard assortment of roles that the subject is encouraged to enact but follows a sequence with neurophysiologic logic—“the engaging of anterior left-sided attentional mechanisms, which, once engaged, can be suppressed, which in turn allows selective inhibition of frontal functions permitting cardinal features of the hypnotic experience such as automaticity and involuntariness to take place.” Gruzelier added that such selective inhibition and enhancement of certain brain attentional systems also explain the dissociation component of hypnosis. Overall, the evidence strongly

Telegram: @medical_k

www.konkur.in

implicates the role of the frontal/parietal system in hypnotic responding, particularly the role of the ACC as an explanatory system for many of the phenomena of hypnosis. High as compared to low hypnotizables, have stronger attentional filtering abilities as manifested in the capacity for focused and sustained focused attention and also in the ability to ignore irrelevant stimuli; that is, high hypnotizability is a condition of both "extremely focused attention and disattention."

The left dorsolateral prefrontal cortex (DLPFC) is part of the neurocircuitry of meta-cognitive monitoring. Low-frequency repetitive transcranial magnetic stimulation of the left DLPFC, which presumably blocked the functioning of the DLPFC, increased hypnotizability. This finding is consistent with the view that suspension of critical judgment occurs in high hypnotizable subjects, and that deactivation of the left DLPFC may play an important role in hypnotizability.

The frontal systems are implicated in both the facilitation and inhibition of motor responding in hypnosis. Functional imaging studies both of patients with motor conversion paralysis and normal subjects given hypnotic suggestions for motor inhibition have shown that similar patterns of functional brain changes are involved in each case, namely right ACC activation and right orbitofrontal activation, along with deactivation of the right primary motor cortex. When high-hypnotizable subjects who respond positively to a range of ideomotor suggestions were given either hypnotic suggestions for limb paralysis or suggestions to feign paralysis, different patterns of brain activation were associated with hypnotically suggested and simulated paralysis.

Hypnotically suggested elimination of interference on the Stroop test is mediated by ACC activation. In the Stroop test, subjects name a color in which words are displayed. Response time is generally slower if the name is different from the color. Hypnotic suggestions to ignore competing responses during the test allow for response override and quicker response to the target stimulus. However, whereas both waking and hypnotic suggestions improve Stroop performance in high versus low hypnotizables, hypnotic induction is not necessary for suggestive reduction in the Stroop effect in high hypnotizables.

High hypnotizables with the ability to respond to hypnotically suggested hallucinations as compared to subjects who could not hallucinate showed activation of the right ACC when they were actually hearing an audiotaped message and also when hypnotically hallucinating the taped message but

Telegram: @medical_k

www.konkur.in

did not show ACC activation when instructed to imagine hearing the message. These data suggest that in terms of brain activation, hypnotic hallucinations are comparable to actual perceptual events and not simply the product of imagination.

Functional imaging studies have shown comparable ACC activation in persons with schizophrenia with auditory hallucinations. With respect to hypnotic visual hallucinations, highly hypnotizable subjects showed activation of the fusiform and lingual areas typically associated with color perception in response to a hypnotic suggestion to perceive a color whether actually shown a color or a gray-scale stimulus. In terms of brain activation, hypnotically hallucinated color perception and actual color perception are similar.

Hypnotic suggestions to increase or decrease pain experience cause changes in the activation of the ACC, insula, and parietal areas, and sometimes deactivation of the primary sensory cortex. Direct suggestions for pain alleviation activate cognitive (via prefrontal and orbitofrontal) and emotional (via insula, inferior parietal, lenticular nucleus and ACC circuitry). These neurobiologic findings are consistent with the view that hypnotic analgesia suggestions may prevent higher cortical processing of nociceptive input, with inhibition being mediated by the cingulate cortex. High as compared to low hypnotizables also show a decreased amplitude in the later P100 and P300 wave components of pain information processing. The difference between high and low hypnotizables in the ability to control pain may represent not only functional but also structural brain differences, in that high hypnotizables who had the ability to control pain had significantly larger corpus callosum size than low hypnotizables.

Overall, the growing consensus is that hypnotic suggestions exert a top-down influence on frontal executive control systems characterized mainly by selective inhibition of various frontal functions. In particular, the ACC plays a central role in the distribution of attention in the context of conflicting attentional demands, in the parallel distribution of attention, in distributing attention between cognitive and emotional processing, in meditating autonomic responses, in coordinating the intensity of attention, in motivational states and the initiation of goal-directed behaviors, in working memory, and in nociceptive experience. The selective inhibition of various frontal systems in general, and the alteration of ACC functioning in particular, in response to verbal hypnotic suggestions, serves as a neurobiologic explanation for such diverse hypnotic phenomena as the

Telegram: @medical_k

www.konkur.in

fading of generalized reality orientation; intense focus and distraction resistance in hypnosis; hypnotic relaxation; hypnotic analgesia effects; the selective inhibition of competing response potentials, as exemplified by response to the Stroop test in hypnosis, or illustrated by hypnotic suggestions for selected deafness or focal blindness; the production of positive hallucinations; the selective recall of personal memories in hypnosis, but also the diminished memory-error monitoring in certain subjects; the efficacy of hypnotic suggestion in evoking strong emotional states; and the seeming involuntary nature of hypnotic responding. It is well established that high hypnotizables have exceptional attentional filtering and sensory-perceptual gating abilities, so high hypnotizability may constitute a selective pattern of brain activation/deactivation.

Heidi Jiang, Matthew P. White, Matthew D. Greicius, and colleagues, did provide a study, Brain Activity and Functional Connectivity Associated with Hypnosis, and have reported a study of 545 healthy subjects with very high hypnotizability or low hypnotizability using two hypnotizability scales to address subjects with high hypnotizability and low hypnotizability to confirm greater functional connectivity between the executive control network (ECN) and the salience network (SN). They utilize functional magnetic resonance imaging to investigate the activity and functional connectivity among three networks in hypnosis. Utilizing a sophisticated study, they were able to address activity in the ECN, SN, and decreased default mode network (DMN) to address whether high hypnotizability is associated with greater functional connectivity between the ECN and SN.

The a priori hypothesis they addressed was that highly hypnotizable subjects relative to low hypnotizables, when hypnotized, would show (1) decreased activity in the dorsal anterior cingulate cortex (dACC); (2) increased connectivity between the ECN regions, such as the dorsolateral prefrontal cortex (DLPFC) and the SN attentional control regions, such as the frontoinsular cortex and the dACC; (3) decreased connectivity in brain regions immediating self-referential processing, such as the medial prefrontal cortex (MPFC) and the posterior cingulate cortex (PCC) (i.e., DMN). Based upon this sophisticated study, Jiang, White, and Greicius et al., did identify three brain regions whose activity and functional connectivity changed during hypnosis consistent with the a priori hypothesis addressed in this study. The findings in this study were evident in the two hypnosis conditions among high, but not low, hypnotizables; and they were different from the memory and rest conditions. Each of

Telegram: @medical_k

www.konkur.in

these major findings was also associated with the intensity of hypnotic experiences reported among the highs. The hypnotic state among the highs was characterized by decreased low-frequency amplitude in the dACC. The dACC is a central node in the SN and has been shown to be critical for attentional control, especially context evaluations, such as anxiety, about what we should attend to and what we can ignore. This study does confirm the findings of Helen Crawford and her associates.

In a seminal neuroscience review article, Mark P. Jensen, Graham A. Jamieson, and Antoine Lutz et al. did summarize the key advances in hypnosis research during the past two decades following a 1-day meeting among hypnosis researchers before the International Congress of Hypnosis in Paris, France. The goal of this meeting was to discuss the state of the science of hypnosis research from the purview of clinical and cognitive neuroscience. The publication from this conference did provide a summary of research activity concerning the key issues and points of agreement and disagreement among the participants concerning the recent advances in hypnosis research.

There were consensus recommendations for hypnosis research that were addressed by the conference participants. The consensus view, based upon this review article, was that despite some barriers to hypnosis research, a great deal has been learned regarding the neurophysiologic underpinnings of hypnosis in the past two decades. Highlights include the clinical research supporting the efficacy of hypnosis for managing a number of clinical problems and symptoms, research supporting the role of various divisions in the anterior cingulate and prefrontal cortices in hypnotic responding and that high hypnotic susceptibility is characterized by an atypical brain connectivity profile.

Another highlight of the neuroscience review article by Jensen, Jamieson, and Lutz et al., is the consensus view that hypnosis entails heightened attentiveness, associated with activation of the anterior cingulate cortex (ACC); enhanced metacognitive distraction-detection, associated with dorsolateral prefrontal activation (DLPFC); being less invested in the default mode, namely mind-wandering associated with persistent self-referential thinking and engaging the negative content of the mind (McGeown WJ, Mazzoni G, Venneri A, et al.); deactivation of the medial prefrontal cortex, associated with top-down (self) regulation; and being aware of moment-by-moment changes in the unfolding experience, associated with an activation of the temporoparietal juncture. Finally, high

Telegram: @medical_k

www.konkur.in

hypnotizability is likely associated with an atypical pattern of learned functional connectivity between these neurocircuits. The overall conclusion would include that as more is learned about the clinical applications of hypnosis treatments, the more individuals suffering from those conditions can be helped with hypnotic treatments—including most certainly chronic pain, IBS, and PTSD, but also likely many other conditions, as well—can be helped.

THE ASSESSMENT OF HYPNOTIZABILITY

As noted earlier, the first standardized hypnotizability scale was the SHSS, which consists of a standardized induction ceremony based on suggestions for progressive relaxation, slower breathing, and going deeper and deeper into trance. Following the induction there are 12 specific suggestions, 9 of which are ideomotor suggestions; the other 3 include suggestions for a fly hallucination (presence of a buzzing fly), posthypnotic amnesia, and a simple posthypnotic suggestion. There are two comparable forms, Form A and Form B, both of which include the same hypnotic induction ceremony, but with somewhat different sets of the 12 specific suggestions. The SHSS is read verbatim to the hypnotic subject, and there is a standard set of scoring rules. Scoring is based on objective, behavioral response to a given suggestion. A given subject can score anywhere from 0 to 12 on the SHSS. An audiotape self-scoring version of the SHSS was also developed—the Harvard Group Scale of Hypnotic Susceptibility (HGS). It contains a similar induction and many, but not all, of the same items as the SHSS. Both the SHSS and the HGS take just about 1 hour to administer, but the HGS is time saving in that its administration does not require the presence of a hypnotist or clinician.

The Stanford group also developed a graded difficulty scale, the SHSS, Form C. It contains a standard induction procedure followed by 12 specific hypnotic suggestions, each of which has been empirically shown to be somewhat more difficult than the previous item. The selection of items on Form C shows greater diversity and range than the items on the A or B scale. It contains only four ideomotor items, five hallucination suggestions, a suggested dream, a suggestion for age regression, and a suggestion for posthypnotic amnesia. There is also a self-scoring audiotape version of Form C, the Waterloo-Stanford Group Scale-Form C. London also used the Stanford scales to compose a standardized scale to assess

Telegram: @medical_k

www.konkur.in

hypnotizability in children—the Children's Hypnotic Susceptibility Scale (CHSS). The Barber Suggestibility Scale is unique in that it measures response to eight suggestions in a standardized manner but does not include a hypnotic induction ceremony. All of these scales meet acceptable standards of reliability and validity.

Some controversy exists about the value of using laboratory-derived hypnotizability scales in clinical settings. Some critics argue that these scales contain a number of challenge items and create a performance-oriented ambiance that is contrary to the holding environment of therapy. Others have argued that low performance on standardized scales may discourage patients from using hypnosis. However, one study showed that given feedback of low scores as compared to high scores, they were *more* not less inclined to request hypnotherapy. Another criticism is that scales like the SHSS A and HGS lack a range in that 9 of the 12 items are ideomotor items. The scales do not contain items representative of the range of hypnotic phenomena directly relevant to the clinical context. The SHSS C has a greater range and is relatively exempt from this criticism. A more practical criticism is that most of these scales require about 1 hour of face-to-face clinician–patient interaction to complete and, in that sense, are not time efficient. The use of audiotape self-scoring versions like the HGS and the WSGC fully addresses this problem.

Having a patient listen to a tape in another office and then returning the self-scored result to the clinician at the end of 1 hour is remarkably time efficient. Moreover, the clinician is able to chart normative data of hypnotizability with little time investment. The HGS is the assessment instrument of choice in clinics seeking normative documentation on hypnotizability with little allotment of time to accomplish this.

A number of standardized clinical scales were developed to meet the needs of clinicians. The Hypnotic Induction Profile (HIP) begins with an eye roll sign, in which the patient is instructed to look upward toward the eyebrows, then toward the top of the head, and then, while continuing to look upward, to close the eyelids slowly. The eye roll sign is alleged to be a biologic indicator of dissociative capacity. The eye roll is measured in terms of the visibility of the sclera between the cornea and the lower eyelid as the eyelids are closing. The eye roll is scored from 0 to 4. Rapid objectivity also fits well into the medical model. Observing the sclera is easily demonstrated on medical rounds and can facilitate debunking myths of the skeptical. Upon closing the eyelids, floating suggestions are

Telegram: @medical_k

www.konkur.in

used to induce a trance state. The patient is then told that the left arm will feel light and will float into the air until a cut-off signal is given. Then the arm is lowered prior to giving the cut-off signal, and hypnotic responsiveness is assessed in terms of the speed and number of prompts given before the arm floats up again. The great advantage of the HIP is that it only takes 5 to 8 minutes to administer. The experienced clinician is able to complete the administration in less than 5 minutes.

As the first standardized clinical scale developed, the HIP has enjoyed enormous popularity among clinicians. The Spiegels have collected a normative sample of HIP scores on almost 10,000 patients and nonpatients. The disadvantage of the HIP is that it lacks range. The instrument is largely constructed around a response to an arm levitation suggestion along with subjective experiences associated with that action. However, because the response to ideomotor suggestions like arm levitation is predictive of response to other dimensions of hypnosis, the choice of building a quick, standardized assessment scale around arm levitation is reasonable.

The Stanford Clinical Scale of Hypnotic Susceptibility (SCSHS) contains a standardized hypnotic induction followed by five specific suggestions: hands moving together, dream, age regression, posthypnotic amnesia, and posthypnotic suggestion. It is administered face-to-face and takes about 20 minutes. The SCSHS has a number of advantages.

It is time efficient, and it assesses mostly the range of hypnotic abilities that are directly relevant to the clinician: dream, age regression, posthypnotic amnesia, and posthypnotic suggestion. The disadvantage is that scoring allows for the ready identification of high hypnotizables but does not easily discriminate between low and moderate hypnotizables.

Because the items are reasonably difficult, a small number of patients score 4 to 5, and the majority score 1 to 2. It is difficult then to know whether a score of 1 to 2 represents low or medium hypnotizability.

Overall, no single standardized hypnotizability scale perfectly meets the needs of the clinician. Clinicians wishing a time-efficient way to assess hypnotizability must decide between the HGS and the HIP, with the HGS having better normative data and greater range and the HIP being better at detecting high hypnotizables. The SCSHS taps the best range of clinically relevant dimensions and is relatively time efficient. Although not always practical, of course, the most empirically sound approach is to administer several standardized hypnotizability scales with the same

Telegram: @medical_k

www.konkur.in

patient, although the scales result in similar but not identical classifications of high-, medium-, and low-hypnotizable subjects.

THE HYPNOTIC INDUCTION CEREMONY

Purpose and Preparation

The hypnotic induction ceremony is a metaphorical performance that suggests a change in conventional verbal discourse. In a more traditional sense, it implies that a ritual to facilitate induction into a different mental state is going to occur. Despite the great variation in hypnotic induction ceremonies, most contain certain common elements. For example, most induction ceremonies contain specific suggestions to focus attention on some target, as well as suggestions to disattend to everything else.

Most induction ceremonies strategically use language to shape the progressively developing and deepening experience: “You are becoming more and more relaxed,” “You are going deeper and deeper into this state.” Some trance inductions, especially with highly hypnotizable subjects, explicitly contain suggestions for entering an altered state of consciousness or trance state, and they may also contain explicit suggestions to enhance or ratify certain trance characteristics such as involuntarism, dissociation, altered time sense, and so on. Hypnotic discourse is often very repetitive. Because repetition and monotony are associated with the destabilization of ordinary waking consciousness, the hypnotic subject becomes more open to unique subjective experiences characteristic of trance. As part of the hypnotic induction ceremony, suggestions are given to increase the subject’s motivation to be hypnotized and find the hypnotic experience desirable and to increase the expectation that the subject will be able to respond successfully to the given suggestions.

Many different inductions are used clinically, but the most successful one will be the one with which both the patient and the practitioner feel most comfortable. Both will have preferences that will influence the success of any given technique. It is appropriate for each clinician to develop their style that facilitates the incorporation of responsiveness to the patient to allow for the progressive depth of trance to occur.

Although many textbooks and pamphlets describe the actual litany that should occur, they are merely templates of ideas that have been shown to work. In the clinical course of intervention, it is imperative that the

Telegram: @medical_k

www.konkur.in

practitioner be able to change course smoothly if it becomes clear that a particular technique or suggestion is not effective in order to allow the patient to remain in a state of relaxed attentiveness. A good guideline is that all hypnosis is self-hypnosis, and the clinician's role is to facilitate the patient's ability to make maximum use of the patient's trance capacity.

Before beginning, it is helpful to prepare the patient for the experience by discovering what their expectations are and modifying them accordingly with prehypnotic preparation. For example, popular culture's depiction of stage hypnosis performances may convey a total lack of control, and such negative expectancies can be corrected during the prehypnotic interview. Discussion of prehypnotic expectancies may also address helping the patient to become more comfortable with the idea of suggestibility and the nature of subjective experiences typically associated with hypnosis.

If the patient fails to enter what he believes is a trance state, then it is beneficial to try to reframe the failure as something positive, such as suggesting that the patient has unusually good control over their muscles and that the discovery of this fact will be very helpful to know for planning future therapy options: The patient can use that control for increasing relaxation and reaching further depths than might not otherwise be considered possible. In most cases, patient expectations play an even greater role in success than the patient's level of suggestibility. Facilitating appropriate expectancy of change will likely enhance the therapeutic alliance and set the stage for induction. Most induction ceremonies are relaxation and/or awareness based, the difference being whether the patient is concentrating on releasing tension or ignoring the body to concentrate on something, such as the rhythm of the breath or walking down stairs. The most commonly used inductions are as follows.

Progressive Relaxation

The patient is asked to relax, first concentrating on slowing the breathing and then progressively releasing tension in all parts of the body, beginning with the feet and ending with the head/eyes.

Holding On and Letting Go

For some patients who are reticent to relinquish control, it is easier to first tense the body and then release the tension. Emphasis is placed on relaxing and feeling safe and secure, and holding on to only as much

Telegram: @medical_k

www.konkur.in

tension as is required for the patient to feel in control enough to avoid anxiety about submission. The patient is asked to take deep breaths, release the breaths completely, and then concentrate on how good it feels to do this. The patient is then asked to progressively tense and release each muscle group, starting either from the feet or the head.

Staircase/Escalator

This is a version of progressive relaxation in which the patient is asked to imagine that they are walking down a staircase with 10 steps to the bottom. At the top of the steps is the patient's current state, and at the bottom is the most relaxed, safe, and comfortable state possible. The patient is instructed to descend each stair slowly on the clinician's invitation, and in each step, the patient relaxes further (often suggestions such as "You will find that you are twice as relaxed on the next step as you were on this last one" are helpful), slows the breath further, and becomes more at ease. As with the previously described techniques, it can be helpful sequentially to mention relaxing muscle groups such as eyes, face, neck, shoulders, chest, abdomen, pelvis, thighs, calves, and then feet on each step.

Eye Fixation/Closure

The patient is asked to stare at a target that is preferably on the wall or ceiling that is somewhere above the normal field of vision so that some eyestrain is provoked. It is then suggested that the patient's eyes are beginning to become heavy and that the body is becoming more and more relaxed. The patient is monitored for signs that this is working, such as blinking, watering eyes, eyelids beginning to droop, and so on. These are noted verbally to the patient as assurance that they are entering the hypnotic state. If sufficient time has passed without the patient closing the eyes completely, they may be invited to do so, with the statement that this is to allow the patient to further experience and imagine the experiences that the clinician will be suggesting.

Visual Imagery Techniques

The patients are instructed to use an image to visualize a scene or scenario from the past, present, or future. Throughout the sequence,

Telegram: @medical_k

www.konkur.in

patients are instructed to relax and focus, and they are reinforced for their style.

Eye Roll Technique

During this application of this technique, patients continue typically with the screening procedure developed by Spiegel, and the technique is reinforced. Patients are asked to roll their eyes to the ceiling while taking a deep breath and holding. They are then given a suggestion for relaxation and for feeling more and more comfortable.

After the induction occurs, the specific strategy begins for most patients, such as for pain, habit control, anxiety, phobia, and so on. Some clinicians describe using the same strategy for all patients, but individual strategies based on each patient's personality traits, motivation, and so on may be more successful. All of these techniques have in common paying attention, focusing attention, and decreasing peripheral awareness.

HYPNOTHERAPY TREATMENT PLANNING AND HYPNOTHERAPY TECHNIQUES

Hypnosis in and of itself is not a treatment. Hypnosis is the *medium* of treatment. Hypnosis is a state of heightened attentiveness (and sometimes an altered state of consciousness and sometimes a condition of heightened suggestibility) within which psychotherapy or suggestions are used for intervention to achieve a goal. The patient, by virtue of going into a hypnotic state, is absorbed in a task, blocks out peripheral awareness, and has rapid assimilation of data.

It is, therefore, imperative to use the best-matched treatment protocol for a given condition. A number of comparative outcome studies have been conducted in which the same treatment protocol was offered with and without hypnotic induction. The overall treatment effect sizes are typically comparable in both the nonhypnotic and hypnotic conditions. The advantage is that a treatment protocol offered to a patient in a hypnotic state generally yields a faster effect for a number of reasons:

1. Discovering and learning new coping strategies is quicker in a nondistracted state.
2. When more focused, the undercurrent of self-talk, schemas, affects, personal memories, and self-states is more accessible than in a

Telegram: @medical_k

www.konkur.in

nonhypnotic state, thereby giving an advantage to hypnosis in exploratory therapy.
3. Hypnosis also mobilizes and intensifies the transference, aiding analytic work.
4. Treatment planning with hypnosis entails decisions.
5. Assessing hypnotizability and deciding whether the patient has sufficient hypnotizability for hypnotherapy.
6. Deciding whether the present problem is appropriate for hypnotherapy.
7. Choosing the approach to hypnotherapy.
8. Choosing the style of hypnotherapy.
9. Using patient interests and personality style to facilitate induction and to maintain a level of trance.
10. As in all treatment, developing a therapeutic alliance with the patient is the first necessary step for successful intervention.

A review of problems most amenable to hypnotherapy is included in the next subsection. There are a number of viable approaches to hypnotherapy. The goal of time-effective *problem-solving hypnotherapy* is symptom ameliorization, for example, in the ameliorization of pain or tinnitus. A good deal of the hypnotherapeutic interventions used in behavioral medicine focus on active coping and problem solving. *Exploratory hypnotherapy* emphasizes the exploration of psychodynamic factors operative in the development and maintenance of symptoms, for example, in the treatment of a conversion disorder.

Exploratory therapy also addresses the exploration of inner resources and active coping strategies to address symptoms. *Supportive hypnotherapy* uses suggestions to enhance the patient's sense of confidence and mastery.

John Hartland called such suggestions ego-strengthening suggestions. *Developmentally informed hypnotherapy* aims at fostering normal development along developmental lines such as self-development, object relations development, and affective development. The hypnotherapist must decide which approach best meets the needs of the given patient's presenting problem.

There are three very different hypnotic styles. *Directive hypnotherapy* is derived from persuasion theory. The hypnotist serves as an authoritative source and gives direct suggestions for symptom amelioration. This model is best suited to cultures in which doctor–patient relationships are more

Telegram: @medical_k

www.konkur.in

hierarchical than egalitarian, as was the case in the United Kingdom, as represented in the older *British Journal of Medical Hypnosis* prior to 1970. *Permissive hypnotherapy* is based on the assumption that hypnotizability is a talent within the patient and that the patient has the inner resources to get well. In permissive hypnosis, the hypnotherapist provides just the right relational conditions in the context of an egalitarian relationship in which the patient is provided with a permissive relational context and encouraged to explore inner resources and coping strategies.

Neo-Ericksonian *indirect hypnosis* is derived from the work of Milton Erickson with difficult patients—those who were not very hypnotizable and/or who had a history of treatment failure. Indirect methods include the strategic use of metaphors and scripts, interspersal technique, and binds, double binds, and paradoxes. Although these methods are well suited for the so-called difficult patient, they are sometimes used as general hypnotherapy techniques. The therapist must decide which hypnotic style is best matched to the given patient. In contemporary Western culture, a permissive approach is best suited to the majority of hypnotherapy patients. Directive hypnotherapy works with a small percentage of patients who fit the profile of higher hypnotizability and lower intelligence. Indirect hypnotherapy is best matched to patients with intractable symptoms of a history of treatment failure.

For example, consider the introduction of hypnotic pain-coping strategies in a 12-week group of eight patients with chronic pain. One of these patients may respond quickly to direct, graded hypnotic suggestions that the pain will become less and less severe over time. The majority of the patients may discover and gradually master individualized pain coping strategies over the first two-thirds of the group using a permissive, individualized approach to group hypnotherapy. Two patients may not respond to either of these approaches. Both may be likely to complain that the pain is becoming worse through treatment. These patients would then be given indirect hypnotic suggestions. For example, such a patient is told that it is very difficult to tolerate the uncertainty, never knowing when the pain will become worse. Therefore, as a means of gaining more control and certainty, the patient is asked to try voluntarily to increase the pain. Such paradoxical interventions, when matched to the right patient, serve to ameliorate the pain.

Although such indirect methods should never be overused, they work well with a particular type of patient. There are two main approaches to

Telegram: @medical_k

www.konkur.in

hypnotherapy: (1) a *protocol-based approach* and (2) an *individualized approach.* In this era of empirically supported treatment, there is a growing trend toward using established manualized treatments that include a set of necessary treatment foci for the treatment to be effective. A well-established treatment protocol derived from outcomes research outside of the hypnosis domain can be used with a patient in a hypnotic state.

This *hypnotic induction plus manualized treatment protocol* is becoming increasingly popular in, for example, the treatment of anxiety conditions, depression, sexual dysfunctions, and behavioral medicine. An alternative approach is to use hypnoprojective techniques (described later) to identify coping resources within the individual that helps the patient to resolve the problem or condition. For example, the hypnotized patient is asked to imagine a video about a person who had a similar problem but discovered ways of overcoming it. A second video is about another person with the same problem who discovered a way to overcome the problem that was very different from that used by the first person. After a series of three to five such scenes, the patient is told to reflect on the scenes until the meaning of each becomes more and more clear and until the patient sees how such scenes inform them about the best way to overcome the problem. Next, the patient is asked to imagine themself in the scene using these coping resources effectively until they begin to develop a sense of mastery. The patient is given a posthypnotic suggestion that thoughts about these coping strategies will naturally come to mind in everyday life whenever the patient notices the very first signs of the symptom/problem occurring. Using this displacement technique, patients discover powerful inner coping resources through the metaphor of the “displaced other” and then learn to apply these coping strategies to their symptoms, first in fantasy and then in everyday life as the symptoms just begin to intensify. The power of the displacement technique rests in the fact that all of the strategies for overcoming the symptoms come from the patient, leading to a strong sense of mastery and self-efficacy. A comparable approach is the inner wisdom method, in which the hypnotized patient is asked to consult with their “inner wisdom” to discover the best way of effectively dealing with a given problem.

There is a large repertoire of hypnotherapy techniques. *Hypnoprojective techniques* entail the symbolization of inner coping resources and unconscious processes. The “theatre technique,” for example, entails

Telegram: @medical_k

www.konkur.in

having the patient visualize a theater with a play spontaneously appearing. To explore coping resources, suggestions can be given that "the play will somehow be about effective ways of coping with (name problem)." To explore psychodynamic processes, suggestions can be given that "the play somehow will be about whatever has contributed to the development of (name problem)." To explore transference, suggestions can be given that "the play will somehow be about the treatment relationship." The hypnotherapist can structure a play with several acts so as to gradually uncover the meaning of a given problem or gradually discover a variety of new coping resources for more effectively dealing with the problem.

Other hypnoprojective techniques include the "television or video technique," the "old house technique," and the "library technique." Not all hypnoprojective techniques use imagery. *Automatic writing and drawing techniques* entail giving suggestions for dissociation of the hand, followed by suggestions that the hand is able to move involuntarily and to make writing or drawing movements on its own. Then suggestions are given that the dissociated hand is able to express inner coping resources and/or unconscious processes. A more detailed discussion of hypnoprojective techniques can be found in Daniel Brown and Erika Fromm's *Hypnotherapy and Hypnoanalysis* and John Watkins' *Hypnotherapy Techniques.*

In Calvert Stein's clenched-fist technique, the patient is asked to make a fist, then scan the body, then imagine all the tension from various sources in the body gradually flowing into the arm and then into the fist until it gets tighter and tighter. Once all of the tension flows into the fist, the patient is told to let it go. Hypnotic suggestions can be given for soothing ("A scene will come to mind that is somehow about a deep sense of soothing or comfort"). Additional suggestions are then used to amplify a feeling of soothing or comfort. The metaphor of an affect dial is useful in regulating the intensity of the affect state. The patient is asked to imagine themself in a video at a time when they are feeling a particular emotional state that is difficult to tolerate.

Then the patient is asked to imagine holding a remote control device with a special volume dial that can turn up or down the intensity of the feeling until just the right level of feeling is found. A wide variety of affect regulatory techniques exist within the hypnotherapy literature, and many

Telegram: @medical_k

www.konkur.in

have recently been collected in Carolyn Daitch's *Affect Regulation Toolbox.*

The field of hypnotherapy contains a number of *methods for the rapid identification and resolution of conflicts.* John Watkins' *ego state therapy* consists in calling forth in a trance each "part of the mind" associated with a given conflict, identifying the adaptive function of each "part," and then suggesting that other "parts of the mind" come forth, giving various perspectives on resolving the conflict. For example, if a patient is not ready to commit to the treatment for problem drinking, the clinician can call forth in a trance the "part of the mind" that wants to stop drinking, then call forth the "part of the mind" that does not want to stop drinking, then heighten the cognitive dissonance between these two "parts," and then suggest that other "parts" come forth that have a perspective on resolving the conflict between the "parts" wanting to stop and not wanting to stop drinking.

Ultimately the dissonance is resolved *within* the patient, and the internal state shifts away from the extreme resistance to stopping drinking. Using Leslie LeCron's *ideomotor questioning technique,* the clinician establishes communication directly with the so-called "unconsciousness mind," which is told that it can communicate directly using automatic ideomotor finger signals, with one finger signifying "yes," another finger "no," another finger "don't know," and another finger "don't want to say." Then the patient's "unconscious mind" is asked a series of questions pertaining to the meaning of a given symptom, such as whether it serves an emotional need, whether it is associated with a past conflict, whether it is associated with a limiting belief, it is a way of identifying with someone, and so on. In this manner, the hypnotherapist is able rapidly and precisely to identify the conflict central to the development of and/or maintenance of a symptom. This ideomotor method has been used extensively in identifying factors involved in resistance to treatment, exploring psychosomatic problems, exploring psychological factors involved in premenstrual symptoms and infertility problems, and accurately assessing motivation and level of risk of suicidal behavior.

In general, a good suggestion for clinicians is to recognize that the hypnotic evaluation can be made part of the overall evaluation and can offer information regarding patient processing and response. Based on patient response to the HIP, Herbert and David Spiegel described patients as ranging along a continuum of low to high that they call the Apollonian–

Telegram: @medical_k

www.konkur.in

Odyssean–Dionysian cluster. Hypnotic and psychotherapeutic interventions are based on each patient's hypnotic capacity.

Prior to doing any hypnotic intervention, it is recommended that a biopsychosocial evaluation be performed along with a mental status exam. Recognizing and understanding the development of the behavior, symptom, or underlying problem can help to avoid later complications. Removing symptoms without understanding their development can lead to negative consequences.

HYPNOSIS—CLINICAL APPLICATIONS

As previously noted, hypnosis has been used as a clinical intervention in medical and mental health care in a variety of settings. Following the recognition of hypnosis as a form of medical treatment by the AMA in 1958, hypnosis has been used in the treatment of a variety of medical problems and a number of medical interventions. Although there is no uniform availability of hypnotic interventions, physicians, psychologists, and other mental health professionals do provide opportunities for patients to undergo hypnotherapeutic interventions for the alleviation of medical problems and as a form of medical intervention. Harold Wain, in the paper "Hypnosis on a Consultation-Liaison Service," described a variety of areas in which hypnosis has been used in the hospital setting.

In psychiatric settings, hypnosis has been employed for a number of psychiatric disorders, which are addressed later. Over the last 25 to 30 years, professional societies for hypnosis have developed beginning, intermediate, and advanced training programs for health care professionals for the application of clinical hypnosis to their patients. Furthermore, there have been a significant number of evidence-based studies that document the efficacy of hypnotic interventions for medical problems, medical procedures, psychiatric disorders, and psychological disorders.

Trauma and Hypnosis

Freud suggested that trauma is an overwhelming experience that creates havoc within the individual and puts into question one's homeostasis and psychological identity. According to David Spiegel, traumatic stress manifests as a feeling of helplessness and loss of control over one's safety.

Telegram: @medical_k

www.konkur.in

Individuals who experience the extremes of arousal during a traumatic event are more likely to experience PTSD symptoms over time. Too high a level of anxious arousal has a disorganizing effect. Too low a level of arousal as a consequence of dissociation results in failure to integrate the traumatic experience. In either case normal processing of the traumatic event is disrupted, and PTSD symptoms are more likely to develop over time. Dissociation is used as a means of defending oneself against what might otherwise be too overwhelming to manage. The effects of trauma are generally classified into immediate aftermath effects, or acute stress disorder; chronic or delayed PTSD; and complex PTSD. Simple PTSD is generally associated with a single or circumscribed series of traumatic event(s).

Complex PTSD is generally a function of multiple comorbid psychiatric conditions, including a number of other psychiatric disorders (sometimes with a major dissociative disorder) and personality disorders. Chronic cumulative trauma, early childhood trauma, and/or trauma aggravated by early childhood attachment disorganization are associated with complex PTSD. When one is contemplating intervention it is always important to look at not only the psychiatric comorbidities but the personality styles of the patient and any medical condition that is occurring prior to intervention. Integrating a biopsychosocial approach is facilitative in gaining positive outcomes. Because the development of simple PTSD after a traumatic event is correlated with higher levels of either anxiety or dissociation during the trauma, many have theorized that hypnosis might be an effective treatment due to its ability to calm anxiety and to breach the dissociative symptoms. Specifically, when hypnotic techniques are used as a way to facilitate exposure and work through the painful memories of the trauma in a controlled way, the frequency and intensity of PTSD symptoms often appear to decrease.

The clinical use of hypnosis as a treatment of trauma was first formally described in the late 19th century by Pierre Janet, and during World War II clinical hypnotic techniques were highly successful in treating soldiers suffering from “combat neurosis.” Since that time, use of clinical hypnosis has continued, both alone and as an adjunct to other psychodynamic and CBTs, as a treatment of acute stress disorder, PTSD, and complex PTSD.

Randomized controlled studies of hypnosis and acute stress disorder, PTSD, and complex PTSD are much less prevalent in the research literature than are case studies. One clinical trial found hypnosis alone to

Telegram: @medical_k

www.konkur.in

be just as efficacious in the treatment of PTSD as psychodynamic psychotherapy and more efficacious than wait-list controls. With respect to simple PTSD, Daniel Brom and coworkers suggested that different treatments were efficacious for different PTSD symptoms: Whereas hypnosis and desensitization were more efficacious for intrusion symptoms, psychodynamic therapy was more useful for avoidance symptoms.

A meta-analysis by Jeffery Sherman, including the study by Brom and coworkers, as well as others, concluded that the beneficial effects of hypnosis for PTSD might be seen more at follow-up than immediately after treatment termination. In a more recent randomized, controlled trial, hypnosis was added to brief CBT in the treatment of acute stress disorder. The findings suggested that CBT combined with hypnosis was more efficacious in preventing re-experiencing symptoms immediately after treatment than CBT alone. However, no differences were found between the CBT alone and CBT-plus-hypnosis groups in terms of prevention of PTSD at the 2-year follow-up: The two groups had a similarly high rate of prevention of PTSD compared to supportive counseling. Manualized hypnotic ego state therapy has also been used as an alternative to CBT for simple trauma.

Because hypnosis has been demonstrated to be effective when used as an adjunct to many CBT and psychodynamic treatments for various disorders, many researchers contend that there should be more systematic research in the use of hypnotic techniques for the treatment of trauma. Reinforcing this recommendation, many case studies have demonstrated the effectiveness of hypnosis in treating PTSD-like symptoms such as dissociation, sleep and dream alterations, and pain, further justifying investigation into these techniques.

Aside from the psychiatric sequelae of a traumatic event, there is often a co-occurring physical trauma as well, and physical recovery and pain management are often an integral part of the overall recovery process. Although medical care is often essential after the trauma, the medical care received in hospital settings can sometimes be viewed by patients as an extension of the traumatic experience.

Similar to other disorders, patients experiencing pain after a trauma are not motivated and are less likely to respond to treatments for acute stress disorder and PTSD prior to the reduction in their physical discomfort. For such patients, pain control is imperative. Complicating the picture is the

Telegram: @medical_k

www.konkur.in

possibility that their pain is a defense against the trauma. Hypnosis has been demonstrated to be a clinically useful adjunctive tool in the treatment of pain, both in trauma and nontrauma patients, and can often be used as a successful analgesic for phantom limb pain that would normally be difficult to treat. Furthermore, recognizing that hypnosis can treat some of the physical symptoms of pain, patients may be more amenable to the use of hypnosis for related trauma residuals, including PTSD.

When used appropriately as a treatment of simple PTSD symptoms, there has been no evidence that hypnotic abreactions retraumatized patients or caused psychotic breaks. Similarly, not only did hypnotic analgesia cause no negative side effects, but it was also demonstrated to produce a multitude of benefits not exclusively related to pain reduction, including increased control over pain, increased sense of relaxation and well-being, decreased stress, and increased positive mood states. Thus, hypnosis might prove to be a better option for highly hypnotizable patients than more “traditional” treatments of pain and PTSD-like symptoms, especially if there is a high risk of medical complications and side effects from the traditional treatments.

Although levels of hypnotizability vary to a large extent among the general population, researchers have found that patients with acute stress disorder, as well as those developing subsequent PTSD, appear to be more hypnotizable than trauma survivors who did not develop acute stress disorder or PTSD. Several studies with standardized hypnotizability scales have suggested that individuals suffering from posttraumatic symptoms tend to be more highly hypnotizable than most other clinical and/or nonclinical groups. However, other studies have suggested that the nature and duration of the trauma play a role in the level of hypnotizability, such that hypnotizability was more highly correlated with those who experienced repeated, as opposed to isolated, traumas. These results were bolstered by similar research findings that chronic dissociation is more likely to occur in the context of repeated traumas than in the context of single traumatic events.

Military combat soldiers seem to be at particular risk of dissociation during traumatic combat situations. Charles Marmar posited that combat soldiers often protect themselves from the full psychological effect of traumatic events by engaging in “peritraumatic dissociation,” which allows them to distance themselves from an event while still staying engaged in a peripheral way. In a subsequent study, J. Douglas Bremner and Elizabeth

Telegram: @medical_k

www.konkur.in

Brett found that patients with PTSD reported higher levels of dissociation during combat-related traumas than did patients with non-PTSD. In fact, when compared to those experiencing non-combat traumas, soldiers citing combat as their worst traumatic experience were more likely to have lifetime PTSD and unresolved PTSD symptoms and were also more likely to be unemployed, fired, divorced, and physically abusive to their spouses. There has been recent significant work at Walter Reed Army Medical Center (WRAMC) and after the move to and merger with Bethesda Naval Hospital, Walter Reed National Military Medical Center (WRNMMC) using hypnosis in the treatment of trauma-related symptomatology in medically hospitalized service members returning from Operation Iraqi Freedom (OIF) and Operation Enduring Freedom (OEF).

Harold Wain and his associates on the Psychiatry Consultation Liaison Service described many techniques and approaches in attempting to decrease psychiatric comorbidity in physically and emotionally traumatized soldiers. They stressed the need to develop a therapeutic alliance with the patient and then use hypnotic techniques initially as a way of facilitating the stabilization of the patient.

In order to decrease the stigma associated with psychiatry, Wain renamed part of the service “Preventive Medical Psychiatry.” Ego strengthening and reframing techniques are used, along with methods to enhance the patient’s assets and help to support ego defenses, using a procedure called “empathic exposure,” in which the patient is asked to recall the trauma, and then their assets are reinforced. Hypnotic recall through age regression or the affect bridge technique is used to help a patient to learn to reframe and master trauma-related symptoms. The affect bridge may be used as the patients are recovering and symptoms remain; they are asked to recall an earlier like feeling while under hypnosis. The affect and cognitions are processed and worked through. If the experience becomes too overwhelming, the patient is taught to go to a safe place or to use the split-screen technique described by Herbert and David Spiegel. The use of these techniques does not preclude other psychological or pharmacologic interventions.

Wain described two cases demonstrating the above approach:

Telegram: @medical_k

www.konkur.in

A 36-year-old male suffered a traumatic above-the-knee amputation while in IRAQ after having been blown out of his vehicle. After being air evacuated to the states and while in the ICU, he heard a door slam, and as that occurred, he jumped and fell out of bed, dislodging his IVs. Upon evaluation, he described hearing what he thought was a blast that reminded him of what occurred in combat. Hypnotic techniques were used to help him decrease his initial startle response. We then went back to talk about the trauma and that he felt somewhat responsible and blamed himself for not changing the route of the jeep. Prior to reliving the incident, he found a safe scene to be absorbed with if his anxiety became too overwhelming for him. He then again described the incident where the jeep was blown up, and he was thrown several feet away, but he crawled back, dragging his leg behind him to save one of the other soldiers strapped into the vehicle that was on fire. He was reinforced for his heroism in saving the individual life and for the strength and determination he demonstrated. This procedure of reinforcing his assets, along with reframing techniques, was repeated for several sessions.

As he began to feel more comfortable, dreams of others getting hurt both in combat and in his civilian life were explored. An affect bridge of going back to an accident he had as a teenager where a passenger in his car was injured while he was driving became very prominent for him. As he was able to work that through, his negative dreams and nightmares ended, and his pain levels decreased.

A 42-year-old married mother of three children had been kidnapped and locked in a large packing trunk. After she freed herself and broke out, her abductors stabbed her multiple times, tied her up, put her back in the trunk, and threw her down a cliff. She eventually managed to break out and crawl to safety. Eventually, she was picked up by a passerby. She reported that others had seen her lying on the road and appeared frightened to approach her. Eventually, 911 was called, and she was transported to a hospital. Following medical stabilization, she was discharged and found herself developing nightmares, re-experiencing avoidance, and having hyperarousal symptoms. She was referred by her internist for treatment and was initially started on 25 mg of sertraline, which was increased to 50 mg 4 days later. She was evaluated on the HIP and determined to be a mid- to the high-range hypnotic subject. She was taught to go to a safe place and to use a

Telegram: @medical_k

www.konkur.in

split-screen technique. She was also given permission to describe her nightmares, re-experiences, and overwhelming anxieties and fears that she faced while being captive, as well as her feelings of abandonment while lying on the road. She was reinforced for her ingenuity in breaking out of the trunk. Her feeling of blame for her capture was reframed while she was under hypnosis. She was taught to calm herself and to reframe her negative feelings about her helplessness. Hypnotic age regression was used to help her master her experiences and facilitate their becoming like a bad movie. Initially, her startle response was used as a signal for her to go to her comfort zone. Age progression was used to help her to rehearse the future. The treatment used the milieu of hypnosis along with exposure, cognitive reframing, psychodynamic approaches, and pharmacology.

Although there is a paucity of randomized, controlled trials studying the effect of hypnotic techniques in the treatment of trauma, leading clinicians and researchers in the field have nonetheless outlined a strong rationale for its use. According to Etzel Cardena, Onno van der Hart, and David Spiegel, there are many solid reasons why hypnosis should be used as an adjunct in the treatment of simple PTSD victims. First, the highly hypnotizable nature of many patients with PTSD allows for greater effectiveness of hypnotic techniques. Similarly, because many patients with PTSD suffer from dissociation, they can recollect, reintegrate, and work through varying parts of their experiences while in a controlled setting under hypnosis.

It is known that some people who have experience a traumatic event may have distorted, fragmented memories of it, and under certain circumstances, as in cases of full dissociative amnesia, the use of hypnotic dissociation could facilitate access to previously forgotten memories or events. Finally, although hypnosis might not be a treatment in and of itself, it is a medium that can expedite treatment and can easily be added to many of the leading interventions. Research has further demonstrated that hypnosis can have a synergistic effect when added to previously established therapies.

With respect to complex PTSD, the standard of care is phase-oriented trauma treatment (POTT), reviewed extensively in Daniel Brown and coworkers' *Memory, Trauma Treatment, and the Law.* Most experts concur

Telegram: @medical_k

www.konkur.in

that the three main phases of treatment are stabilization, memory and representational integration, and postintegrative normalization.

Because processing trauma as a sole treatment focus in complex PTSD can have a disorganization effect, most experts concur that hypnosis helps in the development of a variety of trauma-specific skills and coping strategies, as well as in facilitating the developmental repair of the sense of self, attachment representations, and affect regulatory structures *prior* to trauma processing, as part of a multifocused stabilization phase. Guidelines for the assessment and treatment of complex PTSD, as well a review of outcome studies, can be found in Chris Courtois and Julian Ford's *Complex Traumatic Stress Disorders.*

Hypnosis and DSM-5-TR Somatic Symptom and Related Disorders

Hypnosis in the evaluation and treatment of somatic symptoms as defined in DSM-5-TR is a broad category that has not yet been well studied with evidence-based trials, with the exception of conversion disorders where there are many well-documented case reports.

The association between conversion disorder and hypnosis was first suggested by Pierre Janet in 1907 as a form of autohypnosis. More recent clinicians have also suggested that conversion symptoms may result from spontaneous self-hypnosis involving a dissociation of sensory-motor function in reaction to traumatic events or to other nontraumatic internal conflicts. In a sized sample of patients Wain, while working on a consult liaison service, observed that patients who exhibit conversion disorder symptoms showed a significantly higher capacity for hypnosis. Several Dutch studies demonstrated similar findings. Experts on somatic symptom disorders concur that hypnosis may therefore be used to the clinician's advantage to both diagnose and treat the disorder. Wain often uses his modification of the HIP to ascertain hypnotizability in medical patients who have physical symptoms lacking physical finding. The eye roll measurement fits well into the medical model. Interestingly, Vuilleumier based on new data emerging from functional neuroimaging reported similarities in brain functioning between conversion disorders and hypnotic suggestions but also described differences.

Charcot, Breuer, and Freud in the late 19th and early 20th centuries contributed greatly to the development of the concept of conversion disorder. In the first edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I) conversion disorder was called a conversion

Telegram: @medical_k

www.konkur.in

reaction, in the second edition it was called hysterical neurosis, and in the third and fourth editions the conversion process was restricted to symptoms affecting the voluntary motor and sensory nervous systems. Motor conversion symptoms include nonepileptic seizures, contractures, paralysis, and stance and gait disturbances. Sensory-based conversion includes focal blindness, elective muteness, and conversion pain. Symptoms for which there was some physiologic understanding (generally involving the automatic nervous system) were subsumed under the psychophysiological disorders.

A broadened definition of conversion disorder was used in the DSM-III, which was characterized by symptoms involving any “loss or alteration in physical functioning suggesting a physical disorder” as long as the mechanism of conversion was evident, that is, the symptom was “an expression of a psychological conflict or need.” In the DSM-IV, DSM-5, and DSM-5-TR, conversion disorder was again restricted to symptoms affecting the voluntary motor and sensory systems and where there was incompatibility between symptom and neurologic or medical conditions.

All somatic symptom disorders share in common and are characterized by physical complaints lacking known physical basis or demonstrable physical findings where there is significant distress and impairment. These disorders are conditions characterized by physical symptoms suggestive of but not fully explained by a general medical condition or the direct effects of a substance. Symptoms are not intentionally produced and are not attributable to another mental disorder and cause distress or impairment in important areas of functioning. The disorders include illness anxiety disorder, conversion disorder, psychological factors affecting other medical conditions, factitious disorders, other specified somatic symptoms and related disorders, and unspecified somatic symptoms somatic symptoms and related disorders. The somatic symptoms may transiently help to alleviate the internal conflict and primary gain is established. Secondary gain may also occur, allowing the patient external reinforcement by escaping from the situation, adopting a sick role, and so on.

Once a medical condition has been carefully ruled out, hypnosis can be an effective way to reduce the intensity of the symptoms and give the patient back some control over their discomfort. In particular once the symptom is reduced and a therapeutic alliance is enhanced, the clinician can then use other hypnotic interventions to uncover the traumatic or

Telegram: @medical_k

www.konkur.in

nontraumatic conflict that precipitated the conversion symptom. Wain demonstrates this approach by teaching nonepileptiform patients to allow their fingers to have the tremors and then he begins to look to uncover the causes.

A 19-year-old male is hospitalized after having had a concussion but continued to have nonepileptiform episodes. Upon evaluation he is a mid range to high hypnotic subject who initially was able to obtain symptom substitution with his right index finger gaining tremors as he began sensing he was going to “pass out.” As he gained control we were then able to use age regression to take him back to the injury and he described the comfort he had in escaping from some of the bullying he was receiving. He was able to use self-hypnotic techniques to interrupt the episodes and then to eventually work through the problem and find other coping strategies and deal more effectively with ridicule.

Exploratory hypnotic techniques, such as age regression and affect bridge, are generally used in helping the clinician and patient to identify and understand the nature of the conflict. Procedurally, one would use trance phenomena to take a patient to a safe place prior to going to the conflictual area. This establishes a safety valve for the patient and models a way of moving away from the conflict when anxiety becomes overwhelming. Thus reassured, the patient can face the conflict but transiently find safety without having a dystonic symptom. It further can expedite the attainment of insight, facilitate mastery, and allow for a more rapid working through of the conflict. Helping the patient to find and understand the conflict that perpetuated the need for the symptoms can be expedited. The use of age progression can then also help patients to see themselves facing a similar conflict in the future with the added benefit of having a rehearsal to facilitate success and a more appropriate way of responding. While the patient is resolving the conflict, hypnotic techniques of symptom substitution can be used that are more appropriate—for example, shaking fingers versus having an entire body tremor can be extremely useful. Extinguishing the symptom without exploring the reason for its presence at times can enhance the level of anxiety and/or depression and lead to other potential acting-out behavior.

Telegram: @medical_k

www.konkur.in

Hypnocognitive methods are also used to modify learned behavior. Remembering the symptom is beneficial for one's protection and its ablation can be destructive to one's homeostasis.

A 22-year-old male patient was brought to the emergency room with bilateral blindness. Following an evaluation by ophthalmology, it was determined that the blindness was psychogenic. After initial evaluation by psychiatry, a therapeutic alliance was developed, and hypnosis was used to take the patient to a safe place and then back to the time immediately prior to the blindness. After two sessions the patient was able to describe seeing his wife in an adulterous relationship. At that moment the patient vocalized a desire to harm his wife and her suitor. Immediately after this vocalization, he became amnesic for the event and blind. On describing this under hypnosis, he was given a suggestion that when he became alert "He would only remember what he felt comfortable remembering." Subsequent to the patient becoming alert, he had no idea what had occurred, and each day after the hypnotic intervention was initiated the patient's anger was reframed. When the patient felt comfortable he then confronted his wife. The patient became aware that the amnesia was being used to prevent him from acting out. Use of a psychodynamic, cognitive reframing approach with a hypnotic milieu helped this patient to gain control and understanding of his symptoms. The patient and his wife were then referred for marital counseling.

Telegram: @medical_k

www.konkur.in

A 30-year-old male with a history of bipolar disorder who presented to neurology for a worsening motor tics which included rhythmic flexion of the left wrist and hand, eye blinking and grimacing, left-sided lower extremity repetitive kicking movements, and repeated jerking of the neck and shoulder left upper extremity tremor. The patient underwent a full neurologic work-up which was negative and a trial of medications was without result. After evaluation the patient was screened for hypnotic capacity and was determined to be a midrange subject. He was taught to be sensitive to his physical cues and utilize a hypnotic intervention to curtail symptoms. Following the first session the patient had an immediate reduction in the frequency and amplitude of his tremor. He then practiced the hypnotic technique and was motivated to understand the significance and etiology and gain greater control of the symptom. With a psychodynamic approach the patient recognized the tic was his defense against the anxiety of being shot. And the tremors were his way as a child of expressing his fear responses especially when he perceived his father or other adults might hurt him. Following treatment the patient was able to control his symptoms and the initiation of the hypnosis gave him a sense of confidence to explore more of the psychological conflicts that he had faced.

Telegram: @medical_k

www.konkur.in

A 29-year-old woman was referred for evaluation and treatment of ongoing facial pain that was not responding to traditional methods of intervention. Neurologic evaluation showed no objective physical correlations. Her high mid-range performance on the HIP added support to the potential of a psychological mechanism for the pain. Initially the pain was controlled by a hypnotic intervention, but it returned 24 hours later. Her self-hypnotic technique ceased to be effective. A decision was made to explore more completely the meaning of the pain. Age regression under hypnosis was used, and the patient was regressed to a time prior to the pain.

She related that her brother had been injured by a car while he was running in the street. The patient was babysitting at the time, and her father was so angered that he hit her. Recently her friend's dog ran away, and she felt responsible. As she began to recognize her need to punish herself because of her guilt over what had occurred, she was able to understand her feelings and reframe her thoughts in a more productive manner. An "affect bridge" was also used, and the patient was asked to go to back to a previous time when she fell guilty and was punished. She then was able to describe her feelings of being hit by her alcoholic, abusive father. She continued to gain insight and mastery over the past and was able to ablate her pain.

The foregoing vignettes demonstrate a variety of somatic disorder cases where hypnotic techniques were used to help to resolve the patients gain control over the symptom and resolve the conflicts. They further demonstrate how hypnosis can be used as adjunctive psychological therapy together with reliance on pharmacotherapy, CBT, psychodynamic therapy, and/or eye movement-desensitization-reprocessing (EMDR). Wain advocates the need for the clinician to be viewed as safe and to facilitate the development of trust and a therapeutic alliance to enhance the success of treatment. Hypnotic intervention can be introduced after these needs have been met. The clinician further needs to avoid being impatient and to recognize the consequences of immediate demands for the resolution of the conflict.

Hypnotherapy and Relational Disturbances

Telegram: @medical_k

www.konkur.in

There are two broad categories of relational problems that patients bring to psychotherapy—problems *with* relationships, or attachment pathology, and problems *within* relationships, or focal, recurrent conflictual relational themes played out in most relationships—called core conflict relational themes (CCRTs). Hypnosis is useful for both types of relational disturbance.

Attachment disturbance is assessed in children between 12 and 20 months using the Strange Situation Paradigm, which entails direct observation of an infant and mother in an unfamiliar play room. Children are classified into four attachment types—secure, avoidant (dismissing in adults), resistant (anxious preoccupied in adults), and disorganized. Longitudinal studies have shown that these attachment types are relatively stable and predict preschool, adolescent, and adult attachment behavior. Base rate studies consistently have shown that about 65% of the general population has secure attachment, and about one-third of adults in the general population in contemporary Western culture have one or another of the three forms of insecure attachment.

Use of the Adult Attachment Inventory shows that anxious preoccupied attachment or disorganized attachment is strongly associated with borderline personality disorder. Disorganized attachment is associated with a range of psychopathology. Disorganized attachment combined with physical and/or sexual abuse in later childhood is associated with the development of dissociative disorders in adulthood. Psychodynamic psychotherapy with personality-disordered patients with attachment pathology is based on the interpretation of defenses against attachment along with the provision of a stable, consistent therapeutic attachment relationship that serves as the basis of the development of new internal working models for secure attachment. However, research with the Strange Situation Paradigm in infants shows that it is the *representation* of attachment between 12 and 20 months when symbolic or representational thinking develops, not an attachment relationship per se, that has an organizing effect on lines of development like affect regulation and self-development.

Therefore, hypnotherapeutic imagery focused on the development of positive representations of secure attachment more directly addresses the central problem of attachment pathology, namely the failure to develop positive stable internal representations of a secure base. Using an object relations model, Elgan Baker first articulated the use of hypnotic imagery

Telegram: @medical_k

www.konkur.in

to visualize the therapist as a “good object” and then to visualize interactions between the patient and therapist in which the therapist is seen a nurturing, supportive figure.

Daniel Brown’s hypnotherapeutic approach to treating attachment pathology follows John Bowlby’s model that the establishment of a secure base is naturally followed by exploration. Structured hypnotic visualizations of ideal parent figures are used to develop new, positive internal representations of secure attachment.

An outcome study is underway using this protocol with personality- and dissociative-disordered patients with the pre/post scoring of the Adult Attachment Inventory as the main measure of change in attachment status. In the initial run of the outcome study Brown et al., compared 22 adults treated for 1 to 3 years with the Three pillars attachment-based protocol to 25 control adults had taken a 2-month class on a psychoeducational approach to attachment, but no treatment, followed by 1 to 3 years of mindfulness training. A comparison of post-treatment attachment status found that all subjects in the treatment group had achieved secure attachment, whereas many in the control group had not, a treatment effect significant at the .001 level. Significant effects also occurred for an increase in overall coherence of mind and mentalization. A second group of treatment subjects are now being analyzed. Eric Spiegel classifies hypnotic treatments for attachment into three domains—those that emphasize attunement, those that foster positive internal working models for attachment through having the patient repeatedly represent it, and those that foster metacognitive skills or mentalization.

CCRT maps are more complex. They develop between the third and fourth years of life at a time that the child has developed the capacity for emotional ideas, wishes, complex schemas and beliefs, and psychological defenses. Whereas attachment representations develop from 12 to 20 months at an age prior to the development of narrative memory, CCRT maps develop concurrent with the development of narrative memory and are therefore subject to interpretation in dynamic psychotherapy.

The typical approach to modifying CCRT themes through dynamic psychotherapy takes the following steps:

1. Formulating the CCRT accurately in terms of the underlying wish of what the given patient is looking for in each relationship, the negative reactions of others expected, and the maladaptive reactions of the self in response to not having this wish fulfilled.

Telegram: @medical_k

www.konkur.in

2. Making a test interpretation so that the patient comes to see how this pattern is operative in most relationships—past and current—and in the relationship with the therapist.
3. Interpreting the manifestation of the CCRT elements in the here-and-now transference to the therapist. By adopting an emotionally corrective stance, the therapist tries to alter the structure of the CCRT. Some methods are designed to change the reactions of others, whereas others focus on changing the reactions of the self. Outcome studies show that reactions of others and reactions of the self-elements change in roughly 30 to 50 hours of dynamic psychotherapy that consistently focuses on CCRT themes.

Hypnotherapy can play a useful role in CCRT treatment. Hypnoprojective methods can assist in formulating the CCRT ("The scene will somehow be about the kind of problems that keep coming up in relationships"). Structured hypnotic visualizations can assist in having the patient articulate the best aspects of the central wish and then imagine ideal reactions of others and healthy adaptive reactions of the self toward the goal of developing a new, positive CCRT internal map ("The scene will be about the kind of relationship you wish for, in the best sense," "The scene will be about the ways others respond, in the best sense"). There are no outcome studies specifically on the use of hypnotherapy for CCRT problems. Carolyn Daitch has developed a short-term hypnotherapeutic protocol for anxiety in the context of romantic partnerships.

Hypnosis and Anxiety Disorders

Anxiety disorders can be classified in terms of whether the anxious arousal is more or less continuous, as in GAD and OCD, or discontinuous or episodic. Disorders of discontinuous anxiety can be further classified in terms of whether the source of the anxiety is external, as in specific phobia, or internal, as in panic. Unwanted thoughts are also characteristic of continuous anxiety conditions, with excessive worry about realistic situations being characteristic of GAD and misappraisal of the importance of unwanted, senseless obsessional thoughts being characteristic of OCD. Learned progressive avoidance of unwanted, senseless thoughts makes such thoughts salient and persistent and tags these thoughts with excessive anxiety, thereby justifying the progressive use of compulsive-behavioral and mental rituals to mitigate the anxious arousal.

Telegram: @medical_k

www.konkur.in

Learned progressive avoidance of discomforting bodily sensations and/or unfamiliar situations loosely associated with an increased probability of having panic attacks gradually transforms panic attacks in agoraphobia. Furthermore, while it is well established that exposure-based treatments are effective, each type of anxiety disorder requires a specific type of exposure treatment. For example, because excessive worry generates continuous arousal in GAD, worry exposure in the best-matched treatment. Because discomforting bodily sensations generate panic, exposure to such uncomfortable sensations is critical to successful treatment of panic, as exemplified by fear-of-fear exposure, interoceptive exposure, and panic control therapy (PCT). Because fear of external objects or situations is central to the development of specific phobias, exposure to the feared situations in fantasy and in real life through systematic desensitization is critical to the treatment of phobias.

Because compulsive rituals eradicate anxiety, behavioral exposure and response prevention (ERP) aids the patient to tolerate the anxiety and master it without resorting to the compulsion. ERP alone, however, does not directly address the obsessive thinking. Restructuring core beliefs that cause the misappraisal of senseless, unwanted obsessive thoughts is the best approach for working with the obsessive-thinking component of OCD.

Most clinicians concur that hypnosis is not a treatment; it is the medium of treatment. Hypnosis is merely a state of redistributed attention and heightened focus and, for some patients, an altered state of consciousness or trance that allows greater access to imagery, self-talk, affects, self-states, and inner coping resources than would be available in the normal waking state. However, it is still necessary to bring to hypnotherapy the protocol of treatment that is best matched to the given psychiatric condition. With respect to anxiety conditions, exposure-based cognitive-behavioral treatment protocols consistently show favorable outcomes.

Hypnotherapy can serve as a useful adjunct to the cognitive-behavioral treatment of anxiety disorders. J. Christopher Clarke and Arthur Jackson devoted an entire text to hypnotherapeutic treatment of anxiety disorders. With respect to specific phobias, hypnotherapy is a useful adjunct to desensitization treatment. Sharon B. Spiegel has provided an excellent review of the current issues in the treatment of a specific phobia and has made significant recommendations for innovative applications of hypnosis in the treatment of specific phobias. She fully describes the benefits of

Telegram: @medical_k

www.konkur.in

utilizing hypnosis in the treatment of specific phobias, and she has emphasized that hypnosis does significantly manage resistance to treatment in specific phobias. She has documented that the use of hypnosis does reduce the length of treatment, and she has demonstrated that hypnosis does provide substantial reduction in anxiety, based upon the significant advances in cognitive neuroscience. The therapist and patient construct a stimulus hierarchy from least- to most-feared situations. Exposure consists of imaginal exposure to each situation on the hierarchy, from least to most, first in fantasy and then in real life. Hypnotic desensitization has advantages over nonhypnotic behavior exposure, in that hypnotic treatment entails greater focus, less distraction, richer affective imagery, a greater capacity to control the exposure imagery, enhanced sense of learning and mastery through time distortion suggestions, and greater likelihood of facilitating effective real-life exposure through posthypnotic reinforcement.

Valentine et al., conducted a meta-analytic study of 15 studies on hypnotherapy for anxiety disorders. They concluded “the average participant receiving hypnosis reduced anxiety more than about 79% of control participants” (p. 336). Comparative outcome studies of nonhypnotic behavioral exposure and hypnotic desensitization illustrates that both approaches have comparable treatment effect sizes but that the hypnotic treatment is typically faster for the aforementioned reasons.

With respect to panic, the first proven exposure-based treatment was interoceptive exposure. David Barlow and his associates reasoned that because the escalation of panic states starts with the misappraisal of uncomfortable bodily sensations, exposure to uncomfortable bodily sensation was a core ingredient in successful treatment. In interoception exposure, the patient is given instructions to produce analogs to the kind of bodily discomfort operative in panic states, such as twirling the head around rapidly until becoming dizzy, running in place until becoming winded, or holding the breath for longer periods until becoming uncomfortable.

The rationale of interoceptive exposure is that the patient learns to sit through and master uncomfortable bodily states. Barlow more recently developed a more comprehensive treatment package for panic disorder—PCT—which includes interoceptive exposure, cognitive reframing of panic escalating cognitions, and controlled breathing. Because panic is a rapidly escalating state exacerbated by hyperventilatory breathing, learned

Telegram: @medical_k

www.konkur.in

control over breathing serves to de-escalate the panic state. Hypnotherapy can serve as a viable alternative to PCT.

Interoceptive exposure to uncomfortable bodily sensations is an indirect form of exposure because the bodily discomfort generated by head twirling or breath holding is not equivalent to the bodily discomfort naturally occurring during panic states. In contrast, hypnotherapeutic exposure using a fear-of-fear hierarchy is more direct. The clinician constructs a fear-of-fear hierarchy of least to most intensity of escalating panic experience.

In hypnosis, the therapist suggests the progressive intensification of the panic state from very mild, to moderate, to full intensity, and then instructs the patient to sit through the full discomfort until it diminishes and mastery over the discomfort is attained. The hypnotherapeutic fear-of-fear exposure more closely matches the sequence of cognitive and somatic events operative in the development of an actual panic state than does interoceptive exposure.

Another interesting disorder vocal cord dyskinesia (VCD) in the past has often been diagnosed as a conversion disorder rather than under the anxiety spectrum. This disorder is often known to be an asthma simulator and is characterized by upper airway obstruction and stridor without an anatomic cause. The disorder is highlighted by inappropriate inspiratory vocal cord adduction seen on fiber optic laryngoscopy. This can be distinguished from bilateral vocal cord paralysis by episodic, momentary abduction of the vocal folds during cough or patient distraction. Arterial blood gases values remain normal. These patients rarely exhibit hypoxia or hypercarbia. In addition, chest radiographs do not show hyperinflation or other immune functioning as is characteristic of asthmatics.

Telegram: @medical_k

www.konkur.in

A 26-year-old female with a dx of VCD was referred from pulmonology for evaluation and treatment. She described an incident of sexual abuse at age 16 and had no previous symptoms or recurring thought intrusions or nightmares. She relates her present symptoms began after running and then beginning to gasp for air. Initially the patient is diagnosed with asthma and antiasthmatics are prescribed but all treatments she was refractory to and the symptoms persist. Following laryngoscopy a diagnosis of VCD was determined. The patient reported a successful college and vocational experiences and initially denied any psychological concerns. During the initial evaluation a HIP screening is utilized and she is a mid- to high-range subject. As the arm levitates in the posthypnotic section she then looks with amazement at the involuntarism of the arm and she is given the interpretation that her arm is responding the way other parts of her body can respond as well.

She is then able to recognize what may be occurring with her larynx. She is taught a self-hypnotic procedure to gain control over her symptoms. Whenever she feels tightness in her chest she is instructed to do her self-hypnotic procedure. In later sessions she begins to acknowledge that she is feeling choked by the stress in her present life and recalls a similar sensation when she was choked during a past abuse episode. She begins to acknowledge the feeling of having been held down and overwhelmed. As frequently occurs she begins to discuss more of her past and present trauma and is able to reframe and gain control. An affect bridge is used to help her master her feelings of the past as well as the present. As the intervention progresses the patient slowly begins to acknowledge her difficulty with her present position and her desire to terminate her job. However, she feels compelled to remain in the position because of her contract. She gains motivation to be able to protect herself and her symptoms begin to dissipate. One year after her last treatment there still were no return of symptoms and she was able to regain control. Wain and his colleagues at WRNMMC utilize this approach with many patients with VCD who are referred for treatment. After a pulmonary evaluation and a therapeutic alliance are developed, we initially teach them symptom control then help them understand the underlying conflict.

Telegram: @medical_k

www.konkur.in

With respect to GAD, worry exposure directly addresses the excessive worry that generates sympathetic arousal. The patient first constructs a list of favorite categories of worry. The patient is instructed to intentionally worry about something common on the list, then to think about something worse, then something worse, and so on. Worry exposure is systematic worst-scenario thinking. After a while the content of worst-scenario thinking becomes so extreme that it fails to generate physiologic arousal, and the link between excessive worry and physiologic arousal is broken. There are a number of hypnotic approaches to GAD. Suggestions for relaxation, cue-induced soothing imagery, and the clenched-fist technique address the somatic arousal characteristic of GAD. Direct ego-strengthening suggestions to experience a worry-free state and/or hypnotically assisted worry exposure address the excessive worry characteristic of GAD.

With respect to the treatment of specific phobia, hypnotizability is a strong predictor of hypnotic treatment of flying phobias. Hypnosis reduces the over length of treatment, optimizes relaxation in exposure-based treatments, and builds self-regulation skills in the treatment of phobias. Pre/post neuroimaging studies of patients with specific phobia showed an MPFC top-down dampening of the fear center of the brain, the amygdala (Halsband and Wolf).

With respect to OCD, hypnosis can aid ERP. Hypnotic suggestions are given to intensify and then tolerate the anxiety associated with ritual compulsive behaviors such as checking or washing until a marked reduction in the frequency of compulsions is achieved. Modification of core beliefs that drive the misappraisals of senseless, unwanted thoughts and transform them into obsessions is best accomplished by hypnotic ego state therapy.

For example, if the patient reports a core belief of excessive responsibility, ego state therapy is used to identify the adaptive function of the overly responsible “part of the mind.” Then suggestions are given to contact the part of the mind that is most opposed to the overly responsible part. By accessing that counterpart to the overly responsible part, cognitive dissonance is created. For example, a spontaneous playful part of the mind might be identified as a counterpart to the overly responsible part.

Having heightened the dissonance by calling forth the spontaneous, playful part, the therapist uses conflict resolution strategies to reduce the

Telegram: @medical_k

www.konkur.in

dissonance between the overly responsible and spontaneous parts. Other parts are called on to offer a solution to the conflict between the overly responsible and spontaneous parts. To reduce the dissonance, the system typically shifts away from the extreme position of the overly responsible part. A similar approach is used for modifying any of the other core beliefs operative in maintaining the OCD symptoms until a marked reduction in unwanted obsessive thoughts is reported.

Hypnosis and Depression

Depressive disorders are among the most frequent referrals in psychiatry. The National Institute of Mental Health (NIMH) outcome study on depression showed that antidepressant medication and interpersonal therapy were equally effective, and CBT was modestly effective, in the treatment of major depressive disorder. Assen Alladin studied hypnotherapy combined with CBT as compared to CBT alone in treating depression in a 16-week randomized clinical trial. He found that although both groups significantly improved, the treatment effect size was significantly greater in the hypnosis group, and that hypnosis had an additive effect on traditional CBT treatment of depression. Miaozun Shih and associates conducted a meta-analysis of hypnotic treatment of depression showed a clinical significant effect of hypnotherapeutic treatment that significantly improved symptoms. In hypnosis, depressed patients can be given ego-strengthening suggestions for increased confidence and control, suggestions for positive affective states, and rehearsal of positive, hopeful future events to help the patient to come out of the hole in which they have fallen. Severe depression sometimes can interfere with concentration, thereby challenging the clinician to keep the patient focused on developing positive states and preventing a sense of failure. Hypnosis can be used as an adjunct to pharmacologic approaches with depressed patients.

Hypnosis and Personality Disorders

The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, text revision (DSM-5-TR) defines a personality disorder as follows: A personality disorder is an enduring pattern of inner experience and behavior that deviates markedly from the norms and expectations of the individual's culture, is pervasive and inflexible, has an onset in

Telegram: @medical_k

www.konkur.in

adolescence or early adulthood, is stable over time, and leads to distress or impairment.

A variety of nonhypnotic approaches to the treatment of personality disorders have evolved, ranging in diversity from behaviorally oriented DBT, cognitively oriented schema therapy, and dynamically oriented transference-focused psychotherapy (TFP) to developmentally informed psychotherapy that stresses attachment repair mentalization, self-development, and affective development. Although Marsha Linehan's DBT enjoys great popularity in the United States, outcome studies merely show that patients with personality disorders treated with DBT tend to stay in therapy and have less self-destructive tendencies over time relative to patients in conventional therapy, but no data are available to document whether DBT leads to the clinically effective result of no longer meeting a personality disorder diagnosis. Likewise, Otto Kernberg's TFP shows some promise in diminishing personality disorder criteria, but in comparative outcome studies developmentally informed treatments like Peter Fonagy's mentalization-based treatment (MBT) and cognitive-based treatments like schema therapy consistently show better outcomes than DBT or TFP in terms of numbers of patients who no longer meet sufficient criteria for a personality disorder posttreatment. More recently, outcome measures have included not only personality disorder diagnostic criteria, but also developmentally informed outcomes, such as coherence of state of mind and metacognitive capacity. Such measures are used in the attempt to demonstrate that patients with personality disorder are actually changing the organization of their state of mind in some fundamental way through treatment.

Hypnotherapy holds greatest promise as an adjunct to cognitively based approaches like Jeffrey Young's schema therapy and developmentally informed treatments. The Young Schema Questionnaire serves to identify on which of 18 maladaptive schema domains a given patient with personality disorder measures high or very high. Treatment then targets each of these areas using both traditionally cognitively focused methods, such as testing the evidence and correcting distortions, and emotion-focused methods. The main emotion-focused method entails a reparenting approach in which the therapist adopts an emotionally corrective stance. For example, if the patient characteristically expects abandonment, the patient is asked to imagine the therapist as being fully there, or if the patient expects deprivation, the patient is asked to imagine

Telegram: @medical_k

www.konkur.in

the therapist as providing the kind of care that is most needed. This emotion-focused technique is conducted in a relaxed state with structured waking imagery. A recent comparative outcome study showed that twice as many patients with personality disorder in schema therapy improved as did matched patients with personality disorder in TFP. Young believed that a main component of the success of schema therapy was the emotion-focused reparenting imagery work.

Although Young did not use hypnosis in schema therapy, there is no reason that his emotion-focused technique could not be adapted to using hypnotic imagery. There may be several advantages using hypnosis, especially with hypnotizable patients with personality disorder.

Although patients with personality disorder have a variable self-observational capacity, the hypnotic context may provide a necessary ingredient within which such patients can better resist distract, sustain focus on the emotion-focused imagery, and more quickly and efficiently alter the target maladaptive schema. Hypnotherapy can also serve as a useful adjunct to a developmentally informed approach to the treatment of personality disorders. The work of Elgan Baker and of Daniel Brown illustrates how structured hypnotic imagery can be used to develop positive, stable internal representations of secure attachment.

With respect to self-development, Janine Stevenson and Russell Meares obtained favorable results in reducing a personality disorder diagnosis using Fred Pine's approach to fostering self-development. Hypnotherapy can also be used to foster self-development. The normal line of self-development includes the development of a cohesive self-representation (self-definition), the representation of the self as having an effect on the physical environment and on unfolding events and on eliciting desired responses from others (self-agency), and the linking of positive affective states to the self-representation (self-esteem). Patients with personality disorder with deficits along the line of self-development, such as borderline patients, show deficits in self-definition and agency, and those such as narcissistic patients show deficits in self-esteem development. Repeated structured visualizations are introduced in hypnosis to foster self-definition ("the scene will be about . . . when you are most you . . . your real self . . . the unique qualities that manifest when you are being most yourself"); self-agency ("the scene will be about . . . making an impact on . . . eliciting the kind of responses from others that you need"); and self-esteem ("the scene will be

Telegram: @medical_k

www.konkur.in

about . . . some situation in which you feel especially good about yourself . . . especially like yourself . . . feel especially confident"). Hypnotic suggestions are used to generate the target scene, amplify the positive affect associated with the scene, extend the duration of experiencing the target state of mind, and then transferring that state of mind to situations in which it would normally feel difficult to hold that sense of self. The structured visualizations are repeated in treatment sessions and outside of the sessions in self-hypnosis until they foster a stable, positive internal representation of self-definition, self-agency, and/or self-esteem.

With respect to affective development, hypnotherapy can be used to link the visceral substrate of affective states to imagery and thought in patients with personality disorder who show developmental deficits in the capacity for affect experience. Hypnotically suggested soothing imagery and/or hypnotically structured exposure (hypnotically suggested progressive intensification of affective states so that the patient learns to sit through them) can be used in patients with personality disorder who show deficits in affect tolerance. There are no outcome data on developmentally informed hypnotherapeutic approaches to the treatment of personality disorders.

HYPNOSIS AND PAIN

An excellent review of controlled studies and anecdotal reports concerning research and clinical applications of hypnosis in treating clinical pain. David R. Patterson and Mark P. Jensen's excellent review of evidence-based studies of the use of hypnosis in assessment and treatment of pain disorders. Since the publication of that review, there have been other significant studies documenting that hypnosis has become an important method of intervention in the treatment of acute pain disorders, pain during medical procedures, surgical procedures, and chronic pain disorders.

Hypnosis in Acute Pain Disorders—Procedural Pain Interventions

Over the last 10 years, there has been increasing use of hypnotic interventions in the treatment of acute pain disorders and the alleviation of pain during medical and surgical procedures. There have been evidence-based studies document the efficacy of hypnotic interventions in these

Telegram: @medical_k

www.konkur.in

contexts, and these studies correspond to research findings regarding hypnotic analgesia in the hypnosis laboratory setting. Kendrick et al., have conducted a critical review of 29 randomized clinical trials on the use of hypnosis for procedural pain. The conclusion was that “hypnosis was most effective in minor surgical procedures” (p. 75).

Hypnosis and Burn Care. Hypnosis has been used in the analgesic management of burns. These hypnotic interventions include suggestions with progressive muscle relaxation, followed by suggestions for direct analgesia. Imagery for cooling the inflammation and suggestions for reappraisal of feared bodily harm also have been used. In the various reports in the literature concerning the use of hypnosis in the management of burns, the hypnotic interventions appear to have been efficacious for both debridement of burns and changes of dressing involving burns. These controlled studies have also documented that the hypnotic interventions had significant effect on pain perception, anticipatory anxiety, and relaxation during and after burn care.

In addition to Theodore Barber’s rapid induction analgesia method of hypnosis, other hypnotic interventions have used eye fixation associated with progressive muscle relaxation, guided imagery, and direct suggestions for pain relief in the affected area. Overall, both clinical reports and controlled studies have demonstrated that hypnosis is associated with reduced use of opiate medications, decreased pain ratings, and reduced use of sedative–hypnotics and tranquilizers. Many of these studies included assessment of hypnotizability using the HIP and the Stanford Hypnotic Clinical Scale (SHCS).

Roberts et al., reviewed the literature and described how hypnotic intervention is an effective tool at reducing pain and procedural anxiety with burn patients.

Hypnosis in Obstetrics and Gynecology. In view of the fact that labor pain represents a significant acute pain and that women are certainly motivated for both reduction in pain and diminished anxiety, hypnosis has been used as an intervention in the acute pain associated with labor and delivery. Another benefit reported in both anecdotal reports and controlled studies involves the reduction in stress and anxiety in the labor and delivery process. This reduction in stress and anxiety provides a better maternal environment during both stage II and stage III of labor. The

Telegram: @medical_k

www.konkur.in

literature provides numerous anecdotal reports concerning the use of hypnosis in the labor and delivery process.

Ralph August and Simon Chaisson described using hypnosis as a sole anesthetic for cesarean births. Karl Fuchs in Israel described the successful use of hypnotic intervention with hyperemesis gravidarum.

Hypnosis and Women's Issues

In a study by Karl Fuchs, he demonstrated that hypnotic intervention can be very successful for hyperemesis gravidarum. Out of 51 gravidas patients treated individually, 35 (68.5%) showed excellent results with no vomiting and no nausea, and 2 (3.9%) showed good response and had no vomiting but some nausea. Fourteen (25.5%) patients showed vomiting less than six times per day and had improvement in their nausea and poor response to treatment, and one patient (2.3%) could not be hypnotized in spite of repeated trial sessions. Out of 87 gravida patients treated in groups, excellent results were obtained with 61 patients (70.1%), and 24 patients (27.6%) had no vomiting but some nausea, and 2 patients decreased their vomiting to less than six times per day but had improvement in their nausea.

Gary Elkins and his associates, as well as Cassie Kendrick and associates, have used hypnosis in the treatment of hot flashes in premenopausal women. Maitri Shah and associates found that both hypnosis and medications were equally effective for treating dysmenorrhea.

Hypnosis in the Emergency Room

Past myths about the nature of hypnosis may have contributed to a reluctance among many to use hypnosis in the emergency department. Some feel that hypnosis takes too long and would not be appropriate in acute care situations. The time for formalized trance induction may range from a spontaneous occurrence to several hours. However, given the focused state of the individual in an emergency situation, hypnotic induction is frequently quicker than under other conditions. Frequently, because of the discomforts of the presenting ailment, anxiety, and confusion pertaining to the extent and significance of one's symptoms, patients in the emergency department feel as if they are out of control. However, their preoccupation with acute symptoms may decrease their peripheral awareness and thus narrow their field of concentration,

Telegram: @medical_k

www.konkur.in

enabling them to gain some control. This highly focused state is like a hypnotic trance state.

The psychological trauma associated with physiologic malfunctioning often precipitates an altered state of consciousness for the patient. Awareness of the existence of this altered state (trance or dissociated state) can enable the staff to use it in treatment. In this altered state, the patient may be highly receptive to comments and suggestions. The staff must be very cautious with the words and statements used within the patient's hearing. The same guidelines should be followed with patients who have not been introduced to the formal hypnotic trance. Patients, by virtue of being in a focused state, are vulnerable to staff's comments and assimilate the data rapidly and, at times, without vigilance. This is why a mere suggestion of help or of a positive outcome can be facilitative for a patient in general.

In the emergency department the staff typically adopts a positive, calm, supportive approach to the patient. This supportive style may provide the necessary ingredients for an enhanced therapeutic alliance, which can facilitate the patient's ability to use their trance state more effectively. Many individuals use their trance state without being cognitively aware. The natural trance is frequently used by individuals as a protective measure, and it typically allows individuals to distance themselves perceptually from their discomfort, whether it is physical or emotional. The astute clinician can recognize a patient who is doing this and capitalize on this state. For patients who are having difficulty focusing constructively, the clinician can help to find an appropriate focus for them.

Paul Delfito described the value of hypnosis in the emergency department for treating pain due to orthopedic injuries, burns, corneal abrasions, abdominal distress, headaches, menstrual discomfort, renal calculi, herpetic lesions, muscle spasms, and dental syndromes. Isserson reviewed the impressive usage of hypnosis for clinical emergency care. He suggested that the lack of training has prevented more staff from using this technique.

Wain, working on a Consultation Liaison Psychiatry Service, described similar results with a variety of patients in the emergency department.

Telegram: @medical_k

www.konkur.in

A 32-year-old man presented to the emergency department with a severe headache. He was a chronic migraine sufferer and had been unable to control the pain on this occasion with his propranolol. The emergency department recognized that he had a high hypnotic capacity. The imagery of an icepack being placed on his forehead was suggested. Initially, some real ice was placed on his forehead to help. The patient was able to control his pain completely with this imagery. He did not require narcotics, as he had on previous visits. On follow-up several weeks later, the patient reported being able to use this strategy to control, as well as prevent, migraine attacks, and he no longer had to rely on frequent emergency department visits for pain relief.

A 55-year-old female patient suffering from coronary artery disease presented to the emergency department with severe chest pain. Her cardiac enzymes and electrocardiogram (ECG) were completely normal. The treating clinician used hypnosis, during which the patient reported that her internist had died of a myocardial infarction the previous day. When it was clear that there was no actual cardiac involvement on this occasion, the patient was allowed to reinterpret her perception of the pain. She came to the realization that she had been identifying with her internist, and the pain was her way of grieving his loss. As she began to practice the hypnotic techniques, her pain dissipated. Although pain-free, she was nevertheless observed on a monitor for 24 hours. There continued to be no evidence of myocardial damage. She was discharged pain-free. She returned as an outpatient and again was symptom-free. She found a new internist and was monitored regularly.

Hypnosis for Alleviation of Pain in Bone Marrow Aspirations. Studies have demonstrated the efficacy of hypnosis in reducing the pain of bone marrow aspiration using such techniques as storytelling, fantasy, imagery, and deep breathing. Control studies demonstrate that hypnotic interventions with children provided lower ratings of pain than a control group.

Telegram: @medical_k

www.konkur.in

Some studies also used specific hypnotic interventions involving posthypnotic suggestions for re-entering hypnosis following cues provided by the hypnotherapist. The hypnotic interventions used eye fixation, as well as progressive muscle relaxation, and the involvement of storytelling and guided imagery as methods of hypnotic intervention. The use of hypnosis for bone marrow aspiration in children is associated with the administration of the SHCS for Children. Ernest Hilgard and Samuel LeBaron's study of children's hypnotizability predicted analgesic response, as well as a reduction in anxiety.

Hypnosis in Surgical Procedures

There have been a number of studies and reports describing the use of hypnosis in surgical procedures. Esdaile perhaps highlighted its early use by doing over 300 major procedures between 1845 and 1851. Later studies include hypnosis used in hemorrhoidectomies, anorectal surgery, cesarean sections, cervical surgery, surgical removal of pedicle attachments, neurosurgical procedures, dental surgery, breast surgery, coronary artery bypass surgery, endocrine surgery, hernia repair, and angioplasty. These studies reported efficacy and positive effect on surgery, including reduced postoperative nausea and vomiting, decreased anxiety during the procedure, fewer postoperative side effects, reduced medication use, and quicker recovery time.

Wain published a paper on the use of hypnosis as a sole anesthetic in septoplasty (Fig. 32.19–2). A patient demonstrated total anesthesia during surgery, rapid healing, a decrease in bleeding and edema, as well as analgesia without pharmacology in changing the packing postoperatively. Hypnoanesthesia is not a sole anesthetic for all patients, however—probably only for hypnotic "virtuosos." There are many more patients who can use hypnosedation as an adjunct to chemical anesthesia, thus reducing reliance on the latter and decreasing risks. In his article on hypnosis for septoplasty, Wain reviewed many surgeries in which hypnosis was used as a sole anesthetic or as an adjunct to traditional anesthesia.

Telegram: @medical_k

www.konkur.in

FIGURE 32.19–2. Photographs of septoplasty.

Telegram: @medical_k

www.konkur.in

A 34-year-old man presented with a history of nasal obstruction for many years. He had an injury to the nose at age 12 years and had a continuous obstruction to breathing. He was found to have a grossly deviated septum and a small hump on the nose, which required removal. His physical examination revealed a well-developed, well-nourished 34-year-old man in no acute distress with normal vital signs. Physical examination was unremarkable except for the presence of a grossly deviated nasal septum to the right with total obstruction and total dislocation of the septum to the right nostril obstructing the airway, with compensatory hypertrophy of the inferior turbinates on the left side. Screening on the (HIP) scale resulted in him being a high hypnotizable 4 to 5. A septoplasty was performed under hypnosis. Although no chemical anesthesia was used, an anesthesiologist was in the operating room to ensure efficacy for the patient. Postoperatively the patient was able to change his packing without any pain. The strategy consisted in suggesting that he was absorbed in floating on or near a beach. He had no recollection of the surgery and reported no perception of pain. He was highly hypnotizable.

Hypnosis in Chronic Pain Disorders

In contrast to acute pain and procedural pain, chronic pain is a persistent and intractable pain disorder that persists beyond the time needed for healing to occur from an injury. Although chronic pain is sometimes associated with tissue damage, in the majority of cases tissue damage has not been substantiated.

According to the modified gate control theory of Ronald Melzack and colleagues, chronic pain is mainly a signal detection dysfunction in which a variety of haptic sensory inputs are misinterpreted as pain. Daniel Brown likened the development of chronic pain to the development of panic states, both of which entail a progressive learned misappraisal and phobic avoidance of somatic distress. Extensive phobic avoidance of pain sensations maintains the signal detection dysfunction, in that the patient rarely attends to somatic distress in a way that would allow for correction of signal detection errors. Chronic pain syndrome is also frequently associated with significant cognitive distortions and illness behaviors.

According to Wain, “Nowhere in medicine does there seem to be a stronger link between the physiological, psychological, and sociological

Telegram: @medical_k

www.konkur.in

variables than there is in the understanding of the diagnosis and treatment of the patient with chronic pain. It is the trauma of the pain, suffering, and anguish that unites every physician, nurse, and health care specialist."

Wain further noted that a chronic pain experience is associated with significant problems in coping with associated social and environmental factors. In contrast to acute pain disorders, interventions such as prolonged rest and immobility are frequently contraindicated in the effective management of chronic pain syndromes.

Hypnosis frequently is also used to address the illness behaviors and suffering associated with chronic pain. In *Hypnosis and Behavioral Medicine,* Brown and Fromm described a phase-oriented approach to hypnosis and chronic pain. The first phase entails identification of specific pain coping strategies available to the given patient with chronic pain, followed by the application of these pain coping strategies in trance, along a hierarchy from less intense, peripheral to more intense, target pain locations.

Hypnotic techniques are used to correct negative self-talk and distorted pain beliefs to the extent to which they interfere with the successful application of pain-coping strategies. The second phase is skill development, in which the patient with chronic pain develops mastery over the pain experience within and outside of the treatment session and learns successfully to use a range of pain-coping strategies whenever pain occurs in everyday life. At this stage, phobic avoidance of pain is reduced. The patient learns not only to tolerate pain adequately but also to discriminate a wide range of sensory signals other than chronic pain. The third stage, the rehabilitation phase, addresses the issues of chronicity, for example, the normalization of daily life, developing a healthy, pain-free self-representation, and eliminating analgesic addiction.

Tiara Dillworth and Mark P. Jensen have provided an excellent review of controlled trials that have demonstrated hypnosis is an efficacious treatment of chronic pain. Their studies did review a number of controlled studies that have documented hypnosis is an efficacious treatment of chronic pain syndromes.

Multiple Convergent Pain Management. The Institute of Medicine published a landmark report in 1987 entitled "Pain and Disability: Clinical, Behavioral, and Public Policy Perspectives." The report, prepared by a committee of authorities, contained a literature review, an analysis of

Telegram: @medical_k

www.konkur.in

chronic pain and its treatment, and specific recommendations for future developments in medical research and public policy concerning chronic pain.

Although the Institute of Medicine study suggested the need for further research on the different modes of treatment and their efficacy, it stated that multimodality and multidisciplinary therapeutic interventions lessen the disability and dysfunction associated with chronic pain.

Ronald Melzack and Patrick Wall described multimodality and multidisciplinary therapy for chronic pain as a multiconvergent pain management program that includes physical, psychological (behavioral medicine), and pharmaceutical interventions and interventional anesthesia (Fig. 32.19–3). This type of pain management program uses a rehabilitation and collaborative model of intervention. The psychological interventions include several modes of treatment based on the principles of both operant conditioning and cognitive-behavior management. Hypnosis has a definite role in any treatment program that uses contingency management and cognitive-behavior management approaches to chronic pain. Certain features of the behavior of the patient with chronic pain demonstrate the value of hypnosis as a mode of treatment—specifically, demoralization, suffering, and low self-efficacy.

In addition to the aforementioned psychological problems associated with chronic pain, it is also associated with significant suffering based on the patient's fear that they will be unable to control the pain. The suffering component of the chronic pain experience is also amenable to being ameliorated through hypnotic interventions.

In addition to the medical suffering associated with chronic pain, chronic pain is also associated with demoralization, which is amenable to hypnotic interventions. Because of the influence of cognitive processes on the perception and integration of pain and the significant complications regarding the psychological problems associated with chronic pain, interventions that significantly modify cognition and perception would be efficacious in the management of pain. This observation provides a firm foundation for using hypnosis in chronic pain management.

Hypnosis lends itself to both operant conditioning (contingency management) and cognitive-behavior modification therapies that are well established in multiple convergent pain management programs. In view of the fact that there is a nonspecific (placebo) response and a direct effect of the hypnotic experience, both the nonspecific and the direct effect of

Telegram: @medical_k

www.konkur.in

hypnosis can be used appropriately in the management of chronic pain syndromes.

There are significant anecdotal reports and some cases with controls that demonstrate that patients with higher hypnotizability scores on hypnotic assessment tests generally report greater analgesic effects of hypnosis and significantly improved cognitive functioning through the use of hypnosis. The use of hypnosis should involve multiple interventions during the course of the chronic pain management and self-hypnosis training. In their review “Hypnosis and Clinical Pain,” Patterson and Jensen provided significant evidence concerning the lack of control studies in chronic pain studies. They recommended that hypnosis should be used in a more organized manner in the management of chronic pain. They also suggested that hypnosis may be efficacious in the treatment of the suffering and cognitive distortions experienced by patients with chronic pain. Their review included an important meta-analysis suggesting that more than 70% of the patients in multiple convergent pain management programs could have benefited from adding hypnotherapy to the treatment program. Such interventions could be directed toward both the alleviation of the pain experience and the treatment of the suffering and cognitive distortions associated with chronic pain behaviors.

Telegram: @medical_k

www.konkur.in

FIGURE 32.19–3. Multiconvergent pain management involves multiple interventions that act on different parts of the central nervous system and spinal cord. These interventions substantially diminish the pain, suffering, and depression produced by the chronic pain experience. Hypnosis plays an important role in significantly reducing the pain, demoralization, and suffering of chronic pain. Hypnosis also facilitates the efficacy of biofeedback, behavior modification, stress reduction, and muscle relaxation in multiconvergent pain management. TENS, transcutaneous electrical nerve stimulation.

A more recent meta-analysis comparing hypnosis to behavioral methods for chronic pain Tononori Adachi and his associates found that hypnotic treatment of chronic (nonheadache) pain had a larger treatment effect size as compared to other psychological interventions like cognitive-behavioral treatment or guided imagery.

During the initial evaluation of such patients for hypnosis and self-hypnosis training, they should be given a full explanation of the benefits of this training for the management of their chronic pain, as well as a full understanding of the misconceptions and myths about hypnosis. They should also undergo a hypnotizability assessment, such as the SHCS for Adults or the HIP. David Axelrad developed a method of induction—open neurosensory fixation—for use in the individualized hypnotherapy and self-hypnosis training of the patient with chronic pain. This method, described in the paper “The Role of Hypnosis in Multiple Convergent

Telegram: @medical_k

www.konkur.in

Management of Chronic Pain," includes engaging in eye fixation on a visual source, listening to ambient environmental sounds, experiencing kinesthetic and other pleasurable sensations in the skin, muscles, and joints, and engaging in progressive muscle relaxation (Fig. 32.19–4). This method can be used by patients with high, moderate, or low hypnotic capacity.

Patients with chronic pain should be provided with individualized hypnotherapy that incorporates suggestions for relaxation and progressive muscle relaxation, or some other form of relaxation intervention, that permits the patient to undergo relaxation responses from the hypnotic experience. The suggestions should also be directed toward direct pain reduction and pain relief.

In view of the significant association of depression and demoralization with chronic pain, the hypnotic interventions should also include suggestions that are directed toward alleviation of depression and demoralization.

Displacement suggestions, distraction suggestions, and transformation suggestions may also be employed during the course of the hypnotherapy. Following several individualized hypnotic interventions, the patient should also be provided with training in self-hypnosis in a group setting. The self-hypnosis training experience is an integral part of a hypnotic intervention for patients with chronic pain. During the course of a multiple convergent pain management program, patients should be encouraged to undergo self-hypnosis in a variety of situations that provoke increased pain. Such experiences reinforce the "well" behavior and help the patient to establish self-efficacy and sense of personal mastery.

Ms. D was a 63-year-old White woman referred for symptoms of chronic pain and PTSD caused by the experience of being a passenger in a motor vehicle that was struck by an 18-wheeler. Ms. D had been in the front passenger seat, restrained by a seatbelt and shoulder harness. During the accident, she experienced severe fright and the fear that she would be killed. She had sustained injuries to her left shoulder and neck, which required an emergency room assessment and evaluation. During the emergency room evaluation, a computed tomography (CT) scan of her neck and back reflected significant degenerative disease in her cervical spine, a disk protrusion in her cervical spine, and a degenerative disease in her lumbar spine. An MRI examination also documented these injuries. Subsequent studies also revealed a negative axial CT scan and a negative MRI of the brain. The patient's chronic pain was severe. Because of the patient's significant history of insulin-dependent diabetes and other problems, her orthopedic surgeon and internist recommended conservative pain management interventions. Ms. D also experienced an acute stress disorder, followed by PTSD, after her injuries. Her symptoms included recurrent nightmares and re-experiencing images of the motor vehicle accident. She also exhibited hyperarousal and a significant startle reflex. She reported marked avoidance behavior, avoiding freeway driving, and experiencing increased anxiety and panic attacks whenever a motor vehicle in which she was riding was approached by an 18-wheeler. She reported significantly increased anxiety in response to both internal and external cues reminding her of the motor vehicle accident. The patient underwent treatment for her PTSD, which included individual and group hypnotherapy and a self-hypnosis training program. She was also provided with relaxation exercises and biofeedback training. She also required multiple convergent pain medicine interventions, which included physical therapy interventions and behavioral interventions for her chronic pain syndrome. She was also provided treatment with an SSRI antidepressant. Over the course of her treatment, she was able to use both hypnosis and self-hypnosis training to significantly reduce her anxiety, abort her panic attacks, and significantly diminish chronic pain experiences involving her neck and upper back. This self-hypnosis training program also provided her with improved control over her posttraumatic headaches. Her orientation to the hypnosis experience

Telegram: @medical_k

www.konkur.in

included the administration of the SCSHS, on which she had a score of 5, demonstrating that she had marked hypnotic capacity. The focused open neurosensory induction program Ms. D included eye fixation on a visual object and environmental experiences (sound) and direction of her attention inward to neurosensory experiences, including kinesthetic sensations. She was instructed in diaphragmatic breathing, which is a critical component of most hypnotic inductions and relaxation or meditative experiences. The training program included suggestions calling for eye closure and progressive muscle relaxation. During the course of the patient's training, she was provided with suggestions for diminishing her fear and anxiety associated with both internal and external cues reminding her of the accident, as well as direct suggestions for pain relief in her neck and back. She also incorporated these suggestions for reducing her headaches by imagining having a cold pack placed on her forehead and neck.

Over the course of Ms. D's treatment, she experienced a significant remission of her PTSD symptoms and a significant reduction in her pain experiences, as judged by both the McGill-Melzack Pain Inventory and the Visual Analog Scale.

Mr. G was a 55-year-old African American man who experienced an occupational injury that caused a herniated disk at L4–5. He experienced intractable pain, and he failed to respond to conservative interventions. He underwent a laminectomy and fusion procedure for this injury. Unfortunately, his pain returned, and he was unable to return to full-time employment. Over the course of his medical history, he underwent four additional surgical interventions to his low back region. He was referred to a pain center because of intractable pain associated with significant tolerance to opiate medications. At the time of his admission to the pain program, he was requiring methadone at a dose of 60 mg four times daily, augmented with hydrocodone at 2 mg two to three times daily. Following his admission to the pain medicine program, he was administered the Stanford Hypnotic Susceptibility Scale, on which he had a score of 11, indicating marked hypnotic capacity. At the time of his entry into the program, he was seriously depressed and demoralized. He was provided with cognitive-behavioral management, self-hypnosis training, and physical therapy interventions, emphasizing aerobic conditioning and strengthening exercises. He was also treated with antidepressant medication to assist in the treatment of his depression and his chronic pain syndrome. Mr. G. was also provided with hypnosis and self-hypnosis training similar to that described in the previous case. He was able to use open neurosensory induction to significantly reduce the pain in his back, increase relaxation of his back muscles, and improve his self-image. The hypnosis was also directed toward enabling the patient to experience significant reduction in pain without the need for opiate medications. Based on his training, the patient was able to use self-hypnosis once or twice daily to significantly reduce his pain and discomfort. Over the course of his treatment, he was successfully withdrawn from opiate medications. He was discharged free of opiate medications was successfully rehabilitated through a state-supported rehabilitation program.

Hypnosis in Headache Management

As noted in the review by Patterson and Jensen, far more studies have focused on the use of hypnosis for headaches than for any other etiology of chronic pain. Their review included nine studies that involved some

Telegram: @medical_k

www.konkur.in

controls. The hypnotic interventions in the headache management studies lasted for significant periods of time, and the patients were provided with suggestions for relaxation, visual imagery techniques, verbal reinforcers, and direct suggestions for pain reduction. Patients were frequently provided with self-hypnosis training as a part of their headache management program. The headache management program was also combined with biofeedback training and other methods of autogenic relaxation. A controlled study demonstrated that patients provided hypnotic interventions experience significantly greater pain control than patients provided biofeedback training alone. The hypnotic interventions provided for patients in this study used eye fixation followed by suggestions for relaxation, analgesia, and numbness.

Many of the headache studies reviewed by Patterson and Jensen included hypnotic assessments and measures of suggestibility as a part of the hypnotic intervention program. The researchers, who adopted social influence models for hypnotic responding, also reported that patients provided with such interventions reported significant improvement of their headaches without the induction of a hypnotic state. In another systematic review Flynn found a significant hypnosis treatment effect specifically for migraine sufferers in a randomized trial.

Hypnosis and Irritable Bowel Syndrome

Functional abdominal pain (FAP) and IBS are highly prevalent in both childhood and adulthood. IBS entails gut motility changes and recurrent pain and is accompanied by a functional dissociation of awareness of somatic events combined with excessive worry about bodily experience. Since the pioneering work of P. J. Whorwell and his associates reported in *Lancet* there have been several dozen controlled, evidence-based studies that have demonstrated that hypnotherapy for FAP and IBS is a highly effective treatment both for children and adults. These studies show hypnotherapy to be superior to standard medical care or supportive psychotherapy for the reduction in pain and stabilization of gut motility. Some of these studies also elucidated both the physiologic and psychological mechanisms of the hypnotic effects.

One of the mechanisms of action of hypnotherapy involved changes in both colonic motility and rectal sensitivity. Hypnotherapy also reduced excessive worry and somatic dissociation in patients with IBS. In view of

Telegram: @medical_k

www.konkur.in

these studies, hypnotherapy—individual, group, and self-hypnosis training—is recommended for the treatment of IBS in both adults and children. Vivian Miller and Peter J. Whorwell developed a similar protocol in the treatment of inflammatory bowel disease (IBD), but studies in this area are only just beginning to appear.

Susanna Carolusson has provided an excellent review and significant applications of dynamic hypnosis in the treatment of IBS. She has provided a randomized controlled study of the use of hypnosis to the treatment of IBS.

HYPNOSIS AND ASTHMA

Asthma entails intermittent, variable airways obstruction due to chronic bronchospasm. It may also involve an ongoing inflammatory response. In the 1960s, the Hypnotherapy in Asthma Subcommittee of the British Tuberculosis Association conducted a series of randomized clinical trials using direct hypnotic suggestions to treat asthma. Whereas the results were promising, the findings were largely restricted to subjective outcome measures, with one important exception: Asthmatics treated with hypnosis as compared to a relaxation group showed a significant increase in forced expiratory volume over a 1-year span.

In New Zealand, Timothy C. Ewer and Donald E. Stewart conducted an important randomized, controlled hypnotherapy trial with 39 adults with mild-to-moderate asthma. The hypnosis group underwent six weekly 1/2-hour hypnosis sessions plus daily self-hypnosis. The hypnosis consisted of hypnotic induction, relaxation suggestions, ego strengthening, guided imagery, and direct suggestions for mastery over asthma symptoms. The control group intervention consisted of a nurse review of daily symptom diary entries. The hypnosis treatment group showed a significant reduction in airway obstruction as measured by peak flow, a significant reduction in airway irritability as measured by a methacholine challenge test, and a significant reduction in the use of bronchodilator medication. High hypnotizability strongly predicted a positive treatment response. Marianella Castes and coworkers reported a Venezuelan study in which 35 asthmatic children used guided imagery to change their inflammatory response. The researchers found a significant decrease in forced expiratory volume, a decrease in immunoglobulin E antibodies, and a

Telegram: @medical_k

www.konkur.in

decrease in the number of $CD23^+$ cells, which mediate the inflammatory response.

Unfortunately, neither of these studies has been replicated. Nonetheless, they suggest that hypnosis is possibly efficacious in the treatment of asthma with respect to increasing airway flow, decreasing airway hyper-responsiveness, and possibly curtailing the inflammatory response and that high hypnotizability predicts a positive response. With respect to peak flow, some critics have pointed out that these seemingly positive biologic changes are largely restricted to effects on the large air passages. Nevertheless, given the fact that the magnitude of airway change is clinically significant, especially in high hypnotizables, hypnosis should be seriously considered for this group. Wain demonstrated successful treatment of VCD, an asthma simulator that demonstrates a specific laryngoscopy profile. The symptoms have been shown to be controlled and/or ablated with hypnotic intervention.

HYPNOSIS AND IMMUNE-RELATED DISORDERS

Hypnotically assisted profound relaxation and specific hypnotic suggestions for cooling localized target tissue have been shown to reduce acute inflammation in, for example, burns and also to diminish chronic inflammation associated with autoimmune conditions like rheumatoid arthritis. Stephen Black and his associates found that direct hypnotic suggestions markedly reduced the expected weal and flare in response to a passive transfer skin test to a known allergen but did not alter cellular infiltration. Despite this clear laboratory demonstration of reduced allergic response, there have been only a few clinical studies applying hypnosis to the treatment of the gross symptoms of allergic sensitivity.

The main area in which hypnosis has been used in the treatment of immune-related disorders is psycho-oncology. Hypnosis can be used to facilitate the development of active coping strategies to deal with the crisis of the cancer diagnosis, death anxiety, life disruption following diagnosis, uncertainly of course of illness, helplessness, and noxious medical procedures.

Hypnotic intervention can be used effectively as an adjunct to controlling the nausea and vomiting effects of chemotherapy. Anticipatory vomiting, which is also a common occurrence just prior or even the week of treatment, can also be treated with hypnosis by having the patient learn

Telegram: @medical_k

www.konkur.in

self-hypnosis. Suggestions that Wain and others have used and that have been effective in this area include numbness, relaxation, floating and absorption in a task and/or even suggesting the first sign of the discomfort demonstrates that the chemo is working and having an impact on their body and by relaxing and visualizing the cancer cells decreasing they can help themselves.

Hypnosis can be used to ameliorate psychiatric symptoms associated with a cancer diagnosis, such as depression, anxiety, sleep disturbance, and pain. Montgomery et al., in a systematic review of hypnosis and cancer found that hypnosis for cancer focused on common symptoms like fatigue, sleep disturbances, pain, appetite loss, and dyspnea. Exploratory hypnosis can also be used for meaning making and benefit finding following the initial cancer diagnosis, as well as for enhancing quality of life in the face of the diagnosis.

A meta-analysis of psychosocial interventions in cancer showed that the largest treatment effects are found in altering quality of life, with more modest treatment effects associated with coping enhancement and emotional adjustment. The role of psychosocial interventions in prolonging survival rates is controversial, with studies yielding both positive and negative results. Most studies find that facilitating active coping and encouraging emotional expressivity are associated with improved immune regulation, but it is less clear whether improved immunoregulation affects the overall survival rate. James Hall found that high hypnotizability is a strong predictor of which individuals are more likely to alter their immune response following psychosocial interventions for cancer.

HYPNOSIS AND SEXUAL DYSFUNCTION

The classification of sexual dysfunctions typically corresponds to the three phases of sexual response—desire, arousal, and climax. Conjoint sex therapy is an empirically supported approach to the treatment of disorders of arousal and climax in both men (erectile dysfunction and pre- or postmature ejaculation) and women (frigidity, anorgasmia), in which couples are given a structured series of sexual assignments designed to impart new sexual skills and identify/work through conflicts that interfere with normal sexual response. Hypnosis can be used as an adjunct to conjoint sex therapy in couples. Daniel Araoz's book *The New Hypnosis in*

Telegram: @medical_k

www.konkur.in

Sex Therapy contains a wide range of sex hypnotherapy techniques for supporting conjoint sex therapy.

The consensus among sex therapists is that disorders of desire in men and women (inhibited sexual desire; sexual compulsivity) are more complex in that long-standing unresolved traumatic or neurotic conflicts and maladaptive cognitive learning is important in their development. At the Masters and Johnson Sex Clinic, Mark Schwartz used a combination of traditional conjoint treatment along with dynamic exploratory hypnotherapy to identify the conflicts contributing to sexual desire disorders. Although no randomized clinical trials exist on hypnotherapy for sexual desire disorders, Schwartz's data constitute a large cohort study followed over time that offers promise for hypnotherapy in an area in which outcome success has generally been lacking.

HYPNOSIS AND DERMATOLOGY

One of the classic psychosomatic disorders is neurodermatitis. The link between emotions and skin lesions has been well-reported in the literature. In an early study by Surman et al., they demonstrated that more than half of their patients who had flat warts were able to eliminate them on one side with five sessions of hypnotic treatment. In particular, several clinicians have reported the successful treatment of warts with hypnotic interventions that were refractory to routine dermatologic treatment. One clinician reported the successful removal of penile condyloma acuminatum. Clinicians have also reported successful treatment of ichthyosis, pruritus, alopecia areata, eczema, boils, angular cheilosis, and psoriasis.

Areed Barabasz and his associates found that treatment of human papilloma virus (HPV)-related warts by hypnosis was more effective than medical tissue assault methods in long-term follow-up. In contrast to these clinical reports, some of the research has been less positive. Therefore, it may be appropriate to consider the use of hypnosis if other treatments fail. The more hypnotizable the patient, the more likely it is that physical alterations can occur. The use of hypnotic techniques as an adjunct to other treatments also appears warranted. It is safe to conclude that emotions have a strong effect on the skin and that hypnosis can have an effect on emotions.

HYPNOSIS AND ADDICTIVE BEHAVIORS

Hypnosis and Smoking Cessation

Hypnosis has been used for smoking cessation for many years. Many anecdotal studies have been published, as have several retrospective clinical studies that provide some encouragement for the use of hypnosis in smoking cessation. Unfortunately, many of these studies were limited because they did not include biologic markers of smoking cessation, nor was there randomization. Furthermore, the studies also varied in the amount of hypnotherapy provided during the hypnotic intervention. There are two *major* approaches to using hypnosis for treating smoking: (1) Multimodal cognitive-behavioral treatment conducted in trance. Brown and Fromm described an integrated hypnobehavioral protocol that addresses motivation for treatment; self-monitoring of urges and smoking behavior; nicotine fading; stimulus control; self-regulation of smoking behavior; smoking-related cognitive distortions; the effect of regulatory use of smoking; the social context of smoking; identification and prevention of relapse; and smoker self-image. Single-session or brief hypnosis, as exemplified in the work of Herbert and David Spiegel. The Spiegel approach uses the eye roll induction method, followed by a series of brief health-benefit suggestions designed to increase commitment for smoking cessation and the use of posthypnotic suggestions coupled with self-hypnosis training. During the course of the hypnotic intervention, positive imagery may also be used. (2) Others used a modified approach of the above where strategies are based on first developing the therapeutic alliance with the patient and structuring individual strategies based on their past experiences and what might motivate them to change. Those individual motivations are incorporated into the hypnotic suggestion given during the treatment session and in their self-hypnotic interventions.

At least one study using the longer hypnobehavioral protocol demonstrated that the intervention associated with an intensive hypnotherapy intervention program can be an effective means of achieving smoking cessation. In this one study, the rate of smoking cessation at 26-week follow-up was 40% and was confirmed by an expired carbon monoxide value of 8 ppm or less. The investigators noted that limitations in the study were the small sample size and a lack of measurement of hypnotizability.

Telegram: @medical_k

www.konkur.in

Anecdotal reports of the single-session Spiegel approach included hypnotizability assessment using the HIP. These reports documented significant abstinence in 20% to 35% of subjects, with abstinence rates as high as 40% in subjects with higher hypnotizability scores on the HIP. The Spiegels reported that a consecutive series of 226 smokers referred for the smoking cessation program were treated with a single-session habit restructuring intervention involving self-hypnosis; they were followed for 2 years. The criterion for successful outcome was total abstinence for smoking; 52% of the study group achieved complete smoking abstinence 1 week after the intervention, and 23% maintained their abstinence for 2 years. The hypnotic interventions for smoking cessation also included self-hypnosis training in which the patient was provided with suggestions to minimize negative self-talk and to incorporate the benefits of nonsmoking and the ability to become a nonsmoker. Both approaches typically incorporate basic educational experiences regarding the deleterious physical effects of smoking and the significant benefits of overcoming the smoking addiction. The suggestions provided during the hypnosis generally include increased control in mastery and the positive experiences of healthy living. The suggestions should also be provided to counterbalance the symptoms of withdrawal.

Hypnosis in Weight Management

Hypnosis has been used in a number of weight control and weight management programs. It is generally combined with exercise and comprehensive dietary management. The purpose of a brief hypnotic intervention is to provide the patient with an opportunity to restructure their relationship to food. During the course of the hypnotic experience, patients are provided with a number of suggestions to facilitate greater control over their eating behavior. The hypnotic interventions are combined with a number of affirmations that facilitate the patient's dietary management. Use of imagery may also assist in the patient's weight management. Patients are provided with encouragement to use self-hypnosis on a daily basis to facilitate management of their eating behavior. Brown and Fromm described a manualized, multimodal protocol integrating hypnosis and cognitive-behavioral treatment that addresses motivation for treatment, stimulus control, self-regulation of eating behaviors, problematic eating patterns, managing urges, cognitive control over eating, relapse risk assessment and prevention, and dealing with

Telegram: @medical_k

www.konkur.in

dynamic factors associated with problematic eating. Irving Kirsch found that the addition of hypnosis to a cognitive-behavioral protocol for weight control made a significant contribution to the overall treatment effect.

Entwistle, Webb, and Abayomi have provided an excellent review of the literature concerning the use of hypnosis in weight management programs. Their review does provide an excellent understanding of the value of hypnosis in weight management programs.

Hypnosis and Eating Disorders

Beginning with Pierre Janet's classic case studies more than 100 years ago through the modern hypnodynamic treatment approach of Moshe Torem, hypnotherapy has a long history in the treatment of anorexia and bulimia. Studies consistently have shown that patients with bulimia, and certain patients with anorexia, are more hypnotizable than normal control subjects. Johan Vander Linden in Belgium developed a detailed manualized approach to hypnotherapeutic treatment of patients with eating disorder with and without a history of trauma that combines the development of cognitive-behavioral skills in hypnosis and exploratory hypnotherapy with family therapy. The 13-step eating disorder protocol conducted over a 6-month period addresses providing psychosocial education, lowering medical risk, establishing therapeutic goals, increasing motivation, normalizing eating habits, evaluating progress, enhancing self-esteem, improving bodily experience, learning relaxation, enhancing autonomy, learning to recognize and tolerate negative and positive feelings, addressing trauma, and enhancing relapse prevention. Hypnosis is used in different ways across most of the 13 steps.

Clinical outcome data show that 55% of the patients no longer met sufficient criteria for an eating disorder diagnosis after 1 year, with 70% improvement in patients with bulimia, 52% improvement in patients with restricting anorexia, and only 18% improvement in patients with mixed anorexia and bulimia.

Hypnosis and Complex Habits

Hypnosis has also been used in the treatment of complex habits such as nail biting, tongue sucking, skin picking, and hair pulling or trichotillomania. The plucking of hair may occur for some individuals whose anxieties or internal tensions reach a crescendo, but the behavior becomes so overlearned that it serves to regulate a wide variety of

Telegram: @medical_k

www.konkur.in

affective and cognitive states in the patient. Trichotillomania is defined as the recurrent failure to resist the plucking of hair. Hair, eyebrows, and moustache are the targets. Patients are often unaware of engaging in the behavior. Hypnosis has been utilized in the treatment of complex habits in both individual and group interventions.

HYPNOSIS IN FORENSIC PSYCHIATRY

Hypnosis has been used as a forensic investigative tool to refresh the recollection of witnesses and victims, as well as sometimes suspects, of crimes. In the 1960s and 1970s, hypnotically refreshed memory was openly admitted as testimony in most courts. The forensic use of hypnosis greatly increased its popularity in those years, especially among law enforcement agents. Hundreds of police officers were given brief training in hypnosis. One popular program, for example, consisted of only 32 training hours. Given the general lack of psychological training of the police taking the courses and the cursory training given in forensic hypnotic interviewing, it was inevitable that the quality of investigative hypnosis would deteriorate. Martin Orne first articulated the misuses of forensic hypnosis and was greatly influential in cautioning the courts about abuses of forensic hypnosis and the questionable accuracy of hypnotically refreshed testimony. In the early 1980s, a series of landmark legal decisions changed the future of forensic hypnosis. Many states then adopted a per se *exclusion* standard, according to which hypnotically refreshed testimony was found inadmissible. Other states found the per se rule too extreme and adopted a *guidelines rule* in which hypnotically refreshed testimony was admitted, provided that the hypnotic interview was conducted by a competent mental health professional with specialty training in hypnotic interviewing, that no one else was in the room, and that a tape recording of each session preserved the record so that it could later be reviewed and scrutinized for possible undue influence.

In 1985, the AMA published a cautionary statement specifically on the forensic, not clinical, use of hypnosis. Unfortunately, most of the landmark court decisions limiting hypnotically refreshed testimony and also the 1985 AMA report were premature, in that the findings were written before the greater bulk of research findings on hypnosis and memory had appeared in the professional literature. The AMA report only cited a small number of the scientific studies on hypnosis in print at the time. Likewise, the only

Telegram: @medical_k

www.konkur.in

meta-analytic study on hypnosis and memory included 24 studies, only 4 of which pertained to memory recall. An expanded list of 38 studies was reviewed by Matthew Erdelyi in the same year. Erdelyi included 17 studies on the recall of meaningful material, only 3 of which were included in the aforementioned meta-analysis. Reviews and updates on scientific research on hypnosis and memory that are more representative and inclusive of the available research findings can be found in *Memory Guidelines* by the American Society of Clinical Hypnosis and *Memory, Trauma Treatment, and the Law* by Daniel Brown and coworkers. The main research findings fall into three broad areas: hypnotic hypermnesia, hypnotic pseudomemories, and confidence in hypnotically refreshed memory. *Hypnotic hypermnesia* pertains to the relative *completeness* of memory. Laboratory subjects are shown a series of target stimuli and are then asked to recall or recognize the original stimulus material under waking and hypnotic conditions. Hypnotic hypermnesia occurs if the subject remembers significantly more new information under hypnotic as compared to nonhypnotic conditions. Hypermnesia refers to the amount of information or the completeness of the recollection, not necessarily its accuracy.

Although the results across numerous studies are quite variable, the overall results suggest little or no advantage of hypnosis in recognition memory studies. Results across many studies show a modest increase in the amount of information recalled with hypnosis for more- but not for less-meaningful stimulus material. However, this conclusion is complicated in several respects. First, research designs do not always discriminate repeated recall and hypnotic recall; if the initial recall attempt occurs in the waking state and the second recall in hypnosis, there is no way of knowing whether the advantage of the second recall was due to hypnosis or simply to a second recall. Second, many studies show that hypnotized subjects asked to recall a target event produce a remarkable increase in, yet a widely variable amount, of responses.

Martin Orne hypothesized that hypnosis resulted in a lowering of response criteria, so that subjects used lax criteria when deciding whether to report a memory or other mental content like a thought or image as if it were a memory. However, subsequent research showed that when a shift to lax response criteria occurs, it is more a function of establishing unrealistic expectancies regarding memory retrieval and less a function of a hypnotic procedure per se. Although the *lax response-criteria*

Telegram: @medical_k

www.konkur.in

hypothesis served as the dominant explanation for hypnotic hypermnesia for several decades, a series of experiments in memory research outside of the hypnosis field by Henry L. Roediger and Matthew Erdelyi largely refuted this explanation.

The method used to control the variability in productivity in response to hypnotic hypermnesia suggestions was *forced recall,* according to which subjects were shown a fixed number of stimulus pictures, say 60, and after recalling as many as possible, say 38, were instructed to fill in the other 22 lines on the answer sheet. Unfortunately, although this method controlled for variable response criteria across subjects, it created an additional problem. The findings from many of the studies using the forced-recall procedure show an increase in both accurate and inaccurate information about the target event. This became known as the “hits and misses” view of hypnotic hypermnesia. However, this increase in the memory error rate is likely an artifact of the forced-recall method, which essentially encourages guessing. Research comparing both forced and nonforced recall failed to show any significant differences in the number of correct or incorrect responses in the hypnotic condition.

Overall, if any pattern emerges from these studies, it is that hypnosis may facilitate a modest recall of new information about a meaningful target event, at least in certain subjects, but that the effects of hypnosis per se are not always clearly distinguishable from relaxation and repeated recall effects. Although some critics assert that hypnotic hypermnesia runs the risk of inaccurate recall, this “hits and misses” hypothesis is misleading in that it does not distinguish between the effects of hypnosis per se and the effects of poor interviewing techniques and/or making unrealistic claims about memory retrieval and encouraged guessing.

The research on hypnotic *pseudomemories* tries to decipher the *accuracy or inaccuracy* of the memory obtained. There is an extensive scientific literature demonstrating that some normal (nonhypnotized) individuals are vulnerable to changing their memory reports for a target event when subjected to postevent suggested misinformation. This is known as the misinformation suggestion effect. Vulnerability of misinformation suggestions occurs both in the normal waking state and in the hypnotic context. In the hypnotic context, this is known as the hypnotic pseudomemory effect.

Kevin McConkey, Amanda Barnier, and Peter Sheehan defined hypnotic pseudomemory as “memory reported when a suggestion is given

Telegram: @medical_k

www.konkur.in

following a hypnotic induction that a person will remember specific information that the hypnotist knows (or believes) to be false." Extensive research on the hypnotic pseudomemory effect has compared the response to misinformation suggestions in both high- and low-hypnotizable subjects, in the waking state, and following a hypnotic induction. This extensive research generally shows that pseudomemories were reported both by high and low hypnotizables but at higher rates in high hypnotizables, and also that pseudomemories were reported across hypnotic, waking, and simulation-of-hypnosis conditions. There is a trend that some portion of but not all high hypnotizables who were also hypnotized have at best modestly higher rates of pseudomemories than high hypnotizables in the waking condition or than low hypnotizables in either condition. Cox and Barnier list three types of memory distortion or confabulation produced by hypnosis: (1) That produced by suggested amnesia for everything associated with a target event; (2) That produced by instructions explicitly to fill in the gaps of memory; and (3) That associated with the temporal order of the events in the target experience (memory disorganization).

High hypnotizability, not the hypnotic procedure, per se, is associated with a modest increase in pseudomemory rates. However, Graham F. Wagstaff and his associates found that when high hypnotizables as compared to low hypnotizables are given instructions that imply that hypnosis leads to more, not less accurate reporting that are less likely to produce false memories. However, the consistent finding from hypnotic pseudomemory research is that a hypnotic procedure per se poses no more risk of pseudomemory production than a walking interview procedure. The primary risk factor for inaccuracy due to suggested misinformation is an interview that includes suggested misinformation, irrespective of whether this misinformation is given in the waking state or in hypnosis. The problem of pseudomemory inaccuracy lies in suggestive interviewing and setting unrealistic expectations, not hypnosis. Some critics have argued that the effects of hypnosis and misinformation suggestions are additive and that both contribute to the overall variance to the hypnotic pseudomemory effect. However, an attempt to replicate the findings with a more sophisticated signal detection design failed to replicate the earlier findings that hypnosis had a negative effect on memory accuracy, but did replicate the rather robust finding that suggestive interviewing independent of hypnosis significantly increased

Telegram: @medical_k

www.konkur.in

memory inaccuracy. If anything has been learned from the numerous pseudomemory studies, it is that hypnosis as a procedure per se does not cause pseudomemories, and that interviews conducted with and without hypnosis must scrupulously avoid supplying misinformation, that is, avoid supplying *any* content that has not been already reported by the interview subject.

Martin Orne and Bernard Diamond cautioned against the use of hypnosis because they believed that hypnotically refreshed memory may foster undue confidence about inaccurate memories and that such undue confidence would make such individuals unusually resistant to cross-examination in the courtroom. However, the many research studies pertaining to hypothesized increased target memory confidence following a hypnotic induction have yielded equivocal results: High hypnotizability and/or a hypnotic induction were found significantly to increase confidence in hypnotically retrieved memories in some studies and yet failed to do so in other studies. The pattern of results implies that undue confidence is not a consequence of a hypnotic procedure per se, but rather is a function of directly communicating unrealistic expectancies about hypnotic memory retrieval ("You will be able to remember absolutely everything," "Your memory is like a tape recorder and you can review all the details on a television screen in hypnosis"). Other factors contributing to inflated confidence may include high hypnotizability, less meaningful or ambiguous stimulus material, shorter retention intervals, and permission to guess. There is no compelling evidence that hypnotic procedures per se are necessarily associated with inflated confidence, and in most of the studies demonstrating inflated confidence the magnitude of the effect is not large.

Some clinicians state that undue confidence in hypnotic pseudomemories (memory hardening) would make a witness impervious to cross-examination in the courts. Laboratory studies designed to test Orne's hypothesis have consistently failed to support the memory hardening view. These findings provide no support for the notion that the influence of hypnotic procedures on memory are so powerful that witnesses with hypnotically refreshed testimony cannot be effectively cross-examined or that hypnotically refreshed testimony should be found inadmissible because it is particularly resistant to cross-examination.

The overall findings from extensive research on hypnosis and memory indicate that whereas hypnosis may contribute to a modest increase in

www.konkur.in

new information about a target event, at least in certain subjects, there is little evidence that hypnosis per se contributes to an increase in the memory error rate, and that the greater portion of the variance of inaccuracies associated with hypnotically refreshing memory is best attributed to nonhypnotic factors—mainly to poor interviewing techniques that include fostering unrealistic expectancies about memory retrieval, encouraged guessing, and suggesting misinformation.

As an outgrowth of the enormous research literature on memory retrieval, the misinformation effect, and the effects of interview components on the completeness and accuracy of recall, there is a better understanding of how to conduct nonhypnotic and hypnotic investigative interviews that minimize memory error rate while maximizing the retrieval of new information about a target event. These findings for forensic hypnotic interviewing can be summarized in the following guidelines:

1. *Proper informed consent.* Any forensic hypnotic interview begins with informed consent about the nature of memory, memory retrieval, and hypnosis, the risks and benefits of the procedure, and possible alternatives. In the mental health field, informed consent is not seen as a single event, namely providing information at the onset of treatment, followed by signing a consent form; it is best seen as an ongoing process of open communication and adjustment of the unfolding conceptualization of treatment problems, methods, and goals, as part of an unfolding relationship. In some jurisdictions, clients need to be informed that the use of hypnosis runs the risk that any testimony associated with hypnosis, even in a clinical and not a forensic context, may be inadmissible in court. The guidelines cited earlier from the American Society of Clinical Hypnosis include a sample informed consent form.
2. Certain *personality characteristics* are associated with memory distortion. The Gudjonsson Suggestibility Scale (GSS) is a standardized assessment instrument that assesses the degree to which a given individual is vulnerable to accepting misinformation suggestions, confabulating memory reports, and shifting memory reports in response to the emotional tone of an interview. Administering the GSS at the onset of a forensic examination allows a normative assessment of the risk of memory distortion prior to any forensic interview. The Inventory of Childhood Memories and Imaginings (ICMI) evaluates fantasy proneness. About 3% to 5% of

Telegram: @medical_k

www.konkur.in

the general population is very high in fantasy proneness, which predicts significant internal confabulation of fantasy and memory. Empirically derived instruments like the Structured Inventory of Malingered Symptomatology (SIMS), the Malingering Probability Scale (MPS), and the Structured Interview of Reported Symptoms (SIRS) also help to identify the type of individual in a forensic setting that is likely to malinger psychiatric symptoms, and the Test of Memory Malingering (TOMM) and the SIMS help to identify individuals who specifically malinger memory symptoms. These instruments, albeit not foolproof, allow for a reasonable assessment of a variety of situational and personality factors that predict high distortion of memory reports in a forensic context.

3. *Establishing rapport,* making the patient feel at ease with the interview context, and building a relationship are important components of successful interviewing. The interview can begin with statements like, “I want to get to know you; tell me about yourself, something that is important to you.” This section of the interview also includes the rules of interview, such as the importance of telling the truth and being accurate; the permissibility of saying “I don’t know” or “I don’t want to say”; the fact that if the interviewer repeats a question, it does not mean that the previous answer was incorrect; and the fact that the interviewer really does not know what happened and must rely on whatever the interviewee is able to say about the target event.
4. The preamble should set forth the *expectancies externally supplied by the hypnotist* regarding hypnosis, memory, and memory retrieval. The extent to which explicitly supplied explanations about hypnosis, memory, or memory retrieval overwrites the interviewee’s *a priori* expectancy is unclear. Nonetheless, the forensic examiner should make explicit both the interviewee’s a *priori* and explicitly suggested response expectancies.
5. The preamble should include the *establishment of realistic expectancies* about memory retrieval (“You may or may not recall more about”) and the limits of accuracy (“Some of the things you may recall may be more and some less accurate”) and should include explicit instructions not to guess (“Report everything that comes to mind but do not guess”) and explicit instructions to foster an increase in, not a suspension, of critical judgment (“Throughout the procedure you will retain your best judgment as to which things you report are likely to be more and which are likely to be less accurate, knowing that not all details you report will be accurate”).

Telegram: @medical_k

www.konkur.in

6. Next, the interview focuses on *establishing a waking baseline memory* for a meaningful, neutral event from the same time frame (or developmental age) as the target event. In this section of the interview, free recall is encouraged, "Tell me everything you can about."
7. The interview directly addresses the *target event* without explicit cuing. The interviewer must avoid leading the interviewee or being suggestive. Open-ended questions are desirable, such as "Tell me your understanding about what you're being interviewed about today." For interviewees who fail to disclose the target event to an open-ended prompt, the interviewer can state what they have been told, such as "Officer X told me that you might have witnessed an accident on (date) at (location)." Then, free recall is encouraged, with questions such as "Tell me whatever you can recall about (name target event) from the very beginning to the end."
8. Field research on investigative interviews by child protective service workers or law enforcement agents with children suspected of being abused consistently has shown that the failure of many children to disclose abuse in an initial interview is an artifact of the interview situation. A similar finding comes from field research on adult suspects during police interrogations. In such situations, forensic interviewers typically make the mistake of asking too many closed-ended or option-limiting questions at the onset of the interview.

A series of seemingly innocuous, factually based questions like "What is your name?" "Where do you live?" "What grade are you in?" establishes expectancies that discourage free recall and shapes the interviewee's behavior in the direction of only answering questions posed by the interviewer. Under such circumstances, the volume of free recall is significantly reduced, including much potentially valuable information about the target event. Such field research strongly shows that the greater amount of information and the greater accuracy of that information about the target event occurs in the context of *extended free recall.* There should be at least two periods of extended free recall about the target event—one prior to and one following the hypnotic induction—followed by additional periods of extended free recall in hypnosis in subsequent sessions. Free recall is encouraged by such questions as, "Tell me everything you can remember about."

Hypnotic forensic interviewing is likely to be less controversial when the hypnotic induction conveys a *heightened focus or redistribution of*

Telegram: @medical_k

www.konkur.in

attention but avoids specific suggestions about trance characteristics, for example, involuntariness, the suspension of critical judgment, or dissociative compartmentalization that might bias retrieval. When strong emotional arousal, like fear, has interfered with retrieval of a memory for a target event, some evidence shows that the inclusion of *hypnotic relaxation* and instructions for focused recall increases the recall of meaningful information. After a hypnotic induction, it is best to allow the interviewee an extended duration of free recall of the target event after hypnotic induction. Frequent closed-ended questions should be avoided.

The Cognitive Interview was developed by R. Edward Geiselman and Ronald P. Fisher as an alternative procedure to hypnosis for refreshing memory. It is based on basic principles of memory retrieval, with extended free recall and context reinstatement serving as the main components of the interview. More than 50 laboratory studies exist on memory retrieval with the Cognitive Interview. These studies consistently show that the interview yields around 25% to 35% of new information about a target event, typically without a significant increase in the memory error rate. Apart from the Cognitive Interview, per se, these data strongly support the value of *context reinstatement along with free recall* as a primary memory retrieval technique. In hypnotic forensic interviews, there should be an extended period of free recall, followed by context reinstatement plus free recall. The interviewee is reoriented to the time and place of the target event, asked to place themself in the scene, and then to freely recall the event.

Throughout the hypnotic interview, the interviewer should pay careful attention to the *type of interview questions* used. Instructions that encourage extended free recall are best. After an extended period of free recall, “wh-” questions are acceptable, like “what, where, when?” Research has shown that option posing and yes/no questions are of more limited value. The best guideline is to keep interview questions as open-ended as possible and select questions that pose the greatest number of options as answers.

Introduction of follow-up *probe questions* occurs only after an extended period of free recall and context reinstatement in hypnosis fails to yield any more new information. Probe questions must avoid supplying new information, but instead must simply reflect back to the interviewee their words (“Earlier you said the assailant was ‘tall’; tell me more about ‘tall’”). The entire session should be *videotaped*—not just the hypnotic session,

Telegram: @medical_k

www.konkur.in

but all of the preliminary explanations and the preamble, from the point that the interviewee and interviewer meet. The most important principle of any forensic interviewing is completely to *avoid leading and misleading questions.* The interviewer should not suggest or alter *any* content that has not already been reported by the interviewee.

There are no hard and fast rules as to when to use a hypnotic as compared to a nonhypnotic forensic interview. Reasonably prudent forensic examiners familiarize themselves with the case law on hypnotic admissibility for the jurisdiction is question. Strong case law in a state following a per se exclusion rule would merit caution. Cases entailing the highest standards of evidence, like reasonable doubt in a murder case, also merit caution in choosing a hypnotic forensic interview over the nonhypnotic Cognitive Interview.

Most experts further concur that conducting forensic hypnotic interviews with suspects of crimes fraught with difficulties should be avoided except under special circumstances. Hypnosis is indicated in cases involving full dissociative amnesia that have not been resolved by other methods.

The most frequent, justifiable use of forensic hypnosis is in interviewing witnesses and victims of crimes, not to “solve” the crime, but to provide additional evidence William Wester and D. Corydon Hammond have reported that the most frequent use of forensic hypnosis is interviewing witnesses and victims of crimes not to solve the crime but to provide additional evidence. All evidence derived from hypnotically refreshed testimony, as well as evidence from other, nonhypnotic procedures to refresh memory, like the Cognitive Interview, should not stand alone without independent corroborative evidence. The most common use of forensic hypnosis is in seeking new evidence about a crime from witnesses and/or victims.

The most famous case in which forensic hypnosis provided valuable evidence was the Chowchilla school bus kidnapping in the 1970s. Three assailants kidnapped a school bus of mixed-age children, buried the bus and the children alive in a rock quarry, and demanded a large ransom. The bus driver and some of the older children dug their way out by hand. Later the bus driver was hypnotized and asked about the license plate and other identifying details. Under hypnosis, the bus driver recalled a number of but not all of letters in the license plate, and recall sequence was inaccurate. Nevertheless, the recall of some of the letters accurately along with recall of other unusual features of the assailants’ vehicle led to

Telegram: @medical_k

www.konkur.in

a correct computer identification of the vehicle. Witnesses at the scene of sniper incidents and crime scenes involving suspected serial killers or rapists are interviewed by a team whose practice includes hypnotizing witnesses for the purpose of generating a composite drawing of the assailant to be circulated in the news media. This team's protocol has been effective in successfully apprehending a number of high-profile assailants. Most federal jurisdictions do not follow the per se exclusion rule and follow the guidelines approach. Federal guidelines have been developed for the forensic use of hypnosis.

FUTURE DIRECTIONS

The art and science and the domain of hypnosis have evolved into a biopsychosocial model of diagnosing and treating patients with psychiatric and/or medical disorders. As we continue to explore mind–body interaction one can anticipate increased emphasis on evidence-based controlled studies. Recently, Afik Faerman et al., in a very promising study in 2024, using transmagnetic stimulation demonstrated that levels of hypnotic ability were temporarily enhanced even though hypnotic capacities were considered stable through adulthood, by short stimulation of the of the left dorsal lateral prefrontal cortex. Capacities were measured by a hypnotic screening tool, the Hypnotic Induction Profile. Patients with a diagnosis of fibromyalgia were split into two groups. Those receiving the above stimulation showed a decrease in pain when compared to the sham group who did not receive the same stimulation. This study adds greater credence in reinforcing the view that hypnosis integrates the impact of suggestion on one's neurophysiology. In conclusion, hypnosis is not just a technique; it requires listening, observing, and understanding the patient and this approach further reinforces Osler's quote, "The good physician treats the disease, but the great physician treats the patient who has the disease."

ACKNOWLEDGMENT

This chapter represents an update and revision of previous chapters in this series, most recently by Dr. Daniel P. Brown from the last edition. We are indebted to Dr. Brown for their work and retain much of their prose in this current edition.

32.20 Family and Couples Therapy

HENRY I. SPITZ, M.D., D.F.A.P.A., D.F.A.G.P.A., AND SUSAN SPITZ, A.C.S.W., C.G.P.

The family is the foundation upon which most societies are built. The study of families in different cultures has been a subject of fascination and scientific interest from viewpoints as diverse as sociology, group dynamics, anthropology, ethnicity, race, evolutionary biology, and, of course, the mental health field. The confluence of information gleaned from family studies has set the backdrop against which the contemporary practice of family therapy has evolved.

Historically, the family was not viewed in the most favorable light by early observers. Beginning with Freud, the family was seen as the single most important factor in the genesis and maintenance of psychopathology. Psychoanalysis aimed to repair the damage created by early experiences in the patient's family. Unresolved Oedipal conflicts, maternal over-protectiveness, and rivalrous and excessively competitive sibling relationships typify the focal points that illustrate early psychoanalytic perspectives on the family. In point of fact, while psychoanalytic theory applied to family life afforded a rich descriptive language for the understanding of intrafamilial dynamics, much of which is still in use today, it fell short of intervening in the solution to family problems by actually involving more than one person in the session.

Until the 1950s, psychoanalysis was the prevailing theoretical standard and the primary form of psychotherapeutic treatment available to patients with psychological problems. With the emergence of group psychotherapy and the courageous attempts to break with tradition by forward-thinking, individually oriented

Telegram: @medical_k

www.konkur.in

practitioners who began to see whole families in the therapeutic setting, a sea change in the orientation towards families and family therapy had begun. The central premise of the family as a resource rather than a villain was the critical element in liberating psychotherapists to explore the heretofore-untapped resources for change that were an inherent part of every family.

Modern family and couple therapies see the family and the couple as both part of the problem but also as an essential resource available for the resolution of the presenting problem. Family strengths, as opposed to weaknesses, are reinforced, educational elements offer families new modes of adaptation in place of rigid, well-practiced but dysfunctional interactional patterns, and the therapist is the ally of and advocate for the family and each of its members. The specific ways in which this shift in orientation has come about can be readily seen when one looks at the developments in the family therapy field in its historical context.

HISTORICAL TRENDS

Both family and group therapists often point to the work of Alfred Adler at the Vienna Child Guidance Clinic. Adler's involvement of parents in the therapy for their children, a practice that seems axiomatic today, represents a significant departure from the dyadic psychoanalytic model prevalent at the time. It is not until the 1940s that developments relevant to the evolution of contemporary family therapy practice can be seen. During this decade, the biologist Ludwig von Bertalanffy, applied concepts from mathematics and physics in an attempt to create a unifying theory for human interaction. His work emphasized the systemic nature of the human organism and the capacity for change in open human systems. He saw a system as more than the sum of its parts and capable of interacting with other systems.

Bertalanffy used the concept of equifinality to denote the capability of a system to find many routes to the same solution of a problem. A strong opponent of the dehumanized mechanistic theory prevalent at

Telegram: @medical_k

www.konkur.in

the time, he preferred a view that regarded human systems as ecologic organisms with a well-defined value system.

Midway through the 1940s, simultaneous seeds of family therapy were being sewn. First-generation family therapists, including Murray Bowen working at the Menninger Clinic, and Carl Whitaker, at Emory University, became interested in working with schizophrenic families. John Bowlby's work about infant–mother bonding and the perils of insecure or inadequate attachments in early life and its subsequent impact on critical adult relational issues such as trust and forming an enduring interpersonal bond caught the attention of interested family therapists.

Nathan Ackerman is often credited with being the founding father of family therapy. Trained as a child psychiatrist and psychoanalyst, Ackerman retained his emphasis on understanding individual personalities but also had a broader view of how individuals articulated with one another in ways that clashed or meshed. The logical extension of this point of view was to conduct sessions with the whole family and to intervene in often provocative and confrontational ways that would mobilize covert family conflict such that it was available for examination and change in the session.

In the late 1940s and early 1950s, Gregory Bateson began working in Palo Alto, the city whose name was to become synonymous with other influential family therapists, including Don Jackson, Jay Haley, and Virginia Satir (the Palo Alto group), who conducted their work at the Mental Research Institute. Bateson met Norbert Weiner, a mathematician, and expert in the field of cybernetics, and became intrigued with the application of cybernetics to human systems. Cybernetics enabled the discovery of key constructs in family therapy that included the premise that change was not linear as had been previously assumed, but rather it was circular, determined by both positive and negative feedback loops within the family interaction. The "double bind" is perhaps the best-known example of a negative feedback loop in family communication. The famous mother-to-son comment, "I hate you, you're such an angel," is a case in point.

Later on, Jackson, Haley, and Satir turned their attention to the process of communication in severely disturbed patients and their

Telegram: @medical_k

www.konkur.in

families. They were among the first to understand psychotic communications as having meaning and making a certain kind of sense in schizophrenic families. They began to label communication patterns and coined terms that are widely used today. Jackson studied couples and identified complementary and symmetrical relationships and the decoding of redundant relationship patterns or family and couple “rules.” Satir contributed clinical techniques that were aimed at reducing distance among family members. Her experiential approach and therapeutic use of self-disclosure and appropriate physical interaction with family members was later to be seen in the work of many who followed her.

Jay Haley was influenced by the work of Milton Erickson, an exponent of the use of indirect hypnotic techniques, metaphor, and suggestion. Haley’s therapeutic stance was an active and pragmatic one directed toward the rapid resolution of the presenting problem in the family.

Another central influence in the formation of family therapy came from the work of Murray Bowen. Among his many talents, Bowen was a strong theoretician as well as a clinician. His focus began when working with families with a schizophrenic member, during the course of which he made observations about how family members cooperated to maintain an interpersonal space and a degree of individual differentiation from the undifferentiated family ego mass. Bowen’s awareness of triangulation, a process whereby couples and families involve a third person (extramarital affair; mother–father–child triad) or third “thing” (work, alcohol, and drugs), all of which have the effect of attenuating the fears related to closeness and intimacy in primary relationships.

Three other major figures in the development of family therapy were Carl Whitaker, Lyman Wynne, and Theodore Lidz. Whitaker is perhaps best known for his emphasis on the family therapist’s need to interrupt and repattern disruptive, rigid, well-practiced family habits. His open attitude toward his own work being observed by others was the embryonic beginning of the use of the one-way mirror, the consulting team approach, and the use of videotaped sessions as regular fixtures in couple and family therapies. Though often

Telegram: @medical_k

www.konkur.in

flamboyant in style, Whitaker, as is the case with many noted family therapists who came on the scene later, used themselves as an agent of change employing unpredictable, spontaneous, and often confusing techniques designed to upset the homeostasis of an ineffective family system.

Lyman Wynne was interested in repetitive, stereotypical roles taken by family members and theorized that disordered or communication deviance was the conduit through which transgenerational transmission of irrationality went from one generation to the next. He coined the term “pseudomutuality” to denote the role of a false front presented by families who fear both intimacy and separateness. Although the bulk of Wynne’s work was with schizophrenic families, subsequent research and clinical studies have shown that the patterns he identified go beyond the schizophrenic spectrum and are readily observable in personality, mood, and anxiety disorders.

Theodore Lidz, also working with schizophrenic families, implicated the critical role played by fathers in these families. Prior to Lidz’s work, the main influence on the intrafamilial environment of these families was felt to be the mother. Lidz and his colleagues defined specific destructive patterns of paternal interaction with spouses and children that led to serious adverse psychological consequences. When Lidz worked with dysfunctional couples, he also delineated maladaptive patterns that led to marital discord or disruption. Marital schism, a state wherein partners compete rather than collaborate and fail to integrate their differences in a functional manner, and marital skew, where a conspicuous power imbalance exists, and active antagonism predominates, are the most widely recognized examples of Wynne’s terminology for dyadic relationships.

These family and couple therapy pioneers set the stage for the decades to follow that bore witness to the virtual explosion of family therapy research and practice and the emergence of defined schools of family therapy. The family and couples therapy literature expanded exponentially following the groundwork they laid. Corresponding acceptance of family therapy as a viable clinical entity now supported by empirical research studies gave greater momentum to family and

Telegram: @medical_k

www.konkur.in

couples work and the creation of several mainstream models of family therapy practice.

DEFINITION

Family therapy is a mosaic of techniques, all of which have the shared goal of direct alteration of maladaptive family processes. In point of fact, it is more accurate to speak of family, and couple therapy in the plural as family and couple therapies since the array of interventions with the above goal in mind is impressive. The coalescence of discreet therapeutic orientations has resulted in the creation of several distinct tracks in the actual clinical practice of family therapy. These orientations toward the treatment of family problems will be the subject of the next section.

SCHOOLS OF FAMILY THERAPY

Schools of thought in family therapy are like windows in a greenhouse, each with its own orientation when observing the family through a different pane. Each has its own lexicon, goals, and focal points but all share a common purpose in attempting to find innovative ways to provide time and cost-effective therapies for families in distress.

A representative sampling of the current state of popular family therapy techniques shows the clear linkage between first-generation family therapy described above and how it manifests itself in modern clinical practice. Gurman, in the chart that follows, has simplified the apparent overlap in the different schools by outlining the major schools of family therapy, the influential practitioners of each method, and the focus of each technique (Table 32.20–1). This schema allows one to compare and contrast each family therapy model in more depth.

Cognitive/Behavioral

The *cognitive/behavioral family approaches* have their theoretical base in social learning theory, operant conditioning, and cognitive

Telegram: @medical_k

www.konkur.in

psychology. Cognitive and behavioral therapies require active therapist participation both in structuring the framework of therapy, finding circumscribed as opposed to global goals, and having a planned sequence of interventions and instruction in mind in order to reach the solution of the presenting problem. For the most part, cognitive/behavioral family therapy is brief, symptom focused that places low value on revisiting historical material in sessions. Like most family and couples interventions, with the possible exception of the psychodynamic approach, it is extremely pragmatic, focused in the here-and-now, very structured, interactive, and directive.

The overriding premise is that problems are learned behaviors that are well-practiced and consequently almost reflexive in nature. This model helps expand the couple or family's repertoire of functional communication and actions and, in so doing, incorporates new ways of thinking about familiar but dysfunctional family interactions. For example, the wife who feels that her husband is working too hard delivers that message from a position of caring and concern. The husband in this case "hears" the message as critical of him and feels that his partner is accusing him of being a workaholic and a neglectful father. The cognitively oriented therapist would identify this irrational belief or cognitive distortion, clarify it by supplying an alternative, more positive reading of the message, encourage the use of reality testing to keep catastrophic, or all-or-nothing thought patterns in check and reinforce all new, more adaptive and rewarding responses on the husband's part.

An essential ingredient in adapting individually based cognitive/behavioral techniques to the couple and family milieu is the added emphasis on social exchange theory. This adds a dimension of mobilizing the reward system in the system. Families and couples are taught to replicate those behaviors that increase the number of rewarding interchanges: decrease negatively cast feedback and acquiring collaborative problem solving skills.

The therapeutic tool kit for cognitive/behavioral therapy with families and couples contains many of the same techniques used in individually based cognitive therapy. Positive reframing, cognitive restructuring, insuring a shared base of assumptions and

Telegram: @medical_k

www.konkur.in

expectations between partners and among all family members are all parts of the therapeutic equation.

In order to induce behavioral change, in-session exercises and educational elements are coupled with homework assignments to be completed between sessions. Cognitive/behaviorists do see whole families but feel more comfortable than practitioners from some other schools in seeing those subsystems in the family that are most relevant to the resolution of the identified problem. Therapists of this orientation are also comfortable with the concept of repetitive brief modules of treatment designed to address a specific issue each time over the course of time.

Jacobson and others have validated the benefit of the cognitive/behavioral approach. Advocates of this model have created impressive arrays of instruments for measuring parameters of change. Generally speaking, the cognitive and behavioral therapies are the most specific about technique (what they actually do in family sessions) and about the ways in which they assess the efficacy of their work.

Novel applications of these approaches have been used for parenting skills training, childhood conduct disorders, developmental disabilities, premarital counseling, and bipolar disorder. The integration of cognitive/behavioral family work with other therapies has been helpful with eating disorders, substance abuse, and anxiety disorders.

Table 32.20–1. Schools of Family and Couple Therapy

Therapeutic Approach (Examples)	Core Concepts	Typical Goals	Common Strategies and Techniques	Comments
Behavioral/cognitive-behavioral (James Alexander, Neil Jacobson, Donald Baucom, Gerald Patterson)	Functional analysis Social learning theory Communication and problem solving Attributional style	Resolution of presenting problem Enhanced communication and problem-solving skills Balance between change and acceptance	Communication and problem-solving training Acceptance training/reattribution techniques Parent management, emphasis on behavior/consequences Therapist as educator	Functional analysis, not treatment techniques, is defining characteristic Arguably the most empirically supported of all family and couple methods
Bowen family systems (Murray Bowen, Philip Guerin, Michael Kerr, Monica McGoldrick)	Differentiation of self Triangulation Emotional cutoffs Family emotional system Sibling position	Increased differentiation Detriangulation Cutoffs resolved Improved ability to manage anxiety	Use of genogram Therapist as "coach" Education about multigenerational family processes	Often conducted with only a single patient Influence continues but has waned since Bowen's death
Experiential–humanistic (Susan Johnson & Leslie Greenberg, Virginia Satir, Carl Whitaker)	Communication styles (e.g., placater–blamer) Psychotherapy of the absurd Attachment theory	Fostering creativity (comfort with "craziness") Increased family cohesion Personal growth, self-esteem Tolerance for conflict	Resolving the battle for structure and the battle for initiative Frequent use of cotherapists Family sculpture Use of self Family reconstruction	Since Whitaker's death, symbolic–experiential approach receding in visibility Emotionally focused therapy one of few nonbehavioral or psychodynamic couple methods increasing in influence
Integrative (Alan Gurman, William Pinsof, Douglas Snyder, Froma Walsh)	Importance of and relationships among multiple levels of experience Theoretical and technical eclecticism	Improved communication and problem solving Enhanced interactional insight Presenting problems	Combinations of cognitive-behavioral and psychodynamic methods, in general systems context	Along with behavioral and psychoeducational methods, the most sensitive to research findings Attempts to match interventions to problem and family
Mental Research Institute brief therapy (Don Jackson, John Weakland, Paul Watzlawick)	Distinction between "difficulties" and "problems" Communication processes Symptom as communication First-and second-order change	Resolution of presenting problem Second-order change	Reframing Therapist maneuverability	Historically overlaps strategic, but with important differences (e.g., "function" of symptoms)
Feminist (Virginia Goldner, Rachel Hare-Mustin, Betty Carter)	Raising gender consciousness Underlying effect of gender	Gender equality Recognizing gender inequities	Raising consciousness Identifying and challenging culturally constructed narratives	Not so much a way of intervening as a set of issues to address; has had a pervasive effect on family and couple therapy
Narrative (David Epston, Michael White, Harlene Anderson)	Constructivism "Languaging" "Stories" socially created Problem-saturated descriptions	Resolution of presenting problem Enhancing undiscovered parts of self	Externalization of problems Focusing on "unique outcomes" Creation of new meaning via "re-storying." Therapeutic letters	Currently very popular but rarely acknowledges overlaps with cognitive and behavioral theory
Psychodynamic–psychoanalytic (Nathan Ackerman, Henry Dicks, Clifford Sager, Jill Scharff & David Scharff)	Object relations Projective identification Splitting Scapegoating	Improved insight Genetic (historical) awareness Enhanced empathy De-emphasize presenting problem Disentangle interlocking pathologies	Transference, resistance, and countertransference analysis Creation of holding environment Interpretation Emphasis on therapeutic alliance	Probably influences family therapists' clinical work more than is usually acknowledged
Psychoeducational (Carol Anderson, Ian Falloon, William McFarlane, David Miklowitz)	Biopsychosocial theory Stress-diathesis Expressed emotion	Enhanced family coping skills Improved communication and problem-solving skills Relapse prevention	Survival skills workshops Family management Family information and education Concurrent use of psychopharmacology	Without doubt, the most effective family-based approach for families with a member with major psychiatric disorder
Solution-focused (Steve de Shazer & Insoo Berg, William O'Hanlon, Michele Weiner-Davis)	Core Concepts Focus on solutions, not problems Unimportance of problem etiology Disbelief in resistance	Typical Goals Resolution of presenting problem Creation of solutions	Common Strategies and Techniques Scaling questions Miracle questions Exception questions Client empowerment Coping questions Questions regarding presession change	Comments Grows out of basic Mental Research Institute philosophy, emphasizing solutions more than problems Has made extraordinary claims of effectiveness
Strategic (Milton Erickson, Jay Haley, Cloe Madanes, James Keim)	Power and control Family life cycle Symptom-maintaining sequences Function of problems	Resolve presenting problem Disruption of problem-maintaining sequences	Persuasion Paradoxical injections Insight downplayed Pretend and ordeal techniques	Unfortunate de-emphasis on biology, psychiatric diagnosis, and personality theory
Structural (Harry Aponte, Salvador Minuchin, Jose Szapocznik)	Boundaries Hierarchies Coalitions and alliances Complementarity Engagement–enmeshment	Increased flexibility Adaptability to developmental change Balance between connectedness and differentiation Subsystem functioning	Unbalancing Enactment Joining	Arguably the most influential family therapy approach
Transgenerational (Ivan Boszormenyi-Nagy, James Framo, Laura Roberto-Forman)	Invisible loyalties Ledgers and debts Family mourning Personal authority	More universal than family-specific goals Increased trust Repair ruptured relationships	Multi-directed partiality Family-of-origin sessions Use of co-therapy	Almost all multi/trans-generational methods have significant psychodynamic underpinnings

Family Systems

Family systems formats encompass a broad range of techniques all of which are unified by their belief that the family is a human system with unique properties that contribute to the current emotional and behavioral configuration. Much like a clock with interlocking gears

Telegram: @medical_k

www.konkur.in

where one does not move without affecting the others, without therapeutic intervention, dysfunctional families become synchronous and stuck over time.

Structural

The most frequently employed subdivisions within the systemic approach are the closely allied structural and strategic therapies. Salvador Minuchin and his colleagues at the Philadelphia Child Guidance center were the originators of *structural family therapy*. Their early work with families that had a symptomatic child formed the basis for the observations about dysfunctional patterns in families with a symptomatic member. In particular, strategic therapists look at boundary issues in families to see where the family lies along the spectrum of over-involvement (enmeshment) and detachment (disengagement). Similarly, those who think systemically look for mechanisms within the family that do not serve them well. The detouring of parental marital conflict by focusing on a child with psychological symptoms is a case in point.

Structural family therapy is a very leader-centered modality that uses directives geared to initiate change by stimulating affect, increasing the therapeutic alliance, and by employing both logical and paradoxical instructions that would induce change in the rigid family system. Once identified, the structural family therapist aims to reset the imbalances in the family system through a variety of therapeutic interventions.

Commonly, the structural therapist tries to help the family solve the current problem by defining clear and attainable goals, establishing appropriate generational boundaries, assisting parents to take leadership positions in the family, offering alternative, often provocative viewpoints that differ from the family's skewed understanding of the problem, and restoring or helping to create functional subsystems within the family.

According to Nichols, structural family therapy follows seven steps: (1) joining and accommodating—reducing initial anxieties about therapy; (2) enactment—encouraging spontaneous interaction among family members to demonstrate the properties of the system and to

Telegram: @medical_k

www.konkur.in

allow for insertion of behavioral instructions that run counter to the family's established pattern of behavior; (3) structural mapping—broadening the focus from the identified patient to a family-as-a-whole level; (4) highlighting and modifying interactions—turning the volume up or down in order to illustrate a behavioral sequence; (5) boundary making—aligning relationships between subgroups in the family; (6) unbalancing—using joining maneuvers to induce change in an unequal or destructive dyad or triad in the family; (7) and challenging unproductive assumptions–introducing notions that run counter to the established family belief system. The structure of the family with respect to concepts of boundaries, alliances, splits, cut-offs of relationships, complementarity, and positive and negative subsystems within the larger family system are the focal points for the structural approach.

Life Cycle

As an example of another focus under the umbrella of systemic/structural therapies is the *life cycle approach* favored by McGoldrick. This practice uses the in-session drawing of a genogram, similar to a genetic diagram or family tree but with much more verbal commentary by the family. Bowen created this technique to map and flesh out a family's multigenerational history over time. The assumption that underlies this method is that transition points in normal family development can become sticking points for families who now seek therapy. The use of a life stage, transgenerational orientation helps engage resistant families by depathologizing their current struggles and relabeling it as a common and understandable function of family life.

Strategic

Strategic family therapy has its historical base in the early work of Bateson and the Brief Therapy Group at the Mental Research Institute in Palo Alto. Don Jackson, Jay Haley, Virginia Satir, John Weakland, and Paul Watzlawick are famous charter members of this school. Over time, the ranks of strategic family therapists have been

Telegram: @medical_k

www.konkur.in

joined by other prominent figures in the field of family, including Mara Selvini Palazzoli and the Milan Strategic Therapy group who have incorporated their own variations on the theme of intervening strategically through the use of a team approach, circular questioning, and attempts to provide alternative understanding for dysfunctional or “stuck” family systems.

Noteworthy contributions have come from Jay Haley and Cloe Madanes, building of the hypnotic techniques of Milton Erickson who emphasized a new way of thinking about and changing psychological symptoms. Madanes defined six useful parameters that were essential to understand before formulating a plan of intervention. These include assessing whether the symptomatic behavior is voluntary or involuntary, reorienting power dynamics such that the person who acts the weakest in the family is often the most powerful or controlling, viewing symptoms as part of the communication in the system and determining whether or not maintaining the symptom serves a purpose (albeit maladaptive) for the family; evaluating the hierarchical structure and corresponding role that go with them in order to approximate fairness and equality, understanding the motivational basis (benign or malignant) for problematic behavior, and deciding whether or not the troublesome symptom is a misdirected attempt to gain acceptance love and approval.

Once an appreciation of the presenting problem is attained, a plan for intervening in the system is created. Strategic therapists, like their structural colleagues are very active in sessions and in their use of out-of-session assignments. Stemming from their origins in communication theory, strategic family therapists focus heavily on those forces that generate and reinforce resistance to change in families and work in a brief therapy format alone or with a cotherapist.

Some of the more recognizable techniques include the use of directives, circular questioning, paradoxical messages including prescribing the very symptom for which the family seeks help, assigning rituals or ordeals that disrupt the family homeostasis, and reframing behavior in a less pejorative and pathologic definition to one that emphasizes the protective nature of family or individual defenses. Strategic therapists are keenly aware of the context in

Telegram: @medical_k

www.konkur.in

which the symptom arises in the family. A child's refusal to go to school but their willingness to go out of the home to pursue pleasurable relationships with peers can be a context dependent issue worthy of exploration in family sessions.

Strategic therapists take positions in therapy that poke and test the response surface of the family system. Depending upon the reaction evoked, a strategy is designed to alter the process. Families can be compliant, noncompliant or pseudocompliant in response to directive or prescriptions put forth by the therapist. Noncompliant and responses that are actually resistances disguised as compliance call for astute identification and construction of tasks that tap the roadblocks to change in the family.

An often-cited criticism of strategic therapy is that it is manipulative and nonempathic. On the contrary, reputable strategic therapists are extraordinarily sensitive to the families they are seeing and are aware of the feelings evoked in them when using the strategic interventions. Additionally, strategic therapists are often called upon to see individuals or families who have been refractory to other forms of therapy and where a family may contain a member with a potentially life-threatening condition such as severe anorexia nervosa. When conventional therapies have been ineffective, the creativity, incisiveness, and pragmatism that typify good strategic therapy will often succeed where others have failed.

Experiential/Humanistic

Experiential/Humanistic family therapy is associated with the names Carl Whitaker, Virginia Satir, and, more recently, Susan Johnson's emotionally focused couples therapy format. The practice of family therapy has undergone dramatic change since its inception resulting in an array of technical formats that rely heavily on the here–and–now experience of the family in therapy. Satir retained her focus on communication patterns but added an emphasis on experiencing emotions as they would arise in a nurturing therapeutic climate. Satir was not afraid of showing compassion by touching family members at times of profound emotional experiences. This approach never encourages boundary violations but does advocate human responses

Telegram: @medical_k

www.konkur.in

to authentic suffering, struggle, despair, depression, and other intense affective states. A humanistic belief system and an appreciation of the vicissitudes of inadequate or damaging attachment experiences with their consequent feelings of isolation, deprivation, and emotional hunger form the foundation of most of the popular experiential family therapy experiences today.

A positive but not falsely reassuring tone is the backdrop against which therapy is conducted. The person of the therapist is one of the most powerful aspects of this technique. The therapist's positive belief in the family or couple's ability to change, the conviction that people have untapped resources within themselves that can be mobilized in the service of change, contribute to an optimistic but realistic view that resolution of longstanding problems is possible. This is not to say that experiential/humanistic family therapy is only supportive. Confrontation, in sensitive but direct ways also forms a regular component of the treatment philosophy.

Interventions designed to liberate submerged affect in present time can be accomplished through family sculpting, role playing and other action-oriented methods.

The overarching goal of experiential/humanistic family therapies is to validate aspects of the self and promote emotional well-being. Problem solving is a desirable but less urgent goal than it is in the structural, strategic, and behavioral approaches. Perhaps the renaissance of interest in humanistic family approaches has to do with a reaction to the under emphasis on the internal feeling state of the individual that received less attention in earlier cognitive/behavioral methods and the impact of the impersonal, often insensitive, attitude of managed care and third party payers. Regardless of cause, the experiential and humanistic approaches have earned a secure place in present day family therapy.

Psychoeducational

Psychoeducational family therapy has been and continues to be a mainstay in the integrated treatment of people with severe and disabling mental illness. The value of small groups for emotional support and the dissemination of accurate information about a

Telegram: @medical_k

www.konkur.in

condition shared by members have been amply demonstrated in the group psychotherapy literature. In more recent times, the scope of psychoeducational has branched out to include family problems that are child focused. These include attention deficit disorder, autism spectrum conditions, and a range of behavioral and conduct issues. Families coping with a serious medical condition are also ideal candidates for a psychoeducational experience either as a solo family or in a multifamily group format.

In principle, psychoeducation is a biopsychosocial orientation that provides a vital support function for families in crisis. Initially, psychoeducation helps stabilize a traumatized family system through the provision of a supportive and knowledgeable therapist or interdisciplinary cotherapy team. In the case of medical illness like cancer, a team is ordinarily composed of a family therapist and a coleader with a background in oncology.

Strong emphasis is placed on teaching coping skills to better deal with the condition in question. Much of the original work in psychoeducation addressed schizophrenia and its impact on family life. When applied to psychosis, psychoeducational therapy teaches families several critical skills, including how to tell when someone is showing signs of decompensation, how to arrange for rehospitalization, plans for ensuring the physical safety of all involved, how to be helpful in ensuring that the schizophrenic family member complies with taking medication, and keeping scheduled appointments for out-patient treatment. Techniques to control the level of expressed emotion (EE) to a level that is not overwhelming for the psychotic family member are also essential parts of the psychoeducational approach. Studies have clearly confirmed that lowering the levels of EE is correlated with a reduction of the relapse and rehospitalization rate in patients with schizophrenia. Similarly, psychoeducational methods, in general, have been shown to be more effective than other nonpharmacologic interventions for the prevention of decompensation leading to the need for hospital readmission

Carol Anderson and Ian Falloon are two of the best known exponents of this method and have expanded their use of the

Telegram: @medical_k

www.konkur.in

psychoeducational model to include home visits to hold family meetings, providing intensive, day-long workshops for families and coping strategy seminars for family and significant others involved in the life of a person dealing with schizophrenia. The thrust of these meetings is to help the family understand mental illness as a biologically driven entity and to avoid the temptation to blame, ridicule, or chastise the affected person. Self-care for those family members who are charged with overseeing the daily life of a psychotic family member is strongly advocated in order to avoid caregiver burnout.

The psychoeducational team's stance is very supportive and, in a nonpatronizing way, synthesizes and translates the medical and psychiatric data to the family in a form that they can convert into constructive action. McFarlane has done just this in his list of guidelines for family and friends of schizophrenics. These guidelines orient the family along several parameters: recovery is a slow process, set realistic limits, avoid harsh confrontation or arguments, comply with the psychiatrist's recommendations regarding medication and frequency of visits, avoid drugs and alcohol, and have modest goals for the patient and expect change to occur in small steps over time. This combination of distilled scientific knowledge and applied common sense are emblematic of the psychoeducational model of family therapy.

Very often, psychoeducational practitioners choose to use the multifamily group composed of as few as two or as many as 10 families as participants. The advantages of this format is that it enhances the support elements for families, destigmatizes the shame in having a psychotic family member allows for cross-family learning by seeing in other families in the group what one is unable to see in themselves, facilitates a broader exchange of information and coping strategies among peers, and counters the isolation that often evolves in families consumed by having to care for a medically or psychiatrically ill member.

Psychodynamic

Telegram: @medical_k

www.konkur.in

Psychodynamic family therapy—The thread that runs through psychoanalysis to modern psychodynamic therapies has followed a linear path. Many early family therapists such as Ackerman, Bowen, Jackson, and Minuchin were trained psychoanalysts. Henry Dick's classic book *Marital Tensions* offers an early recognition of the differences in transference and other analytic techniques when working dyadically as contrasted to individual psychotherapy. How to directly apply, adapt, or discard time-honored elements of the analytic model transition to make the transition to family work was the first challenge these therapists faced.

Would it be relevant and appropriate to use the basic cornerstones of psychoanalysis, the analysis of transference and resistance, dream interpretation, the nondemand posture of the analyst, the quest for access to the unconscious mind, and the focus on early childhood experiences as the vehicles for treating families? The history of modern psychiatry tells us that many of the components of psychodynamic theory and practice are applicable to other therapies including group, family, and couple therapies but that significant modifications in technique and attitudinal shifts on the part of the therapist are required in order to do so.

Simply stated, Freudian and earlier analytic models have given way in favor of object relations and self-psychological perspectives. Generally speaking, exponents of the modern psychodynamic school believe that viewing interpersonal as well as individual themes is essential if dynamically oriented family therapy is to succeed. Systemic concepts have been grafted onto the exclusive focus on the inner world of the individual resulting in a broader canvas on which the family therapist works. Empathy, establishing a therapeutic alliance, functioning as a container for intense affects, supplying a secure holding environment for each individual and for the whole family, and providing a tight frame within which to conduct the therapy are all parts of the modern psychodynamic method. Interpretation is used more in this model than in any other family technique. The presenting problem is important but forays into the past life of the family are actively encouraged.

Telegram: @medical_k

www.konkur.in

The leadership style is more active than in traditional dynamic therapies but there is ample room for the development of transference. Using transference as the prototype for how psychodynamic family and couple therapists view modify and work with traditional analytically derived concepts with families and couples, the object relations orientation as advocated by Jill and David Scharff affords an excellent example. In this model, transference in family and couples exists on three levels: contextual transference, focused transference, and shared contextual transference.

Contextual transference relates to the early phase of treatment when the role of the therapist is to identify and address, in a supportive and nurturing manner, those initial anxieties that families have about unfamiliarity with therapy, the administrative aspects of treatment (fees, scheduling, physical setting), and anticipating early resistances. The therapist strives to convey a feeling of emotional safety and serves as a positive “holding environment” or container for real or imagined fears about the therapeutic process.

Focused transference is most closely allied to the transference manifestations in conventional psychoanalytic therapy. It consists of the projections onto the therapist, distortions or misinterpretations of the therapist’s words or actions, and other present-day phenomena that reflect unresolved issues stemming from early childhood experience.

Shared contextual transference is easiest to see when working with couples. It entails understanding a couple’s response to a holding environment, a critical issue for dyadic relationships insofar as one of their major tasks is to create a secure holding environment for each other.

Additionally, recognition of regressive recreations of earlier family configurations, examining triadic transferences, and appreciating the transference issues that determine the process of partner selection in relationships are all illustrative of how transference, a core concept in psychoanalysis has been creatively incorporated into twenty-first century family and couple therapies.

Telegram: @medical_k

www.konkur.in

Narrative

It is not possible to comprehensively cover all the emerging schools of family therapy other than to note that narrative and solution focused therapies are other prominent postmodern constructivist theories about family life. The premise in *narrative therapy* is that the shared narratives constructed over time create the perception of reality embraced by the family often resulting in narrow, rigid family myths and misconceptions. The therapy endeavors to broaden the family perspective by helping the family construct new, shared stories leading to more accurate narratives that, in turn, mediate a change to new behaviors.

Solution Focused

Solution-focused therapy is, as the name implies, a quest for positive resolutions to dilemmas with which the family is struggling. Through the use of a series of techniques that involve pinpointed questions geared to expand the cognitive and behavioral repertoire of the family, the therapist guides people toward new ways of thinking about old issues relying heavily on positive reinforcement, an optimistic attitude that looks toward solutions not problems, and a search for exceptions to the situations that the family feels mired down and powerless.

CLINICAL APPLICATIONS

General Clinical Principles

Family therapy and individual psychotherapy may be viewed as opposite poles of a spectrum of therapeutic interventions each requiring different modes of engagement. Individual therapy is a new relationship where interaction between therapist and between therapist and patient stimulates affects that form the basis for examination in dynamically oriented individual work. Initial goals are to engage the patient and create a relationship into which strong feelings, both past and present will develop.

Telegram: @medical_k

www.konkur.in

In family and couple therapy, the opposite is the case. Families and couples have relationships and histories that predate the new therapy and usually have a surplus of affect that is out of control. Coming in when a crisis has arisen is a frequent entry posture of couples and families. These circumstances call for decelerating interventions designed to stabilize the system. Affective intensity needs to be reduced to a degree that the family system can gain a sense of equilibrium. The family therapist has to find a point of entry into the current family configuration. Doing what is appropriate in early individual therapy would definitely produce untoward results in the family setting. With this principle in mind, it makes clinical sense to understand the strengths and limitations of family and couple therapies and for whom they are best suited and the common clinical management issues that occur that require thoughtful treatment planning and interventions.

Indications and Contraindications

Family and couple therapies are relational therapies. The clinician is primarily focused on the unresolved interactional issues that the family or couple presents at the time of the initial interview rather than on individual diagnoses. Despite this, since family and couples therapy has been demonstrated to be useful in specific psychiatric conditions, some practitioners prefer to use DSM criteria for deciding when family therapy is indicated. In these circumstances, conditions including schizophrenia, bipolar disorder, major depressive disorder, and substance abuse are the yardsticks by which a determination is made about suitability for a family or couples approach. The majority of family therapists prefer a more systemic or group-based orientation when thinking about the indications and contraindications for family or couples therapy (Tables 32.20–2 and 32.20–3).

Telegram: @medical_k

www.konkur.in

Table 32.20–2.
Indications for Family and Couple Therapy

Telegram: @medical_k

www.konkur.in

1. When problems exist across generational boundaries—Grandparents feel excluded from access to grandchildren, conflicts between a father and son or daughter working together in a family business, sharing the living space with more than one generation in the family.
2. At significant times in the family life cycle—Leaving home, birth of a child, contemplating a geographical move, death in the extended family.
3. Whenever a child or adolescent is symptomatic and designated as “the problem”—Adolescent acting out with drugs, alcohol, and promiscuity; cutting; children who refuse to attend school and/or have psychosomatic symptoms.
4. When a couple or family calls or comes in requesting a family therapy.
5. When serious medical or psychiatric illness is present in a family member—cancer, schizophrenia, bipolar disorder.
6. Families stressed due to racial, cultural or religious heritage, interfaith and interracial partnerships.
7. Issues that stem from recombined or blended families—friction between step-parent and biologic child; problems with role definition as parents; children who feel themselves to be in a loyalty bind between divorced parents.
8. Families in which someone intrudes upon or sabotages another member’s individual psychotherapy—intrusive parents threatened by the independence of the adolescent or young adult in individual therapy; parental abuse of power by refusing to pay for treatment.
9. Families or couples where societal pressure and prejudice has significant emotional spill over into family life—gay parents with children; older couples contemplating adoption of a child; common-law partnerships.
10. When sibling issues are beyond the control of the parent(s)—physically assaulting a younger sibling; excessive competition for parental attention and affection.

For couples:

Telegram: @medical_k

www.konkur.in

1. When the chief complaint is presented as a sexual issue—This may indeed be an indication for sex therapy but other unresolved relationship issues masquerading as a sexual problem should be ruled out first.
2. Following the discovery or disclosure of an affair—the threat of divorce or break up; restoring the power imbalance in the dyad.
3. When communication problems are the basis for seeking treatment—escalating anger; repetitive arguments without resolution; emotional detachment and break off of communication.
4. When partnerships are ending and children are involved—partners seek therapy not to resolve relationship issues but to minimize damage to children; decision-making that involves coparenting.

Telegram: @medical_k

www.konkur.in

Table 32.20–3.
Contraindications for Family and Couple Therapy

Telegram: @medical_k

www.konkur.in

1. When a family has an emotionally unstable member or members and the risk of stirring up intense affect in session might lead to decompensation or other adverse effects—schizophrenia, major depression, impulse control disorders, addictions, dementia.
2. When there is a history of violence in the family—elder abuse; domestic violence, drug and alcohol dependence.
3. When a family is collusive, rigidly unified and inflexible in considering that there may be a problem in the family/couple.
4. When therapy runs counter to the belief system in the family—sense of shame; religious or cultural beliefs discourage therapy.
5. When essential members of the family cannot or refuse to be included in the sessions—father feels that “real men” handle problems on their own; family member offers work schedule as a reason for being unable to participate.
6. When family therapy should not be the first-line treatment—detoxification of addicted family members should precede decision for family/couples therapy; psychotic family member who is not adequately medicated.

For couples:

1. When a pairing defense is so strong that both partners recoil at the suggestion of couple therapy; rare relationships where a folie a deux exists such that the couple has a shared delusional system and/or a rigid, ego-syntonic view that they do not require therapy.
2. When the level of motivation is unequal or deceptive—one partner has not disclosed his/her plan to leave the relationship.
3. When a member of the couple has an active relationship with someone other than the partner—extramarital affairs; homosexual relationship simultaneous with heterosexual primary partnership.
4. The threat of domestic violence or crisis creation in vulnerable partnerships—history of physical abuse.
5. In cases of documented child physical, sexual and/or emotional abuse, extreme caution should be exercised before exposing the

Telegram: @medical_k

www.konkur.in

child to the abusing parent(s) even in an ostensibly therapeutic and safe climate of family therapy.

Table 32.20–2 is an integrated model that incorporates both diagnosis and presenting problem as criteria for recommending a family or couple form of therapy.

Assessment and Evaluation

Evaluation procedures take numerous forms in family therapy. It is important to note that aside from data collecting, the initial contact with the family or couple may simultaneously be the first session of their family therapy experience. The most common approach is to see the whole family for family therapy evaluation and both members of the couple for couple therapy. The closer the therapist subscribes to a strict systemic approach the more the requirement that all members be present. Alternatively, other family therapists work with whatever portion of the family system presents itself for the initial session with the thought in mind of recruiting absent members by using the existing forces within the family. The usual time allotment for a first family or couple session is 1 hour but time-extended sessions are common if, for logistical or clinical reasons, a longer meeting would allow for the most comprehensive view of the family/couple system.

Telegram: @medical_k

www.konkur.in

Table 32.20–4.
Couples Therapy Initial Interview

Telegram: @medical_k

www.konkur.in

1. Orient the couple to the joint format—emphasize the need for both partners to be present in order to have input and how couple therapy differs from individual psychotherapies.
2. Request that each person state his/her perception of the problem —a majority of couples experience the locus of disharmony as being in the partner rather than in themselves.
3. Try to engage both partners in the first session—balance all interventions especially praise and confrontation such that neither partner feels rejected.
4. Identify and clarify relationship patterns and structure—is the present problem ongoing since the relationship began or is it in reaction to new circumstances.
5. Formulate the problem without singling out either partner—shift the focus from the identified patient model to the identified problem model—the question is often posed in the following form, “How long has this been a problem for the two of you?”
6. State the purpose and some goals of couples therapy in nontechnical language or jargon—to resolve communication problems; to learn how to fight fairly; to address specific issues around parenting.
7. Think of ways of gaining entry into an established system—wait for a naturally occurring pause before entry or try to interrupt a pattern to see how the couple responds.
8. If couples therapy is indicated, try to define an initial treatment contract and get agreement of both partners to participate—plan for a next meeting and give some indication of what the general focus might be, i.e., communication issues.
9. Anticipate early resistances—denial defenses with alcohol and drug related issues; the temptation to stay with familiar behavioral patterns even though they may not be working but are less frightening than the prospect of change through couple therapy.
10. Clarify myths and misconceptions—joint therapy is more likely to lead to dissolution of the partnership; being in joint therapy is an indication of an unworkable relationship.

Telegram: @medical_k

www.konkur.in

11. Leave time for the couple to ask questions about anything in the session that was unclear or worrisome—common concerns are the expected duration of therapy, cost factors.
12. Assign “homework” if indicated—instruct them to arrange to spend 5–10 minutes each day or alternate days in face to face conversation on any nonconflictual subject without outside distractions that include television, children, or other impediments to engagement with one another.
13. Summarize what you want the couple to take away from the first meeting—point out the themes that appear to be urgent ones; commend the couple for being open enough to explore the possibility of joint therapy.
14. Delineate what your role will be in the therapeutic process—make sure to emphasize how a collaborative treatment model works and that the therapist will be an active participant in the ongoing therapeutic process and will be unavailable for individual phone contacts or sessions that usually result in telling “secrets” to the therapist.
15. Address “housekeeping procedures”—appointment times; frequency and length of sessions; fees; what happens when one partner cannot attend a session; policy about individual sessions during the course of joint therapy; get permission that is HIPPA compliant for communication with other (individual) therapists; obtain informed consent from both partners.
16. Stop on time unless there is a crisis which cannot be handled in any other way than by extending the session—commonly a catharsis of intense feelings is opened up in a first meeting, allow time for both expression of emotion and putting a cognitive structure on it in order to gain closure on the session.

Seven global areas are subject to assessment in the first meeting with a family or couple: (1) the presenting problem (stated as the family defines it); (2) communication patterns; (3) styles of problem solving; (4)regulation of affect; (5) family roles—alliances, splits,

Telegram: @medical_k

www.konkur.in

coalitions; (6) family rules; (7) impulse control; (8) and the prevailing family beliefs, traditions, and narratives.

Pragmatically, the data for the assessment comes from the therapist's observation of the spontaneous interactional patterns and from the specific questions posed by the interviewer (Table 32.20–4). Many of the techniques used in family and couple therapies are interchangeable and applicable to both. The material that follows details the conduct and content of an initial evaluation of a couple with particular emphasis on the role and posture of the therapist but the points outlined apply equally when modified for working with a family format.

These are the general clinical tasks for practitioners of diverse theoretical orientations to cover in the first contact with a couple. In order to ensure that relationship-relevant themes are included in the interview, it is essential that the therapist have in mind a set of variables that will glean the information they need in order to understand the partnership issues and to begin formulating a treatment strategy. Table 32.20–5 lists a practical set of questions and areas of observation that will yield the information most relevant to creating and directing the ongoing treatment process.

When converting principles into practice, the process is rarely without potential pitfalls that call for prompt recognition and astute clinical management. In both family and couple therapies, it behooves the therapist to anticipate that there will be resistance to change. More often than not, this is fear based and can be traversed if the therapist is alert for common roadblocks to progress. To illustrate this point, a representative sampling of the types of clinical management decisions that confront the therapist working with couples and some guidelines for handling them are highlighted in Table 32.20–6.

Common Clinical Management Issues

Telegram: @medical_k

www.konkur.in

1. The absent or resistant partner or family member—joint sessions are not held if one partner (with families, if significant family members) is not present. Doing so runs the risk of unbalancing the therapy, being perceived as participating in a collusive relationship with the partner who is present and risks being told “secrets” by the person seen individually. It also tacitly appears to be sanctioning the idea that that the presence of both partners is not necessary for successful couples therapy.
2. Distinguishing true emergencies from “pseudocrisis” situations—a common resistance to dyadic therapy is to try to create a crisis designed to have an individual relationship with the therapist. The form this very often takes is an urgent individual phone call between sessions. The therapist has to rapidly assess whether there is indeed a true emergency that requires immediate attention or if this is an effort to sabotage the joint therapy. In the latter case, the caller needs to be informed that the content of the call will be shared with the other partner in the next couple session.
3. Communication with other current or past therapists—pivotal in formation can be obtained from prior individual, family, or couple therapists referable to what has worked well and what has not. Obtain informed consent from both partners but make this a nonnegotiable condition of therapy.
4. Problems with payment for sessions—delayed payment, disputes about fee arrangements, and a host of money-related issues not only serve as points of resistance but may also be informative that money matters are an issue for the relationship itself.
5. Management of psychotropic medication issues both pharmacologically and psychodynamically—when one member takes medication it is important to insure that that person is not seen in disadvantageous or “one down” role.
6. Management of “secrets” in relationships and in original families—the therapist should make every effort to avoid situations in which one partner tells something that is not known to the other. This presents a threat to the viability of the entire therapeutic enterprise and must be handled immediately. Not permitting

Telegram: @medical_k

www.konkur.in

individual sessions is the most common method of handling secrets. If, by chance, a person tells a secret by phone or by lingering after the other partner has left at the end of the session, the therapist needs to clearly communicate that it is the person's responsibility to share this information openly, or else the therapist will decide how best to reveal the content to the absent partner.

7. What happens when one partner plans to or has seen a lawyer—many individuals have different motives for seeking couples therapy. In instances where one has contacted a lawyer, the underlying agenda may be one of guilt reduction by leaving the partner in the hands of the therapist rather than his/her stated desire to work on the relationship. In these instances the covert actions of the dishonest partner is a priority issue to be confronted in the next session. The obvious risk is to have one person exposed and vulnerable thinking that they are working toward problem resolution, only to be abandoned by their partner who plans to end the relationship.
8. Videotaping of sessions—the purpose of taping whether for review by the therapist between session to show the couple aspects of problematic and effective communication or for purposes of training and supervision always need to be clearly explained. Obtaining informed consent from both partners is a precondition for audio or videotaping sessions.
9. Confidentiality—as is the case in all psychotherapies, confidentiality is a sine qua non of ethical family and couple therapy practice. Unique forms of confidentiality with couples can occur in a couples group where several couples are privy to intimate details in the lives of other group members. Breaches of confidentiality are grounds for dismissal from the group.
10. Whether or not (and when) to include children or extended family members in sessions—couples with children and those with living parents frequently raise issues in joint sessions that involve family members who are not present. One of the unique aspects of couple and family therapy is flexibility. Couple formats allow for the inclusion of other family basis or for conversion of couples therapy

Telegram: @medical_k

www.konkur.in

to larger family groupings in order to address issues in the larger system.

11. How to handle intense negative affect in sessions—rage, blaming, threats to divorce, potential physical violence are all alarming phenomena in couples therapy sessions. The therapist has to have a tolerance for intense affect, know when to intervene before a dangerous situation escalates, set a clear set of ground rules for the modes of expression of anger and help the couple find more viable mechanisms for dealing with conflict.
12. How to avoid repetitive, unproductive, or destructive interchanges in sessions—a consistent property of systems is the repetitive, cyclical nature of behavioral sequences. Couples stalled in these ways tend to get demoralized and despair over the fate of their relationship. Couple therapists can supply input in the form of feedback both of a general nature and specific observations in the here and now in order to supply new information as fodder for interrupting the recycling of old arguments.
13. How to provide a different experience in the session from what the couple would be inclined to do spontaneously—asking a couple to do something in the session that they are not doing on their own is a central concept in all couple and family therapies. Asking a couple with a problem of sexual inhibition and avoidance to spend the meeting talking about sex allows them to experience that they possess the capacity to do something in the session that they feared might not be possible.
14. What constitutes appropriate timing of interventions in treatment—although couple and family therapies are brief therapies as compared to individual psychotherapy, they still go through definable early, middle, and termination phases. Therapists need to time interventions accordingly. Building a therapeutic alliance must precede the middle or working stage of therapy; otherwise, interventions will be ineffective. Similarly, termination in couples may feel abrupt to patients who have been used to the ritualized, extended termination techniques of individual approaches.

Telegram: @medical_k

www.konkur.in

15. Cotherapy considerations—when a team treats a couple, many advantages accrue but potential pitfalls need to be monitored as well. Splitting the cotherapists is the most common defense against the team format. Opposite-sex coleaders are seen as parental figures and mobilize feelings related to the family of origin in both partners. Ideally, the advantages of cotherapy are the increased option for modeling aspects of healthy communication, respect for differences, and a working partnership between adults.
16. How to make the therapeutic experience one that is sensitive to issues of diversity—It is essential that the couple therapist make themself finely attuned to the variables that fall under the heading of issues related to diversity in the partners that they are seeing. Diversity requires modification of therapeutic understanding and technique in ways that are respectful and free of bias and potentially negative preconceptions. Race, social class, culture, disability, age, gender, financial status, ethnicity, sexual preference, and religion are noteworthy examples of factors that must be incorporated into any treatment plan in order to avert formulaic approaches that disrespect or ignore facts that are central to the identities of the partners. The therapist needs to be vigilant in self-monitoring so that their own beliefs do not insinuate themselves in ways that would hinder or destroy the therapeutic alliance.

COUPLES GROUP THERAPY

Few modalities reflect the interface between family, couples, and group psychotherapies better than a group composed of couples. Couples groups also exemplify the growing trend toward more integrative approaches in family work. In spite of their popularity and utility, couples groups are poorly described in the professional literature.

The prototypical couples group is an out-patient modality composed of three to six couples led alone or by a cotherapy team. The group typically meets once per week for a session of one and a half hours. Groups can be brief, time-limited cognitive/behavioral or

Telegram: @medical_k

www.konkur.in

skills acquisition training models or longer-term psychodynamically focused models with more ambitious individual as well as couples goals.

The benefits for patients of including couples in groups is to counter isolation, destigmatize the idea of having relationship problems, increase the options for handling issues differently by seeing how other couples manage them, enhance the possibilities for varied feedback, experiment with new communication opportunities, and counter depressive and demoralized states that invariably accompany the frustration of unsuccessful efforts to make progress.

Couples groups have distinct advantages for the therapists as well. Coleadership is very desirable in terms of sharing the workload. Working with a partner allows for role modeling and demonstrating behaviors for the couples in the group that reflect alternative modes of handling individual differences, equally distributing power and control, clarifying roles of men and women as individuals and as partners, and opening up issues that couples handle by avoidance. The presence of a coleader permits the balance between therapist support and confrontation of members by having a back-up system not present when one works alone. When it is necessary to confront denial defenses in a group of couples with substance abuse issues, cotherapy facilitates one leader's ability to take a stronger stance than they might when working solo. If necessary, the other therapist can offset any unforeseen negative fallout if it occurs. Alternating these roles between cotherapists over time demonstrates productive styles of collaboration for the group to experience.

For the psychodynamically oriented couples therapist, seeing couples in a group milieu exponentially increases the number and variety of transference possibilities in the leadership and membership vectors. The cotherapy team is often perceived by members as having a therapeutic marriage despite the group's awareness that they might be colleagues who have chosen to work with each other. It is also wise to choose coleaders who have different therapeutic styles but who show mutual respect and readily incorporate suggestions from their coleader. Therapists with an object-relations preference can see the inner world of members enacted in their transactions with

Telegram: @medical_k

www.konkur.in

other part-objects represented by the group leader(s) and fellow members in the group.

Case Vignette

During the middle phase of a couples group composed of four couples, the theme of whether or not to have children arose. One couple had just come from a visit to the gynecologist, who informed them that they were running out of time because of the wife's age. The woman in the couple did not want to have children, but her husband did. His complaint about the marriage was that his wife never was demonstrative in showing her loving feelings for him. He felt her to be detached, distant, and sexually inhibited.

The prevailing sentiment among the other couples who had children was that children only added additional stress to an already stressed relationship. One other couple, however, voiced their different view by describing how their children had enriched their lives. As the talk about going forward and getting pregnant progressed, the group leader noted the nonverbal communication between the ambivalent couple. Whenever the tone of the group leaned toward having children, the wife would reach out and grasp the hand of her husband in a tender way. This invariably had the effect of stopping him from pursuing the topic for fear of the withdrawal of the affection he hungered for. All this transpired without words. Once identified, this repetitive nonverbal pattern was available for examination in the group, and the supportive elements provided by other members and the leader encouraged a frank, direct, and open conversation between the partners, who eventually chose to go forward and attempt to have a child.

Couples groups share many commonalities with multifamily groups in terms of cross-relationship learning, psychoeducational elements, strong support elements common in homogeneous groups, and as a vehicle for reality-testing ideas that are inhibiting progress.

Therapists who are experienced with the couples group modality frequently report that they have more therapeutic leverage once an initial base of group cohesion is established. Group cohesion acts as a supportive buffer that allows the therapist greater freedom to use

Telegram: @medical_k

www.konkur.in

appropriate anxiety-evoking interventions or apply group pressure as a force for change.

A common indication for couples groups is for couples with problems of long duration (years rather than months) where it is felt that the combination of cohesion, a strong therapeutic alliance, the multiplicity of feedback from the group and the leaders, plus the option to apply pressure when needed add up to the empirical enthusiasm expressed for this format.

RESEARCH AND FUTURE DIRECTIONS

Family therapy research presents several challenges. In the broadest sense, family research to date is a robustly evolving process resulting in a much clearer delineation of the significant variables to be taken into account in order to produce clinically relevant, scientifically informed studies. Part of the problem in conducting credible family and couples research on outcomes resides with the multidimensional nature of the individual, couple, and family and therapist levels present in all family work. What and who is being measured are central concerns, as is the selection process of how cases are being assigned for particular therapeutic interventions. Therapist variables such as theoretical orientation, level of experience, how issues of diversity are managed, gender similarities and differences, and the precise form and timing of technical choice are all being studied in the current research climate in family and couples therapies.

As a result, more specificity is being applied to studies in constructing instruments for measuring the outcome of family approaches, understanding what contributes to the process of change in family work, and in randomizing families under study. In particular, greater attention is being paid to clarity of intervention technique with tendency to use those methods that can be replicated under in other settings by other practitioners. Closely allied to this is the notion of goal specificity in family and couple therapies. In cases where a family seeks therapy for help with a member with a chronic mental illness, the target goals can be reduction of caregiver burden, change in familial interaction patterns, regulating affect in the family,

Telegram: @medical_k

www.konkur.in

improved family ability for shared problem solving, or all of the above. Clear and attainable goals make outcome appraisal of treatment an easier process. This is one of the welcome emergent trends in both family and couple research.

Comparisons of different schools of family and couples therapy have not demonstrated superiority of one technique above another. Studies have shown documentable empirical support for behavioral and long term, supportive, psychoeducational family therapy for schizophrenia. The Community Reinforcement Approach is a representative example of a behaviorally based form of social network therapy for alcoholism and substance abuse, and a range of childhood behavioral problems that includes adolescent delinquent behavior and substance abuse, phobic states in preadolescent children, and aggressive behavior in children and teenagers. Problems associated with various aspects of parenting were demonstrated to show benefits following parental stress management training and behaviorally focused parental problem-solving education.

Other interventions that show promise in early studies but lack sufficient large-scale data at present include parent management training (PMT), functional family therapy (FFT), and multisystemic therapy (MST). Adjunctive family and/or couples therapy have a strong foothold as part of a more global treatment plan for conditions that encompass anorexia, alcohol and substance abuse, and bipolar disorder and schizophrenia.

Where great progress is being made in family and couples research is in aligning research findings with direct clinical application, thereby reducing the gap between family studies and family practice.

The state of couple therapy research is also showing great promise in defining those attributes that contribute to better outcome. Of the three prevailing orientations in couples therapy, psychodynamic, behavioral couples therapy (BCT), and emotionally focused therapy (EFT) only the latter two have found empirical research support for their utility. Social exchange theory informed BCT while attachment theory formed the underpinnings for EFT.

Telegram: @medical_k

www.konkur.in

BCT has added cognitive components to the model, but research to date has not demonstrated the appreciable advantage of the combined approach. EFT, on the other hand, has been found to be valuable in several areas of couple functioning: emphasizing the attribution of meaning that partners incorrectly ascribe to their partner's verbal communication and behavior; teaching the exchanges that promote secure attachment; identifying and editing and supplying alternatives to the number and forms of negative cycles of behavior; stressing the beneficial use of intense emotion, and delineating maladaptive interactional patterns that lead to the dissolution of the relationship.

Some specific observations that have emerged from couples therapy research are in the behavioral approaches, lower levels of initial distress were correlated with a better outcome. In EFT and psychodynamic approaches, the stronger the therapeutic alliance and the more both partners of the couple are engaged in therapy, the better the outcome in terms of problem solving, communication alignment, reduction of hostility and blame, perceived partner sensitivity, and a softening of the negative affective tone present upon entry into treatment.

Future directions in family and couples therapies will include closing the gap between statistical studies and their real-world application, a quest for manual-driven therapy protocols that can be standardized for use by many practitioners, the emergence of suggested treatment guidelines for the condition that causes the family/couple to seek help; attention to ethical practice standards that deal appropriately with issues of confidentiality in multiperson therapies; treating specific conditions that include major affective disorders, personality disorders, and developing more sophisticated measures for assessing the process of change and the outcome of therapy. The wingspan of family and couples therapies is expanding and the field will continue to flourish as it accumulates greater experience and specificity with the elements most conducive to positive outcome.

The Covid Pandemic has put families and couples at great risk: separation, isolation, uninterrupted time in confined spaces,

Telegram: @medical_k

www.konkur.in

increased substance abuse, increased domestic violence—physical and emotional, financial concerns, over and under expression of feelings, increase in existing conflicts, and divorce, for example. For those seeking treatment for these issues, Tele-Mental Health has been very useful and may well persist beyond this disruptive disaster in the world.

32.21 Group Psychotherapy

HENRY I. SPITZ, M.D., D.F.A.P.A., D.F.A.G.P.A.

Group psychotherapy has always been an evolving field: sensitive to changes in the cultural climate, reactive to the lessons learned from history, cognizant of world events, aware of developments in scientific research, open to new systems of diagnosis of emotional illness, and updating theoretical orientations and clinical technique in the spirit of providing a level of care that is relevant, effective, and capable of being incorporated into new health care delivery systems.

Over the past years, a range of issues have been integrated to expand group therapy themes. Examples include the results of trauma from sources as broad as posttraumatic stress disorders in soldiers returning from war and others who have experienced childhood psychological, physical, and sexual abuse; gender issues including homosexuality, transgender, lesbian, and bisexuality; internet and computer themes including internet addictions, pornography, gambling, and hand-held phones leading to interpersonal problems; new discoveries in brain structure, genetics, disease, and the course and therapy of central nervous system disease; borderline personality disorder has been studied and dialectic behavioral group therapy has become a successful intervention.

Groups for schizophrenia and serious inpatient and outpatient psychological conditions have earned prominence with the emphasis on cognitive problems, behavioral skills, and socialization learning for its members. Relationship problems of many kinds are common as well. Heterogeneous couples have witnessed an increased divorce

Telegram: @medical_k

www.konkur.in

rate and often seek group therapy as a useful tool in exploring their marriage. New relationship forms that have emerged include same-sex couples, families that consist of a single parent, and homosexual parents.

Group therapy as a core element in the treatment of substance abuse and alcoholism continues to develop. Different group approaches and treatment opinions vary from classic 12 step or alcoholics anonymous groups to mid-range groups as in Recovery Incorporated and lastly, a harm reduction group model where members are taken into group without present sobriety being a requirement.

The list of variety of group approaches is wide ranging. Medical illness, affective disorders, bereavement and isolation, eating disorders, psychopharmacologic problems, geriatric groups, combined individual and group treatment, self-help groups, adolescent and family groups, are a brief overview to set the stage for what follows in this chapter.

FOUR PHASES OF GROUP PSYCHOTHERAPY

The field of group psychotherapy can be conceptualized as being in a new phase of its modern history. The first wave, ushered in by World War II and the enormous amount of psychological carnage that emerged from the war created a pressing need for treating the psychiatric casualties of wartime. Working in a group setting, as opposed to the conventional individual psychoanalytic milieu, facilitated seeing more people in less time and led to an exponential increase in the growth of psychotherapy groups predominantly those of a psychodynamic nature. The paradigm for phase two of group therapy's development was the community mental health movement in the late 1960s and 1970s. The mandate to deinstitutionalize the chronically mentally ill patient from state hospitals back into the community, presented a set of circumstances similar to those following the Second World War—a surplus of those in need of psychological help and a shortage of professionally trained therapists to treat them. The practice of group therapy, particularly in the areas

Telegram: @medical_k

www.konkur.in

of homogeneous groups designed to treat members who shared a common condition expanded during this period. With greater comfort and familiarity in employing group techniques came a corresponding trend toward experimentation with the application of small and large group methods to meet the needs of a broad range of patient populations and psychiatric conditions. The 1990s was the age of health care reform and the third phase. With it again came the pressure to see more people in shorter time frames but the mandate this time had come from a different source: managed mental health care. These four emotionally charged words reflect an economically motivated model of health care delivery that places a high premium on time and cost-efficiency, often at the expense of good patient care. Despite its many drawbacks, managed care allowed creative group therapists to expand our knowledge about brief, symptom-focused treatments and the use and possible hazards of time-limited groups.

The first decade of this century has borne witness to the fourth phase of group work ushered in by the rising threat of terrorism, human and natural disasters, and, consequently, to the influx of group therapies designed to address issues of psychological trauma. The immediate and longer-term reactions following catastrophic events commonly include panic, emotional anesthesia, alienation, social isolation, a profound sense of vulnerability, and a host of symptoms, some of which result in true posttraumatic stress disorder syndromes. The group setting is ideal for help in healing those whose lives have been touched by traumatic events.

DEFINITION

Group psychotherapy is a modality that employs a professionally trained leader who selects, composes, organizes, and leads a collection of members to work together toward the maximal attainment of the goals for each individual in the group and for the group itself. Certain properties present in groups such as mutual support can be harnessed in the service of providing relief from psychological suffering and supply peer support to counter isolation experienced by many who seek psychiatric help.

Telegram: @medical_k

www.konkur.in

Similarly, homogeneously composed small groups are ideal settings for the dissemination of accurate information about a condition shared by group members. Medical illness, substance abuse, and chronic and persistent severe psychiatric conditions including schizophrenia and major affective disorders are cases in point.

HISTORICAL ROOTS

Group therapy has a long and fascinating history spanning more than one hundred years. Early efforts from varied sources are directly traceable to elements of clinical practice today.

Most historians agree that the first recognizable group intervention was conducted in 1905 by Joseph Pratt, an internist treating tuberculosis patients in Boston. The treatment for tuberculosis at the turn of the century consisted of isolating afflicted patients from the general population and housing them in long-term care facilities. Pratt conducted “classes” on the ward designed to educate patients about what was known at the time about their disease. A serendipitous observation by Pratt was that people who attended class regularly seemed to be more compliant with treatment protocols of that era and also seemed to have improvement in their state of depression.

Parallel efforts took place in 1921 when Edward W. Lazell applied the group method to schizophrenic and manic–depressive patients at St. Elizabeth’s hospital in Washington, D.C., and observed similar results. Patients who participated in group sessions appeared to be less depressed and isolated as well as being more accurately informed about their psychological condition and the rationale for the nature of their therapy.

At the same time, Alfred Adler and Rudolph Dreikurs departed from the exclusively psychoanalytically based dyadic models of individual psychotherapy by involving significant others in the lives of the children they were treating at the Vienna Child Guidance Clinic. Parents, schoolteachers, and clinic staff were directly involved in small group sessions designed to integrate the therapy of the children and adolescents with whom they were connected.

Telegram: @medical_k

www.konkur.in

L. Cody Marsh, a minister working at Kings Park State Psychiatric Hospital in New York, used a revivalist–inspirational style to help bridge the alienation he felt was at the root of many of the psychiatric problems of the time. Marsh's now famous quote, "By the crowd they have been broken, by the crowd they shall be healed" captures the spirit of his orientation to mental illness and his emphasis on the need for the social support provided by therapy groups in helping patients cope with their problems.

The 1920s saw a confluence of interest in group dynamics and early group therapies. Sigmund Freud addressed the properties of large groups and their potential for good or dangerous influence in "Group Psychology and the Analysis of the Ego." Jacob Moreno, the founder of psychodrama, was working in Vienna experimenting with the use of intense affect and physical activity in a group setting when he created his "Theater of Spontaneity." In addition to creating psychodrama, Moreno is also cited as the first person to use the term "group psychotherapy" in conjunction with his applications of the psychodramatic technique.

In 1925, Trigant Burrow applied the group method to psychiatric outpatients and is credited with creating the term "group analysis" to describe his technique. In addition, Burrow was interested in the dynamics of small groups and created some of the earliest group "laboratory" formats in which the task of the group was to examine its own internal interaction. Burrow's work represented an extension of Freud's individual focus to the larger social context in which an individual existed.

The 1930s were characterized by efforts to expand the interface between psychoanalysis and group therapy. Louis Wender, in the early 1930s, formed six- to eight-member groups of patients and met with the group two or three times per week. Paul Schilder, working at Bellevue Hospital in New York City was also enthusiastic about outpatient psychoanalytic groups for patients with a broad range of emotional problems.

A key figure in the evolution of group psychotherapy for children and adolescents was Samuel Slavson. Slavson is considered by many to be the founder of modern group psychotherapy. Slavson

Telegram: @medical_k

www.konkur.in

focused on both the individuals and the group itself. His innovative work with activity and play group therapies was based heavily on using the therapy group as a vehicle for observing behavior as participants interacted in group sessions. He combined an analytic superstructure to his observations and utilized the analysis of transference and resistance as mainstays of his technique. Slavson founded the American Group Psychotherapy Association and was also the organization's first president.

The marriage of psychoanalysis and group psychotherapy as practiced by contemporary psychodynamically oriented clinicians is closely associated with the work of Alexander Wolf. Wolf was intrigued by the challenge of adapting the tools of psychoanalysis to the group setting. He believed the depth and availability of transference were accentuated in groups largely because the presence of other people stimulated feelings related to the families of origin of group members. He used dream interpretation, free association, and other analytic staples in innovative ways. For example, the "go-around" or "round robin" technique used in groups to include all members was originally born out of Wolf's efforts to use free association in the group session. He began a session by asking a member to report a dream and then would ask all other group participants to share their own spontaneous associations to the elements contained in the dream.

Significant theoretical and applied group work was taking place in Europe during the late 1930s and through the 1940s following the Second World War. Wilfred Bion, Henry Ezriel, S.H. Foulkes, and E. James Anthony all made seminal contributions to the understanding of the dynamics of groups. Bion focused on the "group as a whole" and delved into the unconscious life of the group using an object relations perspective based in the work of Melanie Klein. Concepts like the "basic assumption group" emanated from Bion's studies of group behavior and have led to a popular subgroup of modern group therapists that subscribe to Bion's precepts.

Ezriel agreed with many of Bion's ideas but emphasized the importance of focusing on the individuals in the group and their unique concerns, as well as concentrating on the whole group level.

Telegram: @medical_k

www.konkur.in

To do so, Ezriel drew attention to interactions and the member-to-member transferences in the “here and now” of the group. In the same vein, Foulkes, a British psychoanalyst, coined the term the “group matrix” which reflected his view of the group as a nexus of communication shared by all members. The matrix took into account the cultural similarities and differences among members along with their styles of communication as reflected in their group interactions. Foulke’s work was significant in integrating historical material with their manifestations in the group process itself, thereby bridging past and present. Foulkes, along with E. James Anthony and others, were instrumental in forming the Group Analytic Society in England.

In the early 1950s, another British figure, Maxwell Jones, created the “therapeutic community” concept. Jones’s ideas were embraced and adapted by clinicians working with the chronic and persistent mentally ill and those dealing with problems related to substance abuse.

The history of group therapy incorporates the contributions of social scientists like Kurt Lewin. Lewin’s field theory helped solidify the view that the group was greater than the sum of its individual parts and that groups were social systems, a concept that had great utility for clinicians in both group and family therapies. The term “group dynamics” was introduced by Lewin.

From the 1950s through the present, enthusiasm for experimentation with the application of group models led to further awareness of the uses and potential liabilities of experiences in a group setting. Among the former was the work of Nathan Ackerman who made noteworthy contributions at the interface between group and family therapy when he began seeing whole families as a unique small group in the therapeutic setting.

Simultaneously, the National Training Laboratories conducted community groups in Bethel, Maine. These groups formed the prototype for the T-group or training group, encounter and sensitivity groups that flourished through the 1960s. Important lessons about the risk factors in groups that were improperly or irresponsibly led and the psychiatric sequelae that followed directly from passive or charismatic

Telegram: @medical_k

www.konkur.in

leadership, extended time formats as in marathon group therapy came from the overzealous use of this group format.

Exponents of new “schools” of group therapy began to emerge. Eric Berne developed transactional analysis, Fritz Perls designed groups based on Gestalt therapy theory, and Robert Goulding’s redecision group therapy are but a few of the burgeoning points of view leading to the broad array of theoretical points of view represented in current group therapy practice.

The appreciation of the small and large group setting as a vehicle for the communication of information about a condition or a set of goals or problem sets shared by its members is as evident in the work of these early practitioners as it is in present-day group work.

THEORETICAL ORIENTATIONS

Many individually derived forms of psychotherapy have their group counterparts. A representative sample of major theoretical orientations toward group therapy can be broadly subsumed under the psychodynamic, interpersonal, and cognitive-behavioral schools of thought.

The *psychoanalytic spectrum* has evolved to include more than classical Freudian psychoanalytic theory. Exponents of the British school of object relations based on the work of Melanie Klein, Ronald Fairbairn, D.W. Winnicott, Harry Guntrip, and other self-psychologists utilize the unique properties of the therapy group to observe and alter the behavioral and ideational manifestations that originate in the inner world of the group member. Group members function as or represent part objects that parallel those that exist in the mind of an individual and are projected onto and enacted within the interactions in the group. In this way, the group provides an unparalleled setting for behavioral information about how group members perceive and misperceive their relationships to fellow group members and to the group leader. Practitioners with this orientation use the group to highlight unresolved issues involving themes of emotional attachment, acceptance and rejection, managing intense affect, and tolerance of frustration.

Telegram: @medical_k

www.konkur.in

Ego psychologists also fall within the penumbra of modern psychoanalytic practices in group therapy. Their theoretical base builds on earlier work by Heinz Hartmann, Ernst Kris, and David Rapaport who viewed Freud's structural theory of mental function into id, ego, and superego components as incomplete. They postulated that a conflict-free or adaptational portion of the ego exists as well. In clinical group work, ego psychologists rely on an appreciation of the mechanisms of defense that members use to counter their anxieties, the utilization of the peer and authority transferences in the group, and on the countertransference reactions of the group therapist.

Group therapy is an *interpersonal* form of treatment. Interpersonal theorists, most notably Irvin Yalom, advocate a group approach that centers on the interaction of group participants in the "here and now" transactions in the group session. Yalom also added universal existential dilemmas to a method that calls for active group leadership in creating an early, cohesive group framework.

Psychodrama is perhaps the most physically active form of group therapy. By employing structured dramatic activities in a group setting, the "director" or group leader guides the 'protagonist" (individual with an issue to be resolved) through a dramatization that is followed by feedback from other group members.

Cognitive and behavioral approaches rely primarily on learning theory and experiential elements to reach their goals. Structured, often manual-driven protocols are utilized in a time-limited group composed of members with a shared set of problems. Cognitive approaches are the most standardized of all group interventions and are, therefore the types of groups that are most easily measured in terms of group process and outcome.

Systems-oriented group approaches have found a bona fide place in group therapy as they have in family therapy. The assumption that the therapy group is an entity larger than the sum of its parts and that each member plays a role in the success or failure of the group enterprise is a central core to the systems approach.

Lesser-known but still actively practiced orientations include *Gestalt, redecision, and transactional analysis group therapies*. The first, based on Kurt Lewin's field theory and the work of Fritz Perls

Telegram: @medical_k

www.konkur.in

and Paul Goodman enjoyed great popularity during the sensitivity and encounter group movement in the late 1960s and 1970s. A central tenet of the Gestalt approach is the emphasis on group process over group content and efforts to mobilize strong affect that stands in the way of a person actualizing their full potential. The group focuses on emotional experience in the present moment and employs a variety of active, noninterpretive exercises designed to heighten self-awareness and to facilitate change.

Closely allied to the Gestalt method is redecision group therapy, a short-term model created by Robert and Mary Goulding as an offshoot of their work with Eric Berne and Fritz Perls. The format encompasses the creation of a clear behavioral contract at the outset. The group therapist aligns with the client's "authentic self" or that part of the person that is searching for new solutions to old impasses. The model eschews the use of the psychodynamic techniques, such as the use of interpretation and the analysis of transference and resistance relying instead on an array of redecision interventions that aim at identifying maladaptive, rigidified, unconscious defenses, and interrupting their reflexive nature in order to substitute more functional responses and problem-solving behaviors.

Transactional Analysis, commonly known as TA, is a component of redecision therapy but is also a stand-alone form of group therapy. Its founder, Eric Berne, replaced Freud's structural theory of the psyche from id, ego, and superego to what he termed "ego states" of Parent ("exteropsychic"), Adult ("neopsychic"), and Child ("archaeopsychic").

Berne codified a series of dysfunctional interpersonal patterns into what he identified as "games" that people engage in repetitively without success. The goal of the therapy group was to identify transactional states among group members and to change childhood "life scripts" into more adaptive adult patterns.

Table 32.21–1 illustrates some of the similarities and differences among representative group formats.

Telegram: @medical_k

www.konkur.in

Table 32.21–1.
Comparison of Major Group Therapy Orientations

	Supportive	Psychodynamic	Self-Help	Cognitive/Behavioral
	Group therapy	Group therapy	Groups	Group therapy
Frequency	1–5 times/week	1–2 times/week	7 days/week	1–3 times/week
Individual screening	Usually	Always	None	Always
Group size	8–15 members	5–9 members	No size limits	5–10 members
Goals	Better adaptation for daily living	Reconstruction of personality dynamics	Social support	Relief of specific symptoms
Indications	Crisis situations; severe emotional	Neuroses; mild personality disorders	Shared life experiences	Phobias; anxiety disorders
Group composition	Homogeneous for level of psychopathology	Balance of similarities and differences	Homogeneous	Homogeneous for similar symptoms
Group focus	"Here and now"; family, vocational, environmental factors	Past and present; intra-group and extragroup dynamics	Education; emotional "sharing"	Training members in methods that control symptoms
Use of confrontation	No	Yes	No	Rarely
Therapist activity	Actively structures and leads the group	Active around interpretation	No formal group leader	Very active in teaching skills to group members
Extragroup contacts	Encouraged	Prohibited or discouraged	Encouraged; formal peer sponsorship	Discouraged
Transference	Not analyzed	Utilized extensively	Not analyzed	Not relevant to the group work
Therapeutic factors	Cohesion; universality; reality testing instillation of hope imparting information	Cohesion; catharsis; family replay; interpersonal learning	Cohesion; universality; education; peer support	Cohesion; universality; education; reinforcement

SELF–HELP GROUPS

Leaderless or self-help group experiences are usually homogeneously composed of participants with a common issue representing an additional use of the group setting as a vehicle for change. Although these groups are not strictly considered a form of psychotherapy they do share a number of parameters and can have therapeutic benefits for participants. Perhaps the best-known examples are the 12-step groups of alcoholics anonymous (A.A.), Al-Anon, adult children of alcoholics (A.C.O.A.), and other substance abuse–centered groups. In addition, many self-help groups are formed around health and illness, loss, or a shared life experience. Cancer support groups, groups for widows or widowers, parents without partners, and bipolar support groups are but a few well-known self-help groups.

THERAPEUTIC POTENTIAL OF GROUPS

Therapy groups contain special properties that can be utilized in the service of change. Some of these factors are unique to the group

Telegram: @medical_k

www.konkur.in

milieu, and others are amplifications of more generic components of all effective psychotherapies. For many years, researchers and practitioners have tried to identify those therapeutic or “curative factors” present in groups in order to determine how they can be used to maximum effect.

Many authors have offered systematized categorizations of the natural resources available in therapy groups over time. Popular examples of these efforts can be seen in the work of Yalom and Leczsz, MacKenzie, and Sadock. Yalom and Leczsz use a 13-point model that includes universality, altruism, instillation of hope, imparting information, corrective recapitulation of the primary family experience, development of socializing techniques, imitative behavior, cohesiveness, existential factors, catharsis, interpersonal learning (both input and output) and self-understanding.

MacKenzie divided the therapeutic factors into four groups: supportive factors, learning factors, self-revelation factors, and psychological work factors. The supportive factors include universality, acceptance, altruism, and hope as contrasted to learning factors such as modeling, vicarious learning guidance, and education. Self-disclosure and catharsis comprise the factors of self-revelation while interpersonal learning and insight round out the psychological work factors in this schema.

Sadock has delineated a more extensive description and definition of therapeutic factors listed in Table 32.21–2.

Depending upon the nature of the group and its stated goals, the group leader draws upon particular therapeutic factors in order to enhance the likelihood of group members deriving maximum benefit from group therapy. As an example, in the early stages of an adult psychotherapy group, the group leader emphasizes those factors that facilitate the creation of a rapid sense of group cohesion. In practice, this means relying on similarities among members, creating an emotionally safe group structure, using the support elements available to the group, avoiding premature confrontation by the therapist, and monitoring intermember hostility.

SELECTION OF GROUP MEMBERS

Telegram: @medical_k

www.konkur.in

The extensive application of diverse group therapies over time has resulted in the liberalization of the inclusion and exclusion criteria for group membership. The selection process is a three-dimensional process consisting of evaluating individuals to see if they are appropriate for group therapy in general; member-to-group matching, does the suitable patient fit into the group for which they is being considered; and therapist-to-group matching, does the leader possess the clinical skills and emotional temperament necessary to understand and lead the group in the most effective way.

Traditionally, the group therapy literature has been more specific about exclusion criteria than inclusion criteria. Contemporary group therapy has been significantly modified from its historical roots in order to incorporate a broader range of difficult personality styles, severe psychopathologic states, and interpersonal deficits. Still, there remains a nucleus of patients for whom group therapy is either contraindicated or the timing of their entry into group treatment is premature.

Among these candidates for exclusion are those inpatients who are acutely psychotic and not stabilized on psychotropic medication, people who are acutely suicidal or for whom the high level of affect in the group might exacerbate their symptoms, and those whose primary language is not the language of the group. Debate continues about whether some conditions formerly considered for exclusion from group therapy can be treated in specialized groups in venues where the leader and the system are tolerant and familiar with the condition shared by members. A person with diagnosis of antisocial personality disorder was virtually certain to be excluded from group therapy. However, groups in prison settings and many substance-abuse groups are examples of the possibility of having homogeneous groups of members with a diagnosis heretofore thought to be unworkable in the group milieu.

Ideally, the person well suited for inclusion in group therapy is one who presents with an interpersonal problem and possesses sufficient motivation to work on the manifestations of these issues as they play themselves out in the ongoing arena of the group. For interactive, outpatient groups, members must have the capacity to empathize

Telegram: @medical_k

www.konkur.in

with others, possess sufficient ego strength to tolerate not being the exclusive focus of therapy, have some capacity for self-awareness or psychological-mindedness, be willing to self-disclose in the group meetings, and to benefit from the reality testing and interpersonal feedback supplied by the group therapist and group members.

In actual clinical practice, many people are referred for group therapy precisely for the very reason that they lack some or all of the aforementioned qualities. This should not be a de facto reason for exclusion from group membership. Pregroup alternatives like participation in a waiting-list group or a short-term orientation to group psychotherapy experience can give the therapist and the patient an expanded opportunity to see a prospective member in action. In so doing, it may become clear that the patient will either not be able to derive benefit from the group or will be a disruptive or undermining influence on the group, in which case, they will be deemed inappropriate for inclusion. On the other hand, pregroup participation can be invaluable in helping the group therapist design a treatment plan that is more patient-specific based on direct experience of the patient's interpersonal interactions.

Objective measures such as the Group Therapy Questionnaire and the Group Selection Questionnaire, both sections of the comprehensive revised CORE (Clinical Outcomes in Routine Evaluation) Battery, yield important data derived from patient self-reports about variables relevant to the decision about who can/is likely to flourish in groups and who should be excluded from group therapies. Once the decision about inclusion has been made, the critical phase of pregroup preparation of the prospective group member follows next.

PREGROUP PREPARATION

All prospective group members must receive a pregroup orientation. Both the individual and group psychotherapy literature attest to the observation that the better prepared a patient is for psychotherapy, the better the outcome. In group therapy, the pregroup phase has been shown to be particularly important in reducing group drop-outs,

Telegram: @medical_k

www.konkur.in

diminishing patient anxiety about group entry, having members with more realistic expectations of group therapy, enhancing motivation for therapy, avoiding goal incompatibility among members, and building a strong therapeutic alliance.

www.konkur.in

Table 32.21–2.
Therapeutic Factors

Telegram: @medical_k

www.konkur.in

Factor	Definition
Abreaction	A process by which repressed material, particularly a painful experience or conflict, is brought back to consciousness. During the process, the person not only recalls, but also relives the material, which is accompanied by the appropriate emotional response; insight usually results from the experience.
Acceptance	The feeling of being accepted by other members of the group; differences are tolerated, and there is an absence of censure.
Altruism	The act of one member's being of help to another; putting another person's need before one's own and learning that there is value in giving to others. The term was originated by Auguste Comte (1798–1857), and Freud believed it was a major factor in establishing group cohesion and community feeling.
Catharsis	The expression of ideas, thoughts, and suppressed material that is accompanied by an emotional response that produces a state of relief in the patient.
Cohesion	The sense that the group is working together toward a common goal; also referred to as a sense of we-ness; believed to be the most important factor related to positive therapeutic effects.
Consensual validation	Confirmation of reality by comparing one's own conceptualizations with those of other group members; interpersonal distortions are thereby corrected. The term was introduced by Harry Stack Sullivan. Trigant Burrow had

Telegram: @medical_k

www.konkur.in

	used the phrase consensual observation to refer to the same phenomenon.
Contagion	The process in which the expression of emotion by one member stimulates the awareness of a similar emotion in another member.
Corrective familial experience	The group recreates the family of origin for some members who can work through conflicts psychologically through group interaction (e.g., sibling rivalry, anger originally toward parents).
Empathy	A capacity of a group member to put themself into the psychological frame of reference of another group member and, thereby, understand their thinking, feeling, or behavior.
Identification	An unconscious defense mechanism in which the person incorporates the characteristics and qualities of another person or object into their ego system.
Imitation	The conscious emulation or modeling of one's behavior after that of another (also called role modeling); also known as "spectator therapy," as one patient learns from another.
Insight	Conscious awareness and understanding of one's own psychodynamics and symptoms of maladaptive behavior. Most therapists distinguish two types: (1) intellectual insight—knowledge and awareness without any changes in maladaptive behavior; (2) emotional insight—awareness and understanding leading to positive changes in personality and behavior.
Inspiration	The process of imparting a sense of optimism to group members; the ability to recognize

Telegram: @medical_k

www.konkur.in

	that one has the capacity to overcome problems; also known as installation of hope.
Interaction	The free and open exchange of ideas and feelings among group members; effective interaction is emotionally charged.
Interpretation	The process during which the group leader formulates the meaning or significance of a patient's resistance, defenses, and symbols; the result is that the patient develops a cognitive framework within which to understand their behavior.
Learning	Patients acquire knowledge about new areas, such as social skills and sexual behavior; they receive advice, obtain guidance, and attempt to influence and are influenced by other group members.
Reality testing	Ability of the person to evaluate objectively the world outside the self; includes the capacity to perceive oneself and other group members accurately.
Transference	Projection of feelings, thoughts, and wishes onto the therapist, who has come to represent an object from the patient's past. Such reactions, although perhaps appropriate for the condition prevailing in the patient's earlier life, are inappropriate and anachronistic when applied to the therapist in the present. Patients in group therapy may also direct such feelings toward one another, a process called multiple transferences.
Universalization	The awareness of the patient that they are not alone in having problems; others share similar complaints or difficulties in learning; the patient is not unique.

Telegram: @medical_k

www.konkur.in

Ventilation	The expression of suppressed feelings, ideas, or events to other group members; the sharing of personal secrets that ameliorates a sense of sin or guilt (also referred to as self-disclosure).

The use of a pregroup orientation session with each incoming group member affords the group therapist an ideal opportunity to accurately inform members about the parameters of the group they will be entering and to anticipate early resistances and behaviors that require sound clinical management in order to prevent avoidable drop-outs from the group. There are many ways to prepare new group members ranging from informal discussions with patients to structured pretraining programs, the distribution of written orientation manuals, employing videotapes of simulated group sessions, group orientations involving many new group members simultaneously, and others. Regardless of the format of the orientation to the group, the group leader is well advised to include an organized pregroup preparation component as a routine part of the pregroup phase of group therapy.

The use of a group therapy orientation checklist is one method of addressing the central elements of pregroup preparation of group therapy participants. Fourteen items comprise the pregroup orientation checklist. Depending upon the type of group and the personality of the incoming member, group leaders have the option to focus more in-depth on those areas on the list which may be most specific to the group and the patient in question and less on the topics which are less applicable to the situation.

The pregroup session not only addresses the “nuts and bolts” of the administrative and logistical aspects of groups, but it is simultaneously the start of the therapeutic process. When viewed from this perspective, the group therapist can accomplish the dual goals of preparing patients for group entry and get a preview of individual issues that will form the therapeutic agenda for a group member when they enter the group.

Group Therapy Check List

GROUP THERAPY ORIENTATION CHECKLIST

1. Goals and general purpose of the group.
2. Composition of the group.
3. The role of the group leader.
4. Observing and recording group meetings.
5. The arrangement of the therapy setting.
6. Time factors.
7. Loss and addition of group members.
8. Rules about attendance.
9. Fees and billing procedures.
10. Coordination of other therapies.
11. Extragroup socialization.
12. Modifications of the group contract.
13. Confidentiality.
14. Questions and answers

1. Goals and general purpose of the group
   The therapist clearly states the purpose and goals of the group. Goals that are vague or too ambitious are to be avoided in favor of goals that are patient and group-specific.
2. The composition of the group
   The therapist tries to convey a picture of the group the patient will be entering without disclosing information that violates the confidentiality of other group members. The goal is to provide the member with an understanding of who will be in the group, why specific members have been selected, and what the size of the group will be.
3. The role of the group leader
   A key concern for new members of any group revolves around what to expect from the group leader. Members who are used to individual psychotherapy may be anxious about sharing the therapist with other group members, puzzled about how help can come from others who themselves have significant emotional

Telegram: @medical_k

www.konkur.in

problems, and wondering how much reliance they can place upon the group leader.

What the group leader actually tells members in the orientation dialogue is aimed at addressing common patient concerns about leadership activity versus passivity; how the relationship with the leader in the group relates to the kind of help they can expect from group therapy; how structured the group will be; will the group leader be available for individual sessions outside the group; and a host of recognizable pretherapy fears which affect new patients in groups.

4. Observing and recording group meetings

   There are settings and circumstances that may call for groups to be observed. In training programs, observation and recording of group sessions are primarily used for the benefit of teaching therapists a particular technique or method. There are also times when recording, especially videotaping of meetings, is used as part of the group therapy itself, as well as a vehicle for training, supervision, and quality control of therapeutic groups. Observation of any kind must be handled openly before the first session and with the patient's informed consent.

5. The arrangement of the therapy setting

   When working with more seriously disturbed, suspicious, paranoid patients or with group members who display excessive amounts of anticipatory anxiety, a simple statement about, and a short visit to, the room in which the group will be meeting helps allay many fears in the minds of these patients.

   During or after the visit to the group therapy room, most people will report some sense of relief, but some will describe the experience in terms that are clinically revealing. Initial reactions like, "The room feels claustrophobic to me." or "The chairs seem so close to each other; can people actually touch you in the group meeting?" are cases in point.

6. Time factors in the group

   The time frame of a group correlates directly with the purpose of the group. Time varies according to the group's goals. As a general rule, short-term groups have a fixed time limit and aim to

Telegram: @medical_k

www.konkur.in

change maladaptive behaviors and/or to teach specific skill acquisition. Ongoing or open-ended groups are more ambitious and aspire to reach many of the same goals as their individual psychotherapeutic counterparts. Personality and attitudinal shifts as well as behavioral change are part of the long-term group model.

Considerations about the optimum time frame for each group session are also addressed in the pregroup orientation. The group parallel of the 45- or 50-minute individual session is the 90-minute group meeting. Examples of variations on the standard time frame designed to meet the unique needs and tolerance level of members include a brief cognitive/behavioral group that meets for 1-hour sessions over the course of 12 weeks and a 30- to 45-minute session group for psychiatric inpatients who may not be able to sit still or tolerate the level of affect that often accompanies a group of longer length.

7. Loss and addition of group members

Every group requires a sufficient number of members in order to reach its stated objectives. Some groups, usually those of a short-term nature, start and end with the same members. If, in the course of the time, members drop out of brief therapy groups they are not replaced. Many short-term therapy groups have a structured protocol for the conduct of each session and groups of this type do not allow for any changes in membership.

Long-term groups employ an open membership model that assumes that members will be leaving the group over the course of its existence. The two primary ways in which members leave a group are by terminating prematurely for psychological or practical reasons or through the realization of their treatment goals. In either case, gaps are left in the group.

Issues of timing are important when considering additions to the group. Long-term dynamically oriented groups do not seek immediate replacements for a departed member. Whatever the reason for a member leaving the group, it still is experienced as a loss by the group membership. The leader needs to allow time for the group to deal with the issues ushered in by the loss of a group

Telegram: @medical_k

www.konkur.in

member. Powerful emotional themes related to death, abandonment, separation, competition, family re-enactment, and loss are but a few of the feelings that accompany the exit of a member who has been in group for a long time. The dynamically inclined therapist in a long-term psychotherapy group can make extraordinarily productive use of the group members' unresolved conflicts related to loss, feelings emanating from inclusion and exclusion, and sibling relationships.

These potent emotions, most of which are historically based, get replayed in the group and are available for therapeutic exploration. Neglecting to address the issues related to loss and addition of group members invites avoidable problems in the ongoing conduct of the group.

8. Rules about attendance

All groups strive to establish regular attendance as a central group norm. It is a primary leadership responsibility to advocate and model regular group attendance. In so doing, the leader makes a position statement by their words and actions about the importance of the group and how vital each person is to the endeavor. Instructing members to call prior to a session if they are going to be absent or late is also discussed in this phase of the pregroup orientation.

Members in groups where absences and lateness are tolerated tend to devalue the group experience, lose confidence in the leader whom they regard as weak, passive, or inadequate, and feel like they are participating in a failure. All of these factors are, at the very least, demoralizing but they may actually be injurious to patients who come to the group with preexisting feelings of low self-esteem, a sense of personal failure, and a reasonable expectation that their lives will be enhanced, not made worse, by their joining a therapy group.

When working with very seriously ill psychiatric patients, rigid restrictions on attendance may be asking patients to comply with a task that is beyond their adaptive capacity. Therapists who work with schizophrenic outpatient groups can modify this portion of the group preparation module to allow for some expected irregularity

Telegram: @medical_k

www.konkur.in

in attendance. If the patient can make an attachment to the group and the system or hospital where the group meets and remain with it over time, these patients may have poor per-session attendance records but those who regard themselves as members of the group or members of the program do well over the longer lifespan of the group.

Higher functioning patients can be held to a higher standard of attendance. For purposes of the pregroup preparation of incoming members, the group leader decides in advance of the group what the policy on attendance will be and orient all members in a uniform way.

9. Fees and billing procedures

The mechanism by which therapy will be paid for is included in the orientation session. Issues of precertification for sessions, proper referral procedure, and compliance with the criteria set forth by third-party payers form the essentials of this process.

The setting of fees has significant clinical implications. Group leaders must decide whether it suits the goals of the group to have a standard fee for everyone in the group or, in cases where finances are a problem for a group member, should there be fee adjustments or a sliding fee scale. Whatever choice is made, it is important for the group leader to be clear about the fee policy for each incoming member and to anticipate the dynamic issues that graft themselves onto the issue of money.

It is common in psychodynamic groups where members pay different fees for group members to feel that the therapist prefers the people who are charged the lowest fees. This is a group replay of unresolved family issues of parental preference of one sibling over another displaced onto what appear to be practical matters involving money. The alert group leader can differentiate genuine issues about money from other psychodynamic and group process issues if he/she takes care to explain to each member the policy for group fees during the orientation meeting.

10. Coordination of other therapies

Group therapy is frequently part of a broader treatment plan for patients. The group leader has the responsibility for coordinating

Telegram: @medical_k

www.konkur.in

the treatment of each group member. In the pregroup orientation session, the therapist goes over other concurrent or potential treatment efforts and discusses how each will be handled.

This aspect of the pregroup member preparation encompasses several important considerations. If the group member is also in another form of psychotherapy, most usually individual, couples, or family therapy, the group leader has to get permission from the patient to contact the other therapist(s) involved in the patient's care at any point the group leader deems necessary. In this way, not only can the group therapist's database of information be expanded, but some potentially troublesome clinical issues, such as the use of "splitting" defenses by group members with borderline personality disorders, an attempt that aims to divide members of the treatment team.

The two other areas to be covered in this portion of the orientation concern medication management and the provisions for hospitalization of patients should that become necessary. When someone other than the group leader is prescribing psychotropic medication for a group member, the leader has to be knowledgeable about the drug regimen. At the same time, the clinician providing the medication can obtain valuable information referable to the patient's response to drug therapy as demonstrated by his individual and interpersonal actions in the group.

When a group member has a history of prior psychiatric hospitalization or has a condition which becomes unstable at times, a plan for how, when, and by whom the patient will be hospitalized must be agreed upon. Patients who become overtly psychotic in group sessions may require admission to an inpatient facility directly from the group. In these instances, the understanding conveyed to the patient in the pregroup orientation is that it will be the group leader who will oversee the decision to hospitalize anyone from the group. The group therapist has to be sure that the patient understands the plan and is in accord with it in order to avoid group crisis situations for which no appropriate contingency plan has been made.

Telegram: @medical_k

www.konkur.in

11. Extragroup socialization

Conventional groups, especially those with a psychodynamic point of view, actively discourage or prohibit contact among members outside of group sessions. The reasons for adopting this group policy are designed to counteract the dangers which can arise when the group leader is not present. The formation of dysfunctional subgroups that exclude other group members, business or professional affiliations which spring from the group, and romantic and sexual relationships that develop between members of the same psychotherapy group are a few of the countertherapeutic results that may follow extramural socialization among group participants.

In some selected groups, the leader may encourage contact among members for some reason that is consistent with the group goals. A “buddy system” in a group of patients who are lower functioning is an example of extragroup contact that is designed to be an extension of the therapeutic group process. Group members are paired together and come to the group and go home together. Since social isolation, loneliness, and coming to group regularly are problems for these patients, the creation of a group-generated plan that involves all members and excludes no one, is qualitatively quite different from spontaneous or planned acting out via outside contacts among members of higher-level groups. The latter is almost always an example of enactment of some issue outside the confines of the group where it would have to be openly addressed.

In the same spirit, some substance abuse groups encourage the creation of a sobriety telephone network among members. The purpose of the networking is to give members who are at risk to relapse into drug use an alternative option whereby they can call a sober group member who will support their healthy efforts to resist using drugs.

Whatever the group therapist decides is in the best interests of the group regarding extramural contact among group members, the pregroup orientation, not the established group, is the time and place to discuss this subject in some detail. Here again, the

Telegram: @medical_k

www.konkur.in

group leader may encounter some prospective group members who are unable to agree to adhere to this portion of the therapeutic contract. These members may have to be screened out for the group on the basis of their high-risk potential for undermining the group effort.

12. Modifications of the group contract

This category concerns the rare but significant instance in which something in a patient's life could be at cross-purposes with their effective participation in the group. Many people in groups have scheduling constraints, however, it is a mistake for the leader to accept a member for the group when it is clear that they will have a regular pattern of absences. Individual requests to change the meeting time or date of the group based solely on any single member's personal limitations regarding scheduling are denied. The time, date, and meeting place are nonnegotiable items unless, for some reason, the therapist has to change the arrangements due to their professional commitments.

The problems that occur when group meeting times are changed to accommodate one member, when episodic absence is accepted, and other deviations from the standard group structure are abandoned, can be of such magnitude as to threaten the viability of the entire group experience.

13. Confidentiality

Effective psychotherapy of any kind cannot take place in the absence of the assurance of strict confidentiality. Incoming members are notified of the gravity of the confidentiality rule and are asked whether or not they feel they can adhere to it. Breaches of confidentiality are grounds for immediate dismissal of a member from the group. Any incoming member who cannot commit to strict confidentiality in the initial interview is excluded from joining the group.

Confidentiality takes on added meaning in group therapy since members have the ability to take information about other people out of the group. In order to protect the confidentiality of all group members, the group leader must draw a clear distinction between gossip and the constructive use of information originating in the

Telegram: @medical_k

www.konkur.in

group to the member's relationships outside of the group. This transfer of learning function encourages group members to apply insights and behaviors learned in the group to significant interpersonal relationships in their everyday lives without identifying the source of information in the group. Rules about confidentiality are restated in the initial group session and again at any point in therapy where potentially sensitive material is discussed.

14. Questions and answers

The preparation session concludes with a portion that encourages patients to ask any questions related to the group they are joining or about any aspect of group therapy in general. It is best to leave time for questions near the end of the meeting after the other checklist items have been explained. Allowing for a question-and-answer period affords an opportunity for the group leader to get a sense of how the pregroup orientation meeting has gone. It also gives the group member and the leader time to go over any areas of confusion or misunderstanding concerning the content of the session.

Since many people enter groups with preconceived notions concerning what actually transpires in group therapy, the pregroup interview encourages the expression of doubts, fears, and irrational beliefs about the upcoming group. The therapist can clarify myths and misconceptions and help ease many of the avoidable anxieties attendant to the process of being a new member of a therapy group.

A sense of mistrust, fear of being attacked in the group, and concerns about humiliation, public exposure, and feeling inadequate often come up in the question–and-answer period. These can all be clinical clues to the leader about the patient's particular difficulty with entry into the group.

Another way of viewing the fears voiced in the interview is to see them as psychodynamic harbingers of the kinds of initial resistances that a person is likely to demonstrate in the interpersonal milieu of the actual group. The group therapist can use this opportunity to join with the patient, reassure them, and

Telegram: @medical_k

www.konkur.in

begin the process of establishing a therapeutic alliance aimed toward facilitating both group entry and retention in the group.

In a newly formed group, once all members have had the pregroup orientation, the stage is set for the first group meeting.

STAGES OF GROUP DEVELOPMENT

Well-designed therapeutic groups go through developmental processes over the course of their lifespan. The stages of group development are characterized by observable individual and group-as-a-whole phenomena. Numerous writers have identified and labeled group stages in keeping with the author's theoretical and clinical belief systems. The American Group Psychotherapy Association's Practice Guidelines for Group Psychotherapy integrated these major historical efforts at defining group stages with contemporary research findings resulting in a consensus about a five-stage paradigm of group development.

In this system, the stages that define the group's progress across its flight path are forming/preaffiliation, storming/power and control, norming/intimacy, performing/differentiation, and adjourning/separation. It is essential that the group leader be aware of the stage of the group's development and intervenes with the most stage-specific techniques available. Ill-timed or poorly sequenced interventions are not only ineffective, they can be damaging to individuals and to the whole group endeavor. Confronting a fragile member before sound group cohesion and support are established is an example of this error.

A fuller description of the elements of the five group stages will serve the twofold purpose of delineating the stages and the phenomenology of each and also shed light on the group leader's role at different points along the therapeutic spectrum. Two caveats to bear in mind are that stages of development are related to the composition, ego strength, and goals of the group and that they are not necessarily linear. Debate exists in the field regarding whether or not gains made in earlier group stages are retained even when a

Telegram: @medical_k

www.konkur.in

member of the group drifts back into an earlier phase posture. Similarly, the capacity and pacing of how far and how fast a group can progress in its development are limited by the level of psychopathology in the group members. With these two caveats in mind, the outpatient interactive psychotherapy group composed of midrange to high-functioning members is an opportune venue in which to appreciate the clinical significance of a developmental model of group therapy.

Preaffiliation

Initial concerns around inclusion and exclusion, acceptance by the leader and other members, the search for similarities, fears of interpersonal aggression, and competitive themes typify the first stage of a psychotherapy group. The group leader's focus is on knitting the nucleus of the group into a cohesive whole.

Therapist interventions encourage identification of goal compatibility among members, modeling and eliciting supportive comments, promoting "here and now" interaction among members, discouraging excessive dependency on the leader, establishing clear group norms, and constructing a secure therapeutic frame to contain the group as it goes forward. A strong educational function also characterizes the therapist's role in the first stage.

Power and Control

Apprehension about the emotional safety of the group, testing the group leader's strengths and weaknesses, negotiating differences with others in the group, and experimentation with self-disclosure and self-assertiveness are hallmarks of the second or "storming" stage. Among the leadership tasks in this phase are mediating power struggles and conflicts in the group, demonstrating firm but fair limit setting, being on the alert for issues that might lead to drop-outs from the group, promoting collaboration among members, and keeping the group on task toward the attainment of its goals.

Performing/Differentiation

Telegram: @medical_k

www.konkur.in

As the group progresses toward a more mature level, intragroup transferences become more apparent. Both vertical (member-to-leader) and horizontal (member-to-member) transferences are accessible. Levels of self-disclosure are higher and deeper interpersonal bonding takes place among members. There is a gradual transition from leader-directed group interplay to members sharing more responsibility for behaving in concert with the group norms. A cooperative group climate and greater reciprocity between members typify the intimacy stage.

The role of the group therapist during this stage can be less active than that in earlier stages however, the group therapist still plays a critical role in guiding the group process and preventing it from getting detoured into unproductive or counter-therapeutic channels. The leader aims to keep the group on track and reinforce those behaviors that promote the acquisition of insight, recognize constructive attempts at problem-solving, encourage the group to keep going forward in a collaborative spirit and to guard against the formation of subgroups.

Norming/Intimacy

Against the backdrop of the secure base of established group cohesion, group members in this stage are more willing to expose deeper feelings that might have activated real or imagined risks at an earlier point in time. This stage is an active one in which members are less afraid to show individual differences. The prevailing group climate is one of mutuality and acceptance. This atmosphere fosters greater understanding of relationships through the experiential learning that comes by virtue of being in stable relationships with others in the group over time.

Leadership focuses on letting the group be more self-sufficient and rewards spontaneous interaction among participants. Empathic responses are valued as are sincere attempts of members to be unselfishly related to others. The leader has to guard against abdicating the leadership role by becoming too passive during this phase. Since the groundwork has been laid for members to know how to express themselves in keeping with the group norms the

Telegram: @medical_k

www.konkur.in

leader may intervene less frequently but still bears overall responsibility for monitoring the group's therapeutic trajectory. Allowing and urging the group to be proactive and trusting the group are issues for the therapist during the phase of establishing intimacy.

Adjourning/Separation

The termination stage of therapy groups is noted for the triad of denial, regression, and recapitulation. In open-ended psychotherapy groups an event often sparks the realization that termination is the last stage of group therapy. Not uncommonly, this occurs when a member announces their plan to stop therapy because they feel that they have realized their treatment goals. Ambivalent feelings are evoked as members contemplate the impact of the loss of a valued member. Feelings of altruism, admiration, and having contributed to a fellow group member's success are accompanied by concurrent feelings of loss, competition, envy, anger, and concerns about each member's future. Members voice anxieties about the viability of the group when a known member leaves during this stage.

The group therapist has many leadership considerations related to an outgoing member and the remaining group. First, a clinical judgment needs to be made in order to distinguish between a genuine resolution of a member's therapeutic agenda versus a flight from the group. The latter is primarily fear-based and as such, calls for the patient to remain in the group to work through the unresolved issues that prompted the desire to terminate prematurely from the group.

Second, the termination phase is notorious for denial defenses, a re-emergence of earlier problems, and regressive behaviors all aimed at demonstrating to the leader that ending the group would be a damaging decision. The group therapist has to help members stay engaged with the plethora of strong emotions engendered by the prospect of losing a close relationship.

The leader conducts a review of the departing member's clinical course and the group's progress. In doing so the contributions made by fellow group members are acknowledged. This helps consolidate gains made for all in the group and helps buffer feelings of despair,

Telegram: @medical_k

www.konkur.in

loss, hopelessness, and sadness that regularly accompany the final stage of group work.

Finally, plans for life after the group are always part of a thorough termination stage. In instances where the whole group is ending, the experience of gaining closure on the group experience and saying good-bye to one another rounds out the tasks of the group leader as the group disbands. An appreciation of group development and the selection of carefully planned, stage-appropriate interventions by the therapist are essential ingredients of any successful therapy group.

LEADERSHIP ISSUES

The role of the group leader is the linchpin upon which the ultimate success or failure of the group enterprise rests. The leader creates, composes, and manages the group process from the selection and orientation of members through the working phases until the group reaches termination. The needs of the whole group and its individual members pose a series of potential challenges for the leader. The group therapist's self-awareness about their strengths and limitations in carrying out these diverse leadership demands is essential for a positive group outcome.

Generic leadership functions and desirable personal and professional qualities in the person of the group leader have been a subject of study since the inception of group psychotherapy. Brabender, Fallon, and Smolar have eloquently outlined the core elements of successful group leaders. These qualities consist of an ability to look into oneself, the capacity for empathy, having a positive belief about the value of group therapy, and possessing good interpersonal skills. Additionally, executive leadership functions that encompass the ability to set and maintain the therapeutic frame of the group experience, a capacity to appreciate multiple simultaneous levels of interaction in the group session, helping members supply accurate meaning attribution to their behavior and maximizing the use of the role of authority figure in the group are other central leadership attributes.

Telegram: @medical_k

www.konkur.in

In terms of specific leadership technique, the leader has to be proficient in tolerating as well as containing intense affect, managing their own countertransference engendered by the group, performing a teaching function for members in which the leader clarifies misperceptions and provides factual information, and uses interpretation in a timely manner. Since the leader is not immune to group pressure, care has to be exercised when using confrontational techniques and with respect to therapist self-disclosure in group meetings. As an example, when the group is in a state where anxiety in members is high and expresses itself in the form of confronting, testing, and challenging the leader, their competence, and/or the value of the group experience, the leader has to be able to separate personal feelings of rejection and inadequacy in favor of focusing on what and why this material is coming up at this point in time.

A helpful rule of thumb for judicious use of therapist self-disclosure is that the therapist should make sure that when self-disclosing information of a personal nature that it meets the criteria of being in their conscious awareness, is confined to the “here and now” of the group, and that the same goal could not be accomplished by other means. In this way, inappropriate or reflexive countertransference reactions by leaders that are harmful to the group are avoided. It is incumbent upon the leader to examine any temptation to self-disclose that has to do with the therapist’s personality as it articulates with the dynamics of the group.

Cotherapy

In many groups, the complexity of issues presented by the group suggests that sharing the leadership responsibility with a cotherapist would be advantageous. The workload on the leader who functions alone can be formidable in certain types of groups. As an example, cotherapy is often used in groups treating drug and alcohol addiction. There are many problems of living which involve the family of the substance abuser and require attention on the part of the group leader. Extragroup issues including legal problems, debt, housing, and employment are all factors which have an impact on conducting a group composed of substance abusers.

Telegram: @medical_k

www.konkur.in

These issues coupled with the empirical observation that staff burn-out is high among those who work exclusively with the problems of substance abuse, has led to a trend to use more than one leader in these groups. Team leadership is advantageous in allowing for the sharing of leadership tasks in the group. The presence of more than one leader increases the options for identification, interaction, and the exploration of intragroup relationships. As a result, the leader's therapeutic load is lightened, and the pace of the group can be accelerated by the presence of two leaders as objects of psychological investment by members.

When cotherapy is utilized, leaders have to be clear about their role and task definition in the group in order to function collaboratively. Coleaders who integrate their realistic differences concerning professional discipline, gender, and theoretical orientation, provide the group with an excellent role model for collaborative function in adult relationships. More opportunities for role modeling and for transference possibilities accrue when an opposite-sex team leads the group. This leadership combination stimulates family feelings in members by having a new therapeutic parental pair with whom members can interact.

A specialized form of cotherapy occurs in some substance abuse groups when a recovered alcoholic or drug addict is part of the therapy team. The recovered user occupies a position midway between that of a leader and a member. Their member-like qualities, including their first-hand experiences with life on drugs and alcohol, add a dimension to the group that cannot be supplied by the professional mental health staff.

In order to be considered for this "elder statesperson" role in the group, former substance abusers must have a documented history of at least 2 years of sobriety. They must also consent to urine screening during the course of the group therapy. The professional staff and recovered counselors meet immediately following each group session to discuss group events and the peer counselor's reactions to them. The postgroup discussion or "rehash" is designed to plan a course for future sessions and to ensure that the dynamics

Telegram: @medical_k

www.konkur.in

of the group do not pose a threat to the sobriety of the counselors themselves.

Variations in this specific coleadership model are also found in groups for bipolar disorder, medical illness, psychological trauma groups, and other conditions where a person has made a recovery and wants to share their experience with others trying to cope with an earlier stage of the problem.

CLINICAL APPLICATIONS

The versatility in the use of the group matrix can be seen in the following descriptions of contemporary innovative clinical applications of group therapies:

Combined Individual and Group Therapy

Many conditions require more than either group or individual therapies alone can supply. The simultaneous treatment of a patient in both one-to-one and group therapy is commonly referred to as "combined therapy." Therapy can be conducted by the same therapist or by two separate therapists. Different clinical issues are engendered by both types of combined therapy.

When the group and individual therapist are the same person, members only in group therapy often see the patient in combined therapy as being in a favored position by the therapist/group leader. This often induces group themes of competition, acceptance and rejection, and unresolved emotional residue from the families of origin of the group members.

In circumstances where one therapist is the dyadic therapist and another is the group therapist, professional colleagues must regularly communicate with each other. This ensures the coordination of a treatment plan for the patient and helps monitor whether the patient is doing an editing or splitting function by reserving some material only for individual therapy and not disclosing it in the group or vice versa.

A patient with a borderline or narcissistic personality disorder is at higher risk to play off one therapy against the other as a resistance to change. Astute use of combined therapy along with a dialectical

Telegram: @medical_k

www.konkur.in

group experience can identify this dysfunctional behavior and offer more adaptive alternatives. Specifically, the personality-disordered patient in combined therapy may use individual therapy to focus on intrapsychic issues and can apply the insights gained in therapy and experiment with new modes of behavior, thinking, and defenses in the safe and controlled interpersonal setting of the dialectic group.

At the same time, groups are concentrated on themes of appropriate interaction with peers and authority figures, the constructive expression of intense feelings, such as anger and intimacy, and the enhanced reality testing which groups provide. These attributes of the group help counter irrational beliefs and socially deviant behavior and offer more viable alternatives. Ideally, consistent communication between therapists staves off avoidable pitfalls and adds to the efficiency of the total therapeutic effort.

Bauer and McBride have created a life goals group program that combines psychoeducational, cognitive-behavioral, and self-management skills training for patients with bipolar conditions.

Groups for Mood Disorders

Affective disorders play havoc with the interpersonal relationships of those diagnosed with mood instability. The advances in diagnosis and psychopharmacologic options for treating depression have been dramatic. Group therapy has proven to be a widely accepted component of the treatment plan for patients with mood disorders. When one looks at the interpersonal sphere of the bipolar patient, their histories are riddled with interpersonal problems.

Conflicts at work, with domestic partners, original family members, and the law are common occurrences. As a corollary, depressed patients are invariably withdrawn from social contact and/or show signs of irritability as a prominent symptom.

A supportive and structured group psychotherapy milieu is ideal for addressing some of the issues that confront patients with serious mood disorders. Educating patients about their condition and the latest pharmacologic options available to them, using the group to focus on learning structured problem-solving techniques while simultaneously experiencing working in a cooperative way with fellow

Telegram: @medical_k

www.konkur.in

group members and staff, plus positive use of reframing techniques designed to counter stigmatization of mental illness are the central components of the life goals paradigm.

Groups for Personality Disorders

The model above is emblematic of many group approaches not only for affective problems but also for personality disorders where affective dysregulation is a core component of the therapeutic agenda. Exponents of group therapy know that group pressure is a powerful force for change that is unique to the group setting. When working with personality disorders, in group therapy, the therapist has more leverage available to induce change in maladaptive behavior, negative attitudinal stances, and interpersonal deficits.

The ingredients in the interpersonal group (IPG) psychotherapy protocol for patients with borderline personality disorder typify current thinking about the utility of groups to achieve significant change. The therapy group brings to light the borderline patient's inner self-system with its feelings of emptiness, hunger for affect and gratification, and the inefficient interpersonal styles they have created in order to reach these ends. The IPG utilizes the dilution of the transference that sharing a group leader provides to turn down the emotional temperature of the group so that the atmosphere is more conducive to learning.

The interpersonal emphasis strives to help the patient form and experience more positive, gratifying identifications with others in the group. Using a theoretical premise that views problems with attachment as a common starting point for the interpersonal difficulties found in people with personality disorder, the group therapist uses a noninterpretive, empathic approach. In contrast to more traditional psychoanalytic approaches, the group leader avoids confrontation that invites strong affect, particularly in the early stages of the group, in favor of functioning as a "container" for the patient's confusion, anger, and dysphoria. Once a therapeutic alliance is formed, the leader works with individuals in the group to counter their self-deprecating beliefs and replace them with a positive group climate of hopefulness and the possibilities for change.

Telegram: @medical_k

www.konkur.in

These techniques rely heavily on the group leader's subjective responses to the behavior by patients in the group and use caring feedback and suggestions of alternative courses of action as the tools to implement change. At the heart of this method is the assumption that in the IGP model, "change is more due to the experience of interactions in the group and less to the acquisition of insights about the genesis of internalized conflicts."

Dialectical behavioral therapy (DBT) has also been adapted to work effectively in groups as well as in the individual setting. Although DBT was originally designed for working with patients diagnosed with borderline personality disorders it has been customized for use with patients with eating disorders, families with suicidal adolescents, and substance abusers. Still, more applications of IGP and DBT-based group therapies are expanding rapidly.

Groups for Anxiety Disorders

Anxiety is present in the vast majority of psychiatric conditions. For many people, it is the primary reason for which they seek professional help. While there are effective pharmacologic agents available for treating aspects of anxiety disorders, group therapies are particularly helpful as either adjunctive or primary modalities of treatment geared to managing the symptoms of anxiety and offering a vehicle for working on the interpersonal fallout from the habits formed by people who have unsuccessfully managed the stressors in their lives.

Groups, particularly those with a cognitive-behavioral orientation (CBGT), have been applied with cognitive behavioral group therapy (CBGT) to the full gamut of anxiety disorders from adjustment disorders through panic disorder up to and including posttraumatic stress disorder and phobic states.

Anxiety, fear, and panic are all characterized by avoidance behaviors. The cognitive behavior therapy (CBT) group aims to empower patients to engage with their anxieties by supplying them with a set of anxiety-reducing skills. Universal components of individual cognitive-behavioral therapies are adapted to the group setting. The advantages of a CBT group are: greater opportunities for

Telegram: @medical_k

www.konkur.in

role modeling, practicing new behaviors in vivo before testing them out in the world outside the group, getting peer feedback from others with similar anxieties, and the positive reinforcement that comes from many people, not just the therapist, which serves to reinforce new habits and thought patterns.

Examples of CBT group techniques include task assignments, including personal journals, and homework assignments, teaching progressive muscle relaxation, meditation, deep breathing, and other stress management mechanisms, and identifying the schemas or belief systems that underlie cognitive distortions. Maladaptive thought processes such as catastrophic thinking, polarized “black or white” thinking, over-personalization can be labeled in-group members, and cognitive restructuring is used to substitute more reality-based responses to stressors.

Cognitive behavioral therapy groups for anxiety-based problems are the fastest-growing form of group therapy today. They have gained clinical popularity for several reasons; the therapeutic interventions are often time-limited; the techniques are clearly described and can be standardized thereby facilitating research on the outcome by self-report, clinician-administered instruments, and/or cognitive and behavioral testing; precise treatment plans can be made into manuals that have a specific agenda and goals for each session, and the role of the group leader is very clearly defined.

Anxiety cuts a wide swath across generations, gender, ethnicity, race, culture, and physical illness. In CBGT commonality of anxiety problems is the central factor around which these groups coalesce. CBGT has the expectation that change will take place outside of the group as well as in formal group sessions. Out-of-session assignments, such as monitoring and recording intrusive thoughts that provoke anxiety are regular staples in cognitively based groups. CBT groups are prototypical of most brief or short-term group psychotherapy models insofar as they have a fixed time frame, a strong educational component, a clear focus for each group session, and very active, directive leadership that strives to keep the group on task and terminates the group at a predetermined point in time.

Telegram: @medical_k

www.konkur.in

The awareness of traumatic conditions experienced by men and women who are returning soldiers has formed a large basis for the application of effective trauma groups.

Groups for Schizophrenia and Other Psychotic Disorders

Group therapy for patients with severe psychiatric disorders has truly come of age. Historically, inaccurate assumptions were made about the viability of therapy groups for psychotic patients. Most of these doubts came from psychoanalytic theory which proposed using techniques that were beyond the capabilities of schizophrenic patients and, in some instances, actually harmful to fragile patients.

Groups address many of the central issues involved in managing patients with severe psychiatric impairment. From crisis control to diagnostic evaluation and as a primary form of psychosocial therapy, the group milieu offers enormous flexibility by creating a foundation for a comprehensive treatment program for the chronic patient. Inpatient, transitional, and outpatient groups all constitute the group resources available to the clinician. The choice of group options is primarily related to the patient's diagnosis and to the stage of severity of the primary psychiatric problem.

Using this paradigm, groups for chronically ill psychiatric patients can be conceptualized as acute, transitional, and maintenance or aftercare in nature. Patients with acute first episodes of a condition or with an exacerbation of a longstanding problem are primarily hospital-based. Inpatient group therapies encompass quiet activity groups, art, poetry, and dance programs; occupational therapy; discussion groups, and community meetings on the inpatient service. Goals that are overly ambitious should be abandoned to suit the relatively brief time period of hospitalization. Simply stated, one of the highest priorities for inpatient groups is to get patients to be comfortable with group therapy. Having a successful group experience in the hospital increases the probability that patients will continue in aftercare groups and not get lost in the transfer from inpatient to outpatient status.

Transition groups refer to the transition from hospital-based treatment to outpatient and community-based programs. The start of this process begins with discharge planning in the hospital. Discharge

Telegram: @medical_k

www.konkur.in

planning groups, social skills training groups, family groups, job-focused behavioral groups, and medication groups are all representative of groups for people in the process of leaving the hospital.

Groups in an outpatient setting are designed to prevent relapse, which would require rehospitalization, and to help participants develop rewarding social, familial, and vocational lives. In general, these groups aim to reduce social isolation, monitor the effect of medication as measured by the patient's level of interpersonal function, aid in reality testing, provide social support, reduce the stigma associated with being mentally ill, and transmit accurate, up-to-date information about the primary condition. Leadership is very active in setting a therapeutic structure around which the group can consolidate. Psychotropic medication is invariably an integral part of group life whether or not the group is a medication group per se.

Most groups for chronic and persistently mentally ill patients are based on principles of supportive psychotherapy. Exploration of unconscious material, delusional themes, and affect related to anger and hostility are to be avoided. The emphasis is on patient strengths and the accumulation of small, incremental successes started in the group and extended to life outside the group. Problem-solving, advice-giving, and teaching new coping strategies, are all hallmarks of outpatient groups for patients with chronic and debilitating mental illness. The emphasis on improving cognitive function is also a central group goal.

Table 32.21–3 illustrates the similarities and differences between groups which have psychotic members and those which do not.

Telegram: @medical_k

www.konkur.in

Table 32.21–3.
Group Therapy With Psychotic and Nonpsychotic Patients

Telegram: @medical_k

www.konkur.in

	Pychosis	Nonpsychotic
Composition	Homogeneous for level of function	Homogeneous: Brief group Heterogeneous: Long-term group therapy
Functional capacity	Poor ego strengths Interpersonal deficits	Able to learn from group feedback Capacity for empathy and altruism
Goals	Crisis intervention Stabilization Improved communication Social skills development	Improved self-perception Improved interpersonal function Resolution of personality issues
Educational elements	Central to the group model	Elective: Yes: Brief groups No: Psychodynamic group therapy
Therapeutic factors	Reality testing Identification Social Support Bolster defenses	Cohesion Challenging defenses Use of transference and unconscious material
Cohesion	Desirable but hard to attain	Mainstray of the group model; easier to attain quickly
Leader role	Active around structuring the group Avoids aggressive and irrational	Spontaneous group interaction Leader is catalyst for group process

Telegram: @medical_k

www.konkur.in

	themes	
Confrontation	Strongly avoided	Actively encouraged
Interpretation	Only on occasion and limited to the "here and now"	Regularly used for in-group transactions and transferential issues
Medication	Almost always part of the group	May or may not be a group issue
Group focus	Present and future	"Here and now" plus historical focus
Socialization	Strongly encouraged	Generally discouraged
Time span	Brief and long-term models	Brief: Symptom focused
	Open-ended "maintenance" group therapy	Long-term: Personality and behavior change
Group participation	Involuntary and voluntary	Voluntary

A group focus on medication compliance, education, socialization, vocation, and psychological integration is the constellation of benefits chronically ill patients can derive from ongoing participation as members of groups.

RESEARCH ISSUES

The field of group psychotherapy has departed from an antiquated, predominantly anecdotal literature to a firm footing in scientific inquiry. Data from well-designed and well-controlled studies attest to value and utility of groups as a primary form of psychiatric treatment. Significant findings related to group cohesion show that pregroup selection and orientation; higher levels of early group structure; balancing individual and intragroup factors; active group leadership,

Telegram: @medical_k

www.konkur.in

facilitating emotional expression, relationship building, and verbal feedback all result in high levels of group cohesion which, in turn, favors positive outcome. The role of a strong therapeutic alliance is also correlated with positive outcomes in both brief and long-term groups.

A greater degree of both specificity of focus and research study design characterizes the cutting-edge efforts to support the clinical enthusiasm for group psychotherapy. Additionally, research instruments have been created to decode the mechanisms by which groups work. Empirical observation and research focus of group work now studies aspects of group process, leadership variables, and therapeutic factors that form the basis for the change resulting from group participation. The CORE Battery developed by the American Group Psychotherapy Association is the best-known example of this effort.

FUTURE DIRECTIONS

There is a clear trend toward eclectic group therapies characterized by technical integration. Greater emphasis is being placed on those group interventions that are specific, documentable, and capable of replication when employed by other practitioners. Many group therapists draw upon a psychodynamic understanding of each group member but their modes of intervention have become liberalized and less restricted to traditional analytically based practice. Cognitive elements, educational components, structured group exercises, and the assignment of tasks based on the expectation of increased patient responsibility for change are but a few of the additional eclectic modes of intervention added to the therapeutic armamentarium.

Training modules and manuals have been created for practitioners and the public covering several critical aspects of group therapy. How to train future supervisors of group therapy, explicating the issues involved in the ethical practice of group therapy and guidelines for teaching a basic course in group psychotherapy representing three examples of a trend to educate practitioners in order to assure quality

Telegram: @medical_k

www.konkur.in

control and to strive to continue to provide first-rate group services to patients.

Beginning in March of 2020 it became clear that our lives had changed dramatically due to the onset of the Coronavirus epidemic. Most of the world went into shock, panic, despair, and retreat. In-person treatment became a deadly choice. For former patients and those seeking help for the first time, a very good option has been through the use of computers and cell phones where a group of people can be heard and seen simultaneously. This mediates feelings of isolation and offers members support for new issues as well as those predating the pandemic. Tele-mental health is a new arena for group work that will undoubtedly outlast the current disaster and be useful in an ongoing way for homebound people and communities far from health services for example.

Times have changed and group psychotherapy has kept pace with them. As new developments occur, tandem reflection in the addition and modification of group technique and sensitive therapeutic styles ensure the progress of group therapy as a welcome transition to modern psychiatric clinical work.

32.22 Psychodrama, Sociodrama, Sociometry, and Sociatry

EDWARD J. SCHREIBER, T.E.P., AND SCOTT GIACOMUCCI, D.S.W., L.C.S.W., B.C.D., C.G.P., F.A.A.E.T.S., T.E.P.

THE PSYCHODRAMATIC SYSTEM

Man does not live alone and does not get sick by himself. His problems develop in groups …. the mental and physical equilibrium of an individual depends to a considerable degree upon the dynamic interplay of these various individual and social forces.—J.L. Moreno

Psychiatrist Jacob Levy Moreno (1889–1974) hypothesized that human beings learn primarily through interaction with relationship systems, which he called social atoms. Moreno believed that an encounter of the self with creative processes, which he defined as spontaneity-creativity, could deepen and encourage growth for individuals and groups. Psychodrama and related action methods of sociodrama and sociometry facilitate creativity, and the discovery of strengths, based upon J.L. Moreno's understanding of human growth, from infancy to the end of life, with spontaneity-creativity as a central factor.

Psychodrama is used as therapy in various forms of education and in training therapists, doctors, lawyers, teachers, social workers, political leaders, public speakers, businesses and organizations, and more. Psychodrama can often be used in conjunction with other forms of therapy. Though at the same time, psychodrama is a comprehensive system and can stand on its own with its own philosophy, theories, and interventions.

Telegram: @medical_k

www.konkur.in

In a psychodrama, one person called the protagonist, works with the director and a group or just individually with a director. In a group, participants may be asked to assume a role in the protagonist's exploration of an aspect of life. Those asked are not obligated to enact any role; it is a matter of choice. The director's role is complex and includes the facilitation of the protagonist, the role players, the group, the multiphased psychodrama process and techniques, and the integration and sharing phase with the protagonist and the group. Psychodrama follows a sequence of phases, which includes the *warm-up, action, and sharing*. In a training program, there is often an additional *processing* phase for students to become skilled in their application of the method.

Sociodrama is related to psychodrama and is a process for a group, organization, or community to explore relevant concerns and issues. In sociodrama, the whole group is on the stage in a role-playing theme, idea, and setting-based encounter in which participants have taken a role to play in the sociodrama. While psychodrama enacts an individual's specific story and roles, a sociodrama enacts a group's collective story using generalized roles. Sociodrama is used in educational settings, in professional development programs for a wide range of professions, and in clinical settings. Sociodrama can be employed to explore social issues, common themes, and social, organizational, and cultural problems.

Sociometry, related to psychodrama and sociodrama, although a method of its own, is used to understand and evaluate and to support, enhance, change, and develop relationship systems and subgroups in organizations. Sociometry is a tested process to address and improve communication, cohesion, functioning, and growth. Sociometry is rich with techniques to measure and examine the often unseen but felt networks which are very much alive and impact a group.

Sociatry (healing society) utilizes psychodrama, sociodrama, and sociometry to study the forces J.L. Moreno described as impacting all of humankind. J.L. Moreno understood there to be *an actual, underlying, dynamic, central structure impacting all formal and*

Telegram: @medical_k

www.konkur.in

informal groups. This underlying structure may be seen in groups looking through a sociometric lens, known within sociatry as the social microscope. The social microscope is an educational tool used to show the forces J.L. Moreno named *the sociodynamic effect* and *the social and organic unity of humankind*. Sociatry deepens our relationship to the creative process, our common humanity, and our interrelatedness.

HISTORY

J.L. Moreno was born in Bucharest, Romania, and received his M.D. in Vienna in 1917. In Vienna, he began The House of Encounter and formulated ideas about the nature of groups, healing, and society. Moreno describes the first psychodrama to have taken place with a large theater audience on April 1, 1921; it was focused on the task of finding a new leader after the collapse of the Austria-Hungarian Empire. In 1925 he immigrated to the United States and beginning in 1929 inaugurated Impromptu Theater in New York City. In the early 1930s, he conducted sociometric research at Sing Sing Prison, the Hudson School for Girls, and public schools in N.Y. While presenting at the 1932 American Psychiatric Association conference in Philadelphia, Moreno coined the terms “group therapy” and “group psychotherapy.” In 1936 Moreno opened the Beacon Hill Sanatorium and the psychodrama theater in Beacon, New York. In 1942, Moreno founds the first group therapy organization, the American Society of Group Psychotherapy and Psychodrama (ASGPP). Later in 1950, he actually petitioned the American Psychiatric Association to start a Group Psychotherapy section and ran for president of the organization–both attempts were unsuccessful. In 1954 he organized the First International Congress of Group Psychotherapy in Toronto, Canada and in 1973 he cofounded the International Association of Group Psychotherapy (IAGP). He is credited with publishing many books, journals, and articles, along with the organizations he began, and his worldwide teaching and training.

J.L. Moreno was a doctor, scientist, psychiatrist, and mystic. To note his mysticism causes alarm for some but is important in

Telegram: @medical_k

www.konkur.in

grasping the fullness of his ideas. It is from J.L. Moreno's integration of mysticism and science that this work has come. As a young man, J.L. Moreno was fascinated with the cosmos, fixated on the realm of the unknown. He dedicated his life and work to understanding and mapping the connections we make and have in life. J.L. Moreno created dozens of techniques, a complex method to experience and integrate this creative force–a kind of intelligence as he found it. He taught and trained thousands of practitioners in this method; how the force of creativity can be found; how to touch it, to the benefit of oneself and others. He was a social scientist as well and placed enormous effort into the investigation and cure of social problems. The goal of J.L. Moreno was ultimately to realize an organic unity within humankind and promote society's movement toward unity and healing.

Zerka Toeman Moreno began her study and work with J.L. Moreno in 1941 after having emigrated from England to the United States. Her path to finding J.L. Moreno and the Beacon, N.Y. Hospital is a remarkable story written in her memoirs *To Dream Again.* Zerka joined J.L. Moreno as his assistant, then wife and primary collaborator. J.L. Moreno's work might be just a footnote in history, were it not for the dedication, insight, and skills of Zerka Moreno. During the long period of their developing the method, Zerka emerged as codeveloper and went on to teach thousands of students throughout the world, and helped heal many wounded souls.

Zerka Moreno coauthored, edited, and helped translate most of J.L. Moreno's books and articles, and served as his primary teacher of the method. After his death in 1974, Zerka Moreno continued to teach and develop psychodrama until her death in 2016 at the age of 99 years old. She authored many articles, chapters, and books, with *To Dream Again–A Memoir* as her last, with this chapter's primary author as editor.

J.L. Moreno and Zerka Moreno were world minded. The issues of access to resources and our attention to those left out were of great importance to their work. J.L. Moreno created a therapy of

Telegram: @medical_k

www.konkur.in

experience, an experience of qualities of being human, to bring understanding and regeneration to individuals and groups.

The method created by J.L. and Zerka Moreno helps many problems. Work is being done throughout the world to bring the method and its practices to assist with the widespread issues we face as a human family. There are many sources of information regarding social application including IAGP, ASGPP, and dozens of other psychodrama associations around the world.

METHODS, TECHNIQUES, CLINICAL ISSUES

The method includes psychodrama, sociodrama, sociometry, group psychotherapy, spontaneity testing and training, role testing and training, the therapeutic stage, the empty chair, role-playing, role models, role relationships, and the exploration of subgroups and systems in organizations, groups, and communities. The method also involves sociometry, surplus reality, tele, the cultural conserve, the social atom, the protagonist, the double, auxiliary egos, the canon of creativity, the director, role theory, role reversal, and a developmental theory based on spontaneity-creativity. Furthermore, there are aspects of Moreno method that are not as widely known, such as the cultural atom, the sociodynamic effect, socio-genetic law, sociostasis, socio-gravitation, the autonomous healing center, and sociatry.

Psychodrama

Psychodrama takes place on a stage. A stage can be like the three-level-stage J.L. Moreno designed (relocated from the original hospital in Beacon, N.Y. to Boughton Place in Highland, N.Y.) or any space designated as a stage separated from the group. The stage is the location in which the psychodrama and sociodrama takes place and in most psychodrama groups today, the stage is simply designated as the center of the room where the group is held. There is flexibility in the stage, the director and protagonist may adjust and change the stage when needed.

Telegram: @medical_k

www.konkur.in

The protagonist works with the director in a group, or just individually with a director. In a group, participants may be asked to assume a role in the protagonist's exploration of an aspect of their life. The director works with the group and group process during psychodrama, although the focus of the group is on the psychodrama and the protagonist. Psychodrama requires a combination of techniques and experiential methods to be complete. In psychodrama, a protagonist may examine aspects of life, from the past, the present, or the future. The protagonist can explore a relationship, a moment in the past or future, an interaction, a scene from life, a dream, parts of self, or internal roles.

According to Zerka Moreno, the effective practice of psychodrama is focused on the integration after catharsis (catharsis of integration) rather than solely accomplishing catharsis (catharsis of abreaction). Lasting change comes from the catharsis of integration–integration of what happened, what was needed but did not happen, what is needed now or in the future, and how this is to be healed or processed. Integration may take place during the psychodrama or days later and may include a new defining and developing of skills, relationships, and roles.

An initial task of the director is to discern the general frame and need the protagonist brings, and to determine a place (scene, setting, situation) to begin the psychodrama. There is a warm-up phase in which the protagonist emerges, and also a warm-up between the director and the protagonist. The director may suggest an initial scene, often elicited during an interview with the protagonist at the beginning of the psychodrama. A psychodrama may commence with scene setting in which the protagonist creates in action and imagination a setting, a scene, or simply wants the empty stage. There is no requirement to begin with the past. Zerka Moreno suggests that what matters is not so much where the psychodrama begins, *but that it begins.* Psychodrama develops a protagonist's capacities and strengths in their work to create, and recreate, in an authentic and adequate way.

The double technique in psychodrama is when a member of the group (who is guided by the director) offers statements and actions

Telegram: @medical_k

www.konkur.in

of support, or stabilization, clarification, amplification to the protagonist during the psychodrama. The double is role-played by someone from the group chosen by the protagonist or the director. The double can add depth, expand expression, extend or clarify statements or feelings, and help the protagonist to gain perspective, to integrate, hold and contain the experiential-based learning.

The mirror technique is when the protagonist is outside of a scene, as though watching-seeing a scene from their life presented by others. A group member may take the place of the protagonist in the scene, and members may be asked to assume other roles. The protagonist gains an observation, perspective, and emotional distance from the events.

Role reversal is a primary technique in psychodrama. It is a directed experience, and as with other techniques, it can be used as therapy, in education, and in training programs. In a role reversal, the protagonist presents what needs to be presented to another, imagined, in a setting or scene, on the stage in the psychodrama. The protagonist offers to “that other” what needs to be said. With direction and when appropriate, the protagonist “takes the role” of that other. The protagonist moves to be in the role of that other and eventually responds from the role of the other. Role reversal can continue for a series of directed exchanges, but the protagonist finishes in their own space, place, and role as themself, with a period of sharing after the psychodrama has been finished. Role reversal may take place with an imagined person, an object, an idea, a place in time, etc. A protagonist may role reverse with lessons in life or, as J.L. Moreno described, with creation.

Role reversal expands creativity, though there are contradictions. If there is difficulty with role reversal, this may indicate that other techniques, such as the double, soliloquy, or the mirror, may be more useful and appropriate. One needs to have strong and secure boundaries to return to. A contraindication and caution are for any role reversal with trauma, perpetrators, or violence of any kind–this will be addressed more fully in a later section. Training is required to facilitate role reversal or any aspect of psychodrama and related methods.

Telegram: @medical_k

www.konkur.in

Sociodrama

In psychodrama, one person is the protagonist; in sociodrama, the whole group participates in action learning. In sociodrama, the group, organization, or community explores concerns, problems, situations, or relevant issues. Sociodrama is used in education, professional development, and in clinical settings. The group is role-playing within a theme, exploring issues in an imagined setting.

Sociodrama has been used to address global warming; and with exchanges between people of differing cultures and religions; with survivors of the Holocaust on both sides; in working with issues and differences between generations; between police and gangs, etc. Sociodrama develops a group in the capacity to double and reverse roles with others, see the world from the point of another, and find new meaning and learning.

Sociodrama is used for training doctors to better understand the experience of being a patient and parents to better know the experience of being a parent. Sociodrama increases communication and cohesion and *tele* (two-way empathy). Sociodrama includes techniques, directorial and group processes, how a sociodrama is directed, and how the concerns, themes, roles, and settings are chosen.

Psychodrama and sociodrama are experientially woven applications of the social atom, encounter, the canon of creativity, role theory, concretization, sociometry, the catharsis of integration, group psychotherapy, and other techniques, which will be explained further in this chapter. It is our relationships in life that can be concretized and explored through psychodrama, sociodrama, and sociometry.

Sociometry and Tele

Moreno hypothesized that human society has an atomic structure, which corresponds to the atomic structure of matter, and that its existence can be brought to an empirical test by social microscopy, related to sociometry. Sociometry is a method for the examination, exploration, and alteration of the connections and dynamics taking

Telegram: @medical_k

www.konkur.in

place within a group, organization, and community. The connections are often felt but often not fully recognized. Sociometry makes the connections visible, approachable to growth and change, to increase communication, creativity, cohesion, and resolution. Moreno's sociometric system was celebrated and adopted by sociologists and many consider his early sociograms and psychosocial network research to be the foundation of modern social network theories and participatory action research.

Sociometry is a method with many instruments for the measurement of connection, the web of tele "meetings" in operation. Telic connections can impact the functioning of a group, organization, and individuals within it, the dynamics of cohesion, inclusion, exclusion, subgroups, etc. Telic constellations form between two or more people, often unrealized in their capacity to harness and unleash a kind of interfeeling that impacts a group's embrace of its members, its creativity, its functioning, cohesion, and learning. Tele is a phenomenon below transference, not always seen, with multiple types of often interlocking relationships and groupings in an organization and community. While transference is a one-way distortion of reality, tele is an accurate two-way connection.

Telic constellations are made visible with sociometry. Sociometric structures and configurations can regenerate to increase communication, cohesion, creativity, and functioning. Sociometry is used in clinical settings, training programs, organizations, educational settings, and in communities.

Zerka Moreno explains tele:

> *Empathy and transference are part of a more elementary and more inclusive process of tele. The process of reciprocation does not enter into the meaning of empathy, and transference is considered the factor responsible for the dissociation and disintegration of social groups. Tele is the factor responsible for the increased mutuality of choices surpassing chance possibility and responsible for the increased rate of interaction among members of a group.*

Telic structures are central to one's personal sociometry, noticed in the feeling between oneself and others. For personal and professional development, sociometry evaluates and measures this.

Telegram: @medical_k

www.konkur.in

With a group, sociometry may knit together positive telic connection and communication. Sociometry can open blocked communication by revealing to the group its telic structures. When the structures are more fully understood, they can be changed and developed in a productive way. Telic structures often operate below the formal organization as a matrix of cohesion or not and function at the moment in time. Sociometry shows a group, the living social atom, the dynamic telic processes commonly unseen but often felt, and the intelligence of life called spontaneity-creativity in action.

THEORIES THAT INFORM THE METHOD

The Social Atom

The social atom is used to depict the relationships of one's life and the nature of each relationship. The social atom can be an instrument used in a written format and as a psychodrama enactment that depicts a social atom by bringing it alive with others taking roles. The social atom can include one's relationship with individuals, groups, animals, communities, or other entities. The social atom may depict the past, the present, and the needed or hoped-for relationships. It is a visual representation of positive, negative, neutral, ambivalent, mutual, and nonmutual relationships.

The social atom depicts those with whom we feel emotionally impacted, connected, or related. The social atom is a relationship map; it brings awareness to relationships. The social atom looks like a bulls-eye; the nucleus represents oneself. In the first circle beyond oneself, one notes those with whom there is such a significant impact. One draws a line connecting self to that other, and there are specific line notations to show the nature of the relationship. Beyond that, in the next circle, one depicts those with impact best depicted at that level, and so on. *The social atom is a depiction of one's own truth and perception.* The spatial distance from the center to others reflects the perception of the nature and impact of those persons. A menu of symbols and lines is given that denote genders, as well as

Telegram: @medical_k

www.konkur.in

positive, negative, neutral, lost, ambivalent, mutual, and one-way relationships.

There is flexibility with this tool, which provides information and insight and points to areas of further exploration. J.L. Moreno believed we are as closely tied to our social atoms as we are to our bodies. The social atom predates the genogram and ecomap by over 40 years and may have influenced their development in the family therapy and social work fields.

Encounter

In 1914, Moreno published a seminal poem articulating his philosophy of the human encounter. This poem highlights the importance of the existential experience of seeing the world and one's self through the eyes of another. The philosophy of the encounter is central to Moreno's developmental theory and is operationalized through the psychodramatic intervention of role reversal (which also influenced Buber's 1923 I and Thou concept, Fritz Perls' development of Gestalt Therapy, and many others).

Encounter represents a theoretical and practical underpinning to psychodrama. Encounter is an action instrument, a basic idea, for an existential dialogue with another, imagined or real. With the encounter, one finds oneself in the *psychodramatic experience of me and not me.* This is an existential fiber in life for what connects us and an experience often had with psychodrama. J.L. Moreno gave a name to the mutual feeling of the essentialness of another, calling that sense of another *tele,* noted earlier in this chapter. The interweaving of tele is explored in psychodrama, sociodrama, and sociometry.

J.L. Moreno wrote about the existence of a primordial nature in life, found within us and within groups. In *To Dream Again–A Memoir,* Zerka Moreno named this primordial nature the *autonomous healing center* within. It is generated in psychodrama to craft a new, novel, and adequate response to life.

This is the case when the protagonist explores a role reversal, in taking another's role in language, behavior, and feeling. One finds a

Telegram: @medical_k

www.konkur.in

sense of what that other might feel like; and what might be learned from this. It is in the encounter of oneself with others and life that spontaneity-creativity is discovered and strengthened. Facilitating role reversal and encounter requires training; for information regarding training and certification for psychodrama, refer to the American Board of Examiners in Psychodrama, Sociometry, and Group Psychotherapy. There are similar Boards throughout the world.

Canon of Creativity: Formula for Change

The Canon of Creativity is a visual diagram to represent a theoretical underpinning to the psychodrama method. The diagram identifies stages of spontaneity-creativity for a person or group–the warming-up process, spontaneity, creativity, and the cultural conservations. It is a map for change that depicts the process of creating something new based on spontaneity-creativity theory. The Canon of Creativity is a theory actualized and brought to life by psychodrama and includes the warm-up where group members prepare for spontaneity-creativity in action. There is then a movement to create something new, which is met at first with resistance. Once resistance is addressed, then renewal and creativity can emerge. There is the movement to form–and presence–in the world and life. The Canon of Creativity can be thought of as a clinical map embodying psychodrama's theory of change which proposes spontaneity as the curative agent in the treatment process. Moreno defines spontaneity as providing the ability for adequate responses to new situations and novel responses to old, reoccurring situations. This framework can be applied to conceptualize the change process psychologically, interpersonally, or within society. The renewal of society was J.L. Moreno's full vision to bring creativity and spontaneity into the culture.

Human Development

Jacob Moreno's developmental theory is simplified into three phases which also reflect psychodrama interventions–the double, the mirror,

Telegram: @medical_k

www.konkur.in

and the role reversal. Zerka Moreno expands on the developmental stages while synthesizing them with Erickson's psychosocial stages in *The Quintessential Zerka.* She outlines periods from birth to death, each stage offering guidance for tasks to be considered developmentally. The developmental stages and tasks are templates for the realization of creative potential and have life tasks for growth.

Psychodrama helps to experience the tasks, even those not originally completed. To become more able to role reverse with others, including groups of people, is one of the developmental tasks. There is a task of completing unfinished business with one's parents and preparing to yield parents back to the cosmos as we eventually ready ourselves to leave this world. Developmental stages include taking on new roles, finishing others, and crafting one's continued path.

It is useful to consider that in each of the developmental phases, different psychodrama tools are highlighted as instruments to help with that phase. Also, in conducting psychodrama, it's wise to have as a mental construct, the notion that what protagonists are showing could be related to the tool needed for a developmental stage being completed.

Role Theory

Role theory suggests that the self develops and emerges through the process and actualization of roles throughout one's life. Humans are fundamentally role-players, and all of our relationships are composed of role relationships. Roles include internal and external aspects or functions of self-ranging from somatic roles, psychodramatic roles, and social roles. Role theory proposes a nonpathologizing and interdisciplinary theory of personality that encompasses psychiatry, sociology, theater, and culture. Role theory is a holistic and comprehensive system of conceptualizing human experience in a biopsychosocial-spiritual context.

Role training, or learning new roles in life, works with a three-stage process: (1) Role-Taking: deciding to take a role or not, addressing ambivalence and resistance, (2) Role-Playing: assuming a role,

Telegram: @medical_k

www.konkur.in

finding role models, examples of how to function with increasing skill in a role, (3) Role-Creating: emerging more fully as oneself and with increasing skill, by creating new and authentic expressions of oneself. Role theory also contains an articulation of various role phenomena and dynamics, including role reciprocity, role conflict, role fatigue, subroles, role-self congruence, and more.

The method considers our psychological and emotional growth comes through how we start, learn, play, live, change, and finish the roles and role relationships throughout our lives. A personality characterized by health has a wide role repertoire, which allows for spontaneous and skillful living. To attend to this consciously can be supported with the methods stated here. Psychodrama can be used to explore and prepare for the roles we want, or want to change, in some fashion.

Surplus Reality

Surplus reality is a wide-ranging theoretical tool for a protagonist and group to explore psychodramatically what can be imagined beyond present reality. A variety of techniques are used to work within surplus reality, which is a foundation for psychodrama. The protagonist creates a psychodrama that includes and can go beyond known reality, using imagination, perception, creativity, and psychodramatic activity. The director helps the protagonist explore the real or imagined and forge an adequate response.

Techniques include role reversal, double, mirror, soliloquy, aside, concretization, presentation of oneself in the role of another, and changing time, space, and location. Surplus reality can involve empty chairs representing people, events, aspects of oneself, stages of life, or anything else. Surplus reality can offer the protagonist an experience as it was needed but did not happen, aspects of the past, present, or future, and roles that may be required.

Surplus reality touches upon imagination and creativity. It opens to new worlds, exploring an event, redoing an event, or exploring an event that never happened. As such, psychodrama is particularly useful in the treatment of trauma in that it can provide corrective

Telegram: @medical_k

www.konkur.in

emotional experiences that would have been impossible otherwise. Auxiliary egos, as they are called, are group members asked to take part in the protagonist's exploration. Regardless of the interaction, in many ways, the protagonist explores strengths, capacities, and resources along with vulnerabilities and creativity. There is a great range of choices that surplus reality offers.

Universalia of Time, Space, Reality, the Cosmos

The psychodrama method uses time, space, reality, surplus reality, and the existential realm of the cosmos, as J.L. Moreno described it, as psychodramatic tools. The past, present, and future are reflected in the here and now, making time a flexible instrument. A protagonist may explore a scene that happened in childhood, then change scenes to one imagined in the future. A sequencing of scenes and times may be explored or markers on one's life timeline.

Psychodrama explores life as it happened or was needed or wished for. The director uses psychodrama to facilitate the protagonist's exploration and repair. The connection of human beings to life relates us to an inherent dignity. Many report psychodrama to be an experiential encounter that reveals this universal dimension.

Warm-Up, Action, Sharing—Structure of Psychodrama

Psychodrama is a three-step process of warm-up, action, sharing, with processing for those in training. The warm-up constitutes approximately one-third of the session, the action phase one-third, and sharing phase one-third. There are many approaches to conducting a warm-up, which can be quite organic to help the group meet one another, for participants to feel present, to make connections to others, and for the director to introduce themes. The warm-up is a natural tendency in human life: we have a warm-up, for example, as a preparation for going to sleep, a warm-up for going to work, or for addressing difficult issues with another. This phase is natural to how we live.

Telegram: @medical_k

www.konkur.in

The warm-up process introduces creativity in some form to the group and individuals. A warm-up may be planned or spontaneous and may include movement, conversation, reflection, art, or music. The warm-up is preparation for the action phase. The director weaves and orients the positive telic connections, enhancing the social atom of the group.

The action phase is the psychodrama or sociodrama itself. In psychodrama, a protagonist may be chosen by the group, self-selected, selected by the director, or scheduled. Some have suggested that a sociometric/democratic selection of the psychodrama topic is the most effective approach as it ensures a protagonist that most represents the group-as-a-whole. This process helps to facilitate a group-as-a-whole experience and side-steps the potential pitfall of doing individual therapy with a group audience. The protagonist enters the stage, and there is often an initial dialogue between the protagonist and the director about goals, boundaries, time frames, and elements of the psychodrama.

The director works in collaboration with the protagonist. The group remains a group, even as some group members may be asked to enact a role in the psychodrama. The action phase often starts with a scene or some expression of present concerns. There may be a number of scenes or just one scene. There is often a peak of action and integration of experiential learning.

Sharing is the final third of psychodrama. With the psychodrama completed, group members share with the protagonist and group how the psychodrama was related to one's life. Those who assume a role in the psychodrama generally share first, initially from the experience of the role, then as it relates to their life. Sharing is not advice-giving or analysis; the director may share as well.

Do–Undo–Redo

Do–Undo–Redo is one option for a methodologic sequence for a psychodrama as a strategy for change and structure for the action phase. The protagonist may begin by showing a condition or concern, perhaps stepping in and out of the concern, concretized in

Telegram: @medical_k

www.konkur.in

some way on the stage. The protagonist may encounter an aspect or aspects they wish to address or change. The protagonist can undo things and, following that, redo them differently or from a different vantage point. There can be a scene and then a redone scene in which something new has been created. There can be the reconstruction of the situation or elements in it. This is a flexible structure adjusted to meet the needs of the protagonist.

One quite beautiful application of this has been the “moments from one’s life” in which the protagonist (often many protagonists) may “relive” an experience in life, often a joyful and enlightening one.

PSYCHODRAMA AS A TREATMENT OF CHOICE FOR TRAUMA

Many are endorsing psychodrama and experiential therapies as a treatment of choice for trauma based on the influx of new neuroscience research illuminating how trauma impacts the brain and body at levels beyond cognition or verbal processing. Psychodrama’s capacity for undoing and redoing moments in the past is ripe with potential for corrective emotional experiences and renegotiating trauma without the need for re-enacting a trauma scene. Trauma can be approached from a place of safety through strength-based roles that promote transformation and post-traumatic growth. In a recent study on trauma-focused psychodrama, participants commented on therapy as being more tolerable and less intimidating than other trauma therapies that they had participated in–even describing it as fun and playful.

Jacob Moreno created psychodrama 100 years ago, long before post-traumatic stress disorder (PTSD) was recognized as a diagnosis in 1980. Although he did not have the same language to articulate what we now know about trauma and its impact on people, most of Moreno’s work (and much of the larger psychodrama community’s work) was with trauma survivors–including immigrants/refugees, inmates, at-risk youth, veterans, and patients with severe mental health conditions in inpatient psychiatric

Telegram: @medical_k

www.konkur.in

hospitals. The emergence of contemporary trauma theory and neuroscience findings both support the use of psychodrama and have been further integrated to refine the use of Moreno's methods in safe and effective ways. When employed without proper training, psychodrama can be retraumatizing or harmful for clients. Its use as a treatment modality with trauma survivors requires advanced training and careful consideration.

PSYCHODRAMA RESEARCH

Psychodrama is used in both psychotherapy contexts and other spheres of practice, such as education, religion, activism, and community life. Its expansive scope, along with its foundation in spontaneity-creativity theory, has made the production of psychodrama research challenging. It has obtained status as an evidence-based practice (EBP) in other countries (especially in Europe), but its establishment within the American mental health system remains insecure. The scarcity of psychodrama's presence in academia further limits its access to research support and funding. Useful resources for exploring psychodrama research further include the research committees of the ASGPP, IAGP, and the Federation of European Psychodrama Training Organizations (FEPTO).

Psychodrama research continues to emerge, supporting its effectiveness in the treatment of various mental health disorders, providing experiential training, and enhancing well-being or social skills. Psychodrama research is also included in the larger research bases of group psychotherapy, creative arts therapies, humanistic-experiential psychotherapies, and body- and movement-oriented interventions–all of which demonstrate levels of efficacy comparable to cognitive-behavioral therapy and other EBPs.

ETHICS IN TRAINING, EDUCATION, AND PRACTICE

Telegram: @medical_k

www.konkur.in

A challenge in conducting psychodrama is keeping the experiential structures intact while having flexibility in the application. This places a demand on the director, educator, trainer, and practitioner to evaluate and apply the psychodrama method with a solid foundation of theory, training, education, practice, and certification. The strategic thinking for directing requires training, supervision, and professional development. The American Board of Examiners in Psychodrama, Sociometry, and Group Psychotherapy sets standards and examines candidates for two levels of national certification: Certified Practitioner (CP) and Trainer-Educator-Practitioner (TEP). The certification process is extensive and requires 780 training hours (among other requirements for entry-level certification). Similar Certification Boards exist in South America, Australia, Europe, and Asia. The American Board has adopted the ethical standards of the American Psychological Association. Psychodrama should not be practiced without Board approved training in accordance with the established certification guidelines. The necessary intensity of the psychodrama training process reflects the complexities of the model and the potential for harm when practiced outside the scope of one's competency.

Though psychodramatists officially adopt the APA code of ethics, Moreno also published a *Code of Ethics for Group Psychotherapy and Psychodrama: Relationship to the Hippocratic Oath,* which is embedded into the philosophy of his approaches. One of his novel ideas articulated in the code of ethics is the empowerment of each patient as a therapeutic agent. He suggests that because each patient has the power to promote healing for each other, patients should also be prompted to commit to aspects of the Hippocratic Oath. Specifically, the code of ethics suggests that the group leader and participants should commit to: (1) do no harm, (2) maintain confidentiality, (3) promote healing for others in the group and contribute to the overall welfare of the group, and (4) foster equality of status within the group, regardless of privilege or marginalized statuses outside of the group.

SOCIAL AND ORGANIC UNITY OF HUMANITY

J.L. Moreno contributed to the ideas of social psychiatry in many ways as he wrote extensively about groups, communities, society, and social forces impacting humankind. He is mostly known as the developer of psychodrama, but was also deeply involved in societal problems, which is depicted in his book *Who Shall Survive?*:

> *The discovery that human society has an actual, dynamic, central structure underlying and determining all its peripheral and formal groupings may one day be considered as the cornerstone of all social science. This central structure—once it has been identified—is either found or discernible in every form of human society, from the most primitive to the most civilized: It is in the genesis of every type of society. In addition, it exerts a determining influence upon every sphere in which the factor of human interrelations is an active agent in economics, biology, social pathology, politics, government, and similar spheres of social action.*

To see society's actual, dynamic, central structure underlying and determining all peripheral and formal groupings offers a perspective on what impacts our present situations. The situation calls for a willingness to reverse roles with others and other groups of people and find what is common among us to find solutions that consider all of mankind and the impacted natural world. Sociatry endeavors to understand this underlying phenomenon in human society and create education for personal and professional development about the underlying structures impacting humankind and the ecologic fabric. It is a creative path for which J.L. Moreno offers:

> *A truly therapeutic procedure cannot have less an objective than the whole of humankind. But no adequate therapy can be prescribed as long as humankind is not a unity in some fashion and as long as its organization is unknown. It helped in the beginning to think, although we had no definite proof, that humankind was a social and organic unity.*

Based on this, it may be an idea developed of necessity. As the whole of mankind is a unity in some fashion, tendencies emerge between different parts, drawing some apart, drawing some together. This may be advantageous for some at times and disadvantageous to others. If true that there is a unity among us, to humanity,

Telegram: @medical_k

www.konkur.in

biologically or otherwise, if a unity of humankind does exist, how can we find and realize it? From this, further research could be generated.

32.23 Other Methods of Psychotherapy

ADAM M. BRENNER, M.D., AND AARON VAN WRIGHT, M.D.

It is well established that a majority of the effectiveness of psychotherapeutic treatments can be accounted for by the common elements that all psychotherapies share. The features shared by all include a healer–patient relationship, in which different roles carry different expectations and a differential balance of power; a nonjudgmental, supportive acceptance of the patient; and an alliance of working together on shared goals. These common elements are rooted in our universal need for attachment and connection. Our brains are designed to seek out attachment when we feel isolated or threatened and to reciprocally be moved by the pain and loneliness of those who reach out to us. Resting on this foundation, psychotherapies of many different stripes are able to provide an experience–sometimes as quickly as the initial session–of feeling

Telegram: @medical_k

www.konkur.in

comforted, finding hope, and experiencing an amelioration of the sense of being alone or marginalized by one's presenting difficulties.

But if all therapies share these comforting elements, what accounts for the existence of so many different psychotherapies? The development of a specific psychotherapeutic method begins with the creation of a psychological model. Each individual model is built upon a unique conceptualization of how psychopathology evolves and what must happen to achieve an effective and satisfying life, either through the resolution of the psychopathology or in spite of the ongoing psychopathology. Thus, psychotherapy is always a learning process, taking advantage of the brain's neuroplasticity and the related human capacity for durable change at the most fundamental levels of being. Yet, as in formal education settings, learning within psychotherapy is a unique process among individuals and requires a diverse range of approaches. One way to understand the wide array of psychotherapeutic methods, therefore, is as an attempt to accommodate the various learning styles.

In addition, what the therapist hopes the patient will learn in the course of treatment is remarkably diverse and often rooted in very different fundamental ideas about the nature of psychopathology and what defines an effective and satisfying life. As an example, the cognitive therapist believes patients need to learn about implicit maladaptive thoughts, which eventually results in changes to deeply held belief systems that contribute to recurrent emotional distress and dysfunctional interpersonal engagement. The psychoanalytic therapist, on the other hand, believes the most effective learning approach involves the exploration of unconscious wishes and conflicts, which allows for the release of long-standing, self-imposed obstacles that hold people back from living life in the fullest way possible. In both instances, the aim is to relieve suffering and promote growth and development that, hopefully, will prevent suffering in the future. How this aim is achieved, and the specific goals that occur within the treatment itself are quite different.

Through the years, new psychotherapeutic approaches have been developed, usually borne out of a desire to fill an identified need in the treatment of mental illness. This section reviews several

Telegram: @medical_k

www.konkur.in

psychotherapies, some with a particular political slant or dealing with a special population, and some older therapies that continue to have discrete followings. Currently, most of these therapies do not have a rigorous evidence base to support their efficacy, but some continue to be studied. In addition, some of the ideas in these treatments are still in use in altered formats and may have relevance in their ongoing influence on the field. Each of these therapies, if effective, has been able to generate and benefit from the comforting elements common to all therapies, but each of them has had very different ideas about what kind of learning will be of benefit to the patient and what the therapist should do to help “teach” the patient.

CLIENT-CENTERED THERAPY

History

Client-centered therapy was created in 1940 by Carl Rogers, a psychologist. Believing that diagnosis, planning, and interpretation manipulate the patient to conform to the therapist’s ideas, Rogers tried only to listen, to understand, and to reflect what he perceived the patient to feel. When Rogers did so, he found that the patient often responded with a deep feeling of personal involvement and the production of new and important material. That passive or nondirective therapy was later named *client-centered therapy* and was published as such in 1951. Rogers’ ideas found wide acceptance and a movement around the principles of the therapy gathered momentum and grew over the next three decades. Rogers himself continued to develop the method and its applications at the University of Wisconsin, the University of Chicago, and Ohio State University and in La Jolla, California, where he died in 1987.

Client-centered therapy is based on the idea that each person has the ability to solve psychological problems and that feeling understood and highly valued aids the forces within to do so. Ideas such as an instinct toward self-realization and limitless inner powers had enormous appeal to the humanistic idealism that was developing at approximately the time that the method was published.

Telegram: @medical_k

www.konkur.in

A focus on the value of the individual and Rogers' later precept that long and particular training was not necessary for becoming a good therapist were similar rallying points for the antiestablishment, antiauthority emotions of the 1960s and 1970s.

Rogers played a major role in wresting the practice of psychotherapy from psychiatry alone and distributing it into the hands of psychology and other disciplines. He is also credited with being the first to research his results, the first to record sessions word by word and in movies and on videotape, the first to publish transcripts of his failures to encourage the study of what goes wrong, and the first to put forward the thesis that one does not need academic degrees to become a therapist. All but the last idea have become well-accepted elements in the field.

Client-centered therapy has been reported to be useful for children and adults, problems of neuroses, situational problems, speech difficulties, psychosomatic problems (e.g., allergies), and, to some extent, psychosis. It has been practiced with individuals and groups, and its principles have been applied in industry, education, child-rearing, and intensive encounter groups. Just before his death in 1987, Rogers was training policy makers and leading communication groups in South Africa and in workshops in Hungary and the former Soviet Union.

Theoretical Issues

The overarching presupposition of client-centered psychotherapy is that a basic, forward-moving force exists within—a tendency to grow, actualize, and integrate. A number of other principles flow from that idea: All people are believed to have the capacity to understand what factors cause them unhappiness and to overcome those factors; to do so, they must bring what is going on inside into awareness; and, effectuate the circumstances that make awareness possible, the therapist must establish a relationship that is warm and accepting.

Rogers believed that human beings immediately attach meaning to whatever is perceived so that perception becomes reality. A group of perceptions is organized as the self-concept—people's

Telegram: @medical_k

www.konkur.in

perceptions of their own characteristics, their relationships with others, and the value they place on those perceptions. Experiences contradicting the preferred perceptions of that organization cause anxiety and must be shut out. In therapy, the structure of the self is relaxed, so that the patient can drop the barrier and admit, “Yes, I do have those parts of myself that are unacceptable.” When this happens, the previously denied parts are accepted and then integrated, and the result is a better-functioning person, one who is less tied up in denial and conflict, more effective, and more tolerant of others than in the past.

The aim of the therapy is to create an interpersonal environment in which the self-structure can relax and in which material can come into consciousness. The therapist sets the three conditions that foster relaxation and the personal growth that follows. The three conditions are *congruence* (or *genuineness*), the ability to be present as a person, to be real in the relationship with the client; *unconditional positive regard*, which conveys to the client, “I accept you as you are, without making judgments or evaluations”; and real *empathic understanding*, a sense of standing in the client’s shoes, seeing the world from that vantage point, and then communicating what is understood from that view to the client. When these conditions are met, the client feels released and understood and is able to accept and integrate, view the world differently, and continue the process by bringing out new material.

Client-centered therapy was first practiced in a course of 5 or 6 hours, then 15 or 20 hours, and, still later, 100 or more hours. Whether the shift was caused by clients’ seeking greater levels of change, the enlistment in treatment of more difficult cases, an evolution in technique, or a fall-off in results after the initial enthusiasm is unclear.

Techniques

The techniques of client-centered psychotherapy serve the goal of having the therapist convey a sense of the worth and significance of the client and the idea that the therapist is trying to understand. Far

Telegram: @medical_k

www.konkur.in

from being laissez faire, the therapist needs to help actively and empathetically clarify what the patient feels. To be entirely nondirective, the therapist restates and reflects a close approximation of the client's feelings. When this is done correctly, clients feel as if the therapist were almost a part of them, working on their problems as they want to work on them; they feel accepted warmly, without any judgmental overtones. The acceptance and empathy are themselves therapeutic.

Rogers cited an example of an explosive 13-year-old boy who was changed and calmed by sessions in which he and the therapist only played tic-tac-toe or in which the therapist allowed silence while the patient sat at the window with his back to him, quietly counting cars. The therapist conveyed respect and belief in the child and the idea that the hour belonged to the child and that the adult would not be shocked by anything he did. The only limitation was that anger was allowed no physical expression, only symbolic and verbal expression.

The therapy aims not to interpret the client's unconscious motivations or conflicts but to reflect what the client feels. As the counselor and the client progressively clarify their feelings within the warm and accepting relationship, denied feelings come to light and can be dealt with and integrated.

Rogers described a male patient with considerable anger. As the therapist accepted the client's feelings and clarified to whom they were aimed, the client came to see which parts were rational and which were not. He was able to say, "If you are like my father, or if I only see you that way, I hate you as I hated him." When the unrealistic aspects were expressed openly, they dissolved, leaving the real relationship in place.

The theory also claims that resistance is overcome rather than interpreted. That is accomplished by the consistent acceptance and valuing of the client, the thoroughly undemanding nature of the relationship, and the empathic effort to clarify the client's feelings.

Telegram: @medical_k

www.konkur.in

A woman with denied anger at her husband embarrassed him with dizziness and faintness at gatherings that were important to him. The therapist consistently reflected her feelings to her with such questions as “You seem to feel…,” “You’re confused by…,” and “It seems to you that….” That clarification helped her to move from affirmations of a good relationship with her husband to recollections of old resentments and the recognition of present ill will. Keeping the focus on her also aborted any tendencies for her to project or accuse the therapist of anything but interest.

Transference is allegedly avoided in a similar fashion. Rogers gave examples of an angry client:

Client: Am I supposed to tell you everything?
Therapist: It’s up to you; you can talk about anything you want to.
Client: I had a big fight with you in my mind as I came here. I thought the whole thing was a fraud—I’m being very frank—you can talk like we do down here almost anywhere if you get someone to listen.
Therapist: It seemed it was kind of a cheat, something you could get anywhere.
Client: It’s like advertisements you see where, for a few dollars, people will sit and listen to you.
Therapist: Just listen to your troubles.
Client: Of course, they don’t have your extensive background, but they do the same thing. Then, after I talked it out with myself, I realized that the reason I was mad at you is because I feel nervous and jittery coming here (pause), because I’m facing something I don’t like to, talking things out myself.
Therapist: So the feelings about someone listening to you being a fraud–you recognize as being connected with your fear and irritation at having to face things in yourself?
Client: That’s right. That’s the real logic.

Telegram: @medical_k

www.konkur.in

In another example with chaotic angry feelings, the following dialogue took place:

Client: I hate you! I wish you never were born!
Therapist: You just hate me bitterly.
Client: I think I'll throw you in the lake. I'll cut you up! You think people like you, but they don't. I wish you were dead!
Therapist: You detest me, and you'd like to get rid of me.
Client: You think my father did bad things with me, but he didn't! You think he wasn't good, but he was! You think I want intercourse, but I don't.
Therapist: You feel I absolutely misrepresent all your thoughts.
Through this type of work, the client later confessed to a hallucination and said: "I had to get rid of this somewhere. I knew you'd understand. It's true I hate myself, but I couldn't say it, so I thought of all the ugly things I could say to you instead."

Rogers wrote that those interviews showed how feelings of transference were dealt with in the same way as other feelings and how a consistent reflection of the client's feelings essentially dissolved a transference issue by helping the client recognize their irrational emotions, after which they could deal with them and what they hid.

Indications

The general indications for therapy are when clients feel that their organized self-structures are no longer effective in meeting their needs in the reality situation or when they perceive discrepancies in themselves or see that their behavior is out of control. The description generally covers problems in the neurotic range, but a client-centered approach has been used with children who are 2 years of age and adults who are 65+ years of age, with people who have mild adjustment problems and disorders diagnosed as

Telegram: @medical_k

www.konkur.in

psychotic, and with persons of all social classes and levels of intelligence. The theory affirms that a trial of the therapy is unlikely to do harm.

Early in the development of the method, Rogers believed that diagnosis was inadequate and prejudicial. Placing the locus of evaluation in the hands of the therapist rather than the client had undesirable consequences, undermining the client's power of self-determination and raising the specter of misuse for social control. Nosologic limitations may have supported this early position, and the social circumstances of the 1960s may have lent it credence, but Rogers' followers believed in it as late as 1987.

In recent years, client-centered therapy is referred to as person-centered therapy. It has been applied in such areas as working with transgender and gender-diverse clients, and in community-based treatment of acquired brain injury (ABI). In the case of transgender and gender-diverse clients, the authors of a recent article discuss the use of a person-centered approach integrated with current scholarship to offer specific interventions for use in these clients. The authors describe using these interventions to focus on treatment of rifts within the individual that are internalized from societal rejection. In the treatment of ABI, one recent article presents a case that successfully incorporated person-centered therapy to treat challenging behaviors and avoid hospitalization.

Ethical Issues, Research, and Evaluation

Rogers' ideas sparked and rode the crest of the humanistic movement in psychology. His emphasis on the value of clients and on the need to accept and respect them in therapeutic relationships was timely and had a refreshing influence on child-rearing, education, and group relations, as well as on psychotherapy. His attempts to train nonprofessionals were less well-received, and the attempts foundered; the method became so simplified that blank verbal repetitions too easily replaced a true empathic congruence and effort to understand.

Telegram: @medical_k

www.konkur.in

Practitioners of client-centered psychotherapy did not believe that diagnosis was particularly useful and did not follow the medical model of illness. That a warm and genuine relationship is sufficient to dissolve resistances that are dynamically motivated and tenaciously held is another tenet open to question. Reflecting on what the client feels without interpreting where it comes from or the purposes that it may serve may drive the client to action as a further defense. Rogers noted that the method is frequently unsuccessful with clients who feel incapable of managing themselves and who insist that the therapist take over; a different approach interprets the client's insistence and resentment, rather than just reflecting them. Similarly, reflection in the face of other intense transferences seems to be less effective than a focus on the fantasies that lend force to the transference.

In its contributions to psychotherapy research, client-centered therapy has been outstanding. Rogers and his followers were the first to record and review transcripts of sessions, the first to document the process of treatment, and the first to do follow-up studies of results. They developed such innovations as the q-sort and scales to objectify the Rorschach test. They showed that, in successful therapy, negative attitudes about the self are replaced by positive attitudes, that acceptance of others occurs in parallel, that psychological tension decreases, and that plans take the place of old complaints. Although initial claims about success in treating schizophrenia patients had to be dropped, and although Rogers and his colleagues did not do controlled comparisons of their method with others, they were able to document that client-centered therapy is effective. By clearly delineating that a successful outcome is associated with genuine acceptance and an empathic congruence that facilitates the recognition and expression of emotion, they recognized two of the features that empower psychotherapy of whatever stripe. Perhaps most importantly, their emphasis on progressive clarification of the client's feelings sounds an insistent cautionary note about the need for clear understanding, rather than facile interpretation based on the assumptions of one's theory.

DIGNITY THERAPY

History

Beginning in the 1960s in the United Kingdom and gaining traction in the United States in the 1980s, the modern hospice movement changed the way in which end-of-life care is delivered, placing an emphasis on maintenance of functioning and physical comfort over aggressive illness-focused treatment. The subsequent establishment of palliative care as a board-certified internal medicine subspecialty in 2006 brought further credibility to the approach championed by the modern hospice movement. The traditional palliative care model uses a multidisciplinary approach to address the far-ranging issues associated with terminal illness, including pain management, assistance with the provision of home medical care, and education and support for caregivers. While the scientific evidence overwhelmingly demonstrates positive gains in quality of life for both patients and loved ones when palliative care methods are utilized, observational studies continue to demonstrate high rates of depression and anxiety in patients with terminal illness. Complicating matters, research also suggests patients with terminal illness, especially those who become sick later in life, do not respond well to traditional antidepressant and anxiolytic treatment approaches.

Beginning in the late 1990s, a group at the University of Manitoba led by Dr. Harvey Max Chochinov set out to address the both prevention of psychological distress and improving response to psychiatric treatment in end-of-life care. Dr. Chochinov and his research group designed and tested a brief, manualized psychotherapeutic approach coined “Dignity Therapy” that was shown to reduce psychological distress in both patients with terminal illness and their caregivers, leading to improved outcomes in quality of life and lower rates of depression and anxiety. Subsequent to the publication of Dr. Chochinov’s research, other groups tested the approach and found similar rates of effectiveness across an even wider range of diagnoses and conditions. This growing body of evidence has led some to call for similar approaches to be

Telegram: @medical_k

www.konkur.in

incorporated not only into routine palliative care practices but also into the care of those with debilitating but nonterminal chronic medical illness.

Theoretical Issues

It is not entirely clear why patients with terminal illness have a high prevalence of depression and anxiety, and why they may not respond as well to traditional therapies. A common formulation is that the decline in physical, cognitive, and social functioning associated with terminal illness leads to a loss of “dignity” on the part of the patient, which in turn, leads to feelings of helplessness, hopelessness, isolation, and despair. Therefore, in order to prevent the development of depression and anxiety and to treat the symptoms of these conditions if they emerge, one must find a way to maintain a person’s dignity as they move toward death.

One of the clear results from dignity research in terminal illness is the mere exploration of dignity with most dying patients leads to the desired therapeutic effect. For some patients, though, a more systematic process is required. When thinking about the development of a systematized management approach, a complex picture emerges. First, dignity is a highly subjective and variable concept, and so common elements must be identified that cut across populations within the context of end-of-life care. Then, careful analysis and categorization of these common elements are necessary so that a cohesive model for dignity can be formed. Finally, a therapeutic process that operationalizes this model must be tested to gauge the validity of the model and the effect of the therapeutic process on those parts of a person’s identity that contribute to dignity. Finally, the model of dignity must be sufficiently dynamic to account for the physical, mental, and social changes that occur with terminal illness, and the therapeutic process must be both accessible and engaging for patients whose ability to participate in traditional psychotherapeutic approaches often is compromised.

Drawing on techniques of narrative, client-centered, and existential psychotherapies and set within a framework of dignity grounded in

Telegram: @medical_k

www.konkur.in

Eriksonian developmental ideals, Dignity therapy seeks to assist patients as they strive to resolve questions and internal conflict surrounding the terminal and often debilitating nature of their illness, their evolving role in pre-existing social constructs, and the impact these two factors have on self-identity.

Dignity therapy aims to promote a lasting sense of generativity while simultaneously engaging in the development of ego integrity. The underlying idea is that very often, terminal illness develops during the final years of one's middle adulthood. It also, then, compresses late adulthood into a much shorter timeframe. One of the keys, therefore, to alleviate psychological distress is to help patients complete the developmental tasks of these life stages. In order to accomplish this feat, the patients are charged with telling their story and describing themselves in their own words, while being prompted by the interviewer with probing questions focused on the exploration of their life's meaning and being refocused continually on those things that appear most central and engender the greatest sense of pride. The end result is a retrospective process that helps patients see their life through a lens of contentment and satisfaction, along with the production of a written portrait, with which patients are allowed to do as they please.

Techniques

Dignity therapy is a brief, manualized psychotherapeutic treatment intended to be delivered on an individual basis by a qualified mental health professional. The treatment typically requires three to four sessions, spaced over a week's time. The duration of each patient visit varies with the specific goals of the session and the volume of material discussed. Typically, though, sessions last between 30 and 60 minutes. Dignity therapy has been validated in outpatient, residential, and inpatient settings.

The basic structure of a course in Dignity therapy is as follows:

Session #1. The first session consists of four main components.

Telegram: @medical_k

www.konkur.in

1. Administration of rating scales—These can be self-report or clinician-administered measurements. The tools used should include, at a minimum, screening questions for depression, anxiety, hopelessness, and suicidality, as well as ratings for sense of well-being and quality of life.
2. Introduction to the process and goals of therapy—Special attention should be given to the collaborative nature of the therapy and the production of the "generativity document," which is the edited written transcript provided to the patient at the conclusion of the therapy.
3. Informed consent for treatment and audio recording—This will have critical importance when considering the ethical implications of the treatment.
4. Written copy of the questions included in the Dignity therapy protocol provided for review and consideration—The same nine questions are used in every course of treatment.

Session #2. The second session is the audio-recording session and begins with the therapist asking the patient the first question on the Dignity therapy question protocol:

"Tell me a little about your life history; particularly the parts that you either remember most or think are the most important?"

The therapist uses the remaining questions included in the Dignity therapy protocol in a flexible manner, following the patient's lead and paying particular attention to the patient's affect to determine when to ask relevant follow-up questions. The goal is not to obtain a response to each question included in the protocol, but to prompt the patient to verbalize those aspects of their life that are viewed as essential to positive self-identity. The therapist utilizes a combination of reflective listening, displays of empathy, dynamic clarification, and existential probing. Additionally, the use of guided imagery and relaxation techniques can be utilized if patients struggle to put together their thoughts or experience acute psychological distress.

Following Session #2, the audio recording is transcribed and edited into a coherent narrative that conveys the tone and message desired by the patient. To this effect, an essential component of this

Telegram: @medical_k

www.konkur.in

editing process is finding a single, concluding statement that captures the patient's desired lasting legacy.

Session #3. During the third session, the narrative produced from the edited transcript of the audio-recorded session is read aloud to the patient. This allows the patient to provide feedback on the historical accuracy of the narrative and to determine if there are any anecdotes or information that should be removed or included. In addition, reflecting upon their own self-portrait evokes a strong emotional response, and this helps to solidify ego integrity.

Session #4. Any feedback provided by the patient is used to create a final draft of the narrative, which is termed the "generativity document." In the final session, this document is provided to the patient, and the patient's plans for the document are considered. Additionally, the patient is invited to reflect upon the therapeutic process. Any concerns expressed by the patient are clarified and addressed. Finally, the initial rating scales readministered to gauge the therapeutic effect of the treatment and to determine if additional treatment steps are necessary.

Clinical Issues

The original research validating Dignity therapy was performed within a fairly narrow patient population, namely, adults from Canada and Australia in hospice-care settings with terminal illness (primarily cancer) and a life expectancy of less than 6 months. Further studies have included more variable demographics, different illness types, and lesser illness severity, including multiple studies done with older adult patients in long-term care facilities without a specific terminal illness.

Notably absent from most of these studies are specific inclusion or exclusion criteria for pre-existing psychiatric symptoms or psychological distress, although these were identified in a large proportion of patients as part of the research protocols. Since all of the studies demonstrated effectiveness across multiple domains (dignity, quality of life, depression, anxiety, hopelessness, suffering,

Telegram: @medical_k

www.konkur.in

etc.) for the whole of the included populations, the research findings suggest Dignity therapy is indicated not just for those persons identified as depressed or anxious, but for all persons as they approach the end-of-life. It should be noted, however, that those persons identified during study enrollment as having significant psychiatric symptoms or psychological distress experienced the most significant positive effect from a course of Dignity therapy.

While Dignity therapy may have widespread application, there are two particular patient groups for whom the effectiveness of the treatment is unknown. Dignity therapy has not been studied in pediatric or adolescent populations, or in patients with significant cognitive impairment. The current approach requires a level of patient engagement and awareness that excludes younger patients and those with cognitive deficits. It is possible Dignity therapy can be adapted to these populations, but additional study will be required.

Ethical Issues

Helping patients resolve inner psychological conflict that is influenced by their terminal condition is a central feature of Dignity therapy. Although acceptance of death is not a primary goal of the treatment, this process often leads to a greater acceptance of human mortality. It is therefore possible to imagine situations in which Dignity therapy could be misused with the purpose of influencing patients as they consider various treatment options to either prolong or foreshorten life. Another risk of Dignity therapy is the potential impact on matters of estate and other legal issues of the generativity document and the audio recording from which it is transcribed. This is why it is essential to obtain the patient's informed consent for both treatment and audio recording and to review the generativity document with the patient before it is revealed to others.

Research and Evaluation

The research generally demonstrates beneficial effects on psychiatric symptoms and psychological distress in those who are suffering. Additionally, Dignity therapy leads to improvements in

Telegram: @medical_k

www.konkur.in

quality of life and overall sense of well-being in patients who are not struggling with the psychological impact of their illness. Finally, there is evidence Dignity therapy has a positive impact on caregivers.

Future research considerations likely include expansion of the Dignity therapy approach to nonterminal illness, the study of Dignity therapy in adolescent and young adult populations, and the adaptation of Dignity therapy for persons who are unable to participate in the process as it currently is constructed (e.g. children and those with cognitive impairments).

PSYCHOTHERAPY FOR THE DEAF

History

Psychotherapy for the deaf is not a particular type of psychotherapy but a group of therapies that are adapted to the needs of a special population—people who develop a profound hearing impairment before speech is established. The impairment is defined operationally as one that renders audition useless as a means of intercourse with the hearing world, and it generally involves a hearing loss of 80 dB or more across the speech frequencies, even with the aid of amplification. Its most obvious consequence is to interfere with the ability to learn language by simple auditory imitation and at the normal time and pace of development.

Psychiatric interest in the deaf began with the work of Franz Kallmann, John Rainer, and Kenneth Altshuler in the mid-1950s. Then the country's most prominent geneticist in psychiatry, Kallmann was approached by a branch of what is now the U.S. Department of Health and Human Services for assistance in obtaining case closure among psychiatrically ill deaf clients. Kallmann recruited Rainer and Altshuler and began a series of normative studies and studies of deaf persons with mental illness. The first effort established an outpatient psychiatric clinic, and subsequent projects developed an inpatient unit for statewide services, a vocational rehabilitation liaison and halfway house program, and consultation programs at a school for the deaf. Centers focused on psychiatry and the deaf were

Telegram: @medical_k

www.konkur.in

subsequently established in Chicago, San Francisco, Washington, and several other cities and countries around the world. At present, a small caucus of psychiatrists interested in working with the profoundly deaf meets regularly at annual meetings of the American Psychiatric Association.

Theoretical Issues

To adapt a given psychotherapy to the needs of persons with profound early deafness demands that the therapist understand what the handicap means to one's life experience and that they take into account the limitations that this experience places on the therapeutic exchange. At the same time, the therapist keeps in mind that people who are deaf also experience the same longings, fears, and conflicts as the general population.

A first guiding principle is that the simple absence of audition has no relevance to innate intelligence potentials; intelligence quotients (IQs) among the deaf follow the same bell-shaped curve as in the hearing. Among the deaf, performance scores are generally higher than verbal scores because of the lag in language development. Deaf children of deaf parents develop vocabulary at the same rate as their hearing peers, albeit in sign language, because their parents are able to communicate with them freely. Occasionally, an enlightened hearing parent learns sign language to provide the only free, two-way accessibility that the handicap allows.

Too often, however, parents are caught up in an educational controversy that has gone on since Alexander Graham Bell and the 1880s, about whether signing discourages the learning of speech. Evidence suggests that an educational approach that embraces all avenues of communication—combining oralism, speech and lipreading instruction, amplification, and sign language—gives the best results. Moreover, the combination supports the exercise of age-appropriate interests and language skills in accordance with their natural developmental timetable. In the absence of a widespread combined educational approach, studies in the 1970s showed that the average deaf adolescent left high school with

Telegram: @medical_k

www.konkur.in

approximately fourth-grade and fifth-grade English and mathematical skills.

As a result of these findings and the urging of mental health professionals, since the 1970s, there has been a major shift in educational practices from a nearly exclusive emphasis on oralism toward some variety of the combined mode of instruction. Pockets of resistance exist and the availability of cochlear implants at a relatively early age may recast expectations and heat up the issue again.

A factor contributing to the endurance of the controversy is that parents are understandably hurt and saddened when the handicap is recognized, and they wish that it would go away. Motivated partly by denial and partly by the commendable desire that their child's life be like any other child's life, parents resist sign language as the visible symbol of the handicap and the harbinger of a separate and sequestered existence. What is lost in the face of these pressures is the recognition that language, generally mediated through audition, brings a tremendous amount of information and experience. Without hearing or the effective alternative of sign language, uncountable hours of speech and lipreading instruction can only provide language late and often incompletely.

Sound also brings nuance and music, and it is the sole distance receptor that scans 360 degrees of the environment at all times, perhaps even in sleep. What may be associated with missing those elements of experience is uncertain.

A final concomitant of deafness, at least in the 90% of those born to hearing parents, is that the parents of deaf children feel confused, uncertain, and, often, guilty. Their own ambivalence, the conflicting advice that they may receive, and the stranger to communication in their midst often makes them overprotective, inconsistent in discipline, and erratic in their hopes and approach.

Techniques

Communication is the sine qua non of psychotherapy. The first requirement with the deaf is to understand what life experiences the

Telegram: @medical_k

www.konkur.in

handicap entails; the second requirement is to interact freely with patients in order to apprehend their personal and particular experiences and to exchange understanding about the details. By adulthood, virtually every person with early profound deafness is comfortable and fluent in sign language (barring an accompanying organic problem that interferes with language acquisition, regardless of mode). Having the therapist equally versed in manual language would be ideal but is rarely possible, despite the fact that a growing number of psychiatrists and others have learned to sign. The problem is lessened to the extent that the patient's language, speech, and lipreading skills are developed. Often, these skills are insufficient to allow the conduct of meaningful psychotherapy, even with exchanges in writing. In such instances, an interpreter is necessary. Deaf persons often rely on interpreters, and the therapist, rather than the patient, may be the one who is uncomfortable with the third party's presence. One must be alert, however, to the interpreter's tendency to interpret when the therapist wants an exact translation; for example, when the patient's thoughts are to be evaluated, the interpreter's efforts to make sense of them may be counterproductive. Supportive psychotherapy can be conducted with the aid of an interpreter, but substantial insightful work probably demands a subtlety of understanding that is only available with manual skill on the part of the therapist or adept speech and lipreading skills on the part of the patient.

Clinical Issues

Less than profound deafness and deafness after speech is well-established are problems of a different nature and require different adaptations. To the extent that language has been developed before the loss of hearing, and to the extent that the loss is remediable by amplification, the patient's life experiences are less affected, and therapy requires less in the way of modification. However, the loss itself, its cause, and the patient's changed life circumstances because of it are factors that affect the person's problems and the therapy.

Telegram: @medical_k

www.konkur.in

A couple of additional points must be kept in mind in counseling the hearing parents of deaf children. Eager for their child to have a normal life, the parents may be impatient with modest results in attempts to remediate the handicap and its effects. Complaints of bad treatment at the hands of many institutions or agencies must be evaluated with that possibility in mind. Also, denial on the part of a family may be brought to an abrupt end with the child's impending adolescence. When parallel play and participation in simple games give way, and the horizons of social interaction loom large, the effects of the handicap become unavoidable, and parents may become depressed.

Research

The educational, developmental, and psychiatric literature on early profound deafness is considerable, but no controlled studies of psychotherapy have been reported. The psychiatric literature, mostly from the 1970s and before, suggests that major mental illness is no more prevalent among the deaf than in the hearing, that impulsive or aggressive behavior may be more common in the presentation of illness among the deaf, and that guilt and psychomotor retardation may be less frequent in cases of depressive disorders in the deaf. Anecdotal reports also indicate that various forms of psychotherapy are as useful in the deaf as in the hearing when modifications in view of the handicap are made.

EXISTENTIAL PSYCHOTHERAPIES

History

Existential psychotherapies are a diverse group of treatments that were inspired by the writings of the existential philosophers and novelists. The therapies emphasize exploring and validating the individual's subjective experience with a minimum of theoretical expectations; fostering greater authenticity in affective experience and decision-making; and confronting the unavoidable and painful limitations of human existence. Defining the essential underlying

Telegram: @medical_k

www.konkur.in

qualities of these treatments in order to create a unifying framework for practice and research has been difficult. There is no single founder of existential therapy to invoke as a defining authority; the philosophies in which existential therapies are rooted differ greatly and are open to multiple interpretations; and the existential stance tends to be suspicious of authority and of overarching systems of meaning, making it inherently inhospitable to attempts to codify the disparate approaches. Nonetheless, there are several significant elements these theoreticians and clinicians share, and which together yield a reasonably coherent body of theory and practice.

Existential philosophy arose in the late 19th and first half of the 20th centuries as a challenge to traditional religious and philosophic optimism, which held that truth could be attained through reason and that individual values could be grounded in the ever-expanding knowledge of the universe. Existentialism asserted that reason has limits, that the universe was a place of arbitrary facts, and that the irrational elements of the human psyche always limit the potential for self-knowledge and social order. Existentialists were suspicious of abstract truths and placed their trust in the reality of an individual's experience. Within this perspective, existentialists showed great diversity and included religious thinkers such as Martin Buber, Soren Kierkegaard, and Paul Tillich as well as secular and atheistic philosophers such as Martin Heidegger, Friedrich Nietzsche, and Jean Paul Sartre. Some, like Sartre and Albert Camus, expressed their ideas in fictional writing that explored the individual's confrontation with the inherent meaninglessness of life and the responsibility to nonetheless make authentic choices.

Kierkegaard and Nietzsche were aware of the profound anxiety and confusion resulting from feeling uprooted from a grounding morality and faith, while at the same time being cognizant of mankind's potential for acts of destruction. Kierkegaard advocated a religious "leap of faith," while Nietzsche pronounced that "God is dead," which if true would leave mankind forced to create new systems of value. As different as they were, both thinkers shared a conviction that a meaningful life requires a profound effort and commitment on the part of the individual.

Telegram: @medical_k

www.konkur.in

The clinicians in Europe who created existential psychotherapy felt that Freud did not adequately address the human need to find meaning in an innately meaningless world. They felt that Freud's technique was profoundly helpful, but that his theory of biologic drives was reductive and overly focused on the physical world. The school of Existential Analysis, represented prominently by Ludwig Binswanger and Medard Boss, grew out of the application of Heidegger's philosophy to problems of psychotherapy. Heidegger created the concept of "being in the world" to define what is unique to human existence, specifically, that man is always both a thing in the world and the creator of meaning and knowledge.

Logotherapy is an existential psychotherapy based on the work of psychologist Viktor Frankl, whose ideas were influenced by his experience as an inmate in Nazi concentration camps. He came to believe that while people cannot control what happens to them, they can choose the attitudes with which they face and respond to their circumstances. Frankl felt this to be a fundamentally hopeful stance, and termed it "tragic optimism."

Somewhat later, Rollo May focused the attention of the psychiatric community on existential psychotherapy and generated substantial interest among American psychotherapists; his particular approach blended humanistic psychology, psychodynamic techniques, and an emphasis on the individual's alienation from their own passions and inner life. Irwin Yalom's case studies and his text *Existential Psychotherapy* were similarly influential in sustaining interest in this existential-humanistic tradition among a broad audience of psychotherapy practitioners.

Theoretical Issues

Existential psychotherapies draw on diverse theoretical roots, which include the elaboration of the phenomenologic method, as well as explorations of alienation and anxiety. Phenomenologists attempt to step outside pre-existing conceptions and ideas about the world in order to experience each new object or person directly. The phenomenologic method, therefore, inspired existential

Telegram: @medical_k

www.konkur.in

psychotherapists to seek a spontaneous empathic encounter with each new patient. Clinicians within this tradition emphasize an engagement with the patient in their unique wholeness. Therapists strive to avoid letting their preconceived ideas about patients and their pathology interfere with their understanding of the patient in the present moment. In their view, a focus on diagnosis, or on ego structure and defenses, is thought to divide the experience of the patient into pieces and miss the opportunity for an encounter with the whole person.

Existential therapists see anxiety and guilt as essential aspects of human existence, and not just responses to specific events or conditions. Anxiety and guilt can be realistic, neurotic, or existential. Realistic anxiety is the signal of actual danger, while neurotic anxiety follows from fantasized, projected, or displaced threats. Existential anxiety is seen as the experience of the dread of nonbeing—which includes death, but also a person's unrealized potential. Realistic guilt is in response to actual crimes or transgression, and neurotic guilt follows from fantasized, generally unconscious, forbidden wishes. Existential guilt means guilt derived from suppressing one's real potential in favor of inauthentic conformity.

Techniques

Although the practice of therapists varies widely, there remain some common points of technical emphasis. First, existential therapists try to find the patient's unique worldview and enter into this experience with the patient. They emphasize the importance of empathy with the totality of the patient—that is, actually "knowing" as opposed to "knowing about" the person. Second, existential therapists attempt to uncover and work through deep anxiety that stems from such universal threats such as aloneness, meaninglessness, and mortality. Third, existential therapists emphasize that all people are subject to inescapable reality-based limits and try to help their patient bear these facts. One such limit is the fact of being who one is and not someone else; another is the impossibility of fully knowing, or being known by, another person. Fourth, existential therapists

Telegram: @medical_k

www.konkur.in

consider the denial of one's mortality and the fear of death to be critical determinants of pathology and focus their attention on these issues. Finally, the therapists support patients recognizing their freedom to choose their actions within these limits, and their freedom to create their own meanings for the events of their lives. The existential therapist pays close attention to whether patients' choices represent their true desires and values of the patient, or whether they are better understood as distractions or narcotics.

Yalom described a patient who presented with compulsive sexual affairs. A dream of a magic bow and arrow was interpreted as representing the use of his phallus to transcend the ordinariness and banality of death and his affairs as providing him with the illusion of immortality. As the patient began to give up the compulsive behavior, it was possible to use therapy to also confront the question "What are people for?" and open up an exploration of existential isolation.

Existential analysis borrowed the technical structure of psychoanalysis (frequent sessions, use of the couch, free association, nondirective exploration), but remains squarely within the frame of the patient's current experience. Therapists eschew interpretations of unconscious conflict, symbolism, or transference and view the essential pathology as that of being closed off to parts of one's own experience. Thus, treatment aims to increase patients' openness to what is disavowed. To this end, some therapists use direct confrontation, paradoxical interventions, and active reframing. The techniques of logotherapy aim to promote the identification of meanings that transcend one's own self; this is done through "self-distancing," which seems very similar to developing and observing ego. Such specific maneuvers are meant to be used in the context of a "Socratic dialogue" that attempts to trigger the patient's own resources of wisdom.

Existential therapy, unlike psychoanalytic approaches, is not primarily developmental in its thinking. The basic concerns of human

Telegram: @medical_k

www.konkur.in

existence—death, freedom, isolation, and meaning—underlie anxiety for patients of any age. And May, reversing the classical psychoanalytic tendency to find present meanings in autobiographical events, suggested that people's understanding of the past is actually determined by their experience of the present and future. As with many contributions of the existential clinicians, these ideas have since been integrated into the body of mainstream psychodynamic thought.

Indications

Existential psychotherapists claim success with this modality in the same range of conditions as dynamic therapies in general—depression and dysthymia, anxiety disorders, complicated bereavement, trauma, adjustment disorders, and the like. An extended application of existential therapy suggests that much of the depressed affect seen in bipolar patients may be better conceptualized as existential despair; thus, psychiatrists should address core existential issues such as the conflict between hope versus demoralization. It has been reported also that logotherapy may be a useful adjunctive treatment for combat veterans whose difficulties include existential concerns such as a foreshortened future, survivor guilt, and a sense of nihilism. A variety of interventions grounded in existential concerns are reported in the psychosomatic psychiatry literature in recognition of the significance of such issues for patients coping with severe or chronic medical illness. Group existential psychotherapies are increasingly reported on as adjunctive treatment for cancer patients. Brief psychotherapeutic interventions for these and other medically hospitalized patients may help the patient move from a position of defeat and hopelessness to one of resilience, agency, and connection with others. Most recently during the COVID-19 pandemic, existential therapy in the form of existential-humanistic therapy was proposed as when employed as beneficial as part of a disaster response program. The pervasive widespread human

Telegram: @medical_k

www.konkur.in

suffering during the global crisis provided a unique opportunity to adapt the approaches of this therapy type to the situation.

Ethical Issues, Research, and Evaluation

There has been little systematic study of the indications or outcomes of existential psychotherapies. It may be that the emphasis on the individual's authentic and autonomous creation of meanings is especially challenging to systematize, and this has created an impediment to empirical study.

The existential therapies aim to understand patients according to their unique life situations and to foster their authentic choices without forcing them to fit into a preordained theory of mental structure or development. The inevitable influence of the therapist's subjectivity, however, has made it increasingly difficult to accept the existential assumption that the patient can be perceived uncontaminated by the therapist's theory and technique. Any attempt to restate the patient's narrative, distill central themes, or define affective currents is likely to be influenced by the therapist's theories of mind, conflict, development, and change. The existential psychotherapists have, however, provided a valuable service to the field of psychotherapy through their impassioned attention to the individual patient's experience and choices and their conviction that it is all too easy for therapists to collude in an avoidance of the existential challenges of mortality, meaning, and disconnection. As a result, the priorities, interests, and techniques of the existential therapies are today often integrated into the work of eclectic therapists of different persuasions.

PARADOXICAL AND STRATEGIC THERAPIES

History

According to the principle of paradoxical intention, fighting the symptoms of performance anxiety increases their severity, but invoking them deliberately may yield the opposite. Milton Erickson

Telegram: @medical_k

www.konkur.in

elaborated those ideas into paradoxical therapy, and the method was further refined and promulgated widely by Jay Haley.

Erickson was a hypnotherapist whose prowess in the use of paradoxical techniques was reputed to be extraordinary. Haley, while working on the double-bind theory of schizophrenia, thought that perhaps there could be therapeutic double binds, as well as pathologic ones. He attended one of Erickson's hypnosis workshops in 1953 and, with John Weakland, began a regular series of visits that endured for 20 years. Haley and his colleagues learned from Erickson and published what they had learned. Others made similar visits or were attracted by the ideas or the stories that they heard, and they added to the reputation and the literature of the growing movement. Haley later developed strategic therapy, essentially a method that applied Ericksonian paradoxical principles, along with other directive techniques, to family therapy.

Interest in Erickson's paradoxical therapy grew over the years and reached its height in the late 1970s and early 1980s. By this time, the method claimed success in treating individuals, couples, and families for a range of problems, including phobias, compulsions, insomnia, schizophrenia, Tourette syndrome, urinary retention, transvestic fetishism, anorexia nervosa, agoraphobia, childhood fecal incontinence, alcohol use disorders, depressive disorders, fire setting, asthma, constipation, truancy, and a variety of sexual performance and relationship difficulties.

Erickson died in 1980, and a foundation was formed to continue the work that he started. He was one of the first to show that brief therapy can be an effective and primary approach. He advocated that therapists should not be just passive listeners but active interventionists and guides; focus on symptoms rather than on dynamics and on action rather than on understanding; prescribe, as part of the treatment, the very resistances and symptoms the patient brought to it; and use indirection and metaphor to achieve the goals of therapy.

Theoretical Issues

Telegram: @medical_k

www.konkur.in

The overarching idea in paradoxical therapy is to embrace and amplify the notion of paradoxical intention and thereby reduce performance anxiety or destabilize a fixed internal or social system. The paradox and the destabilization may be effective in themselves or may cause secondary reverberations, such as increased self-awareness and the evocation of new behavior or emotions that lead to helpful change.

Paradoxical therapy is relatively atheoretical about cause and is not much concerned with it. Behavioral prescription is emphasized, with the idea that altering internal and social feedback loops can alter the system. Symptoms that block change can be made vehicles for it if they are embraced and are prescribed or altered in their timing or the function that they serve. Instructing an impotent patient under no circumstances to try intercourse, for example, may dissipate anxiety and may allow him to do so; telling an insomniac to get up and polish the floors for the rest of the night may similarly invite sleep. Paradoxical therapy also recommends defining the problem clearly, establishing clear goals for the treatment, offering a plan, and enlisting the collaboration of the patient or the family in the suggested strategy.

Techniques

Some of the principles of paradoxical therapy can be directly translated into techniques: Using patients' tendencies toward compliance or defiance—for example, by overtly expecting a relapse and being surprised about improvement; reframing (i.e., relabeling behavior and emotions so that their experience is changed from negative to positive or vice versa); using metaphor, indirect directives, and cryptic paradox; and distancing patients from their symptoms or challenging patients by humor or sarcasm. These techniques and the extent of the therapist activity encouraged in paradoxical therapy are illustrated in the following cases of Erickson and his followers.

Making the Activity Deliberate

Telegram: @medical_k

www.konkur.in

An alcoholic wife secretly hides her bottles, and the husband searches for them with increasing anger. With the relationship at a breaking point, Erickson prescribed that she deliberately hide the bottles and that he searched for them. If he found one, he could keep it. If it eluded him, she would be allowed to drink in peace. He also suggested that they buy a trailer and go fishing, an activity that they both disliked. The reported results were that the drinking abated, and the couple later happily used the trailer to go camping. The deliberate game apparently subverted the purpose of the prior secretive activity, and forcing the couple to share a disliked recreation brought them into close contact (with alcohol unavailable) and pressured them to communicate, enjoy each other, and make pleasant vacation plans.

Prescribing the Symptom

Instead of telling her husband what she felt, a woman would unconsciously start a fight with him when she wanted affection. She was instructed to start a fight on purpose and intensely the next time that she felt empty or unloved. Doing so, she noted the connection and realized that, under attack, her partner could not possibly respond with support or love. She also felt ashamed, and the experience helped her acknowledge and express her wishes more directly.

Aversive Conditioning

Telegram: @medical_k

www.konkur.in

A woman consulted Erickson about her schizophrenic son, who did nothing but sit around the house and moan. Erickson recommended taking him for a drive; she was to drop him off, drive 3 miles farther, then sit and read while she waited for him. After doing that a few times, the son volunteered to walk without being dropped off, and later asked if he could go bowling while she read, because he liked bowling more than walking.

A second patient told Erickson that he could drive only on certain streets and that he would become nauseated, vomit, and faint if he tried to drive outside the city limits. Erickson required him to drive to the edge of town in his best clothes, to park and to lie down in a sandy ditch at the roadside, and to lie there for at least 15 minutes. He was then to drive one or two car lengths farther, repeat the procedure, and do that until he could drive from one telephone pole to the next. He was also told to stop immediately and to get into the ditch at the first sign of any symptoms. The patient reported: “The more I did it, the madder I got. So I just quit and began to enjoy driving.” Thirteen years later, Erickson reported, the former patient still had no trouble driving. Anger and defiance allegedly brought about a cure.

Destabilization

Telegram: @medical_k

www.konkur.in

A boy who was 10 years of age engaged in compulsive, public masturbation; the compulsion had endured for years, despite many treatment efforts. Taking the behavior seriously, the therapist asked the boy to keep a list of when he masturbated and to note when he found it most pleasurable. With the idea that he should do it when he found it most pleasurable (on weekends), he was assigned to do it eight times on Sunday but not on Monday. When the boy failed and masturbated on Monday, the disappointed therapist prescribed that he do it 12 times the next Sunday. When the boy was not up to the task, the therapist suggested that, as punishment, the boy masturbate once daily in public and eight times on Sunday. Masturbation was also prescribed as a punishment for thumb-sucking and as an alternative to homework. Gradually, the boy stopped and even enjoyed his homework.

Examples reported as successful include telling a woman with headaches, which were symptomatic of family relationship problems, that the headaches were probably incurable and that therapy should aim at helping her live with them; asking the parents of a child with severe and long-standing encopresis whether they could tolerate being normal and being better parents than their mothers (the father then threatened the child with laxatives, and the problem disappeared); and combining reframing and negative emphasis or challenge by telling a family with a school-phobic child: “Maybe it’s better she stay at home. It keeps the family from being normal, and being normal may not be tolerable.” (The therapist reported that the family did not get insulted and leave but changed spontaneously to prove him wrong.)

Most recently paradoxical and strategic therapies appear in the treatment literature of anxiety-related disorder and binge eating disorders respectively in the form of *paradoxical timetable therapy* and brief strategic therapy. Paradoxical timetable therapy–also referred to as PTC (Paradox + Timetable = Cure)–pairs the

Telegram: @medical_k

www.konkur.in

previously described paradoxical prescription or disorder symptom with a timetable. The timetable dictates that the planned paradox task should be performed within the limits prescribed or not be performed at all. The components of the paradoxical task and timetable are linked and are prescribed together. A form of strategic therapy called brief strategic therapy recently compared favorably to cognitive-behavioral therapy (CBT) in a 2018 randomized clinical trial in women with binge eating disorder.

Clinical and Ethical Issues

Paradoxical therapy is clearly not a psychotherapy itself but a set of techniques potentially usable in therapy. Making explicit the assumptions that underlie the techniques reveals their range of usefulness and their pitfalls. In addition to the idea that prescribing or restraining the symptoms can reduce performance anxiety, the assumptions are that symptoms always reflect a problem in a social context or relationships, that they are somehow and ultimately volitional, and that they, therefore, respond to being emphasized or manipulated.

Such assumptions may be acceptable in some cases, in which emphasizing the symptom is similar to flooding, an accepted technique of behavioral therapy, and in relationship problems, in which prescribing the symptom or altering the context of its appearance may help the participants recognize their inappropriate emotions or behavior patterns.

Using paradoxical therapy in biologically based illnesses is far more of a problem. Expecting a patient with Tourette syndrome to respond to such techniques alone suggests a volitional element greater than what is present. The basic symptoms of schizophrenia are unlikely to respond to paradoxical therapy, and, although behaviorally conditioned symptoms may respond, the case histories show the difficulty of distinguishing what is conditioned from what is biologically based. The literature about paradoxical therapy is primarily anecdotal, and the rare research study is less enthusiastic than authors who claim widespread success.

Telegram: @medical_k

www.konkur.in

Most importantly, many of the case histories in the literature include manipulations of the patient or the families that may cover or even invite aggressive acting out by the therapist, and some case histories suggest a simplistic conception of illness in which punishment is curative. When the operating field permits behavior that is less than open and straightforward, therapists need even more vigilance and self-awareness than when procedural safeguards protect the patient.

TRANSACTIONAL PSYCHOTHERAPY

History

Transactional analysis or psychotherapy was the creation of Eric Berne, a psychiatrist with psychoanalytic training who parted with the Freudian movement to focus on social interaction as the unit of analysis. *Transactional Analysis in Psychotherapy* was published in 1961, and *Games People Play* was published in 1964; *Games People Play* became a record bestseller, with sales of more than 2.5 million copies. Berne's thesis was that, in social interactions, people seek intimacy, comfort, or recognition, which they get through a series of mutual exchanges or *strokes*. If the ego states of the participants are adult and appropriate, the transaction is harmonious and realistic. Ulterior motives, sponsored by other than an adult ego state, cause discomfort in the transaction, and transactions habitually colored by such motives may become ritualized and predictable.

Written with wit and humor, Berne's books inspired considerable controversy. Some accused him of facile psychologizing better left to cocktail parties rather than true contributions to psychotherapeutic theory and practice. The fact that the movement has endured inspiring a journal, an accrediting body, and an occasional article in the psychiatric literature suggests that a number of its ideas have merit.

Theoretical Issues

Telegram: @medical_k

www.konkur.in

Transactional analysis rests first on the principle that human beings have a hunger for stimulation and contact in the infantile style. When such strivings are blocked, efforts are made to regain intimate contact. Compromises and sublimations are made in that pursuit so that a hint of the original intimacy may suffice, and the stimulus hunger may be satisfied symbolically. Thus, the original physical strokes of caress and comfort are replaceable by metaphorical stroking by which the person is recognized, flattered, or supported and even by acknowledgments that may appear to bring discomfort. A stroke is a fundamental unit of interaction. An exchange of strokes is a *transaction*, the unit of social intercourse; a stimulus from one person produces a corresponding response in another person. Because social stroking satisfies the original infantile need, it follows that any social intercourse is better than none.

In addition, social interactions fill time, provide structure, and help avoid boredom. Interactional programs, all of which contain stroking opportunities, maybe *material* (dealing with reality issues); *social* (the norms and manners of a social order); or *individual* (incidents sneaked into the other programs to get extra, personalized strokes). The sequences of a person's program are developed in line with that person's *life script*, a set of overall goals and patterns, and these sequences are the individual *games*. The games range from harmless and pleasantly satisfying to dangerous and destructive. What develops in a game is assumed to be the purpose of the game, and what eventuates as its end result are the strokes that constitute the aim and the satisfaction.

To understand and diagram the interactions in a game, the theory posits three ego states, the parent, the child, and the adult. In the parental ego state, the person reacts as the parent or as the parent would have directed. In the child state, one may be adaptively compliant or whiny and withdrawing or, as the natural child, rebellious, creative, or impulsive. The adult state appraises reality and acts in tune with it; the adult also moderates between the parent and the child. All three states are present and potentially active at all times.

Telegram: @medical_k

www.konkur.in

When the adult in one person addresses the adult in another and is responded to in adult terms, the stimulus and the response are complementary, and the transaction is smooth. The same is true if the child addresses the parent, and the parent responds appropriately—for example when a child (to parent) demands "Water!" and the parent (to child) responds "Here, baby." Such transactions are normal, two-stroke, harmonious social interactions.

However, if one partner in a couple asks, "Where are my cuff links?" and the other responds, "You're always losing things!" the lines of communication are crossed; the query may be adult to adult, but the response is parent to child, and the situation gets sticky. A comparable child-to-parent cross in response to an adult-to-adult stimulus may occur when one notes to a person driving, "You missed the turnoff," and the driver responds, "You're always criticizing me!"

Such ulterior transactions are the basis of games, which are ongoing series of complementary ulterior transactions progressing to a predictable, defined outcome that satisfies some aspect of the person's life-script strivings. On the surface, the interactions may appear plausible, but their recurrent nature, concealed snares, and predictable payoffs define them as parts of a neurotic game.

The test of a game is that a respondent's refusal to play causes increasingly intense efforts to force its continuation; continued refusal may elicit despair or bewilderment. The cure for a game is recognition of its presence, its rules of play, and its motivation. A cure is signified when the initiator can note with a laugh, "There I go again," and can desist volitionally.

Techniques

Because games generally involve at least two parties, they reveal themselves and are best treated in couples or groups. Transactional analysis has therefore had its most widespread application in couples and group therapies, although it has also been seen as useful in individual treatment. The techniques aim to illustrate the game, dissect the transactions, and frustrate players in their pursuit of strokes. In so doing, the players may learn a considerable amount

Telegram: @medical_k

www.konkur.in

about their life scripts and how they evolved, although that is not necessarily the goal of treatment.

Games are named for convenience of recognition, with the name usually connoting something about the ends sought. Thus, in “if it weren’t for you,” a woman (usually) picks a domineering man to marry, who then forbids her to do things she allegedly wants. She blames him for her unhappiness, they quarrel, their sex life deteriorates, he gives her gifts to make up, and the cycle goes on. In reality, the woman fears the activities for which she says she longs, has a sexual inhibition (which the husband may share), and is pleased by the opportunity to prove that men are tyrannical. In the game of “schlemiel,” a man (usually) messes up or breaks things to be castigated and then forgiven.

Other life games include “debtor,” “alcoholic,” and “see what you made me do.” The aim of each is to obtain one or several ulterior satisfactions without accepting conscious responsibility. In “alcoholic,” the players may include the alcoholic, a persecutor (usually a spouse), a rescuer (often, a health professional), a patsy (who gives money or sympathy), and, sometimes, a connection (who may tempt the alcoholic to drink). Each player may also be in the game for idiosyncratic reasons, games, or strokes. For the alcoholic person, the payoff is the hangover and its chance to indulge in psychological torment and suffering; for the rescuer, it is an opportunity to play “I’m only trying to help you”; for the persecutor, it is an opportunity to play “Look what you’ve done to me.” The antithesis, the goal of treatment, is to have each one recognize the role played and to frustrate the primary player (and the other persons addressed as well) by giving up the role assigned.

Groups may be randomly selected or homogeneous. In treatment sessions, the theory of transactional analysis is taught assiduously; with blackboard illustrations, the aims of treatment are outlined in operational terms; and contracts are made about individual large goals and are redrawn for small, particular steps in the course of therapy. The therapist’s role is active and confrontational but egalitarian.

Telegram: @medical_k

www.konkur.in

Research and Ethical Issues

Interest in transactional analysis peaked long before the advent of criterion-based diagnosis and controlled clinical trials, and little research on it can stand up to today's critical scrutiny. It was claimed to be effective for persons with neuroses, psychoses, personality disorders, sexual disorders, and mental delay; for individuals and groups; and as a means of self-help for young children and teenagers. What seems sensible includes an emphasis that is typical of later cognitive-based treatments—namely, identifying elements of behavior that reflect neurotic problems so that their maladaptation can be acknowledged, their driving emotions and underlying assumptions can be recognized, and the pattern of behavior can be altered. Psychoanalytic therapies share the same aims but include the additional goal of genetic uncovering. Transactional analysis' emphases on confrontation, contracts, homework, active diagramming of conflict, and teaching about behavior are also more like cognitive therapies.

Most recently, transactional analysis interventions were studied for use in outpatient addiction patients participating in a methadone maintenance program. The results suggested that transactional analysis significantly influenced interpersonal problems in a positive way and the client's readiness for treatment. Transactional analysis was also recently used in a 2020 clinical trial to investigate its effect on imprisoned women's self-esteem. The authors reported that transactional analysis in a group-training format improved the self-esteem of the study's intervention group.

The weakness in the system and the potential it has for abuse in work with patients lie in its theoretical assumptions. *Neurotic behavior*, by definition, is not realistically aimed and is often maladaptive. To assume that all bad consequences are deliberately sought is incorrect and unfair. To the extent that such a view is held, important motivations may be missed, and therapy may be tainted by a tendency to level accusations. If this position is avoided, and complaints are not trivialized by being seen routinely as goals, the dissection of social transactions and the focus on personal

Telegram: @medical_k

www.konkur.in

responsibility offered by transactional therapy conform to what is generally considered to be of therapeutic value.

GUIDED IMAGERY THERAPY

History

The use of guided imagery or guided affective imagery as a form of therapy was systematized by Hanscarl Leuner in 1954. Leuner considered himself to be an analyst, and he was influenced by Carl Gustav Jung's interest in active imagination and Johannes Heinrich Schultze's autogenic training. Having confronted himself with disturbing emotions and images during his self-analysis, Jung thought that spontaneous, inner, dream-like images were translations of unconscious emotions and that observing and interpreting them could bring unconscious contents to consciousness. He called the technique *active imagination*, and he made it a part of what clinicians following his analytical tradition would use. Schultze framed the principles of *autogenic training* as a form of self-hypnosis and relaxation training, a mind- and organ-strengthening system based on expansive powers alleged to reside in the mind.

Leuner found that resting comfortably with the eyes closed for some time led to the appearance of images and that an exploration of the images with a guide was a pleasant and beneficial experience. He induced the images actively to shorten the interval before their appearance, added analytical insight to the guided exploration, and so framed *guided affective imagery*.

The ideas of guided affective imagery caught on in the United States and other Western countries, and the treatment was reported to be useful in chronic neuroses, personality disorders, depression, phobias, obsessive-compulsive disorders (OCDs), sexual disorders, hyperhidrosis, substance abuse, anorexia nervosa, ulcerative colitis, and hives. The niche it filled in organized psychiatry, however, was never more than a small one. The ancillary disciplines of medicine, particularly nursing, embraced it with more enthusiasm than did

Telegram: @medical_k

www.konkur.in

psychiatry, and positive claims have been made regarding its use in postsurgical pain control, in general adaptation to illness, and, particularly, in coping and dealing with incurable, progressive disease.

Theoretical Issues

Guided affective imagery attempts systematically and psychotherapeutically to use the human ability to create images. It holds that so-called catathymic images, images appearing before one's closed eyes as if on a screen and ultimately coming together and taking on movement to tell a story, represent a person's interpersonal world in autosymbolic imaginal form. The images include color, plasticity, and action, and the more one is absorbed in them, the richer, more colorful, and more subtle they become. The symbols and the stories project the person's conflicts. Psychoanalytically informed guidance as the person recounts the experience can materially enhance conflict resolution by manipulating the symbols or assisting the story toward a successful outcome. The crucial idea is that influencing the symbols and the story influences the conflict.

Techniques

The patient is placed in a comfortable chair and is taught to practice relaxation, with suggestions of warmth, heaviness, and regular breathing. The patient is then invited to imagine a harmless, pleasant image, such as a flower, and is asked to describe it in detail, to look in its center, or to touch or smell it. Involvement in the images heightens the relaxation and vice versa; the patient soon becomes able to induce a readiness for imagery quickly. The hypnoidal state is ended with a command, such as "Clench your fists, bend your arms, open your eyes, and you are back, awake and refreshed."

When such learning is well-established, the therapist relaxes the patient once more and suggests an image to be used in the therapy —for example, a meadow. The patient is told to nod when it comes into view and then to describe the scene.

Telegram: @medical_k

www.konkur.in

Specific images used in the therapy are classified as basic, intermediate, or advanced, according to the level of conflict that they are likely to involve and the skill and training required by the therapist. Basic images include a meadow, a brook, a mountain, a house, and a wood; intermediate images include a car ride and a rosebush (representing women's and men's sexual feelings toward the opposite sex); and advanced images are such things as a swamp, a volcano, and a lion.

Descriptions of a meadow or a brook (the patient may see a brook in a meadow spontaneously or may be invited to imagine one) reflect current psychological issues. The meadow may be rich and green or scorched to stubble; the brook may be cool and inviting or a raging torrent. The therapist follows and guides with questions, such as "Can you describe that?" "What do you think of it?" or "What do you see as you follow the brook?"

The therapist's understanding is informed by knowledge and theory and determines whether the therapist interprets patients or leads them to helpful activity. The therapist may suggest, for example, that a darkening scene reflects the patient's inner mood or that too perfect a picture shows an effort to mask distress. If patients encounter a fence in the meadow or steep rocks as they follow the brook, the therapist may suggest that the patient climb over or find a way around the obstacle.

Telegram: @medical_k

www.konkur.in

A young male patient saw a mountain from which rose another mountain and an observation tower. The young man had problems with authority and would stutter in the presence of his father or his boss. The therapist interpreted the scene to himself to mean that the young man felt watched and that too much was expected of him. The therapist guided him to ascend the tower, which the patient did successfully but amid images of fearful wandering and threats of thunder; the symptoms resolved.

The suggested motifs represent different aspects of the patient's psychology: The house and the edge of the wood represent one's own person; the brook represents vitality and energy; the mountain and its panorama represent the patient's view of the past, present, and future. The therapist looks to see whether supplies and a warm fire are in the house, what comes out of the wood, and whether the brook is cool and refreshing or an icy harbor of dangerous creatures. The management principle is to resolve the conflict symbolically.

One young student got over a block about taking an oral examination by being led in fantasy to feed a dangerous animal (the professor) coming out of a wood; those fearful of their own impulses might do well to approach such animals, to pat them, and to make friends with them. The guide conducts the exploration, using the symbols as a protective disguise, with empathy and warmth, positive feedback, praise, and, at times, direct suggestion.

Clinical and Ethical Issues

Guided affective imagery combines hypnotherapy with certain psychoanalytic ideas. Its major assumption is that manipulation of the symbols of conflict can resolve the conflict, a tenet that is open to question. The supportive relationship, the sense of involvement and effectuating something through the process, and the direct

Telegram: @medical_k

www.konkur.in

suggestions must contribute considerably to whatever effectiveness the technique has.

Interest in guided image therapy as a formal, psychoanalytically-based psychotherapy has waned. Truncated and modified, however, guided imagery has gained a following in pain control, holistic medicine, and the treatment of incurable illness. Most recently, guided imagery is described in treatment of trauma-related mental health issues. Zehetmair et al. used qualitative semistructured interviews to assess the use of guided imagery and stabilizing techniques in the treatment of traumatized male refugees. The most common disorders in this population include posttraumatic stress disorder (PTSD), anxiety disorders, and depression. The paper suggested that stabilizing techniques and guided imagery are an appropriate intervention in this population. In pain control, it has been reported to be useful as a relaxation and distraction technique, with additional suggestions of finding a second and then several seconds of decreased pain, and so extending the period of pain relief. A recent meta-analysis of randomized controlled trials studied guided imagery's efficacy as an adjunct treatment for fibromyalgia when paired with hypnosis and argued that there is efficacy and tolerability in guided imagery/hypnosis and the combination of hypnosis with cognitive-behavioral therapy in reducing key symptoms of fibromyalgia. The appeal of holistic medicine is to the limitless powers of the mind, a hopeful approach that has found favor in the nursing of patients with cancer and other terminal illnesses.

TRANSPERSONAL PSYCHOTHERAPY

History

Transpersonal psychology grew out of the humanistic movement of the 1960s. Defining itself as "the personal, plus," it means to include all facets of personal psychology and psychiatry *plus* deeper or higher, transcendent experiences. It thus embraces a range of religious and spiritual experiences and parapsychological phenomena, such as conversion; crises of faith; ecstasy, peak, and

Telegram: @medical_k

www.konkur.in

near-death experiences; spiritual mystical experiences; and past-life experiences. Although the term *transpersonal* was first used by William James and later was expanded on by Jung, it was writers such as Abraham Maslow, Robert Assagioli, Ken Wilber, and Stanislav Grof who generated its theoretical underpinnings. Each of these authors developed theories of needs and motivations or of stages of development that encompassed and were roughly modeled on traditional developmental theory but added the extra dimensions required by the transpersonal emphasis. The *Journal of Transpersonal Psychology* started publication in 1969 and continues to exist. The first Council Grove Conference, sponsored by the Menninger Clinic that same year, focused on topics such as meditation, biofeedback, yoga, and psychedelic agents. Since then, several transpersonally oriented institutions were founded, mostly in California, and, for the past several years, approximately 15 dissertations dealing with transpersonal experiences are written yearly. The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth edition Text Revision (DSM-5-TR) includes religious and spiritual problems under Other Conditions That May Be a Focus of Clinical Attention.

Theoretical Issues

In the free-for-all of theory building, several authors have contributed to transpersonal psychology and psychiatry, but no single contribution dominates. Thus, the theory is an overlapping pastiche rather than a coherent whole: Maslow studied a series of self-actualized persons and found them similar to traditional descriptions of enlightened persons. He concluded that human beings have a biologically based instinctive nature that is fulfilled in spiritual self-actualization, and he and Grof coined the term and founded the field of *transpersonal psychology*. Assagioli suggested that each person has many subpersonalities and that a spiritual psychosynthesis is needed to unleash the transforming and creative energies of a *superconscious*, which also exists. Wilber proposes prepersonal, personal, and transpersonal developmental stages; disorders of the

Telegram: @medical_k

www.konkur.in

prepersonal developmental level result in infantile psychoses or narcissistic or borderline personality disorders, disturbances at the personal level give rise to neuroses, and spiritual emergencies, kundalini crises, and dark nights of the soul rest on disturbances at the transpersonal level.

Grof, during 17 years as a scholar in residence at the Esalen Institute in California, experimented widely with psychedelics in psychotherapy and proposed that, in psychedelic and other altered states of consciousness, patients reexperience the trauma of their birth. He suggested the existence of four basic perinatal matrices (BPMs) representing experiences from the entry into the intrauterine state (BPM-I), entry to the birth experience (BPM-II), passage toward a light with intense anxiety and near-death experiences (BPM-III), and culmination in total surrender, a sense of overwhelming and unending love, light, expansion, and forgiveness (BPM-IV). After experiencing or reexperiencing BPM-IV in adulthood, further transpersonal expansions may occur in two domains: Expansion of ego boundaries in ordinary real terms and extensions beyond the usual framework. The first includes a sense of identification with the earth and all of life in the universe, and the second includes spiritual communication, out-of-body experiences, and telepathic, precognitive, and other paranormal experiences. These experiences were often seen as psychotic by traditional psychologists and therefore constitute spiritual emergencies that require special help. Grof urged mental health professionals to learn to distinguish these nonordinary transpersonal states from mental illness.

Techniques

Technique in transpersonal psychotherapy is an amalgam of the generally accepted and the esoteric, depending on the worldview of the practitioner and the issues being addressed. The range is from the psychodynamic and behavioral, through meditative approaches or the recommendation of spiritual texts, to rapid-breathing techniques, guided imagery, and the use of psychedelic drugs to promote altered states of consciousness. The teachings are

Telegram: @medical_k

www.konkur.in

variously applied to a similarly wide range of issues. *Defensive spirituality*, in which religious or spiritual beliefs are used to deny feelings or conflicts, or *offensive spirituality*, in which there is an obnoxious, self-reassuring, but intrusive stance of "having the one true path," may be amenable to dynamic techniques. Similarly, loss of faith or a conversion experience may be dealt with by a sensitive therapist to determine what factors are at work in the patient's life and whether the conversion, for example, is a legitimate search for truth and the comfort of faith or a magical denial doomed to fail. Expressive explorations of hallucinations or delusions or of a psychotic religious experience after the psychosis is controlled are recommended by some as a means of finding personal insights.

Transpersonal psychotherapists also try to distinguish genuine religious experiences from psychoses, the latter being often more terrifying, accompanied by deterioration in other areas of life, and containing delusions of being addressed by specific religious figures. The boundaries, however, are hard to define in *spiritual emergencies*, when the individual feels dazzled by truths too powerful to grasp, or in *kundalini awakenings*, states in which energies expand upward from the base of the spine and explosively alter consciousness. Supportive therapy is recommended in these cases, along with education about the experience. Meditation and the use of mantras, such as "May I be happy" and "May I be peaceful," are also reported to be useful if the patient is having anxiety over a crisis of faith. Near-death experiences may also lead to a transformed view of the world, and support is recommended along with help in "those parts of the ego that may have died."

The traditional psychotherapist and psychiatrist may have difficulty in areas of transpersonal psychiatry that aim to help individuals recognize and realize a presumed "ultimate state that transcends the usual state of functioning, a state of mystical illumination or cosmic unity." Some of these include experiences such as channeling, encounters with unidentified flying objects (UFOs), possession states, and past-life experiences. In these areas, the transpersonal literature is ambiguous, on the one hand, cautiously attesting that such experiences are meaningful to the person and embody content

Telegram: @medical_k

www.konkur.in

relevant to the individual's personality, and, on the other hand, accepting them as normative spiritual experiences, an ultimate state of mystic illumination or cosmic unity that is reflective of a reality beyond the norm.

Research and Evaluation

Research on the paranormal, although always of interest because of its supernatural allure, has failed to confirm the legitimacy of past-life experiences, precognition, psychokinesis, and similar phenomena. Also, because transpersonal psychotherapy is not a single discipline, there have been no systematic studies of its efficacy. The field emphasizes the personally meaningful and possibly transformative effects of things such as conversions or near-death experiences; the importance of religion and mysticism in the lives of many; the difficulty of teasing apart the boundaries between psychiatric illness, personal mystique, and cultural differences in expected experience; and the need for sensitivity in working with patients whose life and experiences are different from one's own.

32.24 Evaluating Psychotherapy: Research Methods, Findings, and Future Directions

Lindsay E. Holly, Ph.D., Megan L. Petrik, Ph.D., and Stephen M. Saunders, Ph.D.

PSYCHOTHERAPY RESEARCH

Telegram: @medical_k

www.konkur.in

The principal goals of psychotherapy research are (1) to understand what the effective components of psychotherapy are and how they work; (2) to determine how patient, therapist, family, and social factors influence the outcome; (3) to improve the effectiveness of psychotherapeutic interventions; (4) to guide the development of new therapeutic techniques and evaluate their effectiveness; (5) and to inform public policies that increase the availability of quality mental health care. Past controversies regarding the ability to examine scientifically various psychotherapeutic techniques have largely been settled.

Valid and reliable methods for measuring therapeutic events and their effects exist including: (1) intensive analyses of patient and therapist variables; (2) in-depth assessment of therapeutic processes; (3) and implementation of outcome measures that assess general distress, symptoms related to specific disorders, and functional impairment. Controlled clinical trials comparing replicable, distinct psychotherapeutic interventions are normative in research, as are sophisticated analytic methodologies, such as growth curve analysis, time-series panel analysis, and structural equation modeling. Most significantly, various methods of meta-analysis and systematic reviews—techniques that combine results across different studies to evaluate the effectiveness of particular treatments for specific patients and problems—have been applied to psychotherapy research.

This section begins by describing research on the characteristics of psychotherapy consumers. Next, definitions of efficacy and effectiveness research are provided, and empirical evidence supporting widely used psychotherapy models is presented. The importance of the therapeutic alliance is reviewed, and research on the impact of patient and therapist variables on treatment outcomes is discussed. Finally, emerging themes and future directions in psychotherapy research are considered.

CONSUMERS OF PSYCHOTHERAPY

Telegram: @medical_k

www.konkur.in

The effectiveness of psychotherapy must be understood within the context of who receives help and how they obtain it. Approximately 20% of the U.S. population meets the criteria for a psychiatric disorder in any given year, but most do not seek formal mental health care. A recent large-scale national survey of mental health service use in the last year found that women are more likely to engage in psychotherapy than men; Individuals identifying as non-Hispanic white are most likely to engage in psychotherapy compared to other ethnic/racial groups, and individuals aged 18 to 44 are more likely to engage in psychotherapy than older adults.

In addition, the likelihood of obtaining treatment increases with emotional distress and functional impairment. Accordingly, those with comorbid mental illnesses or with severely disabling disorders, such as schizophrenia, are the most likely to seek professional help. In contrast, a lack of insurance and concerns about how to pay for services decrease the likelihood of seeking treatment.

However, the primary barriers to mental health care are psychological, including the stigma related to having a mental illness. Negative attitudes toward admitting that one has a psychiatric problem and toward seeking care from a specialty mental health provider have actually increased over the last several decades. Research suggests that this is related to the increasing conceptualization of mental health problems as medical, which may translate into the impression that the problem is permanent. Consistent with this, most who seek care increasingly do so in the general medical sector rather than from a mental health specialist.

EFFICACY AND EFFECTIVENESS

Psychotherapy researchers distinguish between efficacy and effectiveness research. Each has a distinct purpose, methodology, and interpretative context.

Efficacy

Telegram: @medical_k

www.konkur.in

Efficacy studies evaluate the sufficiency of a specific treatment to reduce distress, symptoms, and impairment with a group of patients having a particular psychiatric disorder. To minimize the influence of confounding or extraneous factors, efficacy studies are conducted using randomized clinical trial methodology in a controlled setting. Patients are screened to control for excessive patient variability, and they are randomly assigned to interventions that are being compared. The treatment under investigation might be compared to no treatment, a waiting list, placebo, minimal intervention (e.g., psychoeducation), or an alternative treatment. Therapists are trained to conduct the competing treatments to maximize the integrity of putative therapeutic ingredients. Most studies also perform integrity checks, such as reviews of taped sessions, to see whether the therapy under study was implemented with fidelity.

Most efficacy studies use treatment manuals, which direct (sometimes greatly, sometimes minimally) the therapist with regard to the intervention offered. Thus, treatment manuals have been essential in establishing that certain psychotherapeutic techniques are efficacious. Prominent examples of treatment manuals include Aaron Beck, John Rush, Brian Shaw, and Gary Emery's *Cognitive Therapy of Depression;* Lisa Najavit's *Seeking Safety: A Treatment Manual for PTSD and Substance Abuse;* and Myrna Weissman, John Markowitz, and Gerald Klerman's *Guide to Interpersonal Psychotherapy*. Other manuals have been published in journals and as chapters in books, such as in David Barlow's *Clinical Handbook of Psychological Disorders.*

Effectiveness

Effectiveness studies are concerned with whether psychotherapy delivered in actual clinical settings is effective in reducing the symptoms, distress, and dysfunction associated with mental illness. The experimental controls used in efficacy studies are absent in effectiveness studies, just as they are absent in community settings. Indeed, most effectiveness studies are conducted in the community. For instance, in real-world clinics, patients with comorbid disorders

Telegram: @medical_k

www.konkur.in

are commonplace, whereas they tend to be screened out of efficacy studies. Likewise, at the typical clinic, length of treatment is determined by patient need rather than treatment prescription. Thus, the goal of effectiveness research is to describe patient responses to the typical, community-based delivery of psychotherapy.

Effectiveness studies typically assess the characteristics of settings and providers, the generalizability of the patient samples, the features of treatments that are actually delivered, barriers to treatment experienced by patients, and the average costs associated with treatment. Overall, effectiveness studies have demonstrated that manualized treatments found to be efficacious in randomized clinical trials can be effective when applied in community settings.

Research also tends to find that the magnitude of treatment effects in effectiveness studies is similar to that found in efficacy studies. Effectiveness studies have demonstrated a dose–response relation between the number of sessions attended and the probability of improvement. For example, one study found that about half of patients are measurably improved by their eighth session of treatment. Other studies have found that chronically distressed patients, including those with personality disorders, improve more slowly than those who are more acutely distressed.

The results of effectiveness studies are sometimes seen as more relevant to actual practice than the results of efficacy studies, but both are important to the implementation of evidence-based practice. Although stringent experimental control reduces the likelihood of confounding variables in efficacy studies, the results can have limited external validity (generalizability) because of those very controls. On the other hand, whereas effectiveness research is more likely to be conducted in actual clinical settings, the causal implications of such research must be viewed with caution due to the high likelihood that confounding variables influenced the results.

Systematic Reviews and Meta-Analyses

Common methods to summarize and integrate efficacy and effectiveness research are systematic reviews and statistical meta-

Telegram: @medical_k

www.konkur.in

analyses. Systematic reviews apply specific strategies to assemble, critically evaluate, and integrate relevant studies that address a specific clinical question. Systematic reviews are exemplified in treatment guidelines published by the American Psychiatric Association and other organizations. Meta-analysis is a particular type of systematic review that uses statistical methods to combine and summarize the results of original studies. The individual studies are quantified and coded so that they can be compared with one another. Typically, an effect size is a measure of treatment effect that is calculated for each study by computing the size of the difference between the treated and untreated (or control) groups.

Hundreds of meta-analyses of psychotherapy have been conducted, and most have concluded that psychotherapy is an effective intervention for psychiatric illness across diverse populations and settings. Most meta-analyses have focused on specific disorders (e.g., the average effect of psychological treatment for major depressive disorder) or on specific therapeutic approaches for various disorders (e.g., comparing CBT to other therapies). In general, meta-analytic studies have shown that psychological treatments are vastly more effective than no treatment (e.g., placebo, wait-list controls, or minimal interventions), are about as effective as biomedical treatments (e.g., pharmacotherapy) for most disorders, and are about equally effective when compared to each other.

EFFICACY AND EFFECTIVENESS OF COMMON EVIDENCE-BASED TREATMENTS

Cognitive Therapy

Cognitive therapy is designed to help patients recognize, challenge, and modify irrational or dysfunctional beliefs, ideas, perceptions, and self-statements that are related to maladaptive emotional reactions to negative or stressful events. The general term for modifying such beliefs is “cognitive restructuring,” which entails identifying habitual thinking, understanding that thinking strongly influences emotions,

Telegram: @medical_k

www.konkur.in

evaluating the rationality of thinking, and modifying the thinking if it is found to be erroneous. Cognitive therapy has been investigated intensively because it has highly detailed putative causes and cures so that these components are easy to describe in treatment manuals and examine in outcome studies.

Cognitive therapy has been found to be effective in a variety of psychological disorders. A review of meta-analyses of cognitive therapy concluded that it is highly effective in alleviating the symptoms of mood and anxiety disorders in particular. The reported benefits of cognitive therapy for depression are comparable to those of pharmacotherapy. There are some indications that a combination of psychotherapy and medication is the most effective, but that cognitive therapy may be better tolerated by patients and may have more enduring effects. Specific cognitive techniques found to be helpful in treating depressive symptoms include monitoring mood, identifying cognitive distortions, and creating rational responses. These interventions are typically conducted via daily or weekly logs that allow the patient to keep track of their fluctuating emotional states, to list the related maladaptive thoughts, and to dispute the identified irrational beliefs. Maintenance sessions of cognitive therapy following positive response to the treatment of depression have been shown to reduce relapse rates.

In the treatment of anxiety disorders, cognitive therapy has been shown to be effective with generalized anxiety disorder (GAD), panic disorder, social anxiety disorder, and specific phobias. Patients with GAD benefit from identifying and challenging habitual and irrational beliefs about events and their ability to cope with worry. Similar results for panic disorder have been reported, in which clinically significant reduction in panic symptoms and panic-related cognitions has been demonstrated. Phobic disorders are also amenable, to a somewhat lesser extent, to modifications of anxiety-provoking cognitions. The effectiveness of cognitive therapy with various other disorders, including substance abuse, schizophrenia, personality disorders, and eating disorders, has been documented, if not as extensively as with mood and anxiety disorders.

www.konkur.in

Janice, a 29-year-old married mother of two school-age children, struggled with moderately severe depression on and off for several years before seeking treatment from a cognitive therapist. With the assistance of the therapist, she learned to become aware of negative self-statements and to identify irrational beliefs related to the requirements of being a "good mother." She came to recognize that these thoughts caused her to feel incompetent and generally upset about how her children were doing. She learned to evaluate and appreciate evidence that her children were, in reality, well-adjusted and well-liked by both teachers and peers. Via cognitive restructuring, she learned to challenge and modify her thinking so that she could judge herself more accurately as a good mother. Other long-held, negative beliefs that contributed to depressed mood were also identified and challenged. Four months after terminating treatment, she returned for some "booster sessions" that helped her to get even better at recognizing and challenging excessively negative self-evaluations.

Behavior Therapy

Behavior therapy uses operant conditioning, classical conditioning, and modeling to help patients to change maladaptive behavior patterns that create and maintain psychiatric disorders. Techniques include the use of extinction, positive and negative reinforcement, stimulus control, shaping, and vicarious conditioning. One of the most elemental behavioral techniques is relaxation training, which has been found effective for various problems in hundreds of studies. Through repetition of relaxation-inducing strategies (such as deep breathing or progressive muscle relaxation), patients are trained to voluntarily produce the relaxation response, which alleviates anxiety, depression, involuntary muscle tension, pain, somatic complaints, and various other stress reactions.

Exposure-based behavioral interventions are often combined with relaxation training, and they have been shown to be highly effective

Telegram: @medical_k

www.konkur.in

in the treatment of anxiety and related disorders. The typical behavioral intervention involves confronting a feared stimulus while preventing the usual anxiety-based reaction (e.g., fleeing or engaging in a compulsion). Research has shown that patients will habituate to the feared stimulus and that the fear-based response will extinguish. For example, exposure and response prevention for obsessive-compulsive disorder (OCD) is an extremely effective approach that involves presenting anxiety-provoking stimuli and preventing the patient from performing the compulsions normally engaged in to reduce anxiety. Exposure-based treatments have likewise been shown effective for other anxiety and related disorders, including GAD, posttraumatic stress disorder (PTSD), panic disorder, and both social and specific phobias. Behavior therapy has also been shown to be effective in the treatment of pain disorders, sleep problems, behavioral disturbances (such as those associated with schizophrenia), and substance use disorders.

Behavior therapy is also commonly used to treat childhood psychopathology. Behavioral interventions might be implemented directly with the child. For example, early intensive behavioral interventions, which heavily rely on principles of positive reinforcement, have been shown to improve social skills, intelligence test scores, and school performance for children with autism spectrum disorders. Alternatively, behavioral principles have been successfully taught to parents for the alleviation of distress, symptoms, and impairment related to attention-deficit/hyperactivity disorder (ADHD), oppositional defiant disorder, school phobia, separation anxiety disorder, and enuresis. Behavioral interventions have also been shown effective in reducing self-injury in children with intellectual disabilities.

Telegram: @medical_k

www.konkur.in

Tony, a 10-year-old boy with ADHD, was being treated with a tolerable dose of stimulant medication. On the advice of their pediatric psychiatrist, the family sought adjunctive behavior therapy to deal with Tony's poor school performance. The therapist and his parents developed a behavioral modification program to change his homework-related behavior. They developed a system for rewarding Tony if he engaged in adaptive behaviors, such as writing down homework in his assignment notebook, bringing home any necessary homework-related school materials, and completing and turning in homework assignments. His parents worked with the teacher to set up similar contingencies to reinforce Tony's compliance, positive peer-related behavior, and general attentiveness in the classroom. After several months, Tony's schoolwork improved dramatically. His parents and teacher noted that he appeared to enjoy school more, to be more self-confident, and to be better-liked by classmates.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) combines the effective elements of cognitive therapy and behavior therapy. Although initial iterations of CBT focused mostly on behavioral *or* cognitive interventions, current CBT approaches are intended to help patients develop strategies to change maladaptive thoughts *and* behaviors. For example, CBT for anxiety might include cognitive restructuring to change irrational fears, relaxation training to reduce physiologic arousal, and exposure to extinguish fear reactions.

CBT has been the most extensively studied psychological intervention, and there is ample evidence supporting CBT's efficacy and effectiveness with numerous psychiatric disorders. A review of hundreds of meta-analytic studies determined the average effect size for CBT for different disorders. Regarding depressive disorders, CBT has demonstrated clear benefits as compared to a waiting list or no treatment conditions, but meta-analyses have shown mixed

Telegram: @medical_k

www.konkur.in

results in suggesting CBT is more effective compared to other active treatments (i.e., psychodynamic or interpersonal therapies). CBT and psychopharmacology have been shown to both produce medium to large effect sizes in treating depression, although a combination of both treatments was more beneficial than either alone. Individual studies suggest that CBT is also effective with certain subgroups of patients with depression, including older adults, adolescents, patients with comorbid diagnoses, and low-income minority women.

The effect sizes for CBT for most anxiety disorders and somatoform were consistently medium to large. CBT has also been shown to have a strong effect on treating insomnia, anger, and bulimia. Meta-analytic reviews suggest that CBT has a clear benefit for special subgroups of patients, including treating internalizing disorders in children and emotional distress in older adults. CBT has been shown to have small to medium effects for substance use disorders, with more benefits for cannabis and nicotine dependence, as well as for chronic pain. Although there are small to medium effects of CBT for treating bipolar disorder and schizophrenia, there is less support for the use of CBT without the combination of psychopharmacology for these disorders.

Telegram: @medical_k

www.konkur.in

Dan had experienced disabling panic attacks for 20 of his 45 years but only sought treatment when they started to interfere with his career aspirations. Through his engagement in CBT, Dan learned about the physiology of panic attacks, which helped to reassure him that he would not die of an attack. Based on the use of cognitive techniques, other fears and misperceptions regarding his body's reactions to stress were identified and modified (e.g., that increased heart rate was not a sign of impending heart attack but was a normal biologic response to stress). Using behavioral techniques, Dan was engaged in relaxation training to breathe normally rather than hyperventilate during a panic attack. Over the course of treatment, Dan learned to confront previously feared internal and environmental cues without experiencing a panic attack. After 3 months, Dan felt that he was managing his panic disorder and discontinued treatment.

Third Wave Cognitive-Behavioral Therapies

Over the last 40 years, CBT approaches have evolved with new iterations incorporating a greater focus on contextual, existential, and developmental issues. These approaches have been referred to as "third-wave" cognitive-behavioral treatments and have growing research support.

Acceptance and commitment therapy (ACT) proposes that psychopathology is due to cognitive fusion (unquestioning adherence to the truth of one's thoughts) and efforts to avoid painful experiences, which lead to maladaptive behavioral restriction. ACT attempts to inculcate a more skeptical perspective toward one's cognitive habits, a more accepting attitude toward the pains and foibles of life, and a commitment toward behaviors that are consistent with one's deeply held values. In ACT, there is a focus on altering how a person relates to their internal sensations (e.g., approach sensations with mindfulness and acceptance) rather than a focus on reducing or eliminating such sensations. Over 60 randomized controlled trials have found ACT efficacious for a range

Telegram: @medical_k

www.konkur.in

of psychiatric (e.g., depression, OCD, substance use disorders, PTSD) and medical conditions (e.g., tinnitus, chronic pain).

Dialectical behavior therapy (DBT) proposes that skill deficits in emotion regulation are core causal factors of various disorders. DBT was developed for patients with borderline personality disorder (BPD), but it has also been applied to substance use and eating disorders with positive outcomes. Systematic reviews have demonstrated that DBT is efficacious in reducing nonsuicidal self-injury, suicidal ideation, and other symptoms related to BPD for both adults and adolescents.

Recent iterations of CBT also utilize mindfulness techniques (e.g., mindfulness-based cognitive therapy). Mindfulness refers to a particular way of focusing attention on the present in a nonjudgmental manner. Attitudinal qualities such as curiosity, patience, equanimity, letting go, and trust are important for mindfulness practice. Increasing mindfulness is intended to reduce the pathognomonic habit of ignoring or suppressing one's emotions and thoughts. The practice essentially entails experiencing thoughts and feelings as mental events that may or may not be related to external reality but can be experienced without judgment or fear. A systematic review of over a hundred randomized controlled trials demonstrated that mindfulness-based interventions are effective for alleviating symptoms of depression, anxiety, substance use disorders, smoking, and chronic pain.

Interpersonal Therapy

Interpersonal therapy (IPT) is a structured, time-limited intervention that is based on the notion that interpersonal stress is a causal and maintaining factor in psychological distress. IPT was originally developed to treat depression, and it targets the following four domains: interpersonal deficits, role disputes, role transitions, and complicated bereavement. Therapy involves three phases; the therapist initially links the diagnosis of depression to a specific interpersonal problem, implements strategies for resolving the problem in the middle phase, and finally supports the patient's self-

Telegram: @medical_k

www.konkur.in

efficacy to continually use the strategies after the end of the treatment.

Research has consistently supported the use of IPT, with the majority of studies focusing on the treatment of depression. A recent meta-analysis found that the effect size for IPT was moderate to large compared to control groups in the treatment of acute-phase depression but showed nonsignificant differential effects when compared to other psychological treatments. However, other studies found IPT to have slightly better dropout and remission rates but may take longer to show a therapeutic effect when compared to CBT. When compared to pharmacotherapy, the combination of IPT and pharmacotherapy prevented relapse better than medication alone. For those with subthreshold depression, IPT prevents the onset of major depression. IPT has also been successful in the treatment of depression in particular subgroups, such as adolescents and women with postpartum depression.

Beyond depression, IPT has been shown to be efficacious in treating eating disorders, particularly bulimia nervosa and binge eating disorder, with modest outcomes. In relation to eating disorders, IPT may be most appropriate for patients with bulimia nervosa who are also experiencing interpersonal relationship difficulties. In addition, IPT is efficacious compared to control groups in the treatment of anxiety disorders, with effects comparable to CBT. There is also emerging evidence for the use of IPT for the treatment of PTSD.

www.konkur.in

Maureen sought therapy for depression and anxiety at 45 years of age, 2 years after her youngest of four children departed for college. With her therapist, she was able to recognize that her successful rearing of her children had the unfortunate consequence of their departure from home. Maureen was able to identify and pursue new activities outside of the home, to appreciate and transfer the skills that she had mastered as a successful mother outside of the home, and to reestablish her musical interest and pursuits that had waned while she raised her children. After several months of therapy, Maureen was less depressed and anxious, as she pursued a teaching certificate in music, with the encouragement of her husband, at her community college.

Psychodynamic Psychotherapy

Psychodynamic therapies derive from Sigmund Freud's psychoanalysis. They are intended to promote self-understanding and insight into recurring problems with others. Psychodynamic therapists typically promote the development of a therapeutic alliance, within which the interpersonal problems are recurring in the patient's life transfer onto the therapist. In therapy, these interpersonal problems, which are the result of defense mechanisms and intrapsychic conflicts, are identified, interpreted, and managed with the intent that such understanding and new behaviors then transfer to other relationships and alleviate problems.

Psychodynamic psychotherapies can range in length and intensity from long-term psychoanalysis to short-term psychodynamic psychotherapy. Short-term psychodynamic therapies have been manualized (e.g., Summers and Barber's *Psychodynamic Therapy: A Guide to Evidence-Based Practice*) and evaluated in controlled trials.

Research supports both the efficacy and effectiveness of this treatment, suggesting it may be as helpful as cognitive and behavioral approaches. Some studies suggest that patients in

Telegram: @medical_k

www.konkur.in

psychodynamic therapy better retain long-term gains from treatment. Researchers have documented the effectiveness of psychodynamic therapy in the treatment of various disorders, including depression, substance use, generalized anxiety, panic, and somatic disorders, as well as personality disorders.

Dario, a 34-year-old married father of three boys, sought therapy at the insistence of his wife for recurrent problems with anger and depression, both of which seemed to stem from feelings of inadequacy. His marital relationship had worsened considerably since his wife had started a new job. Toward the beginning of psychodynamic therapy, Dario expressed frustration at the situation but insisted that he did not resent his wife's successful career. Dario's underlying feelings toward his wife became evident in the course of treatment, as the feelings were transferred toward his therapist. His therapist helped him to identify and interpret his feelings of anger, fear, and sadness and to recognize that they were a manifestation of feelings of intense inadequacy and fears leftover from an abusive childhood. Dario was able to confront honestly and openly these feelings with his therapist and, ultimately, with his wife. His anger and depression lessened considerably, and his marriage improved.

TREATMENT VARIABLES RELATED TO OUTCOME

Therapeutic Alliance

Effective psychotherapy requires a therapeutic alliance between the therapist and the patient. This alliance entails the patients' perception that the therapist understands, is capable of helping, wants to help, and genuinely cares for the well-being of the patient. This emotional aspect of the alliance enables agreement between the patient and therapist on the necessary therapeutic tasks to

Telegram: @medical_k

www.konkur.in

achieve the goals of symptom reduction, alleviation of distress, and/or improving life functioning.

Carl Rogers proposed that the alliance is curative in and of itself, theorizing that the patient's experience of a nonjudgmental, warm, genuinely caring attitude on the part of the therapist mediates positive change. Psychoanalytic and cognitive-behavioral theorists, in contrast, argue that the relationship is only a necessary precondition for the implementation of the active ingredients of therapy that are responsible for positive change, such as interpretation or cognitive restructuring.

Research suggests that both perspectives are correct. Several meta-analyses have concluded that there is a consistent relationship between the quality of the alliance and positive outcomes. A strong therapeutic alliance, whether measured from the perspective of nonparticipant observers, the therapist, or the patient, is related to therapy effectiveness. These findings cut across various interventions, and a recent task force on evidence-based therapeutic relationships concluded that the alliance contributes to outcomes as much, and likely more than, the particular method of treatment. Research shows that a positive alliance facilitates patient adherence to treatment, suggesting that it is a necessary condition for successful interventions. Research likewise shows that patients who dropped out of treatment liked the clinician less, felt less respected, experienced a weaker therapeutic alliance, viewed the psychotherapist as more passive, and regarded psychotherapy as being less potent than other interventions.

The alliance is similarly important in nonindividual interventions. Studies examining group therapy have indicated that the benefit of this treatment modality is more likely when there is a strong level of group cohesion. Likewise, studies of family and couples therapy show that the alliance with the therapist is an important predictor of positive response. Research into the causes, uses, and effects of the alliance are ongoing.

Therapist Characteristics

Telegram: @medical_k

www.konkur.in

Psychotherapy interventions and procedures have been extensively studied, typically through the utilization of treatment manuals that specify them. Some research suggests a significant positive relationship between compliance with a treatment manual and outcome, but other research suggests that the therapist's relationship skills and perceived supportiveness may be diminished by excessive compliance with a manual. Moreover, numerous reviews and meta-analyses have concluded that not all therapists obtain equivalent results even if they implement manual-based treatments. Some studies find that therapists determine much of the positive effects of treatment, suggesting a general effect of therapist skill rather than a particular intervention. Perhaps consistent with this, studies have also found that a small portion of therapists accounts for most of the occasional detrimental effects observed in treatment.

The most commonly studied therapist variables are those proposed by Carl Rogers: Research has consistently found therapist in-session empathy, genuineness, and unconditional warmth to be predictive of treatment success. Additional therapist characteristics that predict effectiveness include skill (but not necessarily experience), attention to the therapeutic alliance, capacity to question and adjust their approach, and their perceived ability to handle professional challenges. Research suggests that therapy is most likely to be successful if therapists attend to the therapeutic alliance and make efforts to address potential problems or "ruptures" in the alliance. In contrast, there is minimal evidence to suggest that therapist gender, age, race or ethnicity, socioeconomic background, or indeed therapeutic stance (i.e., preferred treatment modality) is predictive of treatment success.

PATIENT VARIABLES RELATED TO OUTCOME

Patient Demographic Characteristics

Research indicates that most interventions work equally well for individuals of different genders across the lifespan. In fact, a meta-

Telegram: @medical_k

www.konkur.in

analysis found that there is no association between patient age or gender and treatment effectiveness. Given that older adults have been found to prefer therapy over medication, research showing that older adults benefit from various forms of psychotherapy as much as younger adults are important. Broadly, research shows that several types of psychotherapy (e.g., CBT, behavioral therapy) are effective for children and adolescents; however, interventions requiring high levels of insight and advanced or abstract cognitive abilities (e.g., ACT, psychodynamic therapy) may be more challenging for younger patients.

When it comes to ethnic and racial background, research demonstrates that members of minority groups obtain fewer benefits from conventional psychotherapies compared to their non-Hispanic white counterparts. Consistent with this finding, dropout rates are relatively higher for minority groups, especially if the provider and patient come from dissimilar racial, ethnic, and cultural backgrounds. These findings have been shown to be related to a lack of trust, a preference for self-reliance, greater skepticism about the benefits of treatment, more concerns about potential negative effects, and enhanced perceptions of stigma, all of which make both treatment initiation and treatment adherence less likely.

Research further suggests the validity of these concerns. For example, the quality of services available to ethnic and racial minority groups tends to be significantly poorer compared to the services available to non-Hispanic white individuals, including underdiagnosis and inappropriate, ineffective (e.g., nonspecialty), or culturally incompetent treatment. Perhaps not surprisingly, research shows that culturally adapted interventions are typically more effective than conventional interventions for minority individuals, and the multicultural competence of the therapist has been linked to patient outcomes.

Patient Cognitive Characteristics

Numerous cognitive variables have been found to be predictive of success in psychotherapy. Research indicates that motivation to

Telegram: @medical_k

www.konkur.in

change and willingness to engage in the therapeutic process are essential. Related to this, numerous studies have documented that enhancing a patient's motivation to change and participate in therapeutic efforts leads to a greater likelihood of successful treatment. These are likely related to evidence showing that a patient's expectation that therapy will help is a key predictor of effectiveness. Another cognitive characteristic of patients is attachment style, and research shows it is related to the capacity to develop a therapeutic alliance. Evidence also suggests that outcomes are related to a patient's ego strength (i.e., the capacity to question assumptions and perceptions) and intelligence, with higher levels related to better outcomes for both characteristics.

Patient Clinical Characteristics

Investigation of the relationship between patient disturbance and outcome has yielded consistent findings: Patients with less disturbance at the beginning of treatment are relatively healthier at the end of treatment. Paradoxically, however, patient distress is the single best predictor of the likelihood of seeking professional treatment. Specific to mood disorders, patients with high levels of impairment tend to require relatively long-term, intensive treatment. Research has also delineated that the diagnosis of a personality disorder (either as the primary focus of treatment or as a comorbid condition of other disorders) is an indicator of relatively poorer treatment outcomes.

The quality of the alliance appears to be influenced by a variety of intra- and interpersonal patient characteristics. Patients with the capacity for positive social relationships tend to develop a better alliance than defensive or negativistic patients, whereas problem severity does not appear to affect the quality of the alliance. That said, research that tracks the alliance across therapy clearly demonstrates that problems in the alliance can be attended to and repaired via active intervention on the part of the therapist to the benefit of the patient.

Telegram: @medical_k

www.konkur.in

Patient–Therapist Matching

Patient and therapist similarity across age, gender, and racial and ethnic identity appears to be related to treatment outcome. When it comes to age and gender, the extent of the patient–therapist match has been shown to have a small to modest effect on outcomes. Patient–therapist ethnic similarities have been shown to be more related to outcome, and research shows that some racial and ethnic minority patients may prefer a therapist that is ethnically similar.

However, the advantages of matching based on ethnicity might be less important than the cultural sensitivity of the therapist and adjustments to therapy based on cultural considerations. For example, one study examining the effect of matching patient and therapist ethnicity in the treatment of Asian Americans, Mexican Americans, African Americans, and White Americans found that patients who were matched with their therapists on ethnicity stayed longer in therapy, but matching was positively related to outcome only for the Mexican American group. Still, other studies have found that if the therapist tries to address the dissimilarity of patient-therapist ethnicity openly, the therapeutic relationship is strengthened.

Perhaps more important than ethnic match is whether the therapist and patient have compatible beliefs about the causes and treatment of psychological problems. Unfortunately, the explanations of mental health conditions have, for the most part, been based on European and Western notions. Explanations and treatment approaches have largely ignored religious and indigenous cultural explanations for mental health problems. Current professional guidelines and the scientific literature concur: Therapists should not only respect patient beliefs about the etiology of their condition but also should take these attitudes into account when developing and implementing intervention strategies.

Patient–Treatment Matching

There have been efforts to optimize the effects of psychotherapy by matching patient variables to treatment interventions. One example

Telegram: @medical_k

www.konkur.in

is the aptitude-by-treatment interaction (ATI) approach to psychotherapy. This research attempts to identify treatment strategies and procedures that produce optimal outcomes for individual patients. ATI research first categorizes patients and therapists on different characteristics (e.g., resistive, impulsive, extroverted, directive, supportive). Then, ATI research tries to determine which procedures are important to effective treatment in different contexts, whether certain patients are likely to respond to a certain therapist or therapy characteristics, and thus whether patients can be helped most by assignment to certain therapies or therapists.

For example, one study of major depression found that externalizing patients (those who tended to blame their environment for their problems) and patients low in defensiveness did better in cognitive therapy, which is fairly directive. Whereas internalizing patients (those who tended to blame themselves for their problems) and patients high in defensiveness did better in supportive and self-directed therapy.

Another study also found that externally focused patients respond better to more directive therapies, such as cognitive-behavioral psychotherapy. In contrast, highly anxious patients are more responsive to emotion clarification and supportive approaches. Similarly, although supportive therapy has been shown to be more effective with patients having higher levels of distress, cognitive therapy has been shown to be more effective with patients presenting with lower levels of distress. There is some evidence that panic disorder responds best and most quickly to a combination of behavioral and cognitive interventions. ATI research is fairly recent and, by definition, requires standardized therapies.

EMERGING THEMES AND FUTURE DIRECTIONS

The question of whether psychotherapy works has been definitely answered: There is a plethora of evidence from efficacy and effectiveness studies indicating that therapy is effective in alleviating emotional distress and behavioral dysfunction. Two models of

Telegram: @medical_k

www.konkur.in

psychotherapy—the medical model and the contextual model—have competed in the last several decades. The medical model suggests that psychotherapies have specific ingredients that address a specific problem within the patient and therefore account for treatment outcomes. In contrast, the contextual model holds that therapies are effective due to universal relational and psychological factors, which vary according to the therapist's skill and unique presentation of the patient.

Research suggests that both models have merit: Certain psychotherapy methods have been repeatedly demonstrated to be more effective than others in the treatment of certain disorders (e.g., exposure therapy for specific phobia), *and* the therapeutic relationship is a necessary aspect of treatment, regardless of the type of psychotherapy, with therapists' and patients' contributions playing an important role in outcomes. However, the evidence for both models is imperfect, so current psychotherapy research continues to examine the relative importance of specific (e.g., interventions) versus nonspecific (e.g., the alliance) curative factors, differential effects of treatment techniques (i.e., are some interventions more powerful for some clients or conditions?), and the transfer of knowledge gained in the research setting to actual clinical practice.

Relatedly, one of the challenges facing the field is increasing the implementation of evidence-based treatments that have been developed in the laboratory by psychotherapists in community settings. As such, there has been a large increase in the last several years in the number of studies that examine how efficacious clinical interventions can be delivered in usual care settings or target patient-centered outcomes.

In addition, efforts to evaluate the effects of dissemination strategies (i.e., attempts to promote the use of research-supported psychotherapy techniques) via translational research are also on the rise. One advancement in this domain has been in the role of technology in the provision of psychotherapy.

In particular, the recent stay-at-home orders resulting from the COVID-19 pandemic contributed to a significant increase in the use

Telegram: @medical_k

www.konkur.in

of telemedicine. A recent survey of clinical psychologists showed that 85% of clinical work was conducted via telemedicine during the pandemic, compared to just 7% prior to the pandemic. Additionally, psychologists estimated about 35% of their clinical work would remain virtually delivered after the pandemic ends. A recent literature review and meta-analysis found emerging evidence that the effectiveness of videoconference and telephone-delivered psychotherapy is comparable to in-person delivery of care. Further evaluation of the effectiveness of virtual treatment is essential for ensuring evidence-based care for patients and has exciting implications for improving access to high-quality mental health care.

Another trend over the last several years is the emphasis on patient-focused care, which uses research to inform personalized treatment decisions about the effectiveness of a specific treatment with a specific patient. Several systems of case-based decision support have been developed and applied to patient monitoring and therapist feedback. These approaches include the use of a global measure of patient functioning, repeated measurement during the course of therapy, and norms based on large patient and nonpatient samples to assess reliable change and clinically significant change.

One approach uses patient profiling techniques to predict the course of response to treatment, given the clinical characteristics of the patient. Monitored progress can be compared to the expected rate of change qualified by the patient's clinical characteristics. Another method for personalizing treatment is shared decision-making (SDM), an interactive process in which clinicians and patients collaborate to make healthcare decisions. Initially designed for use in medical settings, SDM in psychotherapy usually involves the therapist and patient working together to define the presenting problem, followed by the clinician presenting treatment options as well as the empirical evidence supporting those options and a discussion of the pros/cons of options. The result is a treatment plan that is guided by research and incorporates patient values and preferences. Initial evidence for the utility of SDM in mental health care is encouraging.

Telegram: @medical_k

www.konkur.in

Looking forward, the main questions remaining for psychotherapy researchers focus on maximizing the likelihood of positive effects for as many persons in distress as possible. To this end, several areas of research show promise. In addition to the research outlined above, the development of interventions that target transdiagnostic factors linked to multiple diagnoses (e.g., emotional dysregulation and cognitive appraisal issues) may lead to more efficient and effective treatments. One example is David Barlow and colleagues' *Unified Protocol for the Transdiagnostic Treatment of Emotional Disorders,* which has been shown to effectively treat a range of anxiety, depression, and other emotional disorders.

Second, advancements in neuroscience research have identified several genetic, anatomical, circuitry, and functional causes of behavior as well as measurable brain changes following a successful course of psychotherapy. Further integration of neuroscience and psychotherapy could help develop more comprehensive interventions with longer-lasting effects.

Third, culturally appropriate treatment paradigms are an essential aspect of psychotherapy research. Accounting for cultural factors involves developing new interventions and/or adapting established protocols to address the unique characteristics of patients from traditionally marginalized backgrounds (e.g., racial/ethnic minority, LGBTQIA+, disabled, neurodivergent).

Fourth, understanding treatment failure is a critically important issue, given that the failure rate for certain disorders, such as substance abuse disorders, remains high.

Finally, although there has been some progress in promoting psychological interventions as legitimate and beneficial, there remains an intense and widespread stigma associated with mental illness and its treatment.

33 Biologic Therapies

33.1 Preface

WHAT'S NEW IN THE BIOLOGIC THERAPIES SECTION?

The section is structured in a pharmacologically driven order (rather than the traditional disease-based) and in line with the concepts of *Neuroscience-based Nomenclature (NbN)* (see Chapter 33.1c).

Accordingly, the chapters are arranged in 21 subsections, focusing on pharmacologic domains (i.e., neurotransmitters) and modes of action (e.g., antagonists, reuptake inhibitors). Hence, for example, risperidone is now included in the "dopamine blockers" subsection, categorized as a "dopamine-serotonin antagonist." Concordantly, formerly "antidepressants" such as clomipramine or bupropion are now classified as "monoamine enhancers." However, in instances of unique indications (e.g., sexual dysfunction) or cases where agents of different mechanisms were more intuitively discussed in one "package" (e.g., substance abuse), the chapters remained indication driven.

In order to ease the reader's orientation to the main neurobiologic properties of each drug, an "NbN ID"—stating the pharmacologic domain and mode of action—was assigned to the relevant medications throughout the section.

Finally, aside from new agents introduced in the section (e.g., esketamine, pimavanserin), the current edition expands its scope to the global angle of biologic therapies (the essential list of medicines, biologic therapies in Africa, India, and Latin America) as well as aspects concerning gender and sex differences (e.g., Sex Differences in Psychopharmacological Treatment), and novel fast-acting treatments (e.g., MDMA and psilocybin).

We, the section editors, hope that these changes will help toto present to you, the reader, the depth and richness of the neuroscience fabric of psychotropics.

Joseph Zohar
Sasson Zemach

33.1a General Principles of Psychopharmacology

Olusola Ajilore, M.D., Ph.D., and Mark M. Rasenick, Ph.D.

Psychopharmacology is the use of medications as a treatment for mental disorders. Previous editions of this textbook have chronicled the evolution of psychopharmacology as a medical discipline. The first edition of *Kaplan and Sadock's Comprehensive Textbook of Psychiatry,*

Telegram: @medical_k

www.konkur.in

published in 1967, appeared a decade after the appearance of modern antidepressants, antipsychotics, mood stabilizers, and anxiolytics. Of the nearly 1,700 pages in that first edition, a mere 25 pages were devoted to drugs as treatments for mental disorders. Chlorpromazine (Thorazine), approved by the U.S. Food and Drug Administration (FDA) 15 years earlier, was alone among the drugs acknowledged as being a significant therapeutic breakthrough. Other psychotropic agents, including the benzodiazepines (introduced in 1959), were characterized as playing a minor therapeutic role, serving as adjuncts to psychotherapy or as a last resort for patients failing to respond to therapy. There was no intimation that benzodiazepines would become the most widely prescribed drugs of any type within a few years. Lithium (Eskalith), which had been described as an effective treatment of mania in 1949, was mentioned in a brief paragraph. Indeed, in reading the first edition of *Kaplan and Sadock's Comprehensive Textbook of Psychiatry* and other textbooks of that time, it would have been difficult to predict how psychotropic drugs would soon transform the treatment of mental disorders. In a reversal of positions, psychoanalytic theory, which once served to define the practice of psychiatry, has been supplanted by psychopharmacology as the most widely used form of treatment of psychiatric disorders. However, there is concern by many in the field that psychopharmacology has stalled in the past decade. This crisis is due, in part, to the high cost of failure for new drug trials, particularly as it is difficult to separate out from placebo for many psychiatric drugs. This crisis is also due to insufficient government budgets for basic research. In the absence of new molecular targets, the ability of pharmaceutical companies to develop truly novel psychiatric drugs is in jeopardy. To some degree, there has been relief in recent years. After a relative drought in psychotropic drug development, 2019 alone saw three new FDA-approved medications for treatment-resistant depression, postpartum depression, and schizophrenia. Of note, these medications, esketamine, brexanolone, and lumateperone, represented novel mechanisms of action compared to current medications. Thus, highlighting that in order to advance the current knowledge in the field, it is important to understand the present state of psychopharmacology. It is within this context that this chapter describes the basic principles of both pharmacology and psychopharmacology.

In order to engender a complete understanding of the basic principles of psychopharmacology, it is first necessary to understand the principles of pharmacology—particularly those relating to receptors and cellular signaling. This chapter is organized into two sections: the first section will introduce the basic principles of pharmacology, and the second section will build upon them to discuss general issues with psychotropic drugs.

RECEPTOR PHARMACOLOGY

The majority of drugs used for palliation of psychiatric symptoms either mimic, block, or modify the actions of neurotransmitters, and most do so by binding to receptors for those transmitters. While receptors can be located either on the plasma membrane or intracellularly, the neurotransmitter receptors relevant to the drugs to be discussed in this chapter are transmembrane molecules, with outer surfaces forming binding pockets for the neurotransmitter.

The receptors discussed in this chapter are either ion channels (ionotropic) or metabotropic (G protein–coupled), and many neurotransmitters (e.g., acetylcholine, glutamate, gamma-aminobutyric acid [GABA], and serotonin) act as agonists for receptors in each class. This chapter will discuss the basic biology of many of these transmitters and receptors. It begins with a description of the characterization and quantitation of different receptors.

Receptor Analysis

Telegram: @medical_k

www.konkur.in

There are two basic mechanisms for studying receptors. One is to measure the binding of a ligand (often radioactively labeled), and the other is to measure the physiologic consequences of agonist binding (and the effects of antagonist).

Binding Assays. In order to study receptors with radioligand binding, hormones, neurotransmitters, or their analogs have been labeled with a variety of radioactive compounds. Membranes prepared from cultured cells or brain tissue (or intact cells) can be assayed for their ability to bind these radioactive drugs. The radioactive compounds can be either agonists or antagonists and through the use of these compounds, a quantitation of both the number of receptors and the affinity of those receptors for the drug can be determined.

In order to quantify binding, ligands are added to membrane preparations at known concentrations and competed with nonradioactive ligands in order to determine the extent to which binding is specific. Membranes are trapped on filters, the filters are washed, and radioactivity is determined by scintillation spectrometry. Typical results are illustrated in Figure 33.1a–1. Specific binding can be transformed by Scatchard analysis (Fig. 33.1a–2) to reveal the existence of multiple affinity states for agonists and Hill analysis to determine whether binding is cooperative.

Telegram: @medical_k

www.konkur.in

FIGURE 33.1a–1. Kinetics of ligand (agonist or antagonist) binding. **A:** Measurement of receptors using radioligand binding. Membranes (or cells) are incubated with radioactive agonist or antagonist and collected by sedimentation or filtration. Radioactivity in particulate fractions is calculated and plotted as shown above. Nonspecific binding refers to that portion of the total binding that persists in the presence of an excess of unlabeled compound. Specific binding is saturable, within the range of the experiment shown, but nonspecific binding does not saturate. **B:** Two plots of specific binding versus concentration of ligand. **C:** The approximate Kd is represented by the ligand concentration at 50% saturation of specific binding. DPM, disintegrations per minute. (Reprinted with permission from Felig P, Frohman LA. *Endocrinology and Metabolism*. 4th ed. McGraw Hill Education; 2001.)

FIGURE 33.1a–2. Computational analysis of receptor binding. **A:** Scatchard plots. (Left) a receptor with a single affinity state for the binding of ligand; (right) two-site fit. **B:** Hill plots for the determination of cooperativity in ligand–receptor binding. Three Hill plots are shown here. (**a**) Four binding sites (possibly a tetramer); (**b**) is representative of a single site; (**c**) cooperative binding of fewer than four but more than one site. (Reprinted with permission from Felig P, Frohman LA. *Endocrinology and Metabolism*. 4th ed. McGraw Hill Education; 2001.)

Some receptors are oligomeric. Many ionotropic receptors have multiple subunits, and two or more of these bind agonists, often displaying cooperative binding. G protein–coupled receptors (GPCRs) have been shown to dimerize as well, and this can take the form of homodimers or heterodimers in the case of multiple receptor species. Although dimerization is demonstrably obligatory only for GABAB and sweet or umami taste receptors, many other forms of receptors have been demonstrated to dimerize.

Biologic (Efficacy) Assays. In addition to the direct determination of agonist or antagonist binding to a receptor, the biologic consequences of this binding can be assessed. One of these methods involves a biologic assay. A classical biologic assay utilizes an isolated organ strip, such as the guinea pig ileum, and measures changes in both the frequency and strength of contraction of the intestinal smooth muscle in response to the presence of an agonist. Such a system allows the investigator to coordinate the dose of a hormone with the strength of the response, but quantification is often imprecise.

More recent biologic assays rely on enzyme “effectors” activated subsequent to receptor activation. In the case of the guinea pig ileum, this might involve measuring the cyclic adenosine monophosphate (cAMP) produced by the enzyme adenylyl cyclase subsequent to

Telegram: @medical_k

www.konkur.in

the activation of the β-adrenergic receptor. Higher throughput assays designed to screen drugs that may act as agonists or antagonists for a given receptor might involve fluorescent sensors detecting an increase in Ca^{2+} subsequent to activation of a receptor that activates phospholipase c (e.g., 5HT2A), a process that ultimately increases cellular calcium. Such assays are referred to by the acronym FLIPR (fluorometric imaging plate reader) and are used routinely in the process of drug discovery and development. These high-throughput assays employ fluorescent calcium and cAMP (or other small molecules) sensors to determine GPCR activation and determine the efficacy of an agonist or potency of an antagonist at a given receptor.

FIGURE 33.1a–3. Guanosine 5'-triphosphate (GTP) decreases agonist affinity. In the example shown, the β-adrenergic agonist, isoproterenol, is used to displace the labeled β-adrenergic antagonist, 125I-iodocyanopindolol (ICYP). In the presence of GTP, significantly more isoproterenol is required to displace the iodocyanopindolol. This "right shift" of the binding curve indicates that, in the presence of GTP, affinity for agonist by the receptor is decreased. (Reprinted with permission Felig P, Frohman LA. *Endocrinology and Metabolism*. 4th ed. McGraw Hill Education; 2001.)

Efficacy could also be plotted in a manner similar to that used in Figure 33.1a–1. The X-axis would continue to represent the amount of drug required (potency), and the degree of activation (efficacy) would be represented on the Y-axis.

G Protein Modulation of Agonist Binding. GPCRs show a significant decrease in agonist affinity following the introduction of guanosine 5′-triphosphate (GTP) into the medium. This is demonstrated in Figure 33.1a–3. Isoproterenol, a β-adrenergic agonist, displaces iodocyanopindolol (a radioactive antagonist) with less potency in the presence of GTP. It is suggested that the complex between receptor and G protein represents the high-affinity state for agonist binding. Agonist allows the active receptor to induce the G protein to bind GTP (this will be explained more completely below), which then causes the G protein to dissociate from the receptor. This "free receptor" has a lower affinity for agonists than does the receptor–G protein complex. Note that some antagonists also show the ability to undergo this "GTP shift." As will be noted below, some antagonists also modify the conformation of certain other GPCRs.

Structure and Function of Receptors

Telegram: @medical_k

www.konkur.in

Ionotropic receptors were first to be characterized structurally, as the nicotinic acetylcholine receptors (nAChRs) are present in large concentrations in the electroplax organs of electric fish and eel and proved rich sources of receptor that was modeled by x-ray diffraction. Many years later, outer segments of retinal rod photoreceptors proved a similarly rich source of rhodopsin, the first GPCR to be crystalized by Palczewski and colleagues. While solving the structures of GPCRs more relevant to psychiatry was daunting, Kobilka, Stevens and their colleagues devised a mechanism for modifying these receptors, and a number of pharmacologically relevant GPCRs have now been determined structurally by Roth and colleagues.

In the case of ionotropic receptors, the binding of an agonist elicits a cascade that initially creates a channel for ion conductance. Second messenger systems (elicited subsequent to GPCR activation) modify channel function considerably. In the case of GPCR, activation subsequent to agonist binding results in a change in receptor morphology that releases GDP from the bound G protein α subunit. The subsequent binding of GTP activates the G protein, allowing α subunits to engage intracellular effector enzymes such as adenylyl cyclase or phospholipase and β/γ subunits to engage voltage-dependent ion channels.

Ionotropic Receptors

VOLTAGE GATED. These receptors, which are intrinsic ion channels, are either voltage-gated or ligand-gated. The first class, consisting of Na^+, K^+, and Ca^{2+} channels, possesses sensors (arrays of charged amino acids within transmembrane regions). Many of these receptors have multiple (4 or 5) subunits that combine to form a functional receptor. Several mutations have been identified for voltage-sensitive channels, and these result in a variety of maladies (channelopathies) ranging, in the case of calcium channels, from familial migraine to dystonia (Fig. 33.1a–4).

LIGAND-GATED. These receptors, which also form ion channels that open in response to agonists, often share the quatrameric or pentameric structure of the voltage-gated receptors but have specialized regions that bind one or two molecules of agonist. nAChRs, GABAA receptors, glutamate receptors (either kainate or *N*-methyl-D-aspartate [NMDA]), and 5HT3 receptors fall into this class (Fig. 33.1a–5). While some of these receptors (e.g., nAChR) are regulated by the binding of an agonist, others have more complex regulations. GABAA has binding sites for benzodiazepines that increase agonist potency as well as binding sites within the channel region that decrease chloride conductance, hence acting as convulsants (Strychnine) (Fig. 33.1a–6). Similarly, NMDA receptors, which normally act as Na^+ channels, conduct Ca^+ subsequent to membrane depolarization (Fig. 33.1a–7) and can even participate in rapid remodeling of the synapse. Curiously, glycine, which is an agonist for a Cl^-channel receptor similar to GABAA (but found primarily in the spinal cord), also acts to promote the activity of glutamate at the excitatory NMDA receptor.

FIGURE 33.1a–5. Families of ligand-gated ion channels. **A:** Nicotinic AChR, GABA, and glycine receptor channels are all pentamers and are comprised of many different types of subunits. Their actions are explained in the text. **B:** Glutamate receptors are tetramers, usually comprised of two each of similar subunits. **C:** Purinergic (ATP) receptors are trimmers, each subunits with two membrane-spanning domains. (Adapted with permission from Kandel ER, Schwartz JH, Jessell TM, Siegelbaum SA, Hudspeth AJ, eds. *Principles of Neural Science*. 5th ed. Mcgraw-Hill Medical; 2013.)

Receptors for Growth Factors. Receptors for neurotrophins, such as nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF), have intrinsic tyrosine kinase activity and dimerize upon agonist binding (Fig. 33.1a–8). These receptors include trkA, trkB, and

Telegram: @medical_k

www.konkur.in

p75NTR. Regardless of the specific receptor type, most of the members of this receptor family consist of two subunits. Sometimes receptors form a homodimer and, at other times, a heterodimer. The formation of a dimer, which is a result of receptor activation, leads to autophosphorylation or transphosphorylation of the receptor within its cytoplasmic domain. Consequently, other substrates for that receptor phosphate are found and phosphorylate. Signal propagation often is a result of an activation of a series of kinase cascades resulting in cell growth or differentiation.

FIGURE 33.1a–6. Structure and function of the [GABAA/GABA-A/GABAA] receptor. A model for the receptor shows binding sites for GABA as well as compounds that affect GABA signaling. Activation of the receptor increases chloride conductance. Compounds not binding directly to the GABA site modify (+/-) GABA-[activated/actuated] channel opening. (Created with Biorender.com)

FIGURE 33.1a–7. Glutamate receptors. Three classes of glutamate receptor regulate excitatory synaptic actions in neurons in the spinal cord and brain. Two types of ionotropic glutamate receptor gate ion channels directly. Two subtypes of non-*N*-methyl-d-aspartate (NMDA) receptor bind the glutamate agonists kainate or alpha-amino 3-hydroxy-5-methylisoxazole-4-proprionate (AMPA) and regulate a channel permeable to Na^+ and K^+. The NMDA receptor (left) regulates a channel permeable to Ca^{2+} and Na^+ and has binding sites for glycine, Zn^{2+}, phencyclidine (PCP or "angel dust"), MK801, and Mg^{2+}, which modulate the functioning of this channel in the direction indicated.

FIGURE 33.1a–8. Neurotrophin receptors. **A:** All neurotrophins bind p75NTR, a receptor lacking tyrosine kinase activity. The receptors with tyrosine kinase activity are selective for the molecules indicated in the figure. **B:** Upon activation, the three Trk receptors dimerize, autophosphorylate, and phosphorylate intracellular targets. A variety of survival or differentiation pathways can be activated.

FIGURE 33.1a–9. Model of a "classic" G protein–coupled receptor. The β1-adrenergic receptor is shown. Highly conserved residues (among all G protein–coupled receptors) are shown in black. Boxed residues are conserved in catecholamine receptors and the serine marked with * is conserved in all G protein–coupled serotonin receptors. Diamond residues are involved in G protein coupling. (Adapted with permission of Probst WC, Snyder LA, Schuster DI, Brosius J, Sealfon SC. Sequence alignment of the G-protein coupled receptor superfamily. *DNA Cell Biol.* 1992;11(1):1–20. doi: 10.1089/dna.1992.11.1.)

Metabotropic (G Protein–Coupled) Receptors. GPCRs are a large family of receptors for light, odorants, small molecule neurotransmitters as well as a variety of peptide agonists. It is estimated that somewhere between 30% and 70% of current drugs relate to GPCRs, elevating their importance for psychopharmacology. GPCRs regulate a multitude of physiologic functions through activation of heterotrimeric G protein α and βγ subunits that bind to target proteins to initiate cellular signal transduction cascades, a process that is critically important for neurons and neurotransmitter action. Nearly 1,000 GPCRs have been identified in the human genome and include both chemosensory receptors and receptors for hormones and neurotransmitters. Approximately 100 of these GPCRs have not been linked to an endogenous ligand. These are known as orphan receptors. All GPCRs share a similar structure, which includes seven transmembrane domains, an extracellular amino-terminal, an intracellular carboxyl-terminal, three extracellular loops, and three cytosolic loops (Fig. 33.1a–9). While each of the seven transmembrane domains comprises somewhere between 20 and 27 amino acids, the end-terminal segments, as well as either the extracellular or cytoplasmic loops, can vary greatly among the different receptor types.

Changes in Receptor Conformation upon Agonist Activation. Mutational analysis suggested several regions of GPCRs were involved in coupling to and activating G proteins. Curiously, the elucidation of the crystal structure of the β_2 receptor, suggested that there were distinct patterns among GPCRs and their cognate G proteins.

Receptors with constitutive activity, which are active in the absence of an agonist, can be generated by mutation. The importance of the C-terminal portion of the third intracellular loop

Telegram: @medical_k

www.konkur.in

was demonstrated in studies on the adrenergic receptor that is linked to norepinephrine-induced activation of phosphatidylinositol metabolism.

Another region relevant for G protein coupling is located at the junction between the third transmembrane segment and the second intracellular loop of many GPCRs. This region is delineated by a motif known as E/DRY (Glu/Asp-Arg-Tyr), which is highly conserved among GPCRs, and mutations result in constitutive activation of many different GPCRs.

Some naturally occurring mutations result in constitutive receptor activity. Shenker and colleagues (1993) identified a mutation (Asp578Gly/Tyr) in the sixth transmembrane domain of the luteinizing hormone receptor, which confers constitutive activation. Males carrying this mutation display precocious puberty. Some types of GPCRs display constitutive activity in their normal state. While D1a dopamine receptors require the presence of an agonist to activate G protein, D1b receptors show high-constitutive activity, almost completely activating G protein in the absence of an agonist.

INVERSE AGONISM. The demonstration of naturally occurring constitutive activity for GPCRs raises the possibility that inhibition of such constitutive activity should have a functional effect. Thus, for a number of receptors, compounds exist that simply inhibit the binding of agonists (neutral antagonists), and other compounds exist that inhibit the activity of a constitutively active receptor (inverse agonists). This was demonstrated for the δ opiate receptor in studies that revealed that the “inverse agonist” ICI 174864 lowered the basal activation of Gi by these receptors. Considering the model of receptor–G protein complexes presented above, it would be predicted that inverse agonists would show preferential binding to receptors that were uncoupled to G proteins. Inverse agonism has been demonstrated at a number of receptor types.

Telegram: @medical_k

www.konkur.in

FIGURE 33.1a–10. G protein–coupled receptor (GPCR) internalization and biased agonism. In the long-established model of GPCR signaling, an agonist binds to extracellular and/or transmembrane regions of the receptor, leading to its activation of G protein that results from exchange of GDP for GTP on Gα subunit, creating active Gα and Gβγ subunits. Termination of receptor activation can occur through GPCR phosphorylation by GPCR kinases (GRKs) and concomitant GPCR association with arrestins, which interact with clathrin to internalize GPCRs in endosomes. Recruitment of arrestins to activated GPCRs can also lead to the initiation of distinct arrestin-mediated signaling pathways, including activation of the mitogen activated protein kinase extracellular signal-regulated kinase (ERK) pathway. This can be done absent involvement of G protein, and agonists engaging either G protein or arrestin pathways are referred to as biased. Subsequent to internalization, GPCRs can be trafficked to lysosomes, where they are ultimately degraded, or to recycling endosomes for reinsertion to the plasma membrane. (From Ritter SL, Hall RA. Fine-tuning of GPCR activity by receptor-interacting proteins. *Nat Rev Mol Cell Biol.* 2009;10(12):819–830, with permission from Springer Nature. doi: 10.1038/nrm2803.)

BIASED AGONISM. Endogenous agonists for most GPCRs) activate the receptor so that it engages both a G protein and β-arrestin. While the G protein pathway often generates cellular second messengers, the β-arrestin pathway evokes receptor internalization and a series of β-arrestin-mediated intracellular events. Over the past few years, compounds have been developed that select (are biased for) either the G protein pathway or the β-arrestin pathway. For psychiatry, of clear interest would be the development of compounds that ameliorate pain yet pose low potential for addiction (Fig. 33.1a–10).

ALLOSTERY. The discussion of GPCR agonists and antagonists presented above concerns molecules to that bind to the orthosteric ligand binding site on those receptors. Orthosteric agonists (and some antagonists) have been demonstrated to evoke specific structural changes in the receptor that engages G proteins and initiates the signal transduction cascade. Studies over the last several years have revealed the presence of allosteric sites on receptors. Molecules that bind to these sites, known as positive or negative allosteric modulators (PAM

Telegram: @medical_k

www.konkur.in

or NAM), might regulate the activity of a GPCR by either sustaining (PAM) or restricting (NAM) the active conformation of a receptor elicited by the orthosteric agonist.

Table 33.1a–1.
Mammalian Heterotrimeric G Protein α Subunits

Family	Subtype	Effectors
Gs(S)α	Gsα	Adenylyl cyclase, GTPase of tubulin
	Golfα	Adenylyl cyclase (olfactory)
Gi/oα	Go1α	Adenylyl cyclase inhibition (Gi, o, za) Go2
	Gi1-i3α	K^+ channels; Ca^{2+} channels inhibition (Gβγ)
	Ggust α	K^+ channels; Ca^{2+} channels inhibition (Gβγ)
	Gtα1/2	(transducin) cGMP-PDE in retina
Gq/11α	Gqα	Phospholipase C
	G11α	p63-RhoGEF
	G14α	
	G16α	
G12/13a	G12α	p115RhoGEF and related proteins
	G13α	

RECEPTOR DESENSITIZATION. Receptors are also capable of becoming desensitized. This process involves the attenuation of receptor response in the continued presence of an agonist. The process is quite different for ion channels and ionotropic receptors versus GPCRs. In the case of voltage-gated ion channels, there are processes that either desensitize or actually inactivate channels, and some of these events result from second messengers created subsequent to the activation of GPCRs. Similarly, ionotropic receptors are often modified, either by altering affinity for agonists or by altering channel characteristics. Again, this is due to second messengers, often through phosphorylation events.

GPCRs, however, have specific accessory proteins that mediate their desensitization. During the process, G protein receptor kinases (GRKs), an enzyme family, phosphorylate receptors in the activated (agonist-bound) conformation and these receptors become a target for β-arrestins, which herd them into clathrin-coated pits from whence they internalize. Once internalized, they either recycle back to the surface or are degraded. Figure 33.1a–10 illustrates the process. Of note is the evidence that some GPCRs might either continue to signal while internalized or become activated while localized within the cell.

Heterotrimeric G Proteins. Table 33.1a–1 reveals the current list of G protein α subunits. Currently, there have been identified 17α, 5β, and 13γ genes in humans. Alternative splicing increases the number of available proteins. Each of these G proteins interacts with specific effector molecules. These can be enzymes like adenylyl cyclase, which makes cAMP; phospholipase C, which generates lipid messengers and increases intracellular calcium; or voltage-gated ion channels (particularly K^+ or Ca^{2+}), which are modified by Gβγ subsequent to activation of Gα.

THE ACTIVATION CYCLE. Prior to binding agonists, GPCRs exist in a complex with heterotrimeric G proteins (αβγ subunits). The latter two exist as a “fused complex,” and the former releases GDP and binds GTP upon receptor activation. This shifts the Gα to an active

Telegram: @medical_k

www.konkur.in

conformation and alters the association between Gα and Gβγ in such a manner that both engage effector molecules. Hydrolysis of GTP by a GTPase intrinsic to the α subunit terminates the activation cycle (Fig. 33.1a–11).

RGS Proteins. For many Gα proteins, the GTPase is relatively slow, and regulators of G protein signaling (RGS) proteins facilitate the process. RGS proteins are a family of GTPase-activating proteins with conserved RGS domains (also called the RGS box) of about 120 amino-acid residues in length. RGS proteins interact directly with a subunit of heterotrimeric G proteins to catalyze GTP hydrolysis by enhancing the intrinsic GTPase activities of Gα, thus converting G proteins from a GTP-bound active state to a GDP-bound inactive state and terminating G protein-mediated signaling. While most G protein α subunits have been demonstrated to have their GTPase activated by a member of this large family of proteins, Gsα may be excluded. There are two sorting nexins that associate with Gsα (SNX13 and SNS14) that bind specifically with Gsα and are also known as RGSPX1 and RGSPX2, respectively. It is not clear that these proteins activate GTPase, and RGSPX2 clearly lacks this effect. Curiously, RGSPX2, a brain-specific protein, helps mediate the trafficking of Gsα from the cell membrane and also specifically modulates the cell-surface expression of the Gs-associated 5HT6 receptor.

FIGURE 33.1a–11. Activation cycle for G protein heterotrimers. Activation of the GPCR by agonist (described in Fig. 33.1a–10) evokes release of GDP by G protein α subunit, allowing the binding of GTP. The GTP bound conformation of Gα activates Effector molecules such as adenylyl cyclase of Phospholipase C. The activation of Gα is terminated by the hydrolysis of GTP for GDP. While the GTPase is intrinsic, there are molecules, such as RGS proteins, that facilitate the process.

Telegram: @medical_k

www.konkur.in

Bacterial Toxins and G Proteins. Two bacterial toxins are known to modify G proteins by covalently ADP-ribosylating select amino acids within those G proteins. Cholera toxin inactivates the intrinsic GTPase of Gsα which results in sustained (permanent) activation of Gs and subsequent hyperactivation of adenylyl cyclase. Pertussis toxin primarily acts on Gi and Go proteins and uncouples these proteins from the receptors that activate them. Since a prominent effect of Gi/o is inhibition of adenylyl cyclase, pertussis toxin will attenuate this inhibition with the net effect of increasing cAMP.

Microdomains in the Plasma Membrane and GPCR Signaling

The plasma membrane, while comprised of lipids and proteins, enjoys a more complex organization than would be predicted from proteins floating in a lipid bilayer. Membranes are highly compartmentalized and are rife with domains of highly ordered and less ordered membrane lipids. The more highly ordered regions tend to be cholesterol-rich, and these domains are normally associated with cytoskeletal proteins as well. The term used to describe these areas is “lipid rafts,” and they are thought to range in diameter between 20 and 100 nM. Some of these structures contain the protein caveolin and form invaginated structures known as caveolae (little caves). At this point, these structures are conceptual since they are below the level of resolution of the light microscope. Regardless, they can be manipulated experimentally, and it now appears that neurotransmitter action is, depending on the ligand and second-messenger pathway, facilitated or inhibited in caveolae and lipid rafts. Figure 33.1a–12 shows the postulated organization of signaling molecules into lipid rafts and caveolae. These membrane microdomains have been suggested to be important sites of action for antidepressants and may be instrumental in evoking the disrupted signaling seen in depression.

FIGURE 33.1a–12. Lipid raft microdomains and membrane organization of neurotransmitter signaling molecules. **A:** There are two common raft domains in mammalian cells: planar lipid rafts and caveolae. Both possess a similar lipid composition. Planar rafts are essentially continuous with the plane of the plasma membrane and lack distinguishing morphologic features. By contrast, caveolae are small, flask-shaped membrane invaginations of the plasma membrane that contain caveolins. Caveolins and flotillin can recruit signaling molecules into lipid rafts. Many neurotransmitter receptors (both ionotropic and G protein–coupled), G proteins, and signaling effectors such as second-messenger-generating enzymes are found in lipid rafts. Neurotransmitters might activate receptors that are located both within and outside lipid rafts. **B:** The lipid raft signaling hypothesis proposes that these microdomains organize, spatially, signaling molecules at the membrane, perhaps in complexes, to promote interactions that are necessary for signal transduction. **C:** Alternately, lipid rafts might inhibit interactions by separating signaling molecules, disrupting complexes, and damping neurotransmitter response. (From Allen JA, Halverson-Tamboli RA, Rasenick MM. Lipid raft microdomains and neurotransmitter signalling. *Nat Rev Neurosci*. 2007;8:128–140, with permission from Springer Nature. doi: 10.1038/nrn2059.)

G Protein Effectors

A vast array of cellular processes is mediated by G proteins. These molecules can be either activated or inhibited by G proteins, and either α or βγ subunits have been demonstrated to function as activators. A list of some of these G protein-mediated events is given in Table 33.1a–1, and a scheme is shown in Figure 33.1a–13.

Adenylyl Cyclase Isoforms and Their Regulation

Regulator	Effect	Cyclase Isoform
Gsα	Stimulatory	All
Giα	Inhibitory	I, V, VI
GOα	Inhibitory	I
Gzα	Inhibitory	I, V
Gβγ	Inhibitory	I
Gβy	Stimulatory[a]	II, IV, VII
Forskolin	Stimulatory[b]	I–VIII
Ca^{2+}/calmodulin	Stimulatory	I, III, VIII
Ca^{2+}	Inhibitory	V, VI, IX[c]
PKC	Stimulatory	I, II, III, V, VII
PKC	Inhibitory	IV
Calmodulin Kinase	Inhibitory	III

[a]Enzyme must first be stimulated by Gsα.
[b]Very weak stimulation for type IX.
[c]Requires calcineurin.

Adenylyl Cyclase

This is the effector system that was being studied by Sutherland and Rall in their pioneering work on the activation of glycogen phosphorylase—work that led to the identification of cAMP

Telegram: @medical_k

www.konkur.in

and the concept of intracellular messenger molecules. Adenylyl cyclase, which generates cAMP from adenosine triphosphate (ATP), is a family of nine membrane-bound enzymes (plus a soluble version), each with a different mode of regulation. A common feature of all the adenylyl cyclase enzymes is activation by Gsα and (to varying degrees) by the diterpene, forskolin (Table 33.1a–2). While Giα (three genes encode different forms of protein) was called "i" because it was inhibitory to adenylyl cyclase, only a few forms of adenylyl cyclase are inhibited directly by Giα. Calcium can act to stimulate some forms of the enzyme (in conjunction with calmodulin), and other forms are inhibited by calcium. While all forms of adenylyl cyclase are found in the brain, these calcium-regulated types may be particularly relevant for psychopharmacology, as neurotransmitters that increase calcium (e.g., glutamate or acetylcholine) can also modify cAMP indirectly.

Phospholipases

Phospholipases responsive to G proteins fall into three families: phospholipase A, phospholipase C, and phospholipase D (Fig. 33.1a–14). The products of phospholipase A are metabolites of arachidonic acid and are known as eicosanoids. The eicosanoids fall into the subgroups of prostaglandins and leukotrienes, and these molecules function as extracellular signals. The next group of phospholipids includes those that result from the breakdown of diacylglycerol and inositol phosphates, and these are the result of the actions of the phospholipase C enzymes. Gq and G11 activate phospholipase C, which has the net effect of increasing intracellular cellular calcium, both through the release of Ca^{2+} from intracellular stores and increasing capacitive calcium entry. 5HT2A receptors activate phospholipase C through a Gq intermediary. Finally, phospholipase D, which uses phosphatidylcholine as a substrate, can generate diacylglycerol and phosphatidic acid as well as lysophosphatidic acid. This latter molecule also has extracellular signaling properties.

FIGURE 33.1a–14. Substrates for, and products of, G protein–coupled phospholipases. PAF, platelet activating factor. (Reprinted with permission from Felig P, Frohman LA. *Endocrinology and Metabolism*. 4th ed. McGraw Hill Education; 2001.)

G Protein–Activated Ion Channels

Direct activation of potassium channels by G proteins is important for the agonist-induced, rapid inhibition of membrane excitability in nervous tissue, and is essential for modifying both

Telegram: @medical_k

www.konkur.in

excitation and neurotransmitter release. As noted above, activation of GPCRs induces activation of G proteins, and both Gα and Gβγ can activate effector molecules, in this case, channel proteins. These channels (G protein–gated inward rectifier Kþ channels, GIRK) have been shown to bind directly and become activated by Gβγ. They are strictly voltage-independent, and channel gating requires association with intracellular proteins. Just as prominently (and also resulting in an inhibition of a voltage-activated process), Gβγ subunits inhibit voltage-gated Ca^{2+} channels, attenuating neurotransmitter release. In these processes, the G protein itself is the second messenger (Fig. 33.1a–15). Thus, the activation/inhibition of ion channels is somewhat more rapid than the generation of a second messenger and subsequent modification of channel function by phosphorylation.

INTRACELLULAR SIGNALING PATHWAYS

cAMP is synthesized by adenylyl cyclase and degraded by cAMP phosphodiesterase (PDE), which causes cAMP to be hydrolyzed to 5′AMP. Initial hormonal signals are more likely to regulate cAMP by the activation or inhibition of adenylyl cyclase than they are by altering PDE, but this is primarily because the receptors are coupled to G proteins that then directly stimulate or inhibit adenylyl cyclase. However, activation of a Gq-coupled receptor, an NMDA receptor, or a nAChR will increase cellular Ca^{2+}, which will activate calcium-sensitive variants of PDE, decreasing cAMP.

Telegram: @medical_k

www.konkur.in

FIGURE 33.1a–15. Direct opening of an ion channel by a G protein. In this instance, activation of an mAChR by acetylcholine allows Gβγ to bind to and open a K^+ channel known as a G protein–coupled inwardly rectifying K^+ channel (GIRK). Similarly, Gβγ can bind to and inhibit voltage-gated Ca^{2+} channels.

Regulation of cAMP and Ca^{2+} signaling begins with the activation of specific protein kinases sensitive to those messengers. For cAMP, the primary kinase is protein kinase A (PKA) (Fig. 33.1a–16), while Ca^{2+} activates either calcium/calmodulin-activated kinases (CaM kinase) or protein kinase C, which is activated by Ca^{2+} and diacylglycerol. Each of these has a series of targets that engage a series of intracellular pathways, including modification of ion channels, modification of cytoskeletal elements (and fine cellular structure), and modification of neurotransmitter synthesis, transport, release, or catabolism, as well as modification of gene expression via cyclic AMP response element (CREB) phosphorylation (Fig. 33.1a–17).

Telegram: @medical_k

www.konkur.in

FIGURE 33.1a–16. Activation of cyclic adenosine monophosphate (cAMP)-dependent protein kinase (PKA). Binding of cAMP to the regulatory subunits induces a conformational change, causing these subunits to dissociate from the complex, thereby activating the catalytic subunits. Each regulatory subunit has two cAMP-binding sites, and the release of the catalytic subunits requires the binding of more than two cAMP molecules to the tetramer. This greatly sharpens the response of the kinase to changes in cAMP concentration. There are at least two types of A kinase in most mammalian cells: type I is mainly in the cytosol, whereas type II is bound via its regulatory subunit to the plasma membrane, nuclear membrane, and microtubules. In both cases, however, once the catalytic subunits are freed and active, they can migrate into the nucleus (where they phosphorylate gene-regulatory proteins such as CREB; see Fig. 33.1a–17). (Reprinted with permission from Felig P, Frohman LA. *Endocrinology and Metabolism*. 4th ed. McGraw Hill Education; 2001.)

As a rule, intracellular messages require a specific termination switch, and phosphoprotein phosphatases served this purpose for the phosphorylations described above. Some of these enzymes are specific for PKA (protein phosphatase IIb) or CaM kinase (calcineurin).

Regulation of adenylyl cyclase has been discussed above. The regulation of PDEs is quite complex, and much of it is due to the exquisite and unique subcellular localization of a myriad of PDE species. Further, the localization of cAMP-activated protein kinases (PKA) and a variety of PDEs is regulated by a family of proteins known as A kinase anchoring proteins (AKAPs). These proteins, often referred to as cellular scaffolds, provide a spatial dimension to second messenger signaling as well as a temporal discretion provided by the close physical relationship of the relevant proteins.

FIGURE 33.1a–17. cAMP and Calcium signaling orchestrate gene expression. Mechanisms for cAMP generation, calcium entry, and regulation of nuclear and intracellular calcium-responsive proteins are demonstrated. This scheme also suggests an interface for the action of growth factor receptors, GPCRs, and Ca^{2+}.

Epac, Another cAMP Target

The default cAMP pathway is PKA, but it is noteworthy that other cellular proteins are regulated by cAMP-independent of phosphorylation. One of these cAMP targets is a family of proteins known as Epac (exchange proteins activated by cAMP). These elicit guanine nucleotide exchange and subsequent activation of a number of small G proteins involved in cell growth and synaptogenesis. Furthermore, there are ion channels (particularly important in olfaction) that are directly opened subsequent to the binding of cAMP.

INTEGRATION OF NEUROTRANSMITTER SIGNALS

Most diagrams of synaptic signaling, including those in this chapter, depict a single neurotransmitter engaging a single receptor, which then evokes a programmed series of responses through a set pathway. While as a didactic principle this is useful, neurotransmitter signaling, both at extracellular pathways and within cells, enjoys a far greater complexity. First, hundreds (even thousands) of axons converge upon a single dendrite (or even on a single dendritic spine). Second, a single transmitter, acting through a myriad of receptor types, could evoke multiple intracellular pathways. This is illustrated for serotonin in Table 33.1a–3. Finally, each of these pathways is interdependent, as illustrated by Ca^{2+} and cAMP signaling pathways in Figure 33.1a–18.

GENERAL ISSUES IN CLINICAL PSYCHOPHARMACOLOGY

Telegram: @medical_k

www.konkur.in

Reflecting the expanded role of psychopharmacology, as well as the variety and the sheer number of psychotropic drugs available, the sections on psychotropic drugs that follow represent a virtual textbook within a textbook. These sections are also complemented by discussions in other chapters that focus on the treatment of specific disorders and special patient populations. This section is intended as a review of important principles underlying the selection and use of psychotropic medications. It provides a review of common issues that arise in the clinical setting, as well as considerations for more effective use of available agents. Every effort has been made to provide a comprehensive discussion of the properties of the drugs, as well as guidance on their most appropriate use. Nevertheless, it needs to be emphasized that psychopharmacology is a rapidly evolving field and that many patients experience idiosyncratic or paradoxical responses to treatment.

FIGURE 33.1a–18. Interface among second messenger systems: many roles for calcium. Several conduits for Ca^{2+} signaling are shown and the interactions among them and cAMP signaling pathways are described in the text.

Table 33.1a–3.
Psychotropic Drugs with Postmarketing Black Box Warnings

Drug	Psychiatric Application	Basis for Warning
Clozapine (Clozaril)	Refractory schizophrenia	Myocarditis
Droperidol (Inapsine)	Sedation of agitated patients	Torsades de pointes or QT and QTc prolongation, or both, and other cardiovascular events
Thioridazine (Mellaril)	Psychosis	Torsades de pointes or QT and QTc prolongation, or both, and other cardiovascular events
Divalproex (Depakote)	Acute mania	Hemorrhagic pancreatitis and hepatic failure
Nefazodone (Serzone)	Depression	Acute hepatic failure
Pemoline (Cylert)	Attention-deficit/hyperactivity disorder	Acute liver failure
Antidepressants (in patients <24 years old)	Depression	Increased risk of suicidality
Antipsychotics (for dementia-related psychoses)	Psychosis	Increased risk of mortality

History

For centuries, people have used plant extracts and naturally occurring substances to influence mood and anxiety, modulate sleep and arousal, produce euphoria, and alter consciousness. Notable examples include alcohol, coffee, tea, opium preparations, bromides, and hallucinogens. The use of cocaine-containing soothing syrups and elixirs was common. In the nineteenth and early twentieth centuries, several types of *sedatives* were developed. Some of these compounds, chloral hydrate (Aquachloral Supprettes), and barbiturates, are still in use. From the 1930s to the 1950s, the most effective biologic treatment of a mental disorder was electroconvulsive therapy (ECT). While ECT remains an effective treatment, the image of the so-called “shock therapy” is unpalatable to many patients. In 1931, two psychiatrists in India, Ganpath Sen and Kartik Chandra Bose described the ability of *Rauwolfia serpentina* to reduce symptoms of psychosis, but this report was overlooked by Western medicine for many decades. When rediscovered, reserpine (Serpalan) became one of the first agents to offer a benefit to patients with schizophrenia. Understanding of reserpine’s effects on monoamine neurotransmitters spurred further research into the involvement of norepinephrine, serotonin, and dopamine in the treatment of psychiatric disorders and the synthesis of drugs that targeted these agents. Similarly, published findings on the antimanic properties of lithium salts appeared in 1949 but were neglected by most psychiatrists. It was more than two decades before lithium became accepted as the standard treatment for bipolar disorder.

The field of psychopharmacology evolved rapidly during the second half of the 20th century. It was the nearly simultaneous discoveries of several classes of medications that began the transformation of psychiatric treatment from a psychoanalytic to a biologic orientation. The first

Telegram: @medical_k

www.konkur.in

breakthrough occurred between 1950 and 1952 with the observation by Jean Delay and Pierre Deniker that chlorpromazine—a presurgical antihistamine—brought about dramatic control of psychotic symptoms associated with mania and schizophrenia. The effect of the drug was described as “miraculous” and “astonishing.” Chlorpromazine was released for clinical use in 1954 and, within 8 months, was administered to more than 2 million patients. Patients with long histories of hospitalization owing to disorganized thinking and bizarre behavior demonstrated sufficient improvement to be discharged from their overcrowded institutions. For a time, there were expectations that chlorpromazine and its analogs, then referred to as *tranquilizers,* could eradicate or permanently cure schizophrenia. Although this turned out to be a false hope, newer versions of these drugs improve the quality of life of many patients, enabling them to be productive and live in the community.

In 1952, iproniazid (Marsilid), a drug being tested as a treatment for tuberculosis, was observed to cause a dramatic elevation in mood. Over the next few years, psychiatrists came to recognize this antidepressant action of iproniazid and similar isonicotinic hydrazide analogs. Cases of unexpected hypertensive episodes associated with monoamine oxidase inhibitors (MAOIs) were reported soon after the introduction of these drugs. Some patients died of strokes. An explanation for this so-called cheese reaction did not emerge until 1963 in an article by Barry Blackwell.

Shortly after the discovery of MAOI antidepressant activity, imipramine (Tofranil), a derivative of chlorpromazine, was observed to alleviate depressive symptoms. Imipramine, the first tricyclic antidepressant (TCA), and iproniazid, the first MAOI, became available for clinical use in 1957. Within 1 year of its release, more than 400,000 patients received imipramine for depression.

Despite the progress that has been made in more than a half-century, no antidepressants have surpassed the TCAs and MAOIs in efficacy. Nevertheless, these drugs have never lived up to their full potential because of troublesome side effects and concerns about safety. The dietary restrictions reduced the acceptability of MAOI treatment. The anticholinergic side effects of TCAs and their toxicity in overdose also had a restraining effect on their use.

The availability of meprobamate (Equanil) in 1955 marked the first time that treatment of anxiety had a relatively wide margin of safety. Compared to barbiturates, meprobamate caused less dose escalation and a less severe withdrawal syndrome. By the end of that decade, an even better tolerated and safer alternative emerged. In 1957, the benzodiazepine chlordiazepoxide (Librium) was found to produce sedative, muscle relaxant, and anticonvulsant properties but without significant risk of serious toxicity in overdose or during withdrawal. By 1960, chlordiazepoxide was marketed, soon followed by diazepam (Valium). It is worth noting that chlordiazepoxide was introduced into clinical practice just 2.5 years after its pharmacologic studies were started.

In 1958, Paul Janssen synthesized another important chemical family of compounds used to treat psychoses—the butyrophenones. The prototype of this class—haloperidol (Haldol)—remains one of the most popular drugs used for the management of psychosis. The first typical antipsychotic was synthesized in the late 1950s, but it was another of Paul Janssen’s compounds, risperidone (Risperdal), that became the first widely prescribed *atypical* neuroleptic or serotonin-dopamine antagonist.

Attitudes toward psychotropics were transformed in the early 1980s after reports were published that alprazolam (Xanax) could suppress panic attacks. Until that time, only TCAs and MAOIs had been shown to control panic symptoms, and benzodiazepines were not thought to be effective in treating this severe form of anxiety.

Telegram: @medical_k

www.konkur.in

Based on the newly gained understanding that TCAs block not only norepinephrine reuptake but also serotonin, Arvid Carlsson and his colleagues set out to develop a selective inhibitor of serotonin reuptake. Zimelidine, the first of these selective serotonin reuptake inhibitors (SSRIs), was developed in the early 1970s and was found to be a potent antidepressant. It was marketed in Europe but was quickly withdrawn from clinical use because of a rare neurologic side effect. It was not until the introduction of fluoxetine (Prozac) late in 1987 that an SSRI became available in the United States. Early clinical experience with fluoxetine was followed by the surprising realization by patients and physicians that the drug sometimes produced dramatic responses without the same type of tolerability problems associated with the TCAs. Quickly, first-line treatment of depression quickly shifted from the TCAs to fluoxetine and other SSRIs. Even around the start of the 21st century, the majority of new prescriptions for antidepressant treatments were for SSRIs.

The first psychotropic drugs were thus discovered through observations of behavioral effects in animals or humans. As the mechanisms underlying the actions of these drugs have been determined, it has facilitated rational drug development of new compounds, such as the SSRIs, with more selective action. It also has led to the identification of disorders that are preferentially responsive to specific agents. Patients now have many more treatment options; the drugs used are better understood. One of the more remarkable transformations in the field of psychopharmacology has been the degree to which psychotropic drugs are now routinely prescribed by nonpsychiatrists.

Two large studies have helped to provide a perspective on how difficult it is to differentiate the growing number of psychotropic agents in terms of their overall effectiveness. The findings of these studies, the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) and the Sequential Treatment Alternatives to Relieve Depression (STAR*D) trial, point out that patient responses to medications tend to be unpredictable, that no interventions are effective in all patients with a specific disorder, and that tolerability and safety often become the determinant of treatment success or failure.

The STAR*D trial was a large, federally funded study that investigated treatment effectiveness in a “real-world” sample of depressed outpatients treated in psychiatric and primary care practices. There were 3,671 participants in the trial. It found that remission was more common among patients in their first or second treatment trial (37% and 31%, respectively) than among those requiring three or four trials (14% and 13%, respectively). Patients needing more treatment steps tended to have more chronic depression and more coexisting psychiatric and general medical disorders. Overall, 67% of patients who completed up to four treatment steps reached remission. Results for STAR*D revealed higher relapse rates for those who required more initial treatment steps. Patients were allowed to choose among groups of subsequent treatments, which included cognitive therapy alone or combined with medication, as well as several different antidepressants used alone or in combination. The study failed to show any advantage in terms of switching or combining drugs for one strategy over another. The study found higher relapse rates among patients who failed to reach full remission and among those who went through a higher number of treatment steps to reach remission.

The CATIE study, funded by the National Institutes of Health’s National Institute of Mental Health (NIMH), analyzed the effectiveness of an older (first-generation) antipsychotic medication, perphenazine, versus the newer (second-generation) medications during the initial treatment. It found that the older medication might be more cost-effective for some patients with schizophrenia. Perphenazine was less expensive and no less effective than the newer drugs used in the trial. In phase 1 of the trial, patients were randomly assigned to

Telegram: @medical_k

www.konkur.in

receive olanzapine, perphenazine, quetiapine, risperidone, or ziprasidone for up to 18 months. Clozapine was included in phase 2 of the study. The study found that olanzapine had the longest time to discontinuation in phase 1 but caused the most weight gain and metabolic syndrome. Perphenazine did not significantly differ in overall effectiveness from quetiapine, risperidone, and ziprasidone. There were no differences in neurocognitive or psychosocial functioning in response to medications.

Classification

Traditionally, the classification and categorization of psychotropic medications have been based on the primary indication for these medications. With each subsequent edition of this textbook, the classification and categorization of psychotropic drugs have changed. This is not merely a consequence of the development of new compounds. It is also the result of advances in the understanding of how these compounds produce their clinical effects. It was not long ago that psychotropic drugs were broadly defined as either stimulants or sedatives. The term *tranquilizer* was applied to antianxiety/sedative drugs (minor tranquilizers) and antipsychotics (major tranquilizers). At first, the only antidepressants were TCAs or MAOIs. However, when newer antidepressant drugs emerged in the 1970s and 1980s, they were labeled as second- or third-generation antidepressants.

Defining drugs by their major indications is problematic. For example, the standard categories of drugs are (1) antipsychotic drugs or neuroleptics used to treat psychosis, (2) antidepressant drugs used to treat depression, (3) mood stabilizers used to treat bipolar disorder, (4) antianxiety or anxiolytic drugs used to treat anxious states, (5) hypnotic agents to promote sleep, and (6) psychostimulants to treat attention-deficit disorder. As a rule, clinicians think of drugs primarily in terms of their major clinical application. However, few psychotropic drugs are diagnosis-specific, and most of the newer drugs assume multiple therapeutic roles over time. Benzodiazepine “anxiolytics,” for example, are also very effective as hypnotics. Antidepressant drugs have a wide spectrum of action. Tricyclics like amitriptyline, which have significant histamine H1 antagonism, have been used in urticarial and other dermatologic disorders. Agents such as the SSRIs and venlafaxine (Effexor), all originally used to treat depression, have gained FDA approval as treatments for disorders as diverse as panic disorder, generalized anxiety disorder, social anxiety disorder, obsessive-compulsive disorder (OCD), post-traumatic stress disorder (PTSD), and premenstrual dysphoric disorder and chronic pain. Similarly, all atypical antipsychotic agents have become commonly used as mood stabilizers and as augmentation agents to treat depression and OCD. Such drugs as clonidine (Catapres), propranolol (Inderal), verapamil (Isoptin), and pregabalin (Lyrica), all not officially recognized as psychotropic agents, are widely used to manage a variety of psychiatric disorders. As a result, there is a growing movement to reclassify psychotropic drugs according to the mechanism of action rather than by indication. The major neuropsychopharmacology societies around the world have come together to create a pharmacologically driven nomenclature for psychiatric drugs. While this system, dubbed the Neuroscience-based Nomenclature (NbN), has yet to be widely accepted and adopted, it suggests a more rational way of conceptualizing these medications.

ANTIDEPRESSANT PROPERTIES OF PSYCHEDELICS

In his 2018 book, “How to Change Your Mind,” Michael Pollan presents a lively history of psychedelics from both a recreational and therapeutic vantage point. While that book covers a broad array of psychedelics, this chapter focuses on two compounds, psilocybin (and its

Telegram: @medical_k

www.konkur.in

active metabolite, psilocin) and lysergic acid diethylamide (LSD). For the former, psilocybin has been shown to confer long-lasting antidepressant efficacy following a single administration. In 2019, the FDA designated psilocybin as a “breakthrough therapy” to facilitate its investigation as a rapid-acting antidepressant. This designation accelerates the time scale for full approval, and Oregon voters have authorized therapeutic use. Psilocin, the active psilocybin metabolite, reaches high-levels in the central nervous system (CNS) and is responsible for perceived effects following psilocybin administration. Psilocybin and psilocin are potent agonists of 5-HT2A and 5-HT2C receptors but have some binding activity at all serotonin GPCRs. The Gαq coupled 5HT2A and 5HT 2C receptors have been studied extensively in an effort to understand psilocybin’s hallucinogenic action. Preclinical data from studies designed to understand the antidepressant and anxiolytic properties of psilocybin/psilocin suggests that 5-HT2A/C receptor activation is insufficient to explain psilocybin’s rapid and sustained antidepressant efficacy. Furthermore, clinical trials indicate some correlation between therapeutic effects and hallucinogenic action, but not enough to account for therapeutic success. So, while hallucinogenic effects may depend on 5-HT2 receptor activation, antidepressant effects may not. If the cellular mechanisms underlying psilocin’s antidepressant effects can be identified, it may be possible to develop novel rapid-acting antidepressants that share psilocin’s antidepressant action while avoiding its (not always unwelcome) hallucinogenic side effects. Psilocin, and related psychedelic compounds, evoke 5-HT2A/C receptor desensitization and suppress downstream G protein signaling. Leading to a long-lasting (a week or more) tolerance to psilocybin’s psychoactive effects. This suggests that a desensitized G protein signaling may actually contribute to prolonged antidepressant efficacy, a phenomenon observed recently for monoamine antidepressants. Although less intensively studied than psilocybin, LSD appears to share many of the characteristics, both on the cellular (involving increased neural plasticity) and clinical levels. While the exact mechanisms underlying psilocybin’s long-lasting effects on the brain have not been determined, understanding them may bode well for the development of future antidepressant therapies.

Ketamine

Ketamine will be covered in a separate chapter in this text, but we will add some comments on the properties of this drug and its confluence and contrast with other antidepressants. Ketamine was developed initially as an anesthetic and is still used widely in that capacity. About two decades ago, ketamine began its life as an antidepressant, and intravenous ketamine enjoyed success as a treatment for intransigent depression. The recent approval of nasal esketamine has simplified ketamine administration somewhat, but patients still require monitoring. A single administration of ketamine acts rapidly and provides alleviation of depression for as much as 2 weeks, often for those patients who have failed to respond to other antidepressants. Ketamine has NMDA receptor antagonist properties, but other NMDA receptor antagonists, including those with a binding site on the receptor similar to that of ketamine, lack antidepressant properties. It is suggested that NMDAR antagonism by ketamine increases the synthesis of BDNF, and increased synthesis of BDNF is a nearly universal finding in animal and cellular ketamine studies. However, in addition to the lack of effect of nonketamine NMDA antagonists, hydroxy nor ketamine analogs, which lack NMDA antagonist properties, show antidepressant effects. Furthermore, knockout of NMDA receptor does not attenuate antidepressant effects of ketamine in a cellular model, wherein ketamine mobilizes the G protein Gsa from lipid rafts, similar to most other antidepressants but much more rapidly, resulting in augmented cAMP signaling and increased BNDF production. Recent

Telegram: @medical_k

www.konkur.in

studies suggest that ketamine interacts directly with lipid rafts and receptors for BDNF. For the current edition of this textbook, ketamine will be considered an interesting antidepressant with rapid effects on intransigent depression that acts through a yet-to-be-determined mechanism.

REGULATORY ISSUES

In the United States, the FDA determines the safety and efficacy of medication. The FDA has the authority to approve a drug for clinical use if it is found to be “safe for use” and “effective in use.” The FDA is also charged with ensuring that product labeling is truthful and contains all information pertinent to the safe and effective use of that drug. This includes monitoring the postmarketing experience with a drug, proposing changes in the product information, and overseeing the way in which drugs are manufactured. Antidepressants, antipsychotics, hypnotics, mood stabilizers, and psychostimulants have been among the drugs with additional warnings due to postmarketing monitoring. In addition to the FDA, another level of government regulation is directed by the Drug Enforcement Agency (DEA), which classifies drugs according to their abuse potential. Clinicians are advised to exercise increased caution when prescribing controlled substances (control levels II through IV).

Prescribing Information

FDA-approved product information for marketed drugs appears as a package insert. It is also referred to as *product labeling.* The *Physicians’ Desk Reference* (PDR) is an annual collection of product information for prescription drugs. The product information for most drugs—not just psychotropic agents—contains an extensive list of potential side effects, drug interactions, the need for special monitoring, and restrictions for use. This information reflects the results of critical evaluations submitted to the FDA about the safety and efficacy of the drug for the approved indications. Postmarketing experience is added to the product information over time. The limitations of the prescribing information are evident in the many adverse events that are under-reported during clinical trials and the frequent use of doses of medications in clinical practice that exceed the recommended dosing limits. Product information is also widely available through online resources such as drugs.com and Epocrates.

Black Box Warning

The prescribing information for a drug sometimes contains a *black box warning* to alert physicians about potentially important safety information. The term describes a black box at the beginning of the package insert that encloses the warning. It is considered the strongest warning, being more serious than just bolded text. A black box warning may be included in the product information when a drug is approved by the FDA, or it can be added later. The presence of a black box warning deters some clinicians from using a drug as a first-choice agent. In some cases, manufacturers have decided against bringing a drug to market because of the competitive disadvantage that a warning label confers. A controversial example is the black box warning for the increased risk of suicidality in young patients taking antidepressants issued in 2004. The biostatistician Robert Gibbons and his colleagues noted that prescribing rates decreased and suicide rates increased since the publication of the warning. Studies such as this led to revised wording of the warning by the FDA so that clinicians would not be discouraged from using antidepressants when clinically indicated. In 2005, the FDA issued a black box warning about the increased risk of mortality with the use of atypical antipsychotics for dementia-related psychosis. This was expanded to include conventional antipsychotics in 2008.

www.konkur.in

The longer that a drug has been in clinical use, the better the understanding of its side effect profile. Even though new agents undergo extensive scrutiny for safety and tolerability, clinical trials do not typically capture the full range and severity of all side effects. Most clinical trials are of too short duration and lack sufficient power to detect the full extent of side effect risk. Approximately 10% of all drugs approved in the United States in recent years have acquired a black box warning after marketing or have been withdrawn. In terms of timing, one-half of black box additions occurred within the first 7 years after a drug was marketed. Psychotropic drugs with added black box warnings (Table 33.1a–3) include nefazodone (Serzone), pemoline (Cylert), droperidol (Inapsine), lamotrigine, clozapine (Clozaril), divalproex (Depakote), and thioridazine (Mellaril). In the last-named case, the warning was added after the drug had been in use for many decades. In the context of safer alternatives, the benefits of thioridazine no longer outweighed the risk of cardiac conduction abnormalities. A warning about the risk of stroke in older adult patients with dementia has been added to the prescribing information for risperidone.

Approximately one-half of drug withdrawals due to safety issues occur within the first 2 years after a drug is marketed. Between 1993 and 2002, there were seven drug recalls that followed reports of death or severe health complications. None of these involved psychotropic drugs. This is a remarkable testimonial to an often-overlooked fact: Psychotropic drugs are among the safest drugs available. Since nomifensine (Merital) was withdrawn in 1986, within 1 year of its marketing, no other psychotropic agent has been withdrawn because of serious side effects.

PHARMACOLOGIC ACTIONS

Heterogeneity of response characterizes all psychotropic drugs. Among other considerations, genetic and environmental factors influence individual response to and tolerability of psychotropic agents. Thus, a drug that may not prove effective in large numbers of patients with a disorder can dramatically improve symptoms in some. In these cases, the identification of characteristics that might predict potential candidates for that drug becomes important but often remains elusive. Attention is being focused on gaining a better understanding of the thousands of genes that regulate the expression of drug-metabolizing enzymes and of the complex functions of the brain.

Even drugs within the same class are distinguished from one another by often subtle differences in molecular structure, types of interactions with neurotransmitter systems, differences in pharmacokinetics, the presence or absence of active metabolites, and protein binding. These differences, combined with the biochemistry of the patient, account for the profile of efficacy, tolerability, and safety and the risk-benefit ratio for the individual. These multiple variables, some poorly understood, make it difficult to predict a drug's effect with certainty. Nevertheless, knowledge of the nature of each property increases the likelihood of successful treatment. The clinical effects of drugs are best understood in terms of pharmacokinetics, which describes what the body does to a drug, and pharmacodynamics, which describes what the drug does to the body.

Pharmacokinetics and pharmacodynamics need to be seen in the context of the underlying variability among patients with respect to how drug effects are expressed clinically. Patients differ in their therapeutic response to a drug and the experience of side effects. It is increasingly clear that these differences have a strong genetic basis. Pharmacogenetics research attempts to identify the role of genetics in drug response.

Telegram: @medical_k

www.konkur.in

DRUG FACTORS

Pharmacodynamics

The time course and intensity of a drug's effects are referred to as its *pharmacodynamics.* Major pharmacodynamic considerations include receptor mechanisms, the dose-response curve, the therapeutic index, and the development of tolerance, dependence, and withdrawal phenomena. Drug mechanism of action is subsumed under pharmacodynamics. The clinical response to a drug, including adverse reactions, results from an interaction between that drug and a patient's susceptibility to those actions. Pharmacogenetic studies are beginning to identify genetic polymorphisms linked to individual differences in treatment response and sensitivity to side effects.

Mechanisms

The mechanisms through which most psychotropic drugs produce their therapeutic effects remain poorly understood. Standard explanations focus on ways that drugs alter synaptic concentrations of dopamine, serotonin, norepinephrine, histamine, GABA, or acetylcholine. These changes are said to result from receptor antagonists or agonists, interference with neurotransmitter reuptake, enhancement of neurotransmitter release, or inhibition of enzymes. Specific drugs are associated with permutations or combinations of these actions. Thus, a drug can be an agonist for a receptor, thus stimulating the specific biologic activity of the receptor or an antagonist, thus inhibiting the biologic activity. Some drugs are partial agonists in that they are not capable of fully activating a specific receptor. Partial agonists may also act as competitive antagonists in the presence of full agonists. Some psychotropic drugs also produce clinical effects through mechanisms other than receptor interactions. For example, lithium may act by directly inhibiting the enzyme inositol-1-phosphatase. Some effects are closely linked to a specific synaptic effect. For example, most medications that treat psychosis share the ability to block the dopamine type 2 (D_2) receptor. Similarly, benzodiazepine agonists bind a receptor complex that contains benzodiazepine and GABA receptors.

It is important to note that action mechanisms for most psychotropic drugs are poorly understood and that even the current classification of drugs (e.g., SSRI and 5HT2A antagonist) is problematic. There are two reasons for this. Studies of the binding properties of many drugs have revealed complex patterns of receptor agonism and antagonism. For example, olanzapine has 5HT2 antagonist properties, but it also is an antagonist for 5HT 1B, 1D, 2A, 2C; α1 adrenergic; H1 histamine and D2 dopamine receptors while acting as a partial agonist for dopamine D1 and muscarinic AChR m1 receptors. This polyspecificity has been extensively by Roth and colleagues. The second issue is the assignation of a mechanism based on a single target. For example, while SSRIs do, indeed, inhibit 5HT transport, they do so within hours after being administered, while the clinical effects of these compounds require weeks to develop. Furthermore, at least some biochemical properties have been attributed to multiple classes of antidepressant drugs. SSRIs can elicit these in cells lacking 5HT transporters.

Thus, accounts of so-called mechanisms of action should nevertheless be kept in perspective. Explanations of how psychotropic drugs actually work that focus on synaptic elements represent an oversimplification of a complex series of events. If merely raising or lowering levels of neurotransmitter activity is associated with the clinical effects of a drug, then all drugs that cause these changes should produce equivalent benefits. This is not the case. Multiple obscure actions, several steps removed from events at neuronal receptor sites, may

Telegram: @medical_k

www.konkur.in

well be responsible for the therapeutic effects of psychotropic drugs. These *downstream* elements are postulated to represent the actual reasons that these drugs produce clinical improvement.

Pharmacokinetics

Pharmacokinetic drug interactions are the effects of drugs on the plasma concentrations of each other, and pharmacodynamic drug interactions are the effects of drugs on the biologic activities of each other. Pharmacokinetic concepts are used to describe and predict the time course of drug concentrations in different parts of the body, such as plasma, adipose tissue, and the CNS. From a clinical perspective, pharmacokinetic methods help explain or predict the onset and duration of drug activity and interactions between drugs that alter their absorption, distribution, metabolism, or excretion.

Pharmacogenetic research focuses on finding variant alleles that alter drug pharmacokinetics and pharmacodynamics. Researchers are attempting to identify genetic differences in how enzymes metabolize psychotropics, as well as CNS proteins directly involved in drug action. It is likely that the identification of patient genotypes will facilitate the prediction of clinical responses to different types of drugs.

Drugs differ in their propensity to interact with other drugs. Awareness of potential drug–drug interactions has grown dramatically over the last two decades. Most clinicians need to consult charts or online resources to determine when potential interactions may occur and, if so, how clinically relevant they may be. Whenever possible, it is preferable to use a medication that produces a minimal risk of drug interactions. In addition, it is recommended that prescribers know the interaction profiles of the drugs that they most commonly prescribed.

Examples of pharmacokinetic interactions include one drug increasing or decreasing the concentrations of a coadministered compound. These types of interactions can also lead to altered concentrations of metabolites. In some cases, there also may be interference with the conversion of a drug to its active metabolite. There is enormous variability among patients with respect to pharmacokinetic parameters, such as drug absorption and metabolism. Another type of interaction is represented by interactions involving the kidney. Commonly used medications, such as angiotensin-converting enzyme (ACE) inhibitors, nonsteroidal anti-inflammatory drugs (NSAIDs), and thiazides decrease the renal clearance of lithium, increasing the likelihood of its severe elevation. Drug interactions may be pharmacokinetic or pharmacodynamic.

Pharmacogenetics is being used to study why patients differ in the way that they metabolize drugs. In patients who are ultrarapid or extensive metabolizers, the concentrations of a drug may be lower than expected. There are now commercially available assays that determine the potential of individual subjects for metabolizing various psychiatric drugs in an attempt to create a profile of agents to be used and those to be avoided. Unfortunately, the actual therapeutic efficacy of a compound may not be dictated simply by the ability of the patient to process it since an individual's profile of receptors, transporters, and intracellular signaling cascades (described above) is likely essential to the action of a given agent.

PATIENT-RELATED FACTORS

Response to medication, as well as sensitivity to side effects, is influenced by factors-related to the patient. This is why there is no one-size-fits-all approach to pharmacologic treatment. This is reflected in the finding that, although drugs used to treat a specific disorder

Telegram: @medical_k

www.konkur.in

demonstrate comparable efficacy in head-to-head studies, these drugs are not equally effective in all patients. Patient-related variables include diagnosis, genetic factors, lifestyle, overall medical status, concurrent disorders, and past history of drug response. A patient's attitude toward medication in general, aversion to certain types of side effects, and preference for a specific agent also need to be considered.

Diagnosis

Accurate diagnosis is an integral component of the treatment process. Failure to correctly diagnose a disorder diminishes the likelihood of optimal drug selection. Misdiagnosis not only can result in a missed opportunity, but at times it also can produce a worsening of symptoms. Inadvertently diagnosing and treating a patient in the depressed phase of bipolar disorder as having unipolar depression can result in the induction of mania or rapid cycling. Treatment failure or exacerbation of symptoms should prompt a reassessment of the working diagnosis.

Past Treatment Response

A specific drug should be selected according to the patient's history of drug response (compliance, therapeutic response, and adverse effects), the patient's family history of drug response, the profile of adverse effects for that drug with regard to the particular patient, and the prescribing clinician's usual practice. If a drug has previously been effective in treating a patient or a family member, the same drug should be used again. While this makes intuitive clinical sense, the evidence base for this has not been well-established, particularly for family history of treatment response. One study by Fava and colleagues demonstrated the response to a second trial of fluoxetine after placebo was similar to an initial trial with fluoxetine, suggesting that past performance predicts future results. Current studies like the PReDICT trial, examining predictors of depression remission, will be key in determining relevant patient-related factors that predict treatment response. A history of severe adverse effects from a specific drug is a strong indicator that the patient would not be compliant with that particular drug.

It is helpful if patients can recall the details of past psychotropic drug treatment: The drugs prescribed, in what doses, for how long, and in what combinations. Often while patients may have tried a medication, they may not have had an adequate trial, either by dose or duration. Unfortunately, because of their mental disorders, many patients are poor historians. If possible, patients' medical records should be obtained to confirm their reports. Family members are a good source of collateral information.

Concurrent Medical or Psychiatric Disorders

Initial assessment should elicit information about coexisting medical disorders. In some cases, there may be a medical disorder that is responsible for the symptoms. Patients with thyroid disease who are not adequately treated may appear depressed. Sleep apnea produces depression and cognitive impairment. Rare conditions, such as Kleine–Levin syndrome, can mimic bipolar disorder. A drug should be selected that minimally exacerbates any preexisting medical problems that a particular patient may have.

Recreational drug use, excessive consumption of alcohol, and frequent ingestion of caffeine-containing beverages can complicate and even undermine psychotropic drug treatment. These compounds possess significant psychoactive properties and, in some cases, may represent the source of the patient's symptoms. It is reasonable to ask patients to abstain from the use of these substances at least until the benefits of psychotropic drug treatment have been unequivocally established. Gradual reintroduction of moderate amounts of alcohol,

Telegram: @medical_k

www.konkur.in

tea, and coffee can then take place. Patients can then observe whether there are any untoward effects on their clinical status.

Drug Preference

Some prescribers have obvious favorites among the available psychotropic agents. This bias or *allegiance effect* regarding treatment can stem from a combination of factors. A dramatically successful patient response during an early experience with a new drug can produce a *conversion experience,* in which the prescribing physician forms a highly positive opinion of that drug. Patients being treated by that physician are more likely to receive that medication than alternatives. Previous studies have cited physician experience and prior treatment history as among the most highly ranked factors in treatment selection.

INFORMED CONSENT AND PATIENT EDUCATION

Establishing trust and providing motivation to comply with the medication regimen are essential components of successful treatment. Patients should be informed about treatment options and the probable side effects and unique benefits of each treatment. Patient preference should be respected unless there is a compelling advantage involving efficacy, tolerability, or safety with an alternative agent. If a particular medication is being recommended, the reasons for this recommendation should be explained. Patients are more likely to continue taking their medication if they fully understand the reasons why it is being prescribed.

Physicians no longer have a monopoly over the knowledge regarding psychotropic drugs. Many patients now routinely search the Internet for information about available treatments. What physicians do have is an understanding of the clinical circumstances that would lead to the choice of one drug among the many that are available.

Medication treatment benefits from a strong therapeutic alliance between a clinician and a patient. Given the unpredictability of medication response, the frequent occurrence of side effects, and underlying ambivalence about or fear of taking medication, a positive, trusting relationship serves to improve patient compliance. Repeated failed trials may be needed before a response is seen. A patient's confidence in the physician's knowledge and judgment enables medication trials and more complex regimens, such as the use of multiple medications.

Discussions about drug selection should be documented in notes. In particular, patients who are informed of potential adverse effects report a higher incidence of side effects but do not have higher rates of premature discontinuation.

How the patient and family are engaged in the treatment plan can determine the success of treatment. With the patient's consent, relatives and other clinicians should be instructed on the reasons for the drug treatment, as well as the expected benefits and potential risks. In addition, the clinician may also find it useful to explain the theoretical basis for pharmacotherapy to the patient and other significant parties.

DOSING, DURATION, AND MONITORING

Dosing

The clinically effective dose for treatment depends on the characteristics of the drug and patient factors, such as inherited sensitivity to and ability to metabolize a drug, concurrent

Telegram: @medical_k

www.konkur.in

medical disorders, use of concurrent medication treatments, and history of exposure to previous medications.

Doses used in clinical practice often differ from those used in pivotal studies, which, in turn, form the basis for dosing recommendations that eventually appear in the product information. The reason for this divergence is that patients in pivotal trials are highly selected and are not representative of the people who are ultimately treated. Once a drug achieves widespread use in real-world patients, it might be discovered that the doses needed for optimal efficacy need to be higher than suggested by clinical trial findings. Similarly, the doses needed for tolerability might be lower than thought. Even when a disparity in dosing between actual practice and a clinical trial is established, the package insert is rarely, if ever, changed. This would involve the conduct of costly and time-consuming studies and the submission of an application for change. At times, it may be clinically beneficial to exceed the upper dose limit for a drug—so-called high-dose therapy. However, it is best not to exceed the recommended upper dose threshold without a clear understanding of the potential benefits and risks involved. This caution is particularly important when a drug is associated with a severe concentration-dependent side effect.

Plasma concentrations of many psychotropics can vary up to 10-fold. Thus, to some extent, the optimal dose for an individual is ultimately determined by trial and error, guided by the empirical evidence of the usual dose range for that drug. Some drugs demonstrate a clear relationship between increases in the dose and clinical response. This dose-response curve plots the drug concentration against the effects of the drug.

The *potency* of a drug refers to the relative dose required to achieve certain effects, not to its efficacy. Haloperidol, for example, is more potent than chlorpromazine because approximately 5 mg of haloperidol is required to achieve the same therapeutic effect as 100 mg of chlorpromazine. However, these drugs are equal in their clinical efficacy—that is, the maximum clinical response achievable by administration of a drug.

Drugs must be used in effective doses for sufficient periods. Although drug tolerability and safety are always a consideration, subtherapeutic doses, and incomplete therapeutic trials should be avoided. The use of inadequate doses merely exposes the patient to the risk of side effects without providing the probability of therapeutic benefit. In view of the wide margin of safety associated with most currently prescribed medications, there is more risk of underdosing than overshooting the recommended dose range.

The time of dosing is usually based on the plasma half-life of a drug and its side effect profile. Sedating drugs are given all at night or in disproportionate daily doses at night. The opposite is true with activating drugs. The frequency of dosing is less clear-cut. Most dosing regimens of psychotropic drugs, such as once-a-day versus divided doses, are based on measurements of plasma concentrations rather than receptor occupancy in the brain. Evidence suggests that there is a significant dissociation between brain and plasma kinetics. Reliance on plasma kinetics as the basis for dosing regimens leads to a misunderstanding of necessary schedules.

Duration of Treatment

A common question that a patient typically asks is, “How long do I need to take the medication”? The answer, of course, depends on multiple variables, including the nature of the disorder, the duration of symptoms, the family history, and the extent to which the patient tolerates and benefits from the medication. Patients can be given a reasonable explanation of the probabilities but should be told that it is first best to see whether the medication works for them and whether the side effects are acceptable. Any more definitive discussion of the

Telegram: @medical_k

www.konkur.in

duration of treatment can be held once the degree of success is clear. Even patients with a philosophical aversion to the use of psychotropic drugs may elect to stay on a medication indefinitely if the magnitude of improvement is great. Most psychiatric disorders have high rates of chronicity and relapse. Because of this, long-term treatment is often needed to prevent a recurrence. Nevertheless, the fact remains that psychiatric treatments are not said to cure the disorders they treat but rather to help control the symptoms.

Treatment is conceptually broken down into three phases: the initial therapeutic trial, the continuation, and the maintenance phase. The initial period of treatment should last at least several weeks because of the delay in therapeutic effects that characterize most classes of psychotropic drugs. The required duration of a *therapeutic trial* of a drug should be discussed at the outset of treatment so that the patient does not have unrealistic expectations of an immediate improvement in symptoms. Patients are more likely to experience side effects early in the course of pharmacotherapy than any relief from their disorder. In some cases, medication may even exacerbate some symptoms. Patients should be counseled that a poor initial reaction to medication is not an indicator of the ultimate outcome of treatment. For instance, many patients with panic disorder develop jitteriness or an increase in panic attacks after starting tricyclic or SSRI treatment. Benzodiazepine agonists are an exception to the rule that there is a delay in clinical onset. In most cases, their hypnotic and antianxiety effects are evident immediately.

Ongoing use of medication does not, however, provide absolute protection against relapse. Continuation therapy provides clinically and statistically significant protective effects against relapse. The optimal duration of continuation or maintenance therapy is variable and depends on the clinical history of the patient. Early-onset chronic major depression, for example, has a more severe course and greater comorbidity than late-onset chronic major depression. In addition to early onset, a history of multiple past episodes, the severity of the current episodes, and the length of the current episode would make longer, even indefinite, treatment appropriate.

TREATMENT OUTCOMES

The goal of psychotropic treatment is to eliminate all manifestations of the disorder, thus enabling the patient to regain the ability to function and enjoy life as fully as before they became ill. This degree of improvement below the syndromal threshold is defined as *remission.*

Response and Remission

Remission is the preferred outcome of treatment not only because of the immediate effect on functioning and state of mind but also because emerging evidence suggests that remitted patients are less likely to experience relapse and recurrence of their disorder.

Patients who improve but do not experience a full resolution are considered to be responders. They may exhibit significant improvement but continue to experience symptoms. In depression studies, the *response* is usually defined as a 50% or greater decrease from baseline on a standard rating scale, such as the Hamilton Depression (HAMD) Scale or the Montgomery-Asberg Depression Rating Scale (MADRS). *Remission* is defined as an absolute score of 7 or less on the HAMD Scale or 10 or less on the MADRS. Expectations about the likely degree of improvement should be based on what is known about the responsiveness of specific disorders to medication therapy. OCD and schizophrenia, for example, are more likely to be associated with residual manifestations of illness than major depression or panic

Telegram: @medical_k

www.konkur.in

disorder. The probability of full remission from OCD with SSRI treatment alone over a 3-year period is 38%, and the probability of partial remission is approximately 65%.

Treatment Failure

The initial treatment plan should anticipate the possibility that the medication may be ineffective. A next-step strategy should be in place at the initiation of treatment. Repeated drug failures should prompt a reassessment of the patient. First, was the original diagnosis correct? In answering this question, the clinician should include the possibility of an undiagnosed medical condition or recreational drug use as the cause of the psychiatric symptoms. Second, are the observed symptoms related to the original disorder, or are they actually adverse effects of the drug treatment? Some antipsychotic drugs, for example, can produce akinesia, which resembles psychotic withdrawal, or akathisia and neuroleptic malignant syndrome, which resemble increased psychotic agitation. Long-term use of SSRIs can produce emotional blunting, which can mimic depression.

Intolerance of side effects may be the most common reason for treatment failure. Third, was the drug administered at an appropriate dose for a sufficient length of time? Because patients can vary greatly in their absorption and metabolism of drugs, the clinician may need to measure the plasma levels of a drug to ensure a sufficient dose of the drug. Fourth, did a pharmacokinetic or pharmacodynamic interaction with another drug that the patient was taking reduce the efficacy of the newly prescribed drug? Fifth, did the patient take the drug as directed? Drug noncompliance is a common clinical problem that arises as a result of complicated drug regimens (more than one drug in more than one daily dose), adverse effects (especially if unnoticed by the clinician), and poor patient education about the drug treatment plan. Patients may discontinue medication when they recover, thinking that they are cured and no longer benefiting from the medication.

Treatment Resistance

Some patients fail to respond to repeated trials of medication. No single factor can explain the ineffectiveness of the various interventions in these cases. Strategies in these cases include the use of drug combinations, high-dose therapy, and the use of unconventional drugs. There is limited evidence on the comparative success rates associated with any given strategy. This is one area that illustrates the critical need to develop biomarkers to determine trait, state, and therapeutic response. Often patients are given extended (2 months) drug trials before a decision is made to revise therapy. Thus, it may take 8 months to declare a patient “treatment-resistant.” As indicated above, it is not known whether a given patient is inherently treatment-resistant or whether treatment resistance evolves as a result of repeated failures.

Tolerance

The development of tolerance is marked by a need, over time, to use increased doses of a drug to maintain a clinical effect. This decreased responsiveness to a drug occurs after repeated doses. Tolerance also describes decreased sensitivity to adverse effects of the drug, such as nausea. This phenomenon is used as the basis for starting some drugs at subtherapeutic doses, with the plan to adjust the schedule once the patient can tolerate higher doses. Clinical tolerance appears to represent changes in the CNS, such as altered receptor configuration or density. Drugs with similar pharmacologic actions often exhibit cross-tolerance.

Sensitization

Telegram: @medical_k

www.konkur.in

Clinically manifested as the reverse of tolerance, sensitization is said to occur when there is increased sensitivity to a drug effect over time. In these cases, the same dose typically produces more-pronounced effects as treatment progresses. Conversely, if the therapeutic index is low, as it is for lithium, careful monitoring of serum levels is essential. For most psychotropic drugs, the therapeutic index is high.

Withdrawal

The development of physiologic adaptation to a drug, with a subsequent risk of withdrawal symptoms, has been reported for many classes of psychotropic drugs. Technically, withdrawal should be considered a side effect. The probability and severity of these reactions are remote with most drugs and more common with others. As a general rule, the more abruptly a drug is stopped and the shorter its elimination half-life, the more likely it is that clinically significant withdrawal symptoms will occur. With some short-acting drugs, withdrawal reactions can result from missed doses and during daily intervals between doses. Gradual tapering of medications after prolonged use is recommended when possible. Although this reduces the risk of withdrawal reactions, it does not ensure that they will not occur. So-called sedative hypnotics and opiates are the agents most often associated with mentally and physically distressing discontinuation reactions. In some cases, such as the barbiturates, withdrawal can be fatal.

There are marked differences among agents, even within a given class, with respect to the probability and severity of discontinuation effects. For example, among the benzodiazepines, alprazolam commonly produces more immediate and intense withdrawal symptoms than other compounds. Among the SSRIs, there is a well-described withdrawal syndrome that appears to be more frequent and severe with paroxetine (Paxil). It can, however, occur with any SSRI. Even fluoxetine may be associated with discontinuation symptoms, but the symptoms may be delayed and attenuated due to the long elimination half-life of its active metabolite. These manifestations are subtle and are delayed for weeks after the last dose. Venlafaxine also produces a severe SSRI-like withdrawal syndrome.

In addition to half-life, many variables can influence the likelihood and degree of discontinuation symptoms. Changes in the rate of drug metabolism, for example, can play a role. Paroxetine is primarily metabolized by the cytochrome P450 (CYP) 2D6 isozyme. However, paroxetine is also a potent inhibitor of CYP 2D6. This results in *autoinhibition,* a dose-dependent inhibition of its own metabolism, with a subsequent increase in plasma concentrations of paroxetine. If the dose of paroxetine is decreased or the drug is stopped, the decline in its plasma concentrations can be steep, causing withdrawal to occur. Withdrawal can occur in rare cases in which the dose of a drug is not decreased, but a second agent that had been inhibiting its metabolism is stopped. For example, paroxetine is metabolized via the CYP 2D6 enzyme system. Bupropion inhibits that enzyme. If a patient taking both agents for several weeks discontinues the bupropion, it could result in a rapid increase in the rate of paroxetine metabolism and a consequent drop in plasma concentrations.

The development of sustained-release versions of drugs such as alprazolam, paroxetine, and venlafaxine has not reduced the severity of their withdrawal reactions. The prolonged half-life of those agents results from delayed absorption rather than prolongation of the elimination phase. The frequency of drug dosing is reduced but not the rate of the fall-off in plasma concentrations.

Poor bioavailability with a generic agent may account for an unexpected loss of clinical effect in the emergence of withdrawal symptoms. The occurrence of these events soon after refilling a prescription should prompt examination of the new medication. It should be confirmed whether the dispensed medication and dose are both correct. It is difficult to

Telegram: @medical_k

www.konkur.in

ascertain whether generic medications are truly equivalent, so the possibility exists that differences in potency may underlie adverse changes in clinical status.

Withdrawal symptoms invariably occur hours or days after dose reduction or discontinuation. Symptoms resolve within a few weeks, so the persistence of symptoms argues against withdrawal. Although depletion studies have been shown to provoke a rapid return of symptoms, in clinical practice, psychotic and mood symptoms do not usually reappear abruptly after long-term treatment.

COMBINATION OF DRUGS

According to the American Psychiatric Association Practice Guidelines for the Treatment of Psychiatric Disorders, “the use of multiple agents should be avoided if possible” in the treatment of psychiatric disorders. Although *monotherapy* represents the ideal, *polypharmacy* —the simultaneous use of psychotropic medications—has been commonplace since chlorpromazine was combined with reserpine in the early 1950s. The practice of combining drugs is commonplace, and the merits of various *augmentation* or *combination* strategies are routinely discussed in the literature and at scientific meetings. The mean number of simultaneously prescribed medications has increased in recent decades. In response to some of these trends, The Joint Commission has recently instituted quality measures to reduce the inappropriate use of antipsychotic polypharmacy.

Sometimes distinctions are made between augmentation and combination therapy. When two psychotropics with the same approved indications are used concurrently, this is termed *combination therapy.* Adding a drug with another indication is termed *augmentation.* Augmentation often entails the use of a drug that is not primarily considered a psychotropic. For example, in treating depression, it is common to add thyroid hormone to an approved antidepressant. Some strategies are more popular or are preferred but are not necessarily more effective than any other. Augmentation was built into the treatment algorithm for the STAR*D trial, where there was the option to add either lithium or thyroid hormone. In a STAR*D study that examined these augmentation options, the authors found that lithium and thyroid for equally effective in improving response rates in patients that failed monotherapy but that thyroid hormone was better tolerated.

The widespread reliance on multiple-drug therapy, in the face of official discouragement and the absence of objective evidence supporting this practice, is easy to explain: Many patients do not become well with monotherapy with existing drugs. In a typical scenario, a patient has little or no response to a medication, so the physician adds a second agent to induce a better response. This need not be a second drug, as some studies suggest improved efficacy for SSRIs with the addition of omega-3 polyunsaturated fatty acids (fish oil).

In some cases, the use of multiple medications is the rule. Almost all patients with bipolar disorder are taking more than one psychotropic agent. Combination treatment with drugs that treat depression and a dopamine-receptor antagonist or serotonin-dopamine antagonist has long been held as preferable in patients with psychotic depression. Similarly, SSRIs typically produce partial improvement in patients with OCD, so the addition of a serotonin-dopamine antagonist may be helpful.

Medications may also be combined to counteract side effects, treat specific symptoms, and as a temporary measure to transition from one drug to another. It is common practice to add a new medication without the discontinuation of a prior drug, particularly when the first drug has provided partial benefit. This can be done as part of a plan to transition from an agent that is not producing a satisfactory response or as an attempt to maintain the patient on combined therapy.

Telegram: @medical_k

www.konkur.in

One limitation is that there is increased noncompliance and adverse effects and that the clinician may not be able to determine whether it was the second drug alone or the combination of drugs that resulted in a therapeutic success or a particular adverse effect. Combining drugs can create a broad-spectrum effect and also changes the ratio of metabolites.

The merits of going to a single drug with a different pharmacologic profile include lower risk of drug–drug interactions, simplicity, and lower cost. It is less burdensome to be taking one medication than two or three and is less likely to meet resistance by the patient. Many patients are ambivalent about taking even one medication, let alone two. This practice is less justifiable in newly treated patients than in those who have failed repeated trials.

SPECIAL POPULATIONS

Although every patient brings a unique combination of demographic and clinical variables to the clinical setting, certain patient populations require special consideration. When treating the young, the older adults, and those with medical disorders, awareness of risks associated with medication assumes increased importance. Data derived from clinical trials are of limited value in guiding many decisions because populations in these studies consisted of healthy young adults. Studies of children and adolescents have become more common, so the understanding of treatment effects in this population has grown.

Children

Understanding the safety and efficacy of most psychotropic drugs, when used to treat children, is based more on clinical experience than on evidence from large clinical trial data. Other than attention-deficit/hyperactivity disorder (ADHD) and OCD, commonly used psychotropic drugs have no labeling for pediatric use, so results from adult studies are extrapolated to children. This is not necessarily appropriate because of developmental differences in pharmacokinetics and pharmacodynamics. Dosing is another special consideration in drug use with children. Although the small volume of distribution suggests the use of lower doses than those used in adults, a child's higher rate of metabolism suggests that a higher ratio of milligrams of the drug to kilograms of body weight should be used. In practice, it is best to begin with a small dose and increase it until clinical effects are observed. However, the clinician should not hesitate to use adult doses in children if these doses are effective and the adverse effects are acceptable.

The paucity of research data is a legacy of many years in which manufacturers avoided conducting trials in children because of liability concerns, small market share, and, hence, limited profit potential represented by this population. To correct this problem, the FDA Modernization Act (FDAMA) of 1997 provided special encouragement and incentives to study drugs for pediatric use. Since then, there have been expanded indications for FDA-approved medications to treat psychiatric conditions in children, such as risperidone for the treatment of schizophrenia in adolescents and manic/mixed episodes of bipolar I disorder in children and adolescents ages 10 to 17.

Some drugs used to treat psychiatric disorders carry a higher risk of serious side effects. Lamotrigine, for example, is associated with a substantially higher incidence of serious rash among children than among adults.

Older Adult Patients

Telegram: @medical_k

www.konkur.in

Older adult persons may be more susceptible to adverse effects (particularly cardiac effects) and may metabolize and excrete drugs more slowly, thus requiring lower doses of medication. In practice, clinicians should begin treating geriatric patients with a small dose—usually approximately one-half of the usual starting dose. The dose should be raised in small increments, more slowly than for middle-aged adults, until a clinical benefit is achieved or unacceptable adverse effects appear. Although most geriatric patients require a small dose of medication, there are others who require a full therapeutic dose. Thus, sound clinical judgment and close monitoring are necessary.

A major concern about psychotropic drugs in the older adults is the well-established causal relationship between the use of these agents and falls. It has been shown that older adult users of psychotropic medications have a 47% increased risk of falls. This risk of falls and hip fractures may be minimized by selecting compounds that produce less unwanted sedation, dizziness, parkinsonism, and postural hypotension.

Historically, antipsychotics have been used to treat nonpsychotic, agitated patients. This practice has been called into question primarily as a result of the CATIE-AD trial that showed a limited benefit of atypical antipsychotics in the treatment of agitation in dementia. Although they may reduce paranoia, there was no significant benefit in improving function or quality of life, and there is evidence of worsening cognitive outcomes with these medications. There is an FDA warning regarding the use of atypical antipsychotics in the treatment of behavioral disorders in older adult patients with dementia. Studies have shown a higher death rate associated with their use. Accordingly, antipsychotic drugs should be reserved for psychosis.

Response to treatment is less predictable among older adults than younger adults. Age-related changes in renal clearance and hepatic metabolism make it more important to be conservative with the starting doses of medication, as well as with the rate of dose titration. The frequent presence of medical disorders and the use of medications to treat them make it necessary to recognize how psychotropic drugs interact with nonpsychiatric disorders and medications. Within any class of agents, those with fewer drug interactions or side effects with potentially serious consequences, such as hypotension, cardiac conduction abnormalities, anticholinergic activity, and respiratory depression, are not suitable choices. Drugs that cause cognitive impairment, such as benzodiazepines and anticholinergics, may mimic or exacerbate symptoms of dementia. Similarly, dopamine-receptor antagonists can worsen or induce Parkinson disease, another age-related disorder. Some side effects, such as SSRI-associated syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and oxcarbazepine-associated hyponatremia, occur more commonly in older patients. A common ethical dilemma with the medically ill older adults or those with dementia is the question of their capacity to give informed consent before treatment with psychotropic drugs or ECT.

Medically Ill Patients

When selecting and monitoring psychiatric drugs, the patient's medical disorders and their treatment need to be considered. Most importantly, the medical disorder or disorders and their treatments should be ruled out as a cause of the observed psychiatric symptoms. For example, patients with neurologic or endocrine disorders or human immunodeficiency virus (HIV)–infected patients may experience disturbances in mood and cognition. Common medications, such as corticosteroids and L-dopa, are associated with the induction of mania.

Although obvious, when various options are available, a psychotropic should be chosen that does not exacerbate or counteract the treatment of the existing medical disorder. For example, a psychotic patient with diabetes mellitus is better treated with an agent without the risk of weight gain or glucose dysregulation. Depending on the diagnosis, drugs that might

Telegram: @medical_k

www.konkur.in

treat the primary psychiatric disorder and also cause weight loss, drugs such as bupropion and topiramate (Topamax), can be prescribed for these patients. Patients with obstructive pulmonary disease should not be given sedating drugs, which raise the arousal threshold and suppress respiration. Patients with medical disorders are also taking other medications, which can result in pharmacodynamic and pharmacokinetic interactions. Combined treatment with an inducer of multiple CYP enzymes and a drug that is a substrate for those enzymes could result in subtherapeutic levels, leading to inadequate symptom control. The use of the tuberculosis treatment rifampicin (Rifadin) with carbamazepine is an example. The use of drugs that inhibit CYP 2D6—agents such as paroxetine and fluoxetine—can prevent the conversion of hydrocodone (Robidone) and other opiates into an active analgesic form.

NSAIDs are also a rare cause of perceptual disturbances and psychotic symptoms. Other issues include a potentially increased sensitivity to adverse effects, including increased or decreased metabolism and excretion of the drug and interactions with other medications. Drug interactions are an obvious concern when drugs with a narrow therapeutic range are being used. Any change in the rate of metabolism or interference with the formation and elimination of metabolites can profoundly influence the activity of that drug. Similarly, interactions that interfere with drug metabolism can produce an increase in side effects and toxicity.

As with children and geriatric patients, the most reasonable clinical practice is to begin with a small dose, increase it slowly, and watch for clinical benefits and adverse effects. Determining the plasma drug concentrations may be helpful for such patients, but therapeutic blood concentrations for most psychotropic drugs are neither necessary nor routinely available. Special caution is needed with potential drug–disease interactions. In patients with diabetes mellitus, drugs such as valproic acid or olanzapine, which are associated with increased body weight, and insulin resistance, should be avoided. Patients with a seizure disorder should not receive bupropion, or clomipramine (Anafranil), which lowers the seizure threshold.

Substance Abuse

Many patients who seek or need treatment for a psychiatric disorder engage in chronic use of illicit substances or drink excessive amounts of alcohol. Marijuana is the most commonly used illicit drug in the United States.

Discontinuation of chronic drug or alcohol use can result not only in craving but also in clinically significant psychiatric and physiologic withdrawal symptoms. For many patients, successful treatment of their underlying psychiatric disorder may not be possible in the presence of ongoing marijuana, cocaine, and alcohol use. If several trials of medications fail, hospitalization for detoxification may be necessary. There is little research and no consensus about how to use psychotropic agents in patients who are regular users of cocaine, marijuana, or other recreational drugs. If these agents are used as a method of coping—so-called avoidance coping—it appears to not be effective.

FUTURE DIRECTIONS

After decades of progress in bringing new treatments to the clinical setting, there has been a marked decline in the development or discovery of truly innovative drugs. Although researchers continue to search for medications with new modes of action that are both more effective and better tolerated than existing treatments, there needs to be a better understanding of the underlying neurochemical abnormalities that cause psychiatric disorders. Researchers may be close to significant breakthroughs by which research findings can be

Telegram: @medical_k

www.konkur.in

translated into better treatments. It is also possible that it will be years before new options are available to clinicians. There is a need to be able to predict more reliably which individuals will respond to specific agents because it is clear that there is no “one-size-fits-all” approach to psychopharmacology. There also needs to be more systematic postmarketing surveillance of drugs for potentially serious side effects. In the meantime, it is imperative that clinicians remain current with the clinical literature and remain thoughtful about the drug choices that they make.

33.1b Drug Development and Approval Process in the United States

Amir Kalali, M.D.

SCIENTIFIC CHALLENGES IN CNS DRUG DEVELOPMENT

Anyone following the news will be aware of the challenges faced by the pharmaceutical industry. The financial challenges are driven by many factors, including the "patent cliff," where the expiration of the patents on many recent blockbuster treatments has led to severely reduced revenues for many companies resulting in cutbacks in research and development. Increased scrutiny by payors and governments as to the value and novelty of new treatments, as well as price controls in many countries, has added to these challenges.

Telegram: @medical_k

www.konkur.in

The latest figures estimate that the cost to develop a new drug is an average of $2.6 billion. Drugs that treat CNS diseases take more than a year longer to develop and are less than half as likely to obtain marketing approval as other drugs, according to a newly completed study by the Tufts Center for the Study of Drug Development.

In addition to the financial challenges, companies must leverage basic science to develop new and innovative treatments that are more effective or safer than current treatments available as generics. This has proved particularly challenging in psychiatric disorders for several reasons, including an incomplete understanding of the basic science and lack of a diagnostic system based on etiology, leading to a heterogeneous population in clinical studies.

Add to this the methodologic challenges in conducting clinical trials in psychiatry, including subjective outcome measures, lack of medication adherence, and increasing placebo response; it is not a surprise that this area is seen as high risk and has seen several companies abandon the area. These factors will be further elaborated below.

The good news is that due to the clear unmet patient need, many new companies are entering this area of drug development.

The Basic Science Challenge

In spite of research conducted in both academic and industry settings, including under the auspices of the Decade of the Brain at the end of the 20th century and subsequent large initiatives involving academia, government, and corporate pharmaceutical entities, the pathophysiologic underpinnings of most conditions affecting the CNS are virtually unknown. This lack of understanding of etiology complicates attempts to construct in vitro or in vivo nonclinical models with which to identify or test therapeutic molecules before taking them into the clinical phases of drug development. In addition, when potential compounds are tested in accepted nonclinical models, the benefits conferred in these models do not predict similar benefits in man. An example would be Alzheimer disease. For more than 40 years, a deficit of brain acetyl cholinergic function has been hypothesized to play a role in the condition, and therefore it was rational to test compounds that diminished the metabolism of acetylcholine: acetylcholinesterase inhibitors. Resulting from a global drug development process that tested many compounds with this pharmacologic mechanism of action, four acetylcholinesterase inhibitors have been approved by regulatory authorities to treat dementia of the Alzheimer type. This might be viewed as a triumph of disease understanding, except that these agents offer symptomatic treatment of lesser magnitude and shorter duration than was predicted on the basis of the known acetyl cholinergic deficit.

The Biomarker Conundrum

A more cautionary tale is the meager success of very expensive and long-duration clinical trials that have tested monoclonal antibodies designed to clear beta-amyloid from the brains of patients with the more advanced stages of Alzheimer disease. Beta-amyloid has been considered by some to be a surrogate biomarker for the Alzheimer disease process because the progressive brain deposition of beta-amyloid plaques has been a well-known pathophysiologic hallmark of the disease since its description by Alois Alzheimer more than 100 years ago. Indeed, this lack of translation from bench to bedside is the rule in the field of Alzheimer disease, where more than 99% of clinical trials have failed. Clearly, more predictive nonclinical models and a better choice of surrogate biomarkers are needed.

Telegram: @medical_k

www.konkur.in

THE CLINICAL SCIENCE CHALLENGE: FACTORS IMPACTING SIGNAL DETECTION IN CLINICAL TRIALS

There is no one reason some CNS clinical trials fail. There are multiple factors that occur to one extent or another in any clinical trial. The following section reviews some of the most important of these.

Study Design

Clearly, the design of any clinical trial is a key factor in its success or failure. In general, there are some basic trial principles, such as blinding and randomization, that are followed in most drug development clinical trials. However, sometimes small design changes can have unintended consequences, which emphasizes the importance of thoughtful clinical trial design.

Effect Size

In general, the effect sizes of compounds developed so far for psychiatric disorders are not large, which makes signal detection more challenging. One may argue that if treatments had larger effect sizes, other methodologic issues would not matter.

Dose

Animal models for psychiatric disorders are not good at predicting dosing in humans, and there is a history in CNS drug development of the optimal clinical dose of a compound not being established during the development stage. Several compounds have had negative programs only to be later shown to be effective at different doses.

Diagnosis and Appropriate Patient Selection

Translation from bench to bedside is only one aspect of the issues confronting CNS drug development. Even if clinical research investigators knew a priori that they were about to test the right therapeutic molecules, enrolling the right patients can be just as much of a challenge to successful trial outcomes. The *Diagnostic and Statistical Manual of Mental Disorders* (DSM) provides a standard language by which clinicians, researchers, and public health officials in the United States communicate about mental health disorders. The DSM Fifth Edition (DSM-5), published in 2013, marked the first significant revision since the DSM-IV in 1994.

Although useful for administrative and clinical reasons, as DSM is not based on a biologic etiology of psychiatric disorders, the subjects selected for a trial are clearly a heterogeneous group, and it is not surprising that this dilutes the drug effects shown. There have been recent attempts to categorize patients with new models of diagnosis, such as the NIMH Research Domain Criteria Project (RDoC).

Because there is little understanding of the pathophysiology of CNS disorders, it is not known whether the phenotypically similar features of clinically diagnosed patients may, in fact, result from a multiplicity of underlying genotypes. Compounds with discrete mechanisms of action may offer benefit to patients with only one or a few, but likely not all these underlying genetic etiologies. Given this etiologic heterogeneity of the population with a clinical disease phenotype, how does the clinical trial investigator choose the right patient who might benefit from a promising new compound? Greater knowledge of the heterogeneous pathophysiologic causes and the contributing roles of genetic variants or environmental factors on CNS conditions are necessary.

Telegram: @medical_k

www.konkur.in

Another question to ask is whether one treatment can be realistically expected to treat all aspects of a disorder such as depression, schizophrenia, or dementia? However, currently, in psychiatry, the labels granted by regulatory agencies map to the DSM.

Other fields, such as oncology, have faced these issues earlier, and it has been new knowledge about the basic science and etiology that has led to breakthrough success.

Expectation Bias

This effect describes a situation where either the staff conducting the trial or subjects in the trial or both groups expect that the test drug will confer a benefit or that it is unlikely to do so. In the case of a positive bias, this expectation creates a cognitive bias that increases the effect that is being measured. Suppose a large clinical trial of a new antidepressant molecule (Drug X) is being conducted. Going into the trial, it is already known that Drug X has a mechanism of action that is similar to other drugs which produce true antidepressant effects. It is also known that in a prior, smaller clinical trial, Drug X produced a measurable effect when compared to a placebo. These facts are known by the staff conducting the new and larger trial, and they are also explained to each subject enrolling in the trial as a part of informed consent. These facts may create an expectation of drug benefit in the staff who use rating scales to measure the symptoms produced by depression, and so, the staff may thereby have an unconscious bias toward rating more beneficial effects than are actually present. What might be the outcome of this larger trial? Drug X produces the same benefit as it did in the earlier trial, but a placebo produces a greater effect in this trial, shrinking or completely eliminating any measurable difference in the effects produced by Drug X and placebo.

Subjective Outcome Measures

Unlike objective measures used in other therapeutic areas such as blood pressure measurements, death, or the presence of a microorganism, psychiatry trials currently rely on outcome measures based on questions that subjects answer on a rating scale. These outcome measures are prone to a greater degree of uncertainty (and often a greater variance), as well as issues such as recall bias and inter-rater reliability in a multicenter clinical trial.

Regression to the Mean

As already discussed, variance is a way to capture the random change in repeated measurements of the same variable. In a group of people in whom repeated measurements are performed, some people will have values that are far from the mean on one measurement and values that are quite close to the mean on another measurement—all due to the randomness with which repeated measurements may vary. The presence of an extreme value (one far from the mean) on one measurement, and a value much closer to the mean at another measurement, is what is termed regression to the mean. Extreme values tend to move closer (regress) to the mean on different measurements.

As many trials enroll patients during an exacerbation of their illness, the phenomenon would tend to mean that future measurements would be less extreme even if the subject is on a placebo. This phenomenon will therefore act to diminish any drug placebo difference that might be present.

Increased Interaction with Health Care Professionals

Telegram: @medical_k

www.konkur.in

During the conduct of a clinical trial, subjects are seen much more frequently than in clinical practice, and the visits can last several hours to conduct all the assessments required by the protocol. This increased interaction is well known to increase placebo response.

Medication Nonadherence in Clinical Trials

Another important reason for failed clinical trials is nonadherence to clinical trial medication. Reasons for this are complex and multifactorial in nature. Whether intentional or unintentional, nonadherence to the medication has major consequences in clinical trials leading to a lack of good-quality data and poor signal detection, which can oftentimes lead to an incorrect assumption that a drug is ineffective when it just has not been taken correctly or taken at all.

New digital and mobile technologies are emerging where adherence can be monitored remotely, which allows for active intervention by Investigators with nonadhering patients. While these technologies have great potential, it is important to remember that these are only the instruments that will aid investigators in oversight of treatment adherence and enhanced patient engagement.

Statistical Considerations

The proper use and interpretation of statistical methods are important in interpreting any clinical trial result.

FEW USEFUL DEFINITIONS

Positive, Negative, and Failed Trials

How does the scientist or clinician detect whether a therapeutic molecule (we will call it Drug X) offers a benefit (i.e., greater efficacy) in a clinical trial? One method is to perform a test to determine if the effect of Drug X on a variable of interest (like blood pressure) has a greater benefit when compared to the effect of either an inert agent that cannot be visually distinguished from the molecule (i.e., a placebo) or a greater benefit when compared to some other compound (Drug Y) that is already known to produce a beneficial effect. But then how does one detect whether there is a beneficial difference between Drug X and placebo or between Drug X and Drug Y?

Before this question is answered, one needs to look a little more closely at what happens when a variable is measured over and over again. Again, take blood pressure as an example. Successive measurements of blood pressure in the same person, even when performed just moments apart, will yield different values with each measurement—tiny differences, perhaps, but real ones. A portion of this difference may be explained by physiologic changes in the blood pressure from moment to moment, but another portion of the difference arises simply from small errors in the measurement itself. If this is the case, then how does one decide if Drug X produces the same benefit to drop high blood pressure as Drug Y if measurements of either drug's effect on blood pressure are subject to error? If one does detect a difference in their measured effects on blood pressure, is that difference real, or could it be due completely to the variation in repeated measurements? To circumvent this inherent difficulty in comparing two measurements, statisticians have defined methods to measure the extent to which multiple measurements will result in a spread of their values around the true average (mean) of that measurement. Not surprisingly, one of these methods to detect the random differences between repeated measurements is termed variance. Signal detection methods take the variance of two sets of measurements (say, from two groups of patients, each group

Telegram: @medical_k

www.konkur.in

administered a different treatment) into account to determine, if there is a true difference conferred by the two treatments. There are many statistical methods to compare groups and to test whether the differences appear to be real, and these methods are chosen depending on the type of clinical trial and on the outcome being studied (e.g., a change in a numerical value versus a discrete endpoint, such as death). Typically, the statistician hypothesizes that there is no difference in the signal produced by the two treatments, and then the statistical tests are performed to see if the signal appears to be present after all, suggesting that the initial hypothesis is false (i.e., that there appears to be a real difference between the treatments).

Given these definitions, signal detection methods may, in principle, give rise to three sets of clinical trial outcomes. If the hypothesis is that two treatments are the same, then a positive trial outcome is one in which the effect of Drug X is statistically different from and better than that of another treatment (better than Drug Y, or better than placebo). A negative trial outcome is one in which this statement cannot be made; namely, Drug X produces an effect that is not statistically different from that of another treatment, thereby suggesting no additional benefit of Drug X.

But how does one know that a negative outcome is truly due to a nonefficacious drug, and not simply to some arbitrary factor such as a poor clinical trial design or a poorly chosen patient population—one that does not allow detection of a positive signal even when a positive signal should be present? To answer this question, some clinical trials will add a third treatment that produces a well-known clinical effect. For example, a test drug, Drug X, will be compared to a placebo; and in the same trial, a known beneficial drug, Drug Z, is also compared to placebo. If Drug Z produces a signal that is significantly different from placebo, as it should, and then if the effect produced by Drug X is not different from placebo, then this is a well-designed clinical trial that yields a very interpretable result: namely, Drug X does not produce an effect. However, what if the trial is so poorly designed or conducted that Drug Z itself fails to separate from placebo? This is an example of a failed clinical trial—one that is poorly designed or conducted and which is therefore not even interpretable because even a drug with a known effect cannot be detected.

Repeated Measures

Sometimes companies conducting trials wish to explore the effect of different doses of a compound on multiple symptom domains. Although this sounds like an efficient way to conduct an experiment, it turns out that if there is a small chance that a measured effect of the drug on a single variable is due to chance (and therefore that this is a true effect); it is unfortunately also true that many measurements of many doses on many effects may appear to produce a measurable effect of the drug, and some of these effects are false. Why? Random chance has been multiplied across all these tests due to multiple measurements and a factor termed repeated measurements. Various statistical techniques have been constructed to overcome the effect of repeated measurements.

A more recent development in the statistical design of clinical trials has been alternative clinical trial designs such as adaptive designs and Bayesian methods, but there have been few examples of their adoption in the CNS clinical trials so far.

FUTURE DIRECTIONS FOR DRUG DEVELOPMENT

The cost of developing a new treatment has been increasing to the point that further increases are unsustainable. There is a realization in the pharmaceutical industry that the current model

Telegram: @medical_k

www.konkur.in

has to change. This will drive a much more synergistic model that includes a whole network of collaborators who, by fostering collective scientific creativity, will ensure future long-term success. Competitive and technologic changes in the pharmaceutical industry—from powerful new drug chemistries to innovative R&D partnerships—have the potential to improve productivity that will, in turn, increase output with greater efficiency, less cost, and more value.

Collaborative Networks

Some clinical trial goals require larger and longer trials, namely those designed for disease modification or for long-term follow-up, to examine the durability of effect. For example, in examining clinical trial outcome measures that target negative symptoms in schizophrenia, Laughren and Levin (2011) proposed that for FDA regulatory purposes, a 6-month or longer treatment period was desirable in order to examine the durability of the effect of the therapeutic molecule proposed for that indication.

Taking this trend toward longer trial durations much further, trials designed to examine the effects of treatments for prodromal Alzheimer disease may last 12 to 24 months and involve a large sample size in order to detect small changes in neuropsychological measures and/or in functional or clinical outcomes. To accomplish these large trials, involving many thousands of patients and years of treatment duration, collaborative networks have been established between one or more biopharmaceutical companies, academia, and government agencies. These large collaborations will not only facilitate the conduct of the trials but also decrease the per-entity cost and spread the risk of negative trial outcomes.

Globalization

There has been a marked trend toward drug development programs becoming more and more global. This is occurring for several reasons. Regulators and patient advocates are rightly demanding data that is obtained from ethnically relevant research subjects that address the possibility of differential efficacy and safety and optimal dosing in these populations.

This trend of globalization has its challenges, including more complexity, longer regulatory reviews in some regions, different standards of medical care in some countries, and the transcultural issues in ensuring consistent reliable administering of subjective outcome measures.

Personalized Technology

CNS trials often use outcome measures that require patient entries into diaries. These can include subjective judgments on sleep quality, symptoms of depression, quality-of-life, and functional measures. In the past, these entries were made using paper diaries, but increasingly trials have turned to electronic devices that patients use for their entries. Device-based entries offer a number of advantages over the older paper-based methods. For example, entries can be both time-stamped and immediately uploaded to a trial database. This speeds the acquisition of data, and it also allows the trial analysis staff to determine that entries were made at the times and dates specified by the protocol rather than just before a patient's next clinic visit. Finally, electronic devices are increasingly familiar to people through their use of personal smartphones and other handheld devices; this tends to enhance patient interest in and familiarity with the use of these devices.

The introduction of Apple's ResearchKit (http://www.apple.com/researchkit/) holds the promise of taking clinical research into the mainstream with the availability of clinical research to everyone via their mobile devices, with enabling modules such as eConsent. Digital Medicine is profoundly influencing health care delivery systems and disease management.

Telegram: @medical_k

www.konkur.in

Personalized Medicine

Currently, most treatments available to patients were developed based on their effect on a patient population. It has been a long-held aspiration to develop treatments that are personalized to patients based on factors such as genetics. This goal can be termed personalized medicine.

An example of an efficacy-targeted success in personalized medicine is the use of HER2 screening in patients with metastatic breast cancer. Patients who over-express (are positive for) HER2 have a greater likelihood of responding to trastuzumab (Herceptin).

A similar example of a safety-targeted success is the use of CYP450 testing in order to predict drugs that should be dosed at different strengths in order to avoid excess or poor metabolism of drugs handled by those metabolic paths; and also, to avoid drug: drug interactions. How does this affect the use of psychiatric drugs? Fluoxetine inhibits the activity of CYP2D6, which metabolizes more than 100 commonly used medications. This means that patients taking fluoxetine may be at risk of receiving a functional overdose of other compounds that are metabolized by 2D6 unless the potential for a drug interaction is avoided by measuring 2D6 function in patients taking fluoxetine or by tailoring the doses of coadministered drugs that are metabolized by 2D6.

The field of personalized medicine extends much further than these two examples about its applicability to efficacy and safety. Two basic approaches will be considered: tailoring drugs for the individual and identification of genetic susceptibility to disease.

Numerous large clinical trials targeting CNS and other indications routinely collect genetic information on patients in those trials, allowing the retrospective identification of a gene variant profile that correlates with efficacy or safety signals observed during the trial. If identified, then prospective use of these gene variant profiles is feasible by screening patients for these gene variants in order to predict the efficacy or safety of the drug in question before it is administered to them.

Whole-genome sequencing (WGS) is now available through many avenues for the individual patient. WGS approaches conducted in large populations can help identify variants that confer susceptibility to a variety of conditions, and then individual WGS results can be correlated with these population databases to seek clues about that individual's likelihood of harboring or developing those conditions. Caution must be exerted in applying this information to individual genomic data because of the ethical and interpretative issues that may be encountered. For example, if an asymptomatic individual has a variant profile consistent with schizophrenia, how likely is it that this person will ever be symptomatic? And how will this information influence: that person's lifestyle; the extent to which this information is shared with family members, friends, work colleagues, or insurance providers; the advisability of parenting; or, if already a parent, the extent to which this information is communicated to the offspring? These issues and many others must be carefully considered by each individual in consultation with their health care providers.

Biomarkers

In the broadest sense, biomarkers are any measurable feature of a patient that can serve to predict disease likelihood and severity, disease course, disease response to treatment, or the current general health status of the patient. Optimally, a surrogate biomarker for disease severity with disease severity can be objectively measured; and so, can serve as a clinical trial outcome measure in place of a more subjective "soft" outcome measure such as a symptom rating scale. Biomarkers for psychiatric conditions have been sought for decades. Laughren discussed the last 50 years of psychiatric drug development and concluded that biomarker

Telegram: @medical_k

www.konkur.in

approaches were the most likely methods to help advance the field. This has been echoed by many in the research community. The challenge has been to identify and validate biomarkers meeting these criteria that can be used as trial outcome measures and that would also be accepted by regulatory authorities for drug approvals. To date, this has had no more than limited success in most indications and no success yet in psychiatric indications. Hopefully, the wide variety of imaging, genetic, and other approaches that are underway will soon change this landscape.

Patient Centricity

Traditional drug development processes have not been particularly patient-centric. As an example, research protocols had little, if any, input from patients, resulting in, at times, complex burdensome protocols that either excluded most patients or negatively impacted the recruitment and retention of research subjects and the success of the programs.

More recently, there has been a realization that this needs to change. Also, in some disease areas, especially rare and orphan diseases, patient advocacy groups are themselves funding clinical trials and having a stronger voice.

More “Real-World” Data

One of the criticisms of drug development programs has been that the data generated is not particularly helpful to clinicians in helping them make treatment decisions and choices. This is driven by a misunderstanding of the purpose of phase 2 and phase 3 clinical trials. These programs are conducted to meet the requirements of regulatory authorities, and traditionally it was the postapproval phase 4 studies that were conducted to address questions that would help prescribers understand the optimal use of the new treatment.

As payors across the world have increased their demand for data that justify pricing above generic treatments, it has become imperative to generate this data earlier in the development of new treatments. This will lead to a modification of the issues that are addressed in drug development in preapproval programs.

MORE RELEVANT OUTCOME MEASURES

Traditionally in psychiatric drug development, outcome measures are used, measuring symptom severity and the impact of a new treatment on these symptoms. However, it has become clear that reducing symptoms is not enough. Both payors and patients are looking for the impact on functioning and other novel domains. This will lead to new ways of assessing the impact of a new treatment on patients.

Disease Interception

Throughout the history of medicine, the main focus has been on treating diseases once they have become manifest. It is clear that in many conditions, this may be too late, the clearest example currently being Alzheimer disease. There are efforts underway across neuroscience to identify patients that may be at risk and develop interventions that would prevent the disease before it develops. This approach has implications both for regulatory bodies and payors, if physicians are to intervene that early in the natural history of a disease.

Regulation of Drug Approvals

When clinical trials yield results that demonstrate the potential benefits of efficacious and safe compounds, these data must be submitted to regulatory authorities for their scrutiny before

Telegram: @medical_k

www.konkur.in

approval for marketing is granted. It is important to understand the landscape in which regulatory guidelines have developed in order to put the challenges of drug development into perspective. This section reviews the history and the current U.S. regulatory environment for drug development.

Background

The FDA, according to its mission statement, “is responsible for protecting the public health by assuring the safety, efficacy, and security of human and veterinary drugs, biological products, medical devices, our nation’s food supply, cosmetics, and products that emit radiation. The FDA is also responsible for advancing public health by helping to speed innovations that make medicines and foods more effective, safer, and more affordable; and by helping the public get the accurate, science-based information they need to use medicines and foods to improve their health.” The FDA plays a role in overseeing and guiding the development of the medications and devices that are used in the practice of psychiatry and ensuring that they are effective, offer a favorable risk-to-benefit ratio, are accompanied by adequate directions for use, can be manufactured with reliable quality, and are not promoted in a misleading fashion.

HISTORY OF DRUG REGULATION

The history of American drug regulation features a series of legislative responses to public concerns. A century ago, there were no restrictions on what could be sold as medicine and what claims could be made about the products. *Patent* medicines were widely sold for a variety of ailments. Labels did not list ingredients. Some medicines contained ethanol, opium, morphine, heroin, or cocaine; others contained harmless (and ineffective) ingredients. Popular press accounts of the harms of these *tonics* sold to unsuspecting customers, along with concerns about food adulteration and the dangers of chemical additives, led to the passage of the Pure Food and Drug Act of 1906, championed by Harvey Wiley, head of the Bureau of Chemistry in the Department of Agriculture.

Pure Food and Drug Act of 1906

Wiley law, the Pure Food and Drug Act of 1906, was only six pages long. It prohibited the manufacture and interstate shipment of “adulterated” and “misbranded” foods and drugs. This gave the government the authority to go to court against illegal products but did not require any premarketing approval. Initially, the law also did not outlaw false therapeutic claims. A 1912 amendment declared such claims illegal but required that the government prove fraudulent intent. Thus, the only requirement was that the purveyor of a medication believes that the drug was effective. Regarding labeling, the law required only that a contents statement, if used, must be truthful. Not until a 1913 amendment was a statement of contents required.

Elixir Sulfanilamide Tragedy of 1937

The shortcomings of the 1906 law limited the government’s ability to ensure the safety of drugs. Although the need for reform of drug regulation was apparent by the early 1930s, legislation proposing an expansion of the regulatory authority of the FDA was held up by debate in Congress and opposition from the food and drug industries. Finally, in 1937, a public health scandal emerged that generated the political will to pass the bill. A chemist at Massengill, attempting to develop a palatable formulation for a sulfa antibiotic, created a product that used diethylene glycol as a solvent. No premarket testing, in humans or animals,

Telegram: @medical_k

www.konkur.in

was required under the laws then prevailing, and none was undertaken. As a result of exposure to this solvent (akin to antifreeze), more than 100 people died, and many of them were children. As it happens, the Pure Food and Drug Act gave the government the authority to take action against the manufacturer only because the product was labeled an *elixir.* By definition, an *elixir* uses ethanol as a solvent; had the manufacturer labeled the product a *solution,* it would not have been in violation of any law.

Food, Drug, and Cosmetic Act of 1938

Although there had been other crises associated with the marketing of untested, unsafe drugs, the elixir sulfanilamide tragedy spurred the passage of the Food, Drug, and Cosmetic Act of 1938. This law contained a number of important provisions concerning drug regulation. The 1938 law required that new drugs undergo safety testing, the results of which would be submitted to the FDA in a new drug application (NDA). Premarketing approval of the NDA was required before a drug could be sold. The law also required that drugs have adequate labeling for safe use. Furthermore, it clearly prohibited false therapeutic claims for drugs without the requirement that the government shows fraudulent intent. In addition, the FDA was given authority to conduct factory inspections.

Thalidomide Tragedy of 1962

By the early 1960s, Senate hearings on strengthening the regulation of drugs were once again underway. In the midst of these hearings, chaired by Senator Estes Kefauver, came the news of the devastating effects of thalidomide (Thalomid), which was being marketed in Europe. Although the NDA had been submitted to the FDA for review, the medical officer responsible for the review, Frances Kelsey, had requested additional safety information, and the drug had not yet been approved (of note, as a student, Kelsey assisted in the investigation of the elixir sulfanilamide tragedy). Her role in protecting the American public from the dangers of thalidomide was widely reported and generated support for the passage of what became known as the Kefauver–Harris Amendments in 1962. These amendments required drug manufacturers to prove to the FDA that their products were safe *and* effective before marketing. They established that the evidence of efficacy must be derived from “adequate and well-controlled trials.” Furthermore, the amendments also addressed the use of drugs in clinical trials. Under the Kefauver-Harris Amendments, the current investigational new drug (IND) process was established. Under the law, the FDA had to be provided with full details of the clinical investigations, including drug distribution, and the clinical studies had to be based on previous animal investigations to ensure safety.

After the addition of the efficacy requirement, the FDA commissioned a review by the Institute of Medicine of all drugs approved between 1938 and 1962 to determine whether they were effective, as well as safe. This process, known as the drug efficacy study implementation (DESI), resulted in the removal of some drugs from the market, whereas others were determined to be effective. Nonprescription drugs were also evaluated under a similar process, which resulted in the publication of monographs establishing which ingredients may be “generally recognized as safe and effective” for various conditions.

IND Regulations

After the 1962 amendments, the FDA issued and implemented regulations concerning the investigational use of drugs; these regulations were updated and revised in 1987. The revisions were intended to “ensure FDA’s ability to monitor carefully the safety of patients participating in clinical investigations, while also facilitating the development of new beneficial

Telegram: @medical_k

www.konkur.in

drug therapies." The regulations serve to "focus FDA's attention during the early phase of clinical research on protecting the safety of human test subjects and to give sponsors greater freedom to design, revise, and implement clinical research studies" and to "facilitate consultation between FDA and drug sponsors, once the preliminary human studies have been completed and a drug appears to have marketing potential, to help ensure that the design of major clinical trials is acceptable and will support marketing approval, if the test results are favorable." And beginning in the mid-1970s, the FDA began giving advice on the kinds of studies and data that would be needed to support drug approval. Clinical guidances have been published, setting forth the data needed for drugs in various therapeutic categories.

PDUFA, FDAMA, and Pediatric Provision

Thirty years after the 1962 amendments, frustration over lengthy review times led to the passage of the Prescription Drug User Fee Act (PDUFA) of 1992, which charged fees for NDA review to facilitate the expansion of the FDA's review resources and, in return, ensured action on an application in a specified period of time. PDUFA was renewed with the passage of the FDA Modernization Act (FDAMA) of 1997, which further shortened review times and made additional changes in the review process. The authority to collect user fees was again reauthorized as part of the Public Health Security and Bioterrorism Preparedness Act of 2002 and the Food and Drug Administration Amendments Act of 2007 (FDAAA).

Among the provisions of FDAMA were the pediatric exclusivity provisions. These offered incentives, in the form of an additional period of protection from generic competition, to sponsors for fulfilling an FDA request for pediatric data on their products. In 2002, the Best Pharmaceuticals for Children Act (BPCA) was passed, providing further clarification of the pediatric exclusivity program and establishing a system for conducting studies through the National Institutes of Health for high-priority drugs that were already off-patent or for which the commercial sponsor declined to respond to the agency's request. In the first 10 years after the passage of FDAMA, over 150 submissions of data in response to written requests were evaluated to determine whether pediatric exclusivity should be granted. Among these were studies of a number of psychotropic agents, including antidepressants, antipsychotics, and anxiolytics. In many cases, the results of the studies led to labeling changes stating that safety and efficacy in children had not been established; yet pediatric exclusivity is awarded even in these cases. In addition, under the provisions of the BPCA, upward of 50 drugs have been included on a priority list, including lithium (Eskalith), bupropion (Wellbutrin), and clonidine (Catapres).

Although FDAMA and BPCA established incentives for pharmaceutical companies to conduct pediatric studies, such studies remained optional. Subsequently, in 2003, the Pediatric Research Equity Act (PREA) authorized the agency to require sponsors to conduct pediatric studies as part of its development program. The requirements may be waived, if the drug is not likely to be used in a substantial number of pediatric patients or does not represent a meaningful therapeutic benefit for pediatric patients. In addition, the agency may also waive the requirement, if "there is evidence strongly suggesting that the drug or biologic product would be ineffective or unsafe in all pediatric age groups" or on the grounds that the studies are impossible or highly impracticable. The agency may require that the pediatric studies are submitted as part of the initial application or may defer all or some of the pediatric studies until after the application is approved for use in adults.

The FDAAA of 2007 reauthorized PDUFA, PREA, and BPCA, as well as creating new programs to enhance postmarketing safety surveillance and the FDA's ability to communicate safety information.

STRUCTURE OF THE FDA

There are five headquarters centers in the Washington, D.C., area: The Center for Drug Evaluation and Research (CDER), the Center for Biologic Evaluation and Research (CBER), the Center for Devices and Radiologic Health (CDRH), the Center for Veterinary Medicine (CVM), and the Center for Food Safety and Applied Nutrition (CFSAN). Staff in these offices work primarily on product review and regulatory policy. In addition, a network of field offices throughout the United States focuses on inspection and surveillance, laboratory work, and public and industry education.

Most relevant to psychiatric treatment is the work of CDER, where drugs and therapeutic biologic treatments are reviewed, and CDRH, which has jurisdiction over medical devices such as those used in ECT. This section will address the review of drugs and biologic therapeutic products as undertaken in CDER.

NEW DRUG DEVELOPMENT

The development of a new pharmacologic treatment for a psychiatric (or any other) disorder usually begins with an exploration of a compound's actions in vitro and animal investigations. These investigations may be carried out before involving the FDA. Indeed, initial safety testing in animals is required before beginning human studies that are subject to FDA review. Most compounds are abandoned in these early stages of development. However, those that appear promising and are reasonably tolerated in animal safety studies may go forward in development.

Definition of a Drug

The Food, Drug, and Cosmetic Act defines drugs as:

1. Articles recognized in the official U.S. Pharmacopeia, the official Homeopathic Pharmacopeia of the United States, or the official National Formulary
2. Articles *intended for* [emphasis added] use in the diagnosis, cure, mitigation, treatment, or prevention of disease
3. Articles (other than food) intended to affect the structure or function of the body
4. Articles intended for use as a component of any article specified previously.

Therefore, it is the *intended use* of the substance that defines it as a drug. As soon as a substance is intended for human use toward one of these objectives (i.e., when human studies begin), the substance is, by definition, a drug and is subject to regulation under the drug provisions of the Food, Drug, and Cosmetic Act.

Note that therapeutic biologic products are a subset of drugs. Although the term "drug" is often used to designate a typical small-molecule product and the terms "biologic" or "therapeutic biologic" to designate the large, biologically derived substances used therapeutically, such as monoclonal antibodies, both types of products are considered drugs outside the FDA. In this section, the term *drug* will be used to encompass all products meeting the statutory definition.

Phases of Drug Development

Drug development to support a commercial marketing application proceeds in somewhat overlapping phases. Nonclinical (also called *preclinical*) studies begin before human studies but continue throughout the clinical development period. Each phase of human testing is

Telegram: @medical_k

www.konkur.in

supported by animal tests that are appropriate to the extent of planned human exposure in the ensuing studies. Human studies proceed from basic characterization of the drug product to establishment of efficacy and elucidation of the adverse event profile in the intended population of use. Although the categorizations phase 1, phase 2, and phase 3 are used commonly, the development of a drug does not proceed linearly through these phases. For example, studies of drug–drug interaction and studies of pharmacokinetics in renal or hepatic impairment are both considered phase 1 studies but often occur late in drug development. Finally, unanswered questions or new indications may be explored after the drug has been approved for marketing and are commonly called phase 4 studies.

Nonclinical Studies

Nonclinical studies that are sufficient to establish a tolerable dose and to identify the target organs of toxicity for a new drug must be conducted before the first use of a new chemical entity in humans. A standard battery of animal studies and in vitro studies are required to support a marketing application, with the duration and timing of these studies related to the proposed duration of use of the drug in the clinical program. Thus, acute toxicology studies are needed to support single-dose human administration, whereas longer studies must be completed before using the drug in human studies involving chronic exposure.

Phase 1. Phase 1 studies represent the initial introduction of the new drug to humans. These studies, usually conducted in healthy volunteers, typically in closely monitored (often inpatient) settings, serve to characterize the absorption, distribution, metabolism, and excretion of the compound, to identify overt toxicities associated with drug administration, and to establish a tolerable dose for use in further studies. In some circumstances, phase 1 studies may involve patients and may be designed to provide early indications of the drug's efficacy; examples include drugs intended as chemotherapeutic or anti-HIV agents. Phase 1 also includes studies in which investigational drugs are used as research tools to explore biologic phenomena or disease processes. The objective of phase 1 in commercial drug development is to obtain sufficient information about the drug's pharmacokinetics and pharmacologic effects to permit the design of well-controlled, scientifically valid phase 2 studies. The total number of subjects and patients included in phase 1 studies varies with the drug but is generally in the range of 20 to 80.

Phase 2. Phase 2 includes the initial controlled clinical efficacy studies. These studies typically include carefully selected patients with the disease or condition under study and are usually well-controlled, closely monitored, and optimized for the collection of efficacy data. In phase 2, exploratory work is undertaken to help determine the optimal doses of the drug. In conditions for which no standard outcome measures have been defined, studies may explore different approaches to capturing the effect of the drug. Safety data are collected in this phase to determine the common short-term side effects and risks associated with the drug.

Phase 3. After preliminary evidence suggesting the effectiveness of the drug has been established in phase 2 trials, additional information about effectiveness and safety is needed to evaluate the overall risk-to-benefit relationship of the drug and to provide an adequate basis for product labeling. Phase 3 studies provide this information. The inclusion and exclusion criteria in phase 3 studies are usually broader than in phase 2 in order to select a population that is more representative of the patients who will be exposed to the drug during marketing. Phase 3 studies may include from several hundred to several thousand subjects, including

Telegram: @medical_k

www.konkur.in

individuals with a broad range of typical comorbid conditions and concomitant medications seen in the target population.

Phase 4. Once the drug has been approved, subsequent postmarketing activities may be conducted in phase 4. Studies to elucidate specific issues about a drug, which are considered important for optimal use but not essential to know before drug approval, may be performed. Studies to support approval for additional indications (e.g., use in pediatrics, if not previously established) may also be conducted. Programs of active surveillance for adverse events may be undertaken, as well as the required passive collection of adverse event reports from patients, health care providers, and other sources, which manufacturers must report to the FDA periodically.

IND Review Process. Before beginning human studies, the commercial drug sponsor must submit a request for an IND exemption from interstate shipping laws, or an IND, for review by the FDA. Once the IND is submitted, the sponsor must wait 30 calendar days before initiating any clinical trials. During this time, the FDA has an opportunity to review the IND for safety to ensure that research subjects are not subjected to unreasonable risk.

REVIEW EMPHASIS AND PROCEDURES. According to the Code of Federal Regulations:

FDA's primary objectives in reviewing an IND are, in all phases of the investigation, to assure the safety and rights of subjects and, in phases 2 and 3, to help assure that the quality of the scientific evaluation of drugs is adequate to permit an evaluation of the drug's effectiveness and safety. Therefore, although the FDA's review of phase 1 submissions will focus on assessing the safety of phase 1 investigations, the FDA's review of phases 2 and 3 submissions will also include an assessment of the scientific quality of the clinical investigations and the likelihood that the investigations will yield data capable of meeting statutory standards for marketing approval.

Thus, the reviewers pay close attention to all reviews to determine whether the risks of the study are appreciated, anticipated, communicated, and managed by the sponsor. For later phase studies, they also consider whether the study design is adequate to meet the scientific and regulatory objectives of the study. During the review of an initial IND submission (as well as the review of subsequent submissions of additional protocols and amendments), the interdisciplinary review team approaches these issues from various angles, including clinical study results; chemistry/product quality; pharmacology/toxicology information; clinical pharmacology data; and biostatistics use and results.

Clinical Hold. If no concerns are identified by the interdisciplinary review team, the IND goes into effect, and the studies proposed in the initial submission are permitted to proceed. Once the IND is in effect, additional protocols, study results, and safety information are submitted. For each new clinical study proposed, the review process is similar, but the sponsor is not required to wait 30 days before initiating subsequent studies.

However, at the time of initial IND review or at any time during drug development, the FDA can place human studies under an IND on *clinical hold.* A clinical hold, according to the Code of Federal Regulations, is "an order issued by FDA to delay a proposed clinical investigation or to suspend an ongoing investigation. The clinical hold order may apply to one or more of the investigations covered by an IND."

Under the Code of Federal Regulations, the FDA may impose a clinical hold on an IND for any of the following reasons:

Telegram: @medical_k

www.konkur.in

- Human subjects are or would be exposed to an unreasonable and significant risk of illness or injury.
- The clinical investigators named in the IND are not qualified by reason of their scientific training and experience to conduct the investigation described in the IND.
- The investigator brochure is misleading, erroneous, or materially incomplete.
- The IND does not contain sufficient information required under §312.23 to assess the risks to subjects of the proposed studies.
- The plan or protocol for a phase 2 or 3 study is clearly deficient in its design to meet its stated objectives. When a clinical hold is issued, a sponsor must address the issues that are the basis of the hold before the order is removed, and the study may proceed.

Marketing Application Submission and Review. The culmination of the development program is the submission of the NDA for a small-molecule drug product or a biologics licensing application (BLA) for a therapeutic biologic product. FDA staff have 10 months (6 months for a drug designated as a priority application owing to its potential to offer a breakthrough in treatment) to assess the raw data thoroughly and to compare their own conclusions about the data to the applicant's conclusions presented in written reports. The objective is to determine whether the sponsor (now called the *applicant*) has met the regulatory burden for marketing: Demonstrating efficacy through "substantial evidence" from "adequate and well-controlled investigations, including clinical investigations, by experts qualified by scientific training and experience to evaluate the effectiveness of the drug involved" and demonstrating safety through "all tests reasonably applicable." Therefore, in the course of the review, FDA staff assess whether the clinical studies were indeed appropriately designed and conducted, whether the data support the conclusion that the drug is effective, and whether the proper human and animal safety data ("all tests reasonably applicable") were collected and illustrate a favorable risk to benefit ratio and whether the manufacturing methods and controls are sufficient to ensure consistency of identity, quality, purity, and strength of the product.

SAFETY REVIEW. The purpose of the safety review is two-fold: first, to determine the adequacy of the extent of exposure and the specific tests carried out in the safety evaluation (such as laboratory tests, electrocardiograms [ECGs], and adverse event collection) and to assess whether it meets the standard of "all tests reasonably applicable." For example, approval of a drug in a class known to be associated with a prolongation of the QT interval might be withheld, if a safety review determined that the effects of the drug on cardiac conduction were not thoroughly evaluated. The second purpose is to characterize the safety profile so that the risks of the drug may be weighed against the benefits identified in the efficacy review. Characterization of the safety profile includes identifying and estimating the frequency of common adverse events that are, or maybe, causally related to the use of the drug; identifying factors that predict the occurrence of adverse events, such as age, gender, concomitant medication, or illness; and examining the data for events that suggest problems that are so serious that the use of the drug should be limited or approval withheld altogether. The clinical reviewer evaluates all available safety information and integrates it into an overall picture of the drug's effects.

EFFICACY REVIEW. The review of efficacy, conducted jointly or in parallel by the medical officer and biostatistician, uses raw data from the pivotal clinical trials in the application to confirm the applicant's conclusions about the study results. Any deviations from the protocol-specified study plan are evaluated for possible impact on the outcome of the studies. Reviewers

Telegram: @medical_k

www.konkur.in

analyze the applicant's assumptions about the outcome for protocol violators, subjects who withdraw early from studies, or subjects with missing data. They test the impact of alternative assumptions on study outcomes. The objective of the efficacy review is to determine whether the studies submitted were "adequate and well-controlled" and whether they provide "substantial evidence" of efficacy. For the most important trials, the review also includes clinical trial site inspections by the Division of Scientific Investigation (DSI). By examining the trial site, documentation, source materials, and equipment, the DSI establishes whether there are important violations that call into question the results of the study. Such findings are unusual but do occur as a result of deliberate fraud, error, or incompetence.

Abuse Liability Assessment. For most psychotropics, the NDA also includes a section addressing the abuse potential of the product. Assessment of abuse potential is required for many drugs with CNS activity. This testing may include a battery of in vitro receptor-binding studies, various animal studies of the rewarding properties of the drug, and, if preliminary studies suggest the potential for abuse, human laboratory studies. Data from these studies, as well as other information concerning the chemical structure of the compound and any other relevant data from literature or epidemiologic reports, are reviewed as part of the NDA and are considered in writing the relevant sections of the product package insert. Importantly, these data are also taken into consideration in preparing a recommendation concerning the control of the substance under the Controlled Substances Act. This recommendation is prepared by a team within the Office of the Director of CDER at the FDA and is forwarded through the secretary of Health and Human Services to the Drug Enforcement Administration.

PHARMACOLOGY AND TOXICOLOGY. By the time the NDA is submitted, the nonclinical data include a variety of animal studies. There should be both acute and multidose toxicity studies, the duration of which is determined by the intended use of the product. Also included are reproductive toxicology studies, mutagenicity studies, carcinogenicity studies for chronically used products, and any special toxicity studies (such as dermal sensitization studies for a transdermal product and blood compatibility studies for an intravenous [IV] product). There also should be studies of the absorption, distribution, metabolism, and elimination of the drug in animals because these data are needed to compare the dose response in animals to the dose recommended for humans. In the course of the review, the pharmacologist examines the results of these studies and also critically evaluates the study design and conduct to determine if the data may be accepted as valid.

CLINICAL PHARMACOLOGY. The clinical pharmacology reviewer examines data relevant to understanding all aspects of the absorption, distribution, metabolism, and excretion of the drug. This includes information on any important influences on these parameters, such as food effects, drug interactions, or effects of age, gender, or hepatic or renal impairment. This information is included in the clinical pharmacology section of the label and often forms the basis for important precautions to ensure the safe use of the product. Explorations of exposure–response relationships for efficacy and safety endpoints are also an important part of the clinical pharmacology review. Some pharmacogenomic analyses (analyses of genetically based differences in pharmacology), such as explorations of the role of metabolic polymorphisms, may also be undertaken.

CHEMISTRY/PRODUCT QUALITY. In reviewing an NDA, the chemistry reviewer examines the manufacturing information to determine whether there are appropriate specifications and test methods in place to ensure identity, quality, purity, and strength, as well as consistency from

Telegram: @medical_k

www.konkur.in

batch to batch. For a BLA, the quality reviewer, similarly, is responsible for ensuring the quality, safety, efficacy, availability, and security of therapeutic protein and monoclonal antibody products. The reviewer also evaluates information about stability, including the adequacy of the stability data to support product use, expiration dating, and any concerns about packaging or shipping that might affect stability. In addition, the reviewer takes into account the findings of inspections of the manufacturing facilities, which are undertaken to ensure adherence to the principles of good manufacturing practices. Reviewers of biologic products participate in the actual preapproval and biennial facility inspections. The FDA may withhold approval, if inspections show significant procedural problems at the facilities that are responsible for manufacturing or packaging the product.

REGULATORY DECISION. All the discipline reviews are taken into consideration in making an assessment of whether the drug's benefits outweigh its risks for the intended use in the intended population. If a drug offers significant benefits for a narrowly defined population but carries significant risks, the FDA may decide to approve the drug subject to special conditions to ensure that physicians understand and comply with using the drug only for those in whom the anticipated benefits can be expected to be greater than the possible risks.

If there are unanswered questions or unresolved issues in an application or concerns about safety or lack of efficacy, the FDA may withhold approval. The applicant is issued a letter explaining the deficiencies precluding approval and instructions on how to address these deficiencies.

PRODUCT LABELING. For the physician and the patient, the most obvious product of the NDA review process (apart from the regulatory decision that makes the product available on the market) is the package insert or label. The multidisciplinary review team carefully examines language drafted by the NDA applicant and ensures that the statements throughout the label are supported by the submitted data. The format of the label is set forth in the Code of Federal Regulations (21 CFR §201).

Postapproval (Phase 4). Despite the careful premarket review, postmarketing surveillance of adverse drug effects is also essential. It is evident that all possible side effects of a drug cannot be anticipated based on preapproval studies. The total exposure to an investigational drug during its development depends, to some extent, on the novelty of the compound and on the presence of any specific safety concerns. However, for practical reasons, it is rarely possible to have sufficient premarket exposure to characterize the occurrence of rare adverse events. According to the current recommendations of the International Conference on Harmonization, for new chemical entities that are to be used chronically (or repeatedly but intermittently) in the treatment of conditions that are not immediately life-threatening, the number of patients exposed should be sufficient to detect serious adverse events occurring at a rate of approximately 1 per 1,000 in short-term use. It is recommended that the safety database include at least 1,500 subjects. Of these, 300 to 600 should be treated for at least 6 months, and 100 should be treated for 1 year. Applying the so-called rule of three, if a particular serious adverse drug effect is not observed in the 100 subjects exposed for 1 year, this can provide reasonable assurance that the true cumulative 1-year incidence is no greater than 3%. However, this rule of three represents only 95% confidence limits. It must be noted that even a database of 3,000 subject exposures stands a 5% chance of missing events that occur at a rate of 1 per 1,000, and such a rate may translate into a significant number of occurrences when the drug is introduced into a population of hundreds of thousands.

Telegram: @medical_k

www.konkur.in

Therefore, the FDA maintains a system of postmarketing surveillance and risk assessment programs to identify adverse events that did not appear during the drug approval process. The agency monitors adverse reactions reported by drug companies, consumers, and physicians and seeks out signals suggestive of drug-related events. The agency uses this information to update drug labeling, identify unanticipated drug–drug or drug–disease interactions, spot common medication errors and take action to prevent them, and, on rare occasions, re-evaluate the approval or marketing decision.

POSTMARKETING SAFETY. Due to practical limitations on how many patients can be studied in clinical trials for a new drug, it is inevitable that some safety concerns will come to light until after a new drug is used in a broader population after approval. Unlike Frances Kelsey, the modern FDA reviewer often does not have foreign postmarketing data available to supplement the clinical trial data submitted in the drug application since drugs are now frequently approved first in the United States. In the post-PDUFA era, critics of the FDA raised concerns that the emphasis on bringing new drugs to market more rapidly had led to a failure to identify important safety issues. Several high-profile drug safety issues led the agency to examine its procedures and to launch several initiatives aimed at improving the safe use of medicines, including a dedicated Safety Policy and Communication staff that ensures that physicians, health provider groups, and patients are alerted to important new safety information in a timely manner. The Safety Policy and Communications staff includes a Drug Safety Oversight Board (known as the DSB) that was established to provide independent oversight and advice to the center's director on the management of important and emerging drug safety issues. The DSB provides perspective from scientists not involved in the initial review and approval of a particular marketing application and provides a venue for adjudicating organizational disputes concerning the management of drug safety issues. In 2007, the Safety Policy and Communications Staff launched a new tool for communicating safety issues, the FDA Drug Safety Newsletter, which is distributed electronically and viewable on the FDA's Web site.

FUTURE DIRECTIONS FOR FDA

In 2004, the FDA launched a new initiative known as the *Critical Path Initiative,* which is intended to "stimulate and facilitate a national effort to modernize the scientific process through which a potential human drug, biologic product, or medical device is transformed from a discovery or "proof of concept" into a medical product." By identifying key areas in need of attention and partnering with other agencies and organizations to initiate research, the FDA is working to improve the tools used to evaluate the safety and efficacy of human and veterinary products, as well as the safety and nutrition of food and food ingredients. A list of areas representing high-priority opportunities for improvement was disseminated, and work has been initiated on a variety of projects.

One project specific to psychiatry is an effort under the aegis of the *Biomarkers Consortium,* a public/private biomedical research partnership supported by the Foundation for the National Institutes of Health (FNIH). Among their first projects is an effort to identify genomic biomarkers for treatment response in major depressive disorder. Many other critical path projects are broadly relevant to psychotropic drugs, including work on examining the genetic basis of adverse drug events; work intended to broaden understanding of the biochemical and genetic basis of drug-induced liver injury; a database of digital ECGs collected in drug-approval studies to be used to improve methods of measuring drug effects on cardiac conduction, and efforts to identify nephrotoxic biomarkers that predict the effects of drugs on kidney function.

www.konkur.in

As drug development becomes more and more of a global endeavor, the need for regulatory authorities in different countries and regions to interact and discuss regulatory issues and challenges becomes more important.

CONCLUSION

Drug development in every field has become increasingly complex, costly, and challenging, and in no other therapeutic area is this more evident than in psychiatric conditions. The challenges are enormous in translating from the Gordian knot of poorly understood CNS pathophysiologic processes and nonpredictive models into clinical trials that will have a good probability of success. Nevertheless, there are new technologic and scientific approaches that provide a basis for increased hope as clinical trials for psychiatric conditions move into the 21st century. The goal is clear. Psychiatrists must discover, develop, and obtain regulatory approval for new medicines that will improve the treatment of many unmet or poorly served medical needs in the psychiatric field. Patients are waiting.

33.1c Classification of Psychotropics: Neuroscience-Based Nomenclature (NbN)

Joseph Zohar, M.D., Sasson Zemach, M.D., and Daniel Minkin Levy, M.D.

Psychopharmacology, the scientific study of the effect drugs have on the mind, has redefined psychiatry over the last decades. This process began with a serendipity discovery of chlorpromazine and later on the monoamine oxidase inhibitors (MAO-I). These agents were found to be treatments for psychosis and depression, respectively, and led to the foundation of the concept that mental illness can be treated with psychotropics.

However, the use of the first modern psychotropics predated important revelations concerning pathologic disease processes. These include discoveries regarding dopamine and the D2 receptor in psychosis and the role of monoamines in depression. For years, while more pharmacologic agents were discovered, the knowledge of how they exert their effect was still missing. The gap between neuroscientific insights and clinical practice led to resulted in adapting a disease-based terminology. Soon, intuitive terms such as "antipsychotics," "antidepressants," "anxiolytics," and "mood stabilizers" were broadly used. Later, terms that are not indicative of pharmacologic activities, such as "typical," "atypical," "first-generation antipsychotics (FGA)," and "second-generation antipsychotics (SGA)," were added, in part due to commercial motives.

Currently, disease-based terminology is in use by several classification systems. Internationally, the anatomical therapeutic chemical (ATC), first published by the World Health Organization in 1976 as a monitoring tool, turned out to be a classification system, although this was not the primary intention. The ATC was built as a strict hierarchy, consisting of five levels, each level defined by a different property: anatomical site, therapeutic effect, indication, and chemical structure. The ATC uses terms such as "Psycholeptics" and "Psychoanaleptics," which are no longer in clinical use, to describe psychiatric medications alongside other central nervous system medications (e.g., "Anesthetics," "Analgesics," and "Anti-Parkinson Drugs").

Naming psychotropics following the indications they had been initially used for has unfortunate consequences. Physicians often prescribe "antidepressants" for the treatment of disorders other than depression (e.g., anxiety, obsessive-compulsive disorder [OCD], stress-related disorder). "Antipsychotics" are often prescribed for conditions other than psychosis (e.g., depression, tics, aggression). This discrepancy between terminology and practice is confusing for patients and professionals, opening the gate to stigma ("psychiatry is not a science") and negatively impacting adherence.

Psychiatric disorders affect different brain regions, different neural circuits, and different neurotransmitters. This complexity is reflected in the medication that is used for each disorder. For example, the "antidepressant" class holds 16 different pharmacologically different subgroups. Yet the term "antidepressants" blurs the pharmacologic, and consequently the clinical, differences between those medications. A deep understanding of the different tools

Telegram: @medical_k

www.konkur.in

we currently have is needed when customizing a treatment regime, planning the next pharmacologic step, and analyzing the past pharmacologic history of a patient.

To address the need for new terminology, in 2008, the "Nomenclature Taskforce" was launched with the mission to examine ways of improving the current nomenclature in psychopharmacology. This effort was headed by representatives from five major international organizations (the European College of Neuropsychopharmacology [ECNP], The American College of Neuropsychopharmacology [ACNP], the Asian College of Neuropsychopharmacology [AsCNP], the International College of Neuropsychopharmacology [CINP], and the International Union of Basic and Clinical Pharmacology [IUPHAR]). It was predefined as a nonprofit endeavor funded by the ECNP. The result was a *Neuroscience-based Nomenclature (NbN)*, relying on the growing neuroscience knowledge of recent decades. This pharmacology-driven nomenclature does not conflict with the clinical use of medications and aims to bridge neuroscience and clinical psychiatry, facilitating rational prescribing. It also offers a nomenclature that reflects contemporary neuroscience insights.

Table 33.1c–1.
NbN's Two Domains: Pharmacology and Mode of Action

Pharmacology 10 domains	Mode of Action 9 domains
Acetylcholine	Enzyme inhibitor
Dopamine	Enzyme modulator
γ-aminobutyric acid (GABA)	Ion channel blocker
Glutamate	Neurotransmitter releaser
Histamine	Positive allosteric modulator (PAM)
Melatonin	Receptor agonist
Norepinephrine	Receptor antagonist
Opioid	Receptor partial agonist
Orexin	Reuptake inhibitor
Serotonin	

The nomenclature allows medications to be attributed to multiple domains, and the richness of psychopharmacology is better represented. These two domains reflect the state-of-the-art knowledge as of 2022.

PRINCIPLES OF THE NEUROSCIENCE-BASED NOMENCLATURE

As pharmacology provides better space to name, describe, summarize, and classify psychotropic medicines, it was decided to move from a disease-based to a pharmacology-driven nomenclature. The core concept of the new nomenclature is that a drug is attributed to two *domains*: (1) Pharmacology, which represents the system that is being modulated, and (2) Mode of Action, which details the effect an agent has on said system.

The ***Pharmacology*** domain includes 10 different domains referring to the neurotransmitter, molecule, or system being modified by the medication. These include but are not limited to the monoamine neurotransmitters, γ-aminobutyric acid (GABA), glutamate, and acetylcholine.

The Mode of Action domain includes nine different modes which specify the nature of the action exerted by the medications, such as receptor antagonist, reuptake inhibitor, enzyme modulator, and so forth. Table 33.1c–1 lists the 10 pharmacology and 9 modes of action domains in the nomenclature.

Based on clinical relevance, compounds can be assigned to more than one pharmacology or MoA domain to better reflect their versatility. Those 10 pharmacologic domains and 9

Telegram: @medical_k

www.konkur.in

modes of actions listed in NbN can be used in different combinations to describe close to 150 compounds.

PHARMACOLOGICALLY DRIVEN GROUPING

One of the challenges for the new terminology is to find a way to address groups of medications. Even though there are almost no two drugs alike, the habit of grouping medications with common pharmacology and overlapping clinical applications is rooted deep in our vocabulary. The NbN glossary **(**Table 33.1c–2**)** lists each medication under a class term that should be used when referring to groups of medications. These classes are meant to be broad enough to encompass similar medications while remaining pharmacologically accurate.

DOPAMINE BLOCKERS AND THE TREATMENT OF PSYCHOSIS

Blockade of the dopamine receptor is the cornerstone upon which modern psychiatric treatment of schizophrenia is built, as nearly all medications targeting psychosis block the dopamine receptor with some affinity. The term *Dopamine Blockers* is used here as an umbrella term to describe medications with the common denominator of dopamine blockade, including dopamine receptor antagonists and dopamine-serotonin receptor antagonists.

www.konkur.in

Current Terminologies	NbN Classification		Drugs
	Pharmacologic Domain	Mode of Action	
Antipsychotics	**Dopamine Blockers**		
Typical (1st generation)	Dopamine	Receptor antagonists (D2)	Fluphenazine, haloperidol, perphenazine, pimozide, sulpiride, zuclopenthixol
	Dopamine, serotonin	Receptor antagonists (D2, 5HT2)	Thioridazine, flupenthixol, trifluoperazine, pipotiazine
	Dopamine, serotonin	Receptor antagonists (D2, 5HT2)	Chlorpromazine
Atypical (2nd generation)	Dopamine	Receptor antagonist (D2)	Amisulpiride
	Dopamine, serotonin	Receptor antagonist (D2, 5-HT2)	Loxapine, lurasidone, olanzapine, perospirone, sertindole, ziprasidone, zotepine, blonanserin, iloperidone
	Serotonin, dopamine, norepinephrine	Receptor antagonist (5-HT2, D2, NE alpha-2)	Asenapine
	Dopamine, serotonin, norepinephrine	Receptor antagonist (D2, 5-HT2, NE alpha-2)	Clozapine, paliperidone
	Dopamine, serotonin, norepinephrine	Receptor antagonist (D2, 5-HT2, NE alpha-2)	Risperidone
	Dopamine, serotonin	Receptor antagonist (D2, 5-HT2) and reuptake inhibitor (NET)(metabolite)	Quetiapine
	Serotonin, dopamine	Receptor antagonist (5HT2, D2) and reuptake inhibitor (SERT)	Lumateperone

Telegram: @medical_k

www.konkur.in

Dopamine partial agonists	**Dopamine Partial Agonists**		
	Dopamine, serotonin	Receptor partial agonist (D2, 5-HT1A) and receptor antagonist (5-HT2A)	Aripiprazole, brexpiprazole
	Dopamine, serotonin	Receptor partial agonist (D2, D3, 5-HT1A), receptor antagonist (5-HT2B)	Cariprazine
Stimulants	**Dopamine Enhancers**		
	Dopamine, norepinephrine	Reuptake inhibitors (DAT, NET) and releaser (DA, NA)	Amphetamine (D) and (D, L), lisdexamfetamine
	Dopamine, norepinephrine	Reuptake inhibitors (DAT, NET)	methylphenidate (D) and (D, L)
	Dopamine	Reuptake inhibitor (DAT)	Modafinil
	Dopamine	Receptor agonist (D2)	Pramipexole
Antidepressants	**Monoamine Enhancers**		
Tricyclic antidepressants	Norepinephrine	Reuptake inhibitor (NET)	Desipramine, protriptyline, nortriptyline, maprotiline
	Norepinephrine	Receptor antagonist (alpha-2), reuptake inhibitor (NET)	Mianserin
	Norepinephrine, serotonin	Reuptake inhibitor (NET and SERT)	Lofepramine, amoxapine
	Serotonin, norepinephrine	Reuptake inhibitor (SERT and NET)	Imipramine, dosulepin, clomipramine
	Serotonin, norepinephrine	Reuptake inhibitor (SERT and NET), receptor antagonist (5-HT2)	Amitriptyline, doxepine
MAO-I	Serotonin, norepinephrine, dopamine	Enzyme inhibitor (MAO-A and -B)	Isocarboxazid, phenelzine
	Serotonin, norepinephrine, dopamine	Reversible enzyme inhibitor (MAO-A)	Moclobemide
	Serotonin, norepinephrine, dopamine	Enzyme inhibitor (MAO-A and -B), releaser (DA, NE)	Tranylcypromine

Telegram: @medical_k

www.konkur.in

	Dopamine, norepinephrine, serotonin	Enzyme inhibitor (MAO-B and -A)	Selegiline
SSRI	Serotonin	Reuptake inhibitor (SERT)	Citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline
	Serotonin	Reuptake inhibitor (SERT), receptor partial agonist (5-HT1A), receptor antagonist (5-HT3)	Vortioxetine
	Serotonin	Reuptake inhibitor (SERT), receptor partial agonist (5-HT1A)	Vilazodone
SNRI	Serotonin, norepinephrine	Reuptake inhibitor (SERT and NET)	Duloxetine, milnacipran, desvenlafaxine, levomilnacipran, venlafaxine
NRI	Norepinephrine	Reuptake inhibitor (NET)	Atomoxetine, reboxetine
NDRI	Norepinephrine, Dopamine	Reuptake inhibitor (NET, DAT), releaser (NE, DA)	Bupropion
Tricyclic Antidepressants	**Monoamine Blockers**		
	Serotonin, dopamine	Receptor antagonist (5-HT2 and D2)	Trimipramine
Antidepressants	**Monoamine Modulators**		
	Norepinephrine, Serotonin	Receptor antagonist (NE alpha-2, 5-HT2, 5-HT3)	Mirtazapine
	Serotonin	Receptor antagonist (5-HT2), receptor agonist (5-HT1A)	Nefazodone, trazodone
	Serotonin	Receptor agonist (5-HT1A), receptor antagonist (5-HT2A)	Flibanserin
	Norepinephrine Blockers		
	Norepinephrine	Receptor agonist (alpha-2)	Clonidine, guanfacine, lofexidine

Telegram: @medical_k

www.konkur.in

	Norepinephrine	Receptor antagonist (alpha-1)	Prazosin
Antipsychotic (in Parkinson's Disease)	**Serotonin Blocker**		
	Serotonin	Receptor antagonist (5-HT2A)	Pimavanserin
Benzodiazepines/ Anxiolytics	**GABA Enhancers**		
	GABA	Positive allosteric modulator (GABA-A receptor, benzodiazepine site)	Alprazolam, chlordiazepoxide, clonazepam, clorazepate, diazepam, flunitrazepam, lorazepam, oxazepam
Benzodiazepines/ hypnotics	GABA	Positive allosteric modulator (GABA-A receptor, benzodiazepine site)	Estazolam, eszopiclone, flunitrazepam, flurazepam lormetazepam, midazolam, nitrazepam, quazepam, temazepam, triazolam
Z-Drugs/Hypnotics	GABA	Positive allosteric modulator (GABA-A receptor, benzodiazepine site)	Zaleplon, zolpidem, eszopiclone, zopiclone
	GABA	Positive allosteric modulator (GABA-A receptor, neurosteroid site)	Brexanolone
	GABA	Positive allosteric modulator (GABA-A receptor, alcohol site)	Chloral hydrate, chloral betaine
	GABA	Positive allosteric modulator (GABA-A receptor, barbiturate site)	Clomethiazole
	GABA	Receptor agonist (GABA-B)	Baclofen
	GABA	Receptor agonist (GABA-B, gammahydroxybutyrate [GHB])	Sodium oxybate (GHB)
	GABA Blocker

www.konkur.in

	GABA	Receptor antagonist (benzodiazepine receptor)	Flumazenil
	Glutamate	Receptor antagonist (NMDA)	Esketamine, ketamine
	Glutamate	Receptor antagonist (NMDA)	Memantine
	Glutamate Enhancers		
	Glutamate	Yet to be determined	Acamprosate
Mood Stabilizers	**Cation Channel Blockers**		
	Glutamate/GABA	Voltage-gated sodium and calcium channel blocker	Carbamazepine, oxcarbazepine
	Glutamate/GABA	Voltage-gated sodium channel blocker	Lamotrigine
	Glutamate/GABA	Yet to be determined	Valproate
	Glutamate/GABA	Facilitation of GABA transmission, receptor antagonist on AMPA and KA	Topiramate
	Glutamate/GABA	Voltage-gated calcium channel blocker	Gabapentin, pregabalin
Mood stabilizer	**Lithium**		
	Lithium	Enzyme interactions	Lithium
	Histamine Blockers		
	Histamine	Receptor antagonist (H1)	Diphenhydramine, hydroxyzine
	Histamine, dopamine	Receptor antagonist (H1, D2)	Promethazine
	Histamine Enhancer		
	Histamine	Receptor antagonist (H3)	Pitolisant
	Opioid Blockers		
	Opioid	Receptor antagonist (μ, κ, d)	Naloxone
	Opioid	Receptor antagonist (μ, δ), receptor partial agonist (κ)	Nalmefene
	Opioid	Receptor antagonist (μ, κ, d)	Naltrexone

	Acetylcholine	Receptor partial agonist (nicotinic receptors)	Varenicline
Hypnotics	**Melatonin Enhancers**		
	Melatonin	Receptor agonist (MEL1, MEL2)	Melatonin, ramelteon
	Melatonin	Receptor agonist (M1, M2), receptor antagonist (5-HT2B, 5-HT2C)	Agomelatine
	Orexin Blocker		
	Orexin	Receptor antagonist (OR1, OR2)	Suvorexant
	Enzyme Blocker		
	Alcohol	Enzyme inhibitor (mainly liver)	Disulfiram

[a]Each medication is attributed to two domains. Pharmacology and Mode of Action, alongside a class term (e.g., dopamine blocker, monoamine enhancer).

Despite their central role in the treatment of psychosis, dopamine blockers are broadly used for other indications; vice versa, psychosis can be treated, in cases, without dopamine blockers (as in the case of pimavanserin for Parkinson disease psychosis). Dopamine blockers are an essential component in the treatment of affective disorders. For example, in unipolar depression, aripiprazole, risperidone, and olanzapine are often used as augmenting agents. In bipolar disorder, dopamine blockers are important tools in the treatment of mania, depression, and relapse prevention alongside lithium, valproic acid, and carbamazepine, regardless of the presence of concordant psychotic symptoms. Clinical practice and guidelines suggest haloperidol, olanzapine, quetiapine, and risperidone can be especially useful for agitation in severely ill, but not psychotic patients.

Telegram: @medical_k

www.konkur.in

The application of dopamine blockers is also indicated in disorders outside of the affective and psychotic spectrums. Tic disorders are often treated, albeit in small doses, with pimozide, haloperidol, risperidone, and aripiprazole. Some dopamine blockers are used for behavioral modification, as risperidone is frequently used to reduce aggression and conduct problems in children and adolescents. Interestingly, depending on the specific drug, treating OCD with a dopamine blocker can be beneficial or hazardous; low doses of risperidone or aripiprazole are proven helpful augmentation strategies for serotonergic enhancers, especially for OCD patients with a comorbid tic disorder, while clozapine was reported to worsen OCD symptoms.

Using NbN helps discriminate between the different dopamine blockers with a higher resolution. For example, olanzapine, previously classed as an "atypical antipsychotic/SGA" is now defined under the pharmacologic domain of "dopamine, serotonin," and the "antagonist" mode of action. In comparison, brexpiprazole, another "atypical," has the pharmacology domain "dopamine, serotonin" as well–but with two modes of action: "partial agonist and antagonist" (Table 33.1c–2). In contrast, sulpride and amisulpride, previously FGA and SGA, respectively, are now both dopamine antagonists. This approach better highlights the differences and similarities of the different dopamine blockers.

DOPAMINE ENHANCERS

Complimentary to the dopamine blockers, dopamine enhancers is a term for the class medications that primarily increase dopamine levels, indicated for the treatment of attention deficit hyperactivity disorder (ADHD) and narcolepsy. Medications in this group include amphetamine, lisdexamfetamine, methylphenidate, and modafinil **(**Table 33.1c–2**)**. Some of these medications were previously known as "stimulants." This term is a counterintuitive one since a large portion of patients suffering from ADHD actually displays hyperactivity. Since the term "stimulants" is not in line with the calming effect those medications have on patients, a more clinically accurate term for this class is dopamine enhancers.

FIGURE 33.1c–1. Medications for Depression. According to the current nomenclature, only "monoamine enhancers" are considered to be "antidepressants," while (a) many of them are used for other disorders (e.g., anxiety, OCD, PTSD) and (b) nonmonoamine enhancer drugs are also effective in the treatment of depression.

Telegram: @medical_k

www.konkur.in

MONOAMINE ENHANCERS AND THE TREATMENT OF DEPRESSION

Monoamine enhancers are medications that raise monoamine levels by reuptake inhibition, receptor activity alteration, or metabolism inhibition. This group includes groups such as the "tricyclic antidepressants" and the MAO-I, SSRI, SNRI, and serotonin partial agonists. Trazodone, nefazodone, and mirtazapine are considered Monoamine *Modulators* due to their multimodal mode of action. While still considered the hallmark in the treatment of depression, monoamine enhancers and modulators are diverse and play a role in the treatment not only of depression but of other disorders such as generalized anxiety disorder (GAD), post-traumatic stress disorder (PTSD), and OCD.

A heterogeneous disorder, depression varies between individuals in several aspects. While the monoamine hypothesis of depression was the catalyst for the biologic study of the disorder, it is recognized today as a multifactorial one. Hence, the treatment of depression requires a tailored approach, combining the different clinical presentations, symptomatology, biologic/health parameters, concomitant medications, and neuroscientific insights (e.g., complicated neuronal interactions, connectivity, plasticity, and relevant circuitry). Often, optimal treatment of depression includes medications outside the monoamine enhancers class, as some dopamine blockers, cation channel blockers, and lithium (see below) have proven to possess independent efficacy in the treatment of depression.

For instance, aripiprazole, a partial dopamine D2 and serotonin 5HT1A receptor agonist, is approved by the FDA as adjunctive therapy for major depressive disorder. Likewise, quetiapine, first approved for the treatment of schizophrenia in 1996, can also be used in the treatment of depression and is considered a first-line treatment for bipolar depression in part for its activity as a serotonin 5HT1A partial agonist. Other examples of drugs that are widely used either as monotherapy or as augmenting agents for depression despite not being considered "antidepressants" (according to current nomenclature) are olanzapine, lithium, and lamotrigine (Fig. 33.1c–1).

Respectively, while some medications have an antidepressant activity while not being considered "antidepressants," other medications termed "antidepressants" are often prescribed for conditions different from depression. Moreover, not all monoamine enhancers are the same; some effectively treat disorders while others do not. One example is related to the treatment of OCD; it is not treated with "antidepressants" but with serotonin reuptake inhibitors (SRI). Yet very effective "antidepressants" such as desipramine are inferior in treating OCD. In addition to being used in treating depression (e.g., the first-line therapy for depression), SRIs are also used as an approved treatment for anxiety and stress-related disorders. Similar is the class of serotonin-norepinephrine reuptake inhibitors (SNRI) (e.g., duloxetine, venlafaxine), a class of monoamine enhancers indicated for chronic pain. The norepinephrine–dopamine reuptake inhibitor (NDRI) bupropion is indicated both for depression and as an aid to smoking cessation.

Finally, inaccuracy is not limited only to the clinical indications but also to the neurobiologic functioning itself. For example, while the term SNRIs refers mostly to agents such as venlafaxine, duloxetine, or milnacipran, the "tricyclic antidepressants" imipramine, and clomipramine, although sharing similar properties, are not labeled as such.

To conclude, NbN replaces the term "antidepressants" with "monoamine enhancers." This approach helps to group and differentiate the various medications based on pharmacology and MoA while remaining clinically relevant. Consequently, "antidepressants" such as

Telegram: @medical_k

www.konkur.in

clomipramine (a “tricyclic antidepressant”) and venlafaxine (“SNRI”) are now considered to be of the same group of SNRI, despite different molecular structures.

FIGURE 33.1c–2. NbN two main domains, pharmacology and mode of action, and additional dimensions. *Approved Indications* dimension states which indications are officially approved by major regulatory bodies (e.g., Food and Drug Administration [FDA], European Medical Agency [EMA]); the *Efficacy and Side Effects* dimension specifies whether there is evidence to support the compound’s use in indications additional to the ones approved by regulators (e.g., narcolepsy for methylphenidate, mirtazapine as a sleep promoter). Under “side effects,” only frequent or life-threatening side effects are listed; the Practical Notes dimension contains clinical knowledge including metabolism and dosing. The *Pregnancy* dimension displays current information on safety of use during pregnancy and lactation. Finally, the *Neurobiology* dimension summarizes empirical and clinically relevant data from preclinical and clinical studies.

CATION CHANNEL BLOCKERS, LITHIUM, AND THE TREATMENT OF BIPOLAR DISORDER

“Mood Stabilizers” is a term often applied to medications used in bipolar disorder. This class of medications includes agents that were first used for epilepsy (e.g., carbamazepine, valproate, lamotrigine) and lithium.

The term “mood stabilizers” is problematic for several reasons. For once, these drugs are commonly used for psychiatric indications other than bipolar disorder (e.g., unipolar depression, schizoaffective disorder, aggression, and impulsivity). Secondly, many other agents also possess mood-stabilizing properties, mainly dopamine blockers.

Replacing this term with NbN is challenging, as knowledge of how the therapeutic psychiatric effect is achieved is yet to be discovered. The term “cation channel blockers” emphasizes the important role of voltage-sensitive sodium channels (VSSC) and calcium channels in the basic function of those medications. However, it is not limiting the role of “mood stabilization” to these agents alone and does not limit the “stabilizing” effect to “mood” alone.

Due to its long-standing enigmatic MoA, lithium stands as its own pharmacologic domain (which is still unknown) as an “enzyme modulator.”

ADDITIONAL LAYERS TO NBN AND CLINICAL AIDS

While the pharmacology and MoA domains represent the main pharmacologic properties of each medication, they do not tell the whole story. Since finer details often separate one drug

Telegram: @medical_k

www.konkur.in

from the other, each drug in the new nomenclature has a profile with additional fields (dimensions) that hold relevant information–**Approved Indications, Efficacy and Side Effects, Practical Notes, Pregnancy, and Neurobiology** (see Fig. 33.1c–2 caption). Two clinical aids were made public to help utilize contemporary knowledge and make it accessible to clinicians and patients-the NbN application and website (see Fig. 33.1c–2). They demonstrate the "full picture" that each medication possesses.

Finally, two complementary versions of the NbN app aim to widen its relevance to child and adolescent (C&A) psychiatry and the general public (patient and family, P&F). NbN C&A contains information relevant to medications used for children and adolescents. To help demonstrate the scientific basis of psychiatric medication and consequently to decrease stigma, a third application and website, NbN P&F, was developed, providing information based on the NbN concept in a simple language.

CONCLUSION

Current neuroscience knowledge indicates that mental disorders are heterogeneous and need precise treatment. For instance, many patients do not respond to first-line treatment for depression, and there is often a need to select a specific treatment for their particular depression (considering genetics, medical history, symptoms, and course). At this point in therapy, overinformed or misinformed patients are likely deterred by the fact they are being prescribed medications labeled utterly different than what they suffer from (e.g., "antipsychotics" for nonpsychotic patients or "antidepressants" for anxiety).

During the initiation and management of psychiatric disorders, disease-based nomenclature often requires clarification, explaining to a confused patient that it is indeed the appropriate treatment despite the drug "class." This confusion may add further distress to an already tense situation, as the patient may feel their condition was not well-understood or their treatment does not match their symptoms, potentially harming the trust needed for treatment adherence and success. Furthermore, terms such as "mood stabilizer," "antipsychotic," and "sedative" may be perceived as judgmental. This may increase shame, especially in a social climate where the stigma on mental health and mistrust toward psychiatry still exists.

From the clinician's point of view, grouping drugs by indication has little use when prescribing. Whether they are called "antidepressants," "antipsychotics," "sedatives," or "hypnotics," this vocabulary does not represent differences or similarities between one another, either by neuroscientific attributes or by clinical application. The use of the current indication-based terminology neither encourages psychiatrists to utilize contemporary evidence-based knowledge for prescribing medications nor helps to change the habitual prescribing of a limited number of drugs.

An NbN presents a shift from disease-based to pharmacology-driven classification. It supports the application of scientific rationale to the prescription process for psychiatric medications, accommodates contemporary insights, and helps to avoid patient confusion. By bridging the gap between psychiatry and other fields of medicine, it presents the rich fabric of the neuroscience basis of psychotropics.

The NbN application is available on Android and iOS devices free of charge. It is constantly updated based on new scientific insights and feedback. It was designed for daily practice with an entirely searchable database, taking advantage of the multiple axes the classification is built on. Various versions, including NbN and NbN C&A, are suitable for clinicians, while NbN P&F was designed to "translate" the NbN "language" to the public. The NbN website (NbN.science) is also accessible, offering the same databases along with additional information.

33.2 Dopamine Blockers ("Antipsychotics")

33.2a Dopamine Antagonists

MARTIN T. STRASSNIG, M.D., AND PHILIP D. HARVEY, PH.D.

Neuroscience Based Nomenclature (NbN)	
Amisulpiride, fluphenazine, haloperidol, perphenazine, pimozide, sulpiride	
Pharmacologic Domain	Dopamine
Mechanism of action	Receptor antagonists (D2)
Chlorpromazine, loxapine, thioridazine	
Pharmacologic Domain	Dopamine, serotonin
Mechanism of action	Receptor antagonists (D2, 5HT2)

HISTORY

There is now emerging agreement that antipsychotic drugs should be differentiated based on their individual side-effect profiles in addition to their efficacy. 5-HT_{2A} and 5-HT_C inverse agonism (or antagonism), in addition to dopamine D2 antagonism, has been a mainstay of dividing newer from older antipsychotics, but several of the (older) first-generation agents (e.g., clozapine [Clozaril], thioridazine [Mellaril], melperone [Buronil], and cyamemazine) have considerable 5-HT_{2A} antagonism as well, making the distinction less useful. Moreover, it has become increasingly clear that SGAs differ from each other in many properties and are not a homogeneous class either. As a result, the recently proposed Neuroscience-based nomenclature (NbN) aims to realign psychotropics in terms of their pharmacologic properties. For antipsychotics, instead of the

Telegram: @medical_k

www.konkur.in

previously common first-versus second-generation antipsychotics division, their underlying mechanism is emphasized over a disease-specific nomenclature. That is, for “antipsychotics,” dopamine–receptor antagonists and dopamine–serotonin antagonists will henceforth be used. This allows for a mechanism-rather than disease-based classification while also rendering the previous dichotomy of first-versus second-generation antipsychotics obsolete.

Some of the dopamine D2 receptor antagonists are represented among the first group of effective agents for schizophrenia and other psychotic illnesses. They include fluphenazine, haloperidol, amisulpride, pimozide, and perphenazine. Although many of these drugs have gradually been replaced by dopamine–serotonin, serotonin–dopamine, and serotonin–dopamine–norepinephrine antagonists in the United States, dopamine antagonists remain the most commonly prescribed antipsychotics in many parts of the world, and as cost considerations have become more prominent, dopamine D2 receptor antagonists remain frequently prescribed in the United States as well.

These agents are highly effective for nearly all disorders that result in psychotic symptoms. However, these drugs have important limitations: They can cause acute and chronic neurologic symptoms that, especially at higher doses, significantly limit their effectiveness; they are ineffective or only partially effective for a substantial proportion of psychotic patients; the minimally effective dosage has frequently not been determined, and therefore patients may be over-or undermedicated; and they have limited efficacy for some of the most important signs and symptoms of the most common psychotic illness, schizophrenia. In higher dosages, the motor symptoms may induce “secondary” negative symptoms, such as akinesia, emotional blunting, apathy, and cognitive impairment.

Despite their limitations, dopamine blockers have played an important role in the management of psychosis. The modern era of psychopharmacology began with the discovery of chlorpromazine (Thorazine), the first effective antipsychotic, in the early 1950s. The annual increase in state and county mental hospital beds in the United States that had occurred since the beginning of the 20th century reversed sharply after the arrival of antipsychotics. This occurred because most psychotic patients with schizophrenia and other psychotic illnesses became clinically stable enough to be discharged from hospitals after they received drug treatment. Moreover, patients with stabilized illnesses

Telegram: @medical_k

www.konkur.in

became candidates, at least in theory, for psychosocial treatments and rehabilitation. There is also evidence suggesting that treatment with dopamine blockers can improve the long-term course of schizophrenia.

The dopamine blockers have wider applicability than for the treatment of schizophrenia. They are effective for treating psychosis regardless of its cause. As a result, dopamine blockers are utilized for many patients with psychoses associated with physical origins, bipolar illness, major depression with psychotic features, and schizoaffective disorder, predominantly in the acute phases of illness.

The first phenothiazines were the first effective antipsychotic drugs. Drugs from this class were originally used as antihelminthics in veterinary medicine and as urinary antiseptics in humans. In 1950, Paul Charpentier, at the Rhóne-Poulenc Laboratories in Paris, synthesized chlorpromazine, a drug that appeared notable as a mild antihistaminic that was also sedating. Henri Laborit, a surgeon with an interest in drugs that would decrease preoperative anxiety and prevent postsurgical shock, convinced the Rhóne-Poulenc Laboratories of the importance of identifying compounds that would relax patients and make surgical shock less likely. Chlorpromazine appeared to fulfill these criteria, but it also appeared qualitatively different from other sedating drugs. Patients appeared indifferent toward the environment and more tranquil. These properties led Laborit to convince psychiatrists, including Jean Delay and Pierre Deniker, to administer chlorpromazine to patients with mania and schizophrenia. In 1952, these authors reported their observation that chlorpromazine was effective in treating mania and schizophrenia. Within a year, the atmosphere in Paris's psychiatric hospitals had improved substantially. The discovery of chlorpromazine's effectiveness for psychosis represents the beginning of modern psychopharmacology in that it indicated that drugs could have specific effects on the symptoms of mental disorders that went beyond sedation. Moreover, the availability of drugs with direct effects on mental disorders became a powerful tool for laboratory studies with animals, leading to a greater understanding of how drugs affect the brain and information about the nature of the illnesses that were affected.

The use of chlorpromazine was reported by Lehman and Hanrahan from Montreal in 1954, and it rapidly captured the interest of U.S. psychiatrists. In 1955, Henry Brill, the assistant state mental health commissioner in New York, initiated the general use of chlorpromazine and reserpine in state hospitals in that state. Although reserpine was also

Telegram: @medical_k

www.konkur.in

an effective antipsychotic, its side effects led clinicians to prefer chlorpromazine, and, as a result, it is no longer used for treating psychosis because of its side effects, such as depression, suicidality, dysphoria, and orthostatic hypotension.

In 1953, reports surfaced indicating that chlorpromazine could cause neurologic adverse effects, predominantly parkinsonian symptoms. Although some individuals warned that these symptoms were evidence of neural toxicity, others suggested that the dosage should be increased until patients experienced a mild form of parkinsonism, termed the “neuroleptic threshold” dose. Later that year, clinicians noted that chlorpromazine could also result in forms of persistent dyskinesia, a syndrome that would later be called tardive dyskinesia (TD). Thus, information about the side effects of the family of dopamine-blocking medications has been available since their introduction.

The introduction of chlorpromazine, itself a dopamine-serotonin antagonist, was followed by the introduction of other prototypical dopamine D2 antagonists, including the phenothiazines perphenazine (Trilafon) and fluphenazine (Prolixin). In 1958, the first effective butyrophenone, haloperidol (Haldol), was introduced by Paul Janssen from Janssen Pharmaceutica in Beerse, Belgium. The first diphenylbutylpiperidine (Orap) was introduced in 1963. The first long-acting pure dopamine D2 blocker, fluphenazine enanthate, was introduced in the early 1960s. Although this and subsequent long-acting agents, such as haloperidol decanoate, had similar effectiveness and side effects to other antipsychotics, they provided a method for administering an antipsychotic without requiring patients to take daily oral medication, improving treatment adherence and reducing relapse and rehospitalization rates.

CHEMISTRY

The dopamine blockers have historically been referred to by a number of titles, including neuroleptics, major tranquilizers, and antipsychotics (typical or FGAs). The designation neuroleptic was suggested by Deniker, who noted the tendency of these agents to have neurologic side effects and thus appear to “take the neuron,” based on the observation that neurologic side effects are inevitably associated with antipsychotic activity. However, the effectiveness of drugs such as clozapine suggests that

Telegram: @medical_k

www.konkur.in

causing neurologic side effects are not necessary to treat psychosis. Thus, referring to a side effect of these agents rather than the primary clinical effect may be misleading. The term *major tranquilizer* referred to the strange quietness or blandness (or *ataraxia,* Latin) that had been associated with those agents. However, the suggestion that these agents function by their tranquilizing effects is also misleading.

In this section, the dopamine receptor antagonists, per NbN, are classified according to their pharmacologic mechanism (Table 33.2a–1). This new method is probably more useful to clinicians since this classification provides information about the mechanism rather than being entirely disease-based and potentially nonspecific, broadening the therapeutic armamentarium beyond psychosis ("antipsychotics"). The antipsychotic drugs come from a number of chemical classes, each with somewhat different pharmacokinetic properties. The differences can have important effects on the clinical use of the drugs. The phenothiazines benzamides have a somewhat different structure from the butyrophenones and the diphenylbutylpiperidines, which also share similar metabolic pathways. This overview will focus on haloperidol as a representative compound. Since the pharmacokinetics of the long-acting agents differs substantially from the short-acting agents, they are discussed separately.

Table 33.2a–1.
Dopamine D2 Receptor Antagonists: Adverse Effects

Drug Name	Chemical Classification	Therapeutically Equivalent Oral Dosage (mg)	Side Effects			
			Sedation	Autonomic	Extrapyramidal Reactions[a]	Weight Gain
Pimozine Orap	Diphenylbutyrophenone	1.5	+	+	+++	++
Fluphenazine Permitil Prolixin	Phenothiazine; piperazine compound	2	+	+	+++	++
Haloperidol Haldol	Butyrophenone	2	+	+	+++	++
Perphenazine Prolixin+	Phenothiazine; piperazine compound	8	++	+	+++	++
Amisulpride[b]	Benzamine	n/a	+	+++	++	++

+, minimally present; ++, moderately present; +++, present in most patients.
[a]Excluding tardive dyskinesia, which appears to be produced to the same degree and frequency by all agents with equieffective antipsychotic dosage.
[b]Approved in the United States for intravenous postoperative nausea and vomiting.

Phenothiazines

All the phenothiazines have the same three-ring structure with different side chains joined at the nitrogen atom of the middle ring (Fig. 33.2a–1). The activity of the group can be affected by substitutions at position 2 or

Telegram: @medical_k

www.konkur.in

10. The phenothiazines are usually categorized into three classes based on substitutions at position 10. These substitutions have important effects on the pharmacologic characteristics of the phenothiazines. Thus, substituting an *aliphatic* side chain results in a drug with relatively low antipsychotic potency, such as chlorpromazine. These agents also tend to be sedating and cause anticholinergic and hypotensive effects at their effective dosages. Chlorpromazine has a chlorine atom at position 2. If the chlorine atom is eliminated, the resulting drug is promazine (Sparine), a weak antipsychotic. Substituting a *piperidine* ring at position 10 leads to an effective group of antipsychotics characterized by thioridazine and mesoridazine (Serentil). These drugs have similar potency and side effects when compared with the aliphatic phenothiazines. Fluphenazine (Prolixin) and trifluoperazine (Stelazine) are representative antipsychotics with a *piperazine* group substituted at the 10th position. Piperazine phenothiazines have fewer anticholinergic and autonomic effects but a greater affinity for D2 sites and, as a result, produce more EPS. A number of piperazine phenothiazines have been esterified at a free hydroxyl group with ethanoic or decanoic acid to produce injectable long-acting antipsychotics.

Butyrophenones

This class of antipsychotic drugs is characterized by a substituted phenyl ring, which is attached to a carbonyl group attached by a 3-carbon chain to a tertiary amino group. Most of the clinically useful butyrophenones have a piperidine ring attached to the tertiary amino group. Haloperidol is the representative drug for this class. It and other butyrophenones tend to be potent D2 antagonists and have minimal anticholinergic and autonomic effects, resulting in reduced sedation compared to phenothiazines. Haloperidol, a substituted piperidine, is the most commonly used (and oldest) drug in this class. Other important butyrophenones include droperidol (Dropletan), a short-acting, sedating compound that is commonly used to control agitation; and spiperone (Spiroperidol), an agent with very high affinity for D2, 5-HT_{2a}, and 5-HT_{2b} receptors that are commonly utilized for labeling receptors in animal studies and in PET scanning.

Diphenylbutylpiperidines

Telegram: @medical_k

www.konkur.in

This group of agents is similar in structure to the butyrophenones. Pimozide (Orap), the only diphenylbutylpiperidine available in the United States (indication solely for Tourette syndrome), is derived from the butyrophenone benperidol. It has a long half-life: 20 to 26 hours. Doses of 20 mg or higher are associated with seizure risk and QTc prolongation. This agent has been removed from the market for psychotic conditions because of those reasons. Penfluridol (Semap) and fluspirilene (experimental) are antipsychotics from this group that are not available in the United States.

Benzamides

NbN–amisulpiride, sulpiride

Amisulpride (Solian), a sulfur-containing benzamide, has an unusual property in that at lower doses (100 mg to 300 mg a day), it tends to stimulate rather than block dopamine release, producing antidepressant effects, rendering it potentially useful for the treatment of schizophrenia patients with negative symptoms. At higher, standard doses, amisulpride may not have any direct effects on negative symptoms. Amisulpride was not approved by the Food and Drug Administration for use in the United States until February 2020, but it has been used in Europe, Israel, Mexico, India, New Zealand, and Australia to treat psychosis and schizophrenia. Its current U.S. approval is as an intravenous infusion for postoperative nausea and vomiting (10-mg dose).

Thioxanthenes

This group shares a similar three-ring structure with the phenothiazines but has a carbon atom substituted for nitrogen at position 10. Chlorprothixene (Taractan) is an effective low-potency *aliphatic* thioxanthene agent with an antipsychotic potency and a side-effect profile similar to its phenothiazine counterpart, chlorpromazine. Thiothixene (Navane), clopenthixol (Sordinol), and flupenthixol (Depixol) are thioxanthenes with a *piperazine* substitution. Again, their clinical characteristics resemble those of their phenothiazine counterparts. As a result of their double bond at position 10, these agents have geometric isomers, with the *cis* isomers demonstrating greater antipsychotic activity.

Dibenzoxazepines

This class of antipsychotic drugs has a three-ring structure with a seven-member center ring. Loxapine (Loxapac), a dibenzoxazepine, is the only drug from this group that is available in the United States. Clozapine, a dibenzodiazepine, differs from loxapine in having nitrogen instead of an oxygen atom in the middle ring, as well as differences in side chains.

Dihydroindoles

These derivatives are structurally related to serotonin, melatonin, and indole hallucinogens, such as dimethyltryptamine. The only dihydroindole available in the United States was molindone (Moban), the only antipsychotic agent without known weight gain liability. Molindone was temporarily discontinued because of a business decision by its generic manufacturer and was reintroduced in 2018.

PHARMACOLOGIC ACTIONS

Pharmacokinetics

Plasma concentrations of short-acting drugs rise rather rapidly during what is referred to as the absorption phase and then decline during a distribution, metabolic, and elimination phase. Each of these three phases is influenced by different factors related to the chemical structure of the agent (Table 33.2a–2).

Absorption

In general, the dopamine D2-blockers are well-absorbed when they are administered orally or parenterally. As with most drugs, oral administration leads to less predictable absorption than parenteral administration. Liquid concentrates are absorbed slightly more rapidly than pills. Plasma concentrations of the drugs usually reach peak levels 1 to 4 hours after ingestion and 30 to 60 minutes after intramuscular (IM) administration. In general, IM preparations reach their peak concentrations sooner than oral drugs and, as a result, have an earlier onset of action. For example, IM administration of most antipsychotics results in peak plasma levels in about 30 minutes, with clinical effects emerging within 15 to 30 minutes. Oral administration of most FGAs results in a peak plasma level in 1 to 4

Telegram: @medical_k

www.konkur.in

hours. A number of factors can interfere with the GI absorption of these drugs, including antacids, coffee, smoking, and fatty foods.

Drugs usually reach a steady state in about three to five half-lives. Thus, steady-state levels for haloperidol and many other dopamine blockers are reached in about 3 to 5 days since their half-lives are about 24 hours. The bioavailability (i.e., the amount of drug reaching the systemic circulation) is substantially greater—as much as 10-fold—when dopamine D2 blockers are administered parenterally. This difference may result from the incomplete absorption of the drug in the GI tract and from the extensive metabolism of oral drugs during the first pass, mainly through the liver.

Distribution

The initial decline in the plasma concentration of an antipsychotic (or any drug) results primarily from drug distribution into various bodily compartments. Since antipsychotics are highly lipophilic, they tend to accumulate in tissues such as fat, lungs, and brain. Brain levels of antipsychotics tend to be substantially higher than plasma levels. Since plasma and brain levels are in equilibrium, measuring plasma levels is sufficient for estimating brain levels. However, behavioral effects may last substantially longer than the blood levels indicate. For instance, sexual side effects may last for several weeks after the last dose of chronic treatment.

Most dopamine D2 blockers are highly protein bound. For example, more than 90% of drugs such as fluphenazine and haloperidol are bound to plasma protein. The remaining unbound portion is the drug that is available for passing through the blood–brain barrier. In theory, conditions that alter the amount of plasma protein, such as malnutrition, will also alter the amount of bioavailable antipsychotic drugs. This is potentially important for drugs that are protein bound for 98% or more.

Metabolism and Elimination

The metabolism of antipsychotic drugs is largely hepatic and occurs through conjugation with glucuronic acid, hydroxylation, oxidation, demethylation, and sulfoxide formation. Haloperidol has only one major metabolite, reduced haloperidol, which has substantially less antidopaminergic activity than the parent compound. However, reduced

Telegram: @medical_k

www.konkur.in

haloperidol is converted back to the parent compound and, in this manner, may contribute to the antipsychotic activity.

Most dopamine D2 blockers are metabolized by the cytochrome P450 2D6 and P450 3A subfamilies in the liver. Since these same isoenzymes also metabolize a number of drugs that are commonly combined with antipsychotics, a number of important drug–drug interactions are possible. These are discussed in the section on drug–drug interactions.

Patients demonstrate substantial differences in the extent to which they metabolize these compounds. This explains, in part, the marked differences among patients in the oral neuroleptic dosages required for treatment. This, along with differences in absorption, may also explain the 20-fold variation in plasma concentrations that can be found among patients treated with the same dosage of a dopamine D2 blocker.

Table 33.2a–2.
Pharmacokinetics of Selected Dopamine D2 Receptor Blockers

Drug	Bioavailability (%)	Protein-Binding (%)	Vd (L/kg)	Cp 12 hours $t_{1/2}$ (hours)	Active Metabolites	Postdose (ng/mL)
Perphenazine	25	90–95	10–35	8–21	None known	0.5–5.0
Fluphenazine	20–50	90–95	—	14–24	7-Hydroxy	0.2–3.0
Haloperidol	40–70	92	10–35	12–36	Reduced haloperidol	2.0–18.0

Vd, volume of distribution; Cp, concentration in plasma after 12 hours.

The systemic clearance of FGAs is high as the result of a high-hepatic extraction ratio. As a result, only negligible amounts of the unchanged drug are excreted by the kidneys. Phenothiazines and their metabolites are excreted in the urine and feces.

Pharmacokinetics of Long-Acting Antipsychotics

The pharmacokinetics of long-acting injectable antipsychotics differs markedly from those of short-acting oral and injectable drugs. Long-acting fluphenazine and haloperidol are administered as esters dissolved in sesame oil. The oil is injected into a muscle, and the drug gradually diffuses from the oily vehicle into the surrounding tissues. The rate-limiting step appears to be the rate of diffusion since once the drug enters the tissue, it is rapidly hydrolyzed, and the parent compound is released. Long-acting compounds, however, are absorbed continually during the interval between injections. Moreover, for patients who have received

Telegram: @medical_k

www.konkur.in

multiple injections, the drug will be absorbed from multiple injection sites simultaneously. As a result, it takes long-acting compounds much longer to reach a steady state, and they are eliminated much more slowly than their oral counterparts. For example, the decanoate forms of haloperidol and fluphenazine each require about 3 months to reach steady state, and substantial plasma concentrations can be detected up to several months after therapy has been discontinued. This has consequences for prolonged side effects and potentially for TD risk, even after discontinuation of therapy.

Older Adult Patients. Older adult patients require lower-than-usual dosages of dopamine D2-blockers for a number of reasons. These include decreased renal clearance, decreased cardiac output, decreased liver size, and decreased CYP450 enzyme. In addition, older adult patients may be more sensitive to the parkinsonian side effects of the drugs. Recently, dopamine and dopamine-serotonin blockers have been associated with increased mortality risk in older adult patients with dementia.

PHARMACODYNAMICS

The pharmacodynamics of an antipsychotic describes its activity at important sites of action, particularly at its brain receptors. Recent findings in neuroscience have provided important information about the effects of dopamine D2 blockers at a number of different receptor sites, how these effects influence groups of neurons, and how activity at receptors is translated into intracellular events.

MECHANISM OF ACTION OF DOPAMINE RECEPTOR ANTAGONISTS

The Dopamine Hypothesis

The dopamine hypothesis states that antipsychotics reduce psychotic symptoms by decreasing dopamine activity. It was originally proposed by Arvid Carlsson from Sweden and other basic scientists based on the observation that haloperidol and chlorpromazine raised the levels of dopamine metabolites in dopamine-rich areas of the mouse brain, interpreted as dopamine antagonism, and compensation of self-regulating

Telegram: @medical_k

www.konkur.in

systems by increasing dopamine production. Other investigators noted that dopamine D2 blockers (and dopamine-serotonin blockers) inhibit the activation and stereotypical behaviors of rodents induced by amphetamine. This effect has been found to be a reasonably reliable predictor of antipsychotic activity in patients. Moreover, the dose-response relationships in animals provide information about the likely clinical dosage range for patients. These behaviors are thought to be mediated by dopamine and have been used as screening devices to identify compounds that are likely to have clinical efficacy as antipsychotics. Possibly the most convincing but clearly indirect evidence supporting a role of dopamine in psychosis comes from the observation that all drugs—at least to this date—capable of reducing psychosis are also dopamine antagonists, including partial dopamine agonists. Moreover, agents that are associated with increased dopamine activity, such as amphetamine, methylphenidate, or cocaine, tend to worsen symptoms in patients with schizophrenia. At persistent high dosages, these drugs may cause psychosis in individuals without pre-existing psychiatric disorders.

Clozapine	250 × 2	2,500	46	36
Clozapine	250 × 2	1,600	55	52

A role for dopamine in their antipsychotic activity, originally proposed by Carlsson, the Nobel laureate, was given strong support by the work of Solomon Snyder from Johns Hopkins University and Philip Seeman from the University of Toronto in the mid-1970s. Using similar receptor binding methods, both found that the antipsychotic potency of a number of drugs was highly correlated with the drug's affinity for D2 receptors. More recent studies using highly selective D2 receptor ligands and PET indicate that dopamine receptor antagonists are effective when approximately 80% of D2 receptors in the striatum are occupied. Higher occupancy rates may be associated with more parkinsonian side effects without greater effectiveness. In contrast, clozapine is effective when only 40% to 60% of D2 receptors are occupied (Table 33.2a–3). Although it remains unclear why clozapine is effective at lower levels of D2 occupancy, it has been

Telegram: @medical_k

www.konkur.in

suggested that activity at other receptors, particularly 5-HT_{2A} receptors, may contribute to clozapine's clinical activity and to its major active metabolite, *N*-des-methyl clozapine (NDMC), which has partial D2/3 receptor agonist activity in addition to being a strong 5-$HT_{2A/2c}$ inverse agonist (or antagonist). The 5-HT_{2A} antagonism by itself has been suggested to have antipsychotic effects, albeit not as strong as D2/3 antagonism (Fig. 33.2a–2). NMDA receptor agonism at the glycine site may increase its efficacy as well.

Several studies using PET scanning have found that there is no difference in D2 receptor occupancy in the striatum between individuals who respond to an antipsychotic and those who do not. This finding suggests that processes beyond the dopamine receptor affect the response, that dopamine blockade in the striatum is not the mediator of behavior change, or that there are subgroups of patients whose psychosis has origins different from the majority who do respond to treatment.

FIGURE 33.2a–2. Blockage of dopamine release. (From Seeman P, Lee T, Chau-Wong M, Wong K. Antipsychotic drug doses and neuroleptic/dopamine receptors. *Nature.* 1976; 261(5562):717–719, with permission from Springer Nature. doi: 10.1038/261717a0.)

The Effects of Dopamine D2 Blockers on the Dopamine System

Dopamine neurons with cell bodies in the ventral tegmental area (the A_{10} cell group in rat brain) project via the meso-limbo-cortical dopamine system to the nucleus accumbens, amygdala, and the neocortex. Dopamine cells in the substantia nigra (the A_9 cell group) project to the caudate putamen via the nigrostriatal system. It has been proposed that activity in the meso-limbo-cortical system explains the antipsychotic activity of drugs, whereas neurologic side effects such as EPS and TD result from activity in the nigrostriatal system. Thus, drugs with preferential activity at meso-limbo-cortical sites would result in clinical effectiveness with fewer neurologic side effects. However, the reason that the

Telegram: @medical_k

www.konkur.in

dopamine-serotonin blockers have fewer EPS has been attributed to having additional effects on the 5-HT_{2A} receptors, which increases dopamine turnover.

Advances in molecular biology have led to the cloning of a number of dopamine receptor subtypes. The discovery of these subtypes has raised the question of their possible role in the treatment of psychosis. Dopamine receptors can be classified into two groups: D1-like (D1 and D5) and D2-like receptors (D2, D3, D4). Moreover, each of these receptor subtypes may have variants that have the potential to explain heterogeneity in drug responses. As mentioned previously, the antipsychotic potency of dopamine receptor antagonists is highly correlated with their affinity for D2 receptors. This relationship has not been established with other dopamine receptor subtypes. Nevertheless, certain characteristics of receptor subtypes suggest that they may contribute to clinical responses. For example, a role for D4 receptors has been suggested by clozapine's high affinity for this subtype. Unfortunately, multiple attempts to bring selective D4 antagonists to the market have failed for lack of antipsychotic efficacy. The localization of D3 receptors in limbic areas suggests that these subtypes may be clinically important for antipsychotic effects, and some antipsychotics have substantial binding at both D2 and D3. In contrast, D1 receptor blockade may be undesirable, as D1 stimulation in the cortex is associated with better cognitive functioning, and selective D1 antagonists have been reported to cause suicidality.

Studies of the dopamine system in animals and man have suggested important interactions between the subcortical and prefrontal dopamine systems that may affect responses to dopamine blockers. Lesions in the prefrontal cortex of rats' result in increases in dopamine activity in the striatum, suggesting that these two systems have important functional linkages. Similarly, increases in dopamine activity in the prefrontal cortex are associated with decreases in striatal activity. Also, a number of investigators propose that negative symptoms of schizophrenia are associated with decreased dopamine activity in the prefrontal cortex, whereas psychotic symptoms are generated by subcortical increases in dopamine activity in the striatum and temporal lobe. In this model, an effective antipsychotic covering both positive and negative symptoms would increase dopamine activity in prefrontal areas and decrease activity in subcortical areas.

Telegram: @medical_k

www.konkur.in

Other clinical evidence for the role of dopamine in the antipsychotic effects of dopamine receptor antagonists comes from studies of homovanillic acid (HVA), a metabolite of dopamine. In these investigations, changes in plasma HVA after the introduction of an antipsychotic are used to reflect changes in dopamine activity in the brain. These studies indicate that plasma HVA rises soon after patients begin treatment with an antipsychotic and then falls below pretreatment levels in the subset of patients who improve clinically. Moreover, a number of studies indicate that patients with high levels of plasma HVA prior to drug treatment are more likely to improve than those with lower levels. These findings suggest that improvement in an antipsychotic agent is associated with an overall reduction in dopamine activity. Since subcortical areas have the greatest contribution to dopamine activity in the brain, this finding may not reflect cortical dopamine activity.

Studies that monitor the intracellular firing rates of dopamine neurons have also contributed to an improved understanding of the effects of antipsychotics. Chiodo, Grace, and Bunney have reported that the administration of haloperidol to rats resulted in a short-term increase in the firing of midbrain dopamine neurons followed by a prolonged decrease in firing that has been referred to as “depolarization inactivation.” It has been proposed that the antipsychotic effects of these drugs are associated with a decrease in the firing rate. Taken together with the studies of plasma HVA, these findings suggest that for an antipsychotic response to occur, the blockade of D2 receptors is an initial response that must be followed by a decrease in dopamine activity.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Design

Next to chlorpromazine, dopamine D2 blockers were the first specific compounds identified for treating a major mental illness. Their effectiveness, conclusively proven, challenged the views of some clinicians who believed that psychosis was a psychological reaction related to early experiences and that only psychological treatment could have antipsychotic effects. This initial skepticism was valuable in that it helped inspire the development of controlled clinical drug trials aimed at

Telegram: @medical_k

www.konkur.in

demonstrating the effectiveness of medication in treating psychosis. Early studies, such as those initiated by the Department of Veterans Affairs (VA) and the National Institute of Mental Health (NIMH), were influential in establishing objective research methods. One principle, now widely acknowledged, is for an antipsychotic (or any other new drug) to be considered effective; it should yield a better outcome than a placebo. That principle controls for nonspecific improvement that occurs because of a number of factors, such as (1) spontaneous fluctuations in symptoms; (2) the rate of spontaneous improvement for the illness; (3) the expectation of improvement, which is related to starting a new drug; (4) the subject's protection from environmental and psychosocial stresses that may occur with hospitalization; and (5) other environmental factors such as the hospital milieu and psychological treatments that can lead to improvement.

Two other principles that reduce sources of bias are random assignment to a treatment group and double-blind evaluation methods. Random assignment ensures that differences in outcome between the groups (usually between those receiving a drug and those receiving a placebo or between two different active groups) are not attributable to patients with different expected outcomes or drug responses being assigned to one group. An example would be a study in which patients who are more severely ill are assigned to a particular group or if patients who are predicted to improve spontaneously are assigned preferentially to the drug group rather than the placebo group. Double-blind methods were developed to ensure that bias by patients or by those who evaluate the outcome does not influence the study. For example, a person who performs a clinical rating may be prejudiced toward rating patients who are receiving a drug as more improved than patients who are receiving a placebo. Double-blind methods also protect against bias in the manner in which treatment is administered. For example, a treating clinician may give more attention to a patient who is receiving a certain drug.

A number of modifications in trial methods have been developed since the first studies aimed at treating psychosis, although the principles of random assignment and blindness remain important. For example, treating acutely ill patients with schizophrenia with dopamine D2 blockers has become a standard of care and has led some to question the ethical use of placebos when effective treatments are available. Alternative methods for demonstrating the efficacy of a compound have included

Telegram: @medical_k

www.konkur.in

showing that it is as effective as an antipsychotic agent with proven efficacy or showing that a dosage thought to be subtherapeutic is less effective than a higher dosage. Since maintaining unawareness of treatment assignments is often difficult to preserve when a drug has known side effects, active placebos with side effects but without CNS effects have been used. However, inexperienced evaluators tend to overinterpret side effects as being secondary to active treatment rather than to active placebo, which also is associated with similar side effects, even if less frequent. Recent research has indicated that high interrater reliability and centralized ratings may decrease variance even further, while the increased number of sites and more rating scales, raters, and rater changes may increase variance and therefore decrease the likelihood of separation from placebo.

INTERPRETATION

Acute Psychosis

Numerous double-blind clinical trials have demonstrated that dopamine D2 blockers are more effective than placebo for reducing symptoms of psychosis. The initial studies were carried out in the 1960s by the NIMH, reviewed by Donald Klein and John Davis, who concluded that with the exception of mepazine (Pacatal) and promazine, all of these agents were effective. These and subsequent studies also demonstrated that antipsychotics are effective for every subgroup of patients with schizophrenia. In 2009, the Schizophrenia Patient Outcomes Research Team (PORT) updated prior reviews and concluded that there is clear evidence that dopamine D2 blockers are effective for reducing positive symptoms during acute psychotic episodes. PORT recommendations also suggest that choosing antipsychotics should be based on individual preference, prior treatment response and adherence history, medical history and risk factors, the individual medication's side-effect profile, and long-term treatment planning. Studies found that amisulpride can be safely administered at an optimal dose immediately, not needing a titration phase and thereby aiding in acute symptom control.

Controlled clinical trials have demonstrated that dopamine D2 blockers are effective in reducing psychotic symptoms, such as hallucinations and paranoid ideation, to a greater extent than anxiety and depression. Improvements individual patient experiences on these agents vary

Telegram: @medical_k

www.konkur.in

considerably. For many patients, dopamine D2 blockers can lead to a complete remission of psychotic symptoms. The early studies from the NIMH indicate that 60% of drug-treated patients improved to the extent that they achieved a complete remission (albeit temporarily) or experienced only mild symptoms; the remaining 40% will continue to experience psychotic symptoms, and approximately 8% of them are not improved with drug treatment. A comprehensive meta-analysis published in 2019 in JAMA that compared 32 oral antipsychotics showed that amisulpride was the second most effective antipsychotic at reducing overall symptoms in schizophrenia patients (behind clozapine) and the most effective in terms of reducing positive symptoms. The analysis also ranked amisulpride better than clozapine in terms of tolerability and side effects.

Positive psychotic symptoms, which include hallucinations and delusions, are more responsive to dopamine D2 receptor antagonists than are negative symptoms, such as blunted affect, emotional withdrawal, and lack of social or vocational interest, or disorganized symptoms, such as impaired attention and impaired communication. Although these latter two groups of symptoms are less responsive than psychotic symptoms, double-blind studies indicate that these symptoms improve to some degree. Amisulpride, at lower doses, tends to stimulate rather than block dopamine release, producing antidepressant effects, rendering it potentially useful for the treatment of schizophrenia patients with negative symptoms. EPS can cause secondary negative symptoms, compounding symptom burden. Patients with parkinsonism may demonstrate fewer expressive gestures and diminished interest in their environment. Anticholinergic antiparkinsonian medications, aimed at mitigating parkinsonian and other EPS symptoms, sometimes recommended prophylactically when used with dopamine D2 receptor antagonists, have been consistently shown to impair memory in patients who require these drugs, while EPS may worsen cognitive test scores that require intact motor function.

As a group, women tend to respond better and to require lower dosages than men. Unfortunately, there are no biologic or clinical indicators that can be used to predict treatment response other than the patient's prior responses.

The time course of treatment response in acute psychosis has been studied in some detail. Most patients who manifest an eventual positive

Telegram: @medical_k

www.konkur.in

response to dopamine D2 blocker treatment manifest improvements in their psychotic symptoms very early after the initiation of treatment. Studies have shown that by 3 or 7 days, eventual responders are showing detectable changes in symptoms. It has been reported that the maximum treatment gains with dopamine D2 blockers occur by 2 weeks, and there is little evidence of delayed onset.

Maintenance Therapy

A number of studies have compared dopamine D2 blockers to placebos for preventing relapse in patients who have been stabilized following a psychotic episode. These studies provide strong support for continuing these medications when patients have recovered from a psychotic episode. A review of 24 double-blind studies of maintenance antipsychotic therapy found that in all studies, many more patients relapsed when they were not receiving an active drug. A meta-analysis that included most of these studies reported that approximately 72% of patients will relapse in a year on placebo compared to only 23% on a conventional antipsychotic. A more recent review cited 66 studies in which antipsychotics were withdrawn. The mean relapse rate was 53% for patients withdrawn from medication, and 16% for patients maintained on an antipsychotic. The more robust the remission prior to discontinuation (the lower the psychosis ratings) is, the longer the time until relapse.

A number of investigations have focused on the usefulness of continuing medication for patients who have recovered from a first episode of schizophrenia. Again, maintenance medication showed a substantial advantage, although relapse rates were lower for remitted first-episode patients when compared to multiepisode patients. Other studies indicate that patients who have been well and stable on an antipsychotic for years have a high likelihood of relapse when their medications are discontinued.

Earlier studies by Donald Johnson suggest other advantages for maintenance of antipsychotics in schizophrenia. He found that patients who relapsed when they were receiving dopamine D2 blockers had episodes that were less severe than those in patients who had discontinued their drugs. Drug-maintained patients were less likely to have episodes of self-destructive behaviors, violence, and antisocial acts when compared with patients who were not receiving medication. Patients who were not receiving medication were also more likely to require

Telegram: @medical_k

www.konkur.in

involuntary hospitalization. Patients who discontinued their medications ended up, on average, receiving more total medication over time because the dosage needed to treat acute relapses is much higher than the dosages usually prescribed for preventing relapse. Many of these findings have since been replicated. The common denominator is that maintenance therapy with antipsychotics benefits patients with schizophrenia and substantially reduces relapse risk and reduces hospitalization rates. Depot antipsychotics appear to be more effective for relapse prevention than oral medications. This would suggest there is a more prominent place for depot antipsychotics in relapse prevention in schizophrenia, including haloperidol and fluphenazine decanoate. One recent study pointed out that there was no difference in relapse rates between the long-acting dopamine D2 blocker haloperidol and dopamine–serotonin blocker paliperidone over 24 months, although side effects rates differed. Haloperidol decanoate caused more and more frequent EPS, while paliperidone palmitate caused more hyperprolactinemia (McEvoy et al., 2014).

Medication compliance is a serious problem for patients with schizophrenia, with up to 50% of patients failing to comply with recommended (oral) treatments. Importantly, only a fraction of new patients adheres to their initial antipsychotic medication after their first hospitalization, with some estimates as high as 95% over a multiyear period. A substantial proportion never even collect their initial prescription; the initiation of depot antipsychotics during hospitalization significantly reduces rehospitalization rates as compared to oral antipsychotics.

A number of statistics also indicate the limitations of pharmacotherapy for chronic schizophrenia. Even among treatment responders, as many as 40% are permanently disabled, and most of the other patients fail to recover to a full extent. In addition, more than 80% of patients are not fully employed and require public support. In large cities, individuals with schizophrenia comprise 14% to 50% of the homeless population. The rate of completed suicide is about 10%, with suicidal ideation and suicide attempts occurring in 70% or more of cases, and the mortality rate is increased due to greater accident proneness.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

Effects of Dopamine D2-Blockers on Motor Systems

Telegram: @medical_k

www.konkur.in

Animals administered high doses of a dopamine receptor antagonist develop a syndrome consisting of immobility, increased muscle tone, and abnormal postures called catalepsy. In addition, these agents decrease spontaneous motor activity in rodents. These motor effects in animals and humans are caused by dopamine receptor blockade in the striatum and the substantia nigra.

In humans, all dopamine D2-blockers produce EPS, in line with their antipsychotic potency, including parkinsonism (i.e., stiffness, akinesia, bradykinesia, tremor, and shuffling gait), dystonia (i.e., abrupt onset, sometimes bizarre muscular spasms affecting mainly the musculature of the head and neck), and akathisia (with objective and subjective restlessness). These effects differ from antipsychotic effects in that they have a more rapid onset and are potentially amenable to adjunct treatment. In addition, prolonged treatment with dopamine receptor antagonists can lead to the development of late-appearing abnormal movements of TD. Both short- and long-term motor effects in patients are discussed in a later section.

Neuroendocrine Effects

Antipsychotic drugs influence the secretion of hormones in the pituitary and elsewhere mainly due to their blockade of dopamine receptors. Prolactin secretion is tonically inhibited by dopamine in the pituitary gland. As a result, dopamine receptor antagonists can increase serum prolactin concentration in the clinical dosage range, in line with their antipsychotic potency. This elevation sometimes produces gynecomastia, galactorrhea, and erectile dysfunction in men. Dopamine D2-blockers also suppress levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). These changes can lead to amenorrhea and inhibition of orgasms in women. There is also evidence indicating that Dopamine D2-blockers such as Haloperidol can inhibit the release of growth hormone (GH).

THERAPEUTIC INDICATIONS

Indications for dopamine receptor antagonists are shown in Table 33.2a–4.

Acute Psychotic Episodes in Schizophrenia and Schizoaffective Disorder

Telegram: @medical_k

www.konkur.in

Schizophrenia is usually an illness that is characterized by periods of relapse and remission. Acute psychotic episodes are usually identified as periods during which patients demonstrate the emergence or worsening of positive or disorganized symptoms of schizophrenia, such as hallucinations, delusions, and disorganized behavior and communication.

Attention has focused on whether dopamine D2 blockers should be considered the preferred antipsychotics for acute episodes of schizophrenia. This issue was considered by a group of experts who met in 2001 to consider important issues in the pharmacotherapy of schizophrenia. The consensus opinion at that time was that dopamine–serotonin blockers should be favored over dopamine D2 blockers for first-episode patients or when a history of drug responses was unavailable. The group supported the use of dopamine D2 blockers over dopamine–serotonin blockers for patients who have responded well to dopamine D2 blockers without experiencing EPS; for patients who have responded better to dopamine D2 blockers than dopamine–serotonin blockers; and for patients who respond better to depot forms of dopamine D2 blockers.

Between 2005 and 2007, the results of large multicenter clinical trials provided important information about the relative effectiveness and side effects of dopamine D2- and dopamine–serotonin blockers. These results

Telegram: @medical_k

www.konkur.in

challenged the view of some that the newer agents were more effective and had fewer adverse effects than their predecessors. The most important studies were a NIMH trial known as CATIE (Clinical Antipsychotic Trial of Intervention Effectiveness), a randomized open trial from the United Kingdom National Health Service known as CUtLASS (Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study), and EUFEST (European First Episode Schizophrenia Trial), another randomized open trial completed in Europe. These trials are important because they were each relatively large for a nonpharmaceutical drug study, and they were neither sponsored nor designed by pharmaceutical company sponsors.

The first phase of CATIE compared the dopamine–serotonin blockers, olanzapine (Zyprexa; 7.5 to 30 mg per day), ziprasidone (Geodon; 40 to 160 mg per day), quetiapine (Seroquel; 200 to 800 mg per day) and the dopamine—serotonin–norepinephrine antagonist risperidone (Risperdal; 1.5 to 6.0 mg per day), to one dopamine-D2 antagonist, perphenazine (8 to 32 mg per day), a midpotency phenothiazine. The subjects were 1,493 patients with schizophrenia who, on average, were in their 40s and who had been ill for more than 14 years. The primary outcome was the time that patients remained on their assigned drug. The results, reported by Jeffrey Lieberman and coworkers in 2005, demonstrated similar efficacy of all drugs in terms of time to discontinuation. However, patients with TD were excluded from the perphenazine group, which may have given this agent an advantage. Patients treated with perphenazine were more likely to discontinue their medications for EPS, even with the exclusion of participants with TD. Patients receiving clozapine and olanzapine experienced weight gain and lipid elevations. Despite modest prolactin elevation, risperidone was the best-tolerated antipsychotic. The trial was too brief to compare the risk of TD among the different agents.

CUtLASS randomized 227 patients to either a dopamine–blocker, dopamine–serotonin blocker, or dopamine–serotonin–norepinephrine blocker. Prior to randomization, the patient's psychiatrist selected the drug that the patient would be assigned. The results were published in a report by Peter Jones and coworkers. There was no significant difference in scores on the Quality-of-Life Scale, the primary outcome instrument. Moreover, there were trends suggesting advantages for the dopamine D2 blockers. The size of the sample was too small to compare the effectiveness of individual antipsychotics.

Telegram: @medical_k

www.konkur.in

EUFEST compared several dopamine–serotonin blockers, olanzapine, quetiapine, ziprasidone with a low dose (1 to 4 mg) of the high-potency Dopamine D2 blockers haloperidol and amisulpride in the treatment of first-episode schizophrenia. The pragmatic trial found high-discontinuation rates (highest with haloperidol), and symptom reductions and rehospitalization rates were virtually the same in all groups. Alongside olanzapine, amisulpride had the lowest rates of discontinuation for any reason across an entire year. The results of these trials do not mean that older and newer antipsychotics are equivalent in their side-effect profiles. The differences in EPS liability may have been underestimated in CATIE. First, eliminating patients with evidence of TD may have excluded those who were most vulnerable to discomforting EPS side effects. Moreover, while there were no differences in EPS ratings for parkinsonism and akathisia between perphenazine and the SGAs, it is interesting to note that the higher rate of discontinuations for EPS among the perphenazine-treated patients suggests that ratings may not have been adequately sensitive. However, most of the studies documenting large differences between these drugs may have used what would now be considered excessive doses of haloperidol, a drug with an incidence of EPS, which may have exaggerated the difference between the two types of agents.

The current body evidence does not support the earlier belief that the dopamine–serotonin or dopamine–serotonin–norepinephrine blockers are more effective than dopamine D2 blockers. However, the dopamine D2 blockers are more likely to cause EPS and, as noted below, are probably more likely to cause TD. Perhaps dopamine D2 blockers should be prescribed in lower dosages than historical uses. If patients are treated with dopamine D2 blockers, they should be regularly monitored for EPS, particularly drug-induced parkinsonism and akathisia, and they should be assessed for evidence of TD.

Maintenance Treatment in Schizophrenia and Schizoaffective Disorders

Dopamine D2 blockers are effective in decreasing the risk of psychotic relapse in patients who have recovered from a psychotic episode. National and international guidelines indicate that after the acute phase of treatment for a first episode, treatment should continue for at least 1 year, but there is no consensus regarding the total duration of treatment, if the patient remains symptomatic. In case of multiple episodes, maintenance

Telegram: @medical_k

www.konkur.in

treatment should be continued for at least 3 to 5 years and often indefinitely.

Mania

Dopamine receptor antagonists are effective for reducing excitement and psychotic symptoms in mania. Dopamine D2 receptor antagonists tend to have a more rapid onset of action than antimanic drugs, including lithium (Eskalith), valproic acid (Depakene) (divalproex [Depakote]), and carbamazepine (Tegretol). This observation has led to the widespread practice of combining antipsychotic and antimanic drugs during the first days of treatment of severe excited states before the antimanic compound has its onset of action. When the antimanic compound has become effective, the dosage of the antipsychotic can usually be reduced, or the drug can be discontinued. Although there is only limited evidence supporting the use of dopamine D2 receptor antagonists for the long-term management of bipolar mood disorder, it is common clinical practice to manage some patients with severe illness with maintenance antipsychotics combined with antimanic agents. Some studies indicate that patients with mood disorders are more vulnerable to developing TD than schizophrenia patients, suggesting the importance of using dopamine D2 receptor antagonists as briefly as possible and only when clearly indicated. The advent of dopamine–serotonin antagonists has preempted these arguments because some of these agents are approved for acute, as well as maintenance treatment of bipolar disorder and are also commonly available as generic medications.

Depression with Psychotic Symptoms

Patients with major depressive disorder may develop psychotic symptoms such as hallucinations or delusions. These patients tend to demonstrate a more robust improvement when an antipsychotic is added to an antidepressant agent. Although most studies have focused on perphenazine, fluphenazine, and haloperidol, there is no evidence that any single dopamine receptor antagonist is more or less effective than any other for this indication, barring side-effect considerations. The added benefits of dopamine D2 receptor antagonists are most apparent for those patients who are tormented by severe delusions. When the psychotic symptoms have remitted, the antipsychotic should be withdrawn.

Telegram: @medical_k

www.konkur.in

Delusional Disorder

Delusional disorder is characterized mostly by “nonbizarre” delusions, that is, delusions that are within the realm of possibility for the patient. Moreover, patients rarely hallucinate, and their behavior is rarely bizarre. Patients with delusional disorder will often demonstrate substantial improvement when they are treated with a dopamine receptor antagonist.

Borderline Personality Disorder

Borderline personality disorder is characterized by a pervasive pattern of instability that affects mood, interpersonal relationships, and self-image. Some patients with severe forms of this disorder may experience transient psychotic states, particularly when they are under stress. These states may be characterized by suspiciousness, ideas of reference, impulsiveness, and aggressiveness.

Low dosages of haloperidol have been found to be effective in some of these patients, although there is no evidence indicating that other dopamine D2 blockers are less effective. Unfortunately, most trials have been relatively brief, and it is unclear how medications affect the overall course of this disorder and how medications interact with psychotherapeutic management that these patients usually require.

Substance-Induced Psychotic Disorder

A number of drugs, including amphetamines, cocaine, alcohol, and phencyclidine, can cause psychotic symptoms that occur while the patient is intoxicated or during drug withdrawal. These symptoms are usually time-limited and remit within hours or days, depending on the concentration of drug ingested and the rate of elimination. Dopamine D2 blockers may reduce these substance-induced psychotic symptoms, reducing dangerous behaviors or unusual suffering. Benzodiazepines may be helpful in calming the patient until psychotic symptoms remit. Some authors recommend prescribing benzodiazepines rather than dopamine receptor antagonists for phencyclidine intoxication. In some circumstances, it may be helpful to follow the patient’s untreated course in order to differentiate drug-induced syndromes from schizophrenia or bipolar disorder.

Dopamine D2 receptor antagonists are also useful for patients with hallucinations or delusions that occur with alcoholism, particularly for

Telegram: @medical_k

www.konkur.in

chronic alcoholic hallucinosis. Benzodiazepines are more appropriate than antipsychotics for uncomplicated alcohol withdrawal, and dopamine receptor antagonists can be prescribed as an adjunct, if withdrawal delirium develops. However, dopamine receptor antagonists should be prescribed carefully since these drugs may increase the likelihood of seizures that occur during alcohol withdrawal.

Impulse Control Disorders

There is a long-standing but controversial practice of prescribing dopamine receptor antagonists for individuals with extremely poor impulse control and a propensity for violent behavior. This practice is not supported by controlled clinical trials and may be appropriate only when other measures such as the use of SSRIs, carbamazepine, lithium, or β-blockers have failed. In such instances, non–weight gain–inducing dopamine–serotonin and dopamine–serotonin–norepinephrine antagonists may be more appropriate.

Delirium and Dementia

Low doses of high-potency dopamine D2 receptor blockers, especially if administered intravenously, can be useful in the treatment of the psychotic symptoms and agitation associated with delirium that may be due to organic conditions. Interactions with the anticholinergic properties of low-potency drugs may exacerbate or prolong toxic deliriums caused by anticholinergic agents.

Dopamine D2 receptor blockers can be useful for reducing agitation and psychotic symptoms that are related to dementia, Wernicke syndrome, and Korsakoff syndrome. A number of carefully done double-blind studies have found that dopamine D2 receptor blockers are superior to placebo for treating agitated older adult patients. A review by Janicak found that 66% of geriatric patients with “organic” psychosis improved on an antipsychotic compared to 35% who improved on a placebo. Low dosages of dopamine blockers are usually preferable for older adult patients with dementia. The treatment of older adult patients is complicated since many take multiple medications and are vulnerable to drug–drug interactions, hypotension, and falling episodes, as well as an added anticholinergic burden. Nevertheless, the adverse effects of these drugs should be weighed against the dangers of agitation in older adult patients. Clinicians should be aware that akathisia can present itself as agitation in these

Telegram: @medical_k

www.konkur.in

patients and that the risk of TD is markedly increased with extended dopamine-blocking treatment in older patients.

Childhood Schizophrenia

Schizophrenia infrequently has its onset during childhood (before age 17). Termed early onset schizophrenia (EOS) and associated with higher rates of premorbid abnormalities, children with schizophrenia may have symptoms that are similar to those in adults with schizophrenia, with a similar thought disorder and perceptual abnormalities but the reduced occurrence of systematized delusions. Clinical experience indicates that children improve with antipsychotics, and there are a number of controlled trials available to demonstrate this effect. It is particularly important to treat children with the lowest effective dosage of an antipsychotic because of increased vulnerability to side effects. Children are more prone to developing extrapyramidal symptoms associated with dopamine D2 receptor antagonists but are also more likely to experience weight gain and metabolic abnormalities with these agents. Antipsychotic drugs may impair learning in this population.

Pervasive Developmental Disorder

Patients with pervasive developmental disorders may demonstrate periods of hyperactivity, screaming, and agitation with combativeness. Although there are few controlled studies for this disorder, patients tend to improve with dopamine D2-blocking agents. Since these agents may impair learning, there is concern that they are overprescribed in some settings.

Tourette Syndrome

Tourette syndrome is a neurobehavioral disorder that is associated with motor and vocal tics. Motor tics may involve a single muscle group or several, thus appearing as purposeful movements. Similarly, vocal tics may involve an inarticulate sound or actual words. Often the words are socially inappropriate or even obscene. Milder tics may not require pharmacotherapy. However, when the tics are disabling, antipsychotic medication can be effective in reducing the severity of both motor and vocal tics. Although haloperidol and pimozide are the most commonly

Telegram: @medical_k

www.konkur.in

used agents, there is little evidence indicating that other agents are less effective.

Huntington Disease

Huntington disease is a genetically transmitted disease that follows an autosomal dominant type of heritability with 100% penetrance. The median age of onset is 35 to 40 years, but childhood onset (high number of CAG repeats) and much later onsets also occur. Once the diagnosis is made, death will follow in 15 to 20 years. Patients who eventually develop Huntington disease may display psychiatric symptoms and cognitive impairment years before the diagnosis of Huntington disease is made. The most common psychiatric symptoms are cognitive impairment, depression, irritability, apathy, obsessive-compulsive symptoms, and suicidality. These may progress to a psychotic delusional state or sometimes are followed by manic or hypomanic episodes. Some individuals may demonstrate symptoms that closely resemble schizophrenia with delusions and hallucinations (less than 10%).

Dopamine, dopamine–serotonin, and dopamine–serotonin–norepinephrine blockers are believed to be useful during the early stages of the illness to reduce chorea. However, double-blind studies are lacking. They also may be effective in managing irritability, paranoia, hallucinations, violent tendencies, and bizarre behaviors. Dopamine D2 blockers are usually preferred, but all agents appear to be effective. Clinicians should be aware of acute EPS, particularly in the rigid forms of the disorder. There is no dosing guidance. At present, it is believed that the long-term benefit does not merit their use, particularly as TD, other EPS, and akathisia may resemble Huntington disease's later-stage symptomatology. Recently, the FDA-approved tetrabenazine (Xenazine, an amine depletor, like reserpine) for the treatment of chorea in Huntington disease. Tetrabenazine should not be used to prevent the occurrence of choreoathetotic symptoms, as there is evidence that tetrabenazine has no neuroprotective benefits. However, dysphoria, depression, suicidality, and dysphagia have been noted. Deutetrabenazine (Austedo) is currently approved for the treatment of Huntington disease-associated chorea. No long-term studies are available.

Parkinson Psychosis and Lewy Body Disease

Telegram: @medical_k

www.konkur.in

Dopamine blockers are contraindicated in these conditions because they have the potential to markedly worsen parkinsonian syndromes and may lead to precipitous dystonic reactions.

Psychiatric Disorders Due to a Medical Condition

Dopamine receptor antagonists are effective for a broad range of medical conditions that result in psychosis. This category includes endocrinopathies and psychoses associated with temporal lobe epilepsy. Dopamine receptor antagonists are also helpful for patients with psychotic symptoms that can result from steroids.

Other Indications

Antipsychotics are also effective for treating ballismus, an illness characterized by abnormal activity of the axial and proximal musculature. Because of their antiemetic effects, dopamine receptor antagonists are sometimes prescribed for severe emesis associated with chemotherapy or postsurgical nausea. Patients with intractable hiccups are sometimes aided by dopamine receptor antagonists. Metoclopramide (Reglan), a dopamine receptor antagonist, is commonly prescribed for patients with gastroesophageal reflux and delayed gastric emptying. For obvious reasons, psychosis associated with Parkinson disease cannot be treated with these agents.

www.konkur.in

Neurologic Side Effects

The most serious side effects of dopamine receptor antagonists are neurologic and are largely confined to the extrapyramidal motor system (Table 33.2a–5). These EPS are, in turn, separated into acute effects that occur in the first days or weeks of treatment and chronic effects that occur after patients have received medications for months or years.

Acute Extrapyramidal Syndromes

All the dopamine receptor antagonists are associated with EPS. Since EPS, particularly parkinsonism, is believed to be caused by decreased dopamine activity in the basal ganglia, it suggests that this toxic effect is inescapable given that blockade of D2 receptors is associated with the antipsychotic effect of these agents. EPS correlate with their affinity for D2 receptors in the basal ganglia. Acute EPS, which includes dystonia, akathisia, and drug-induced parkinsonism, have their onset relatively soon after the initiation of antipsychotic drug treatment. They remit soon after the drugs are discontinued. In contrast, tardive EPS syndromes occur after months of treatment and commonly persist after medications are discontinued.

Akathisia. Akathisia comes from the Greek word *akathizein,* which means inability to sit still. It is the most common acute manifestation of EPS and often the most distressing. One study found that 41% of patients treated with a dopamine antagonist had mild akathisia, and an additional 21% had moderate to severe akathisia. The most common clinical manifestations consist of shifting the weight from foot to foot, walking on the spot, inability to keep the legs still, feelings of inner restlessness, and the shifting of body positions in a chair. Patients with akathisia may describe a compelling urge to walk or to initiate movement. In mild cases, patients may experience a subjective feeling of restlessness but not show increased motor activity. Akathisia may appear on the second or third day of antipsychotic treatment but more frequently has its onset after 5 days.

Differentiating akathisia from behaviors that are related to the psychotic illness may be difficult. Feelings of restlessness or agitation may result in irritability or anxiety, or even aggressive behavior. Psychotic patients with akathisia may appear more hostile or belligerent. This could lead clinicians to incorrectly conclude that the patient requires an increase in medication, which, in turn, could worsen this side effect. Akathisia is also

Telegram: @medical_k

www.konkur.in

thought to be a correlate of poor antipsychotic drug response. The use of these agents by inexperienced practitioners in nursing homes may lead to behavior deterioration.

Acute Dystonia. Acute dystonia consists of intermittent and sustained spasms of the muscles of the head and the neck, leading to involuntary movements. They can be experienced as the most frightening side effect of dopamine blockers, particularly when patients experience the sudden onset of what may appear to be a form of paralysis.

Ten percent of drug-induced dystonia occurs during the first hours of drug treatment, and 90% occurs within the first 3 days. Common types of dystonia include opisthotonos, a rigid contraction of the back muscles with arching; retrocollis and torticollis of the neck; oculogyric crisis, a spasm in which an eye or both eyes are turned upward; macroglossia and tongue protrusion, which can lead to choking; and laryngeal dystonia. Rarely, dystonia of laryngeal or pharyngeal muscles can lead to sudden death.

Younger patients, particularly young males, are more likely to develop dystonia. They are more common when patients are treated with large dosages of dopamine blockers. Dystonia almost always respond rapidly to antiparkinsonian medications and can usually be prevented by either pretreatment with antiparkinsonian medications or by limiting the antipsychotic dosage prescribed.

Drug-Induced Parkinsonism. Patients on dopamine receptor antagonists may experience all the common motor symptoms of idiopathic parkinsonism, including rigidity, bradykinesia, shuffling gait, and tremor. These side effects commonly occur during the first 5 to 30 days of treatment and may persist until the dosage is lowered, treatment is initiated, or dopamine blockers are discontinued. The examination will usually reveal a positive glabella tap. The first evidence of drug-induced parkinsonism may be a diminished arm swing or decreased facial expressiveness. Risk factors for drug-induced parkinsonism include increasing age, dosage, a history of parkinsonism, and underlying basal ganglia damage (e.g., vascular insult).

In its milder forms, drug-induced parkinsonism may appear as a decrease in spontaneous gestures, a masked facial expression, apathy, unspontaneous speech, and difficulty in initiating usual activities, so-called akinesia. These symptoms may be difficult to distinguish from the negative or deficit symptoms of schizophrenia. Patients with akinesia may

Telegram: @medical_k

www.konkur.in

also appear to be depressed. The tendency of patients with akinesia to not cross their legs can be helpful in diagnosing this side effect.

Management of Acute Extrapyramidal Syndromes

Anticholinergic agents are the most effective treatment of EPS. For acute dystonias, IM or intravenous (IV) diphenhydramine (Benadryl) (50 mg, 25 mg in children) or IM or IV benztropine (Cogentin) (0.5 to 2 mg IM or IV) or other anticholinergics alleviate this uncomfortable and often frightening side effect within minutes after the drug enters the bloodstream. Oral anticholinergic agents are usually prescribed for the management of parkinsonism and often for akathisia. Reducing the dosage of the antipsychotic is often effective, but it is common for patients to experience EPS at the minimum dosage that is needed to manage psychosis. Amantadine (Symmetrel), an antiviral agent that affects dopamine release, is also effective in reducing most EPS. This antiviral agent should not be used for this indication as a first-line agent. Direct dopamine agonists (e.g., bromocriptine [Parlodel]) and indirect dopamine agonists (e.g., levodopa [Dopar]) are not preferred, as they may aggravate psychotic symptoms.

Anticholinergics are frequently, but not always, effective for treating akathisia. β-Blockers, particularly propranolol (Inderal; 10 to 80 mg a day), have been found to be effective for treating akathisia and are preferred by many clinicians. The effectiveness of β-blockers may result from akathisia being a disturbance in the normal balance between dopamine and norepinephrine. Studies have shown that 5-HT_{2A} antagonists can reduce haloperidol-induced akathisia.

Anticholinergic antiparkinsonian medications should be prescribed with caution in combination with low-potency FGAs and some antidepressants since the combined anticholinergic activity may lead to a number of side effects, including hyperthermia and delirium. A sustained tachycardia may also occur. Further caution is warranted in the use of these agents in individuals with glaucoma, ileus, urinary retention, or prostatic hypertrophy. Because many over-the-counter cold remedies, sedatives, and sleep aids contain anticholinergic agents and antihistamines, patients should be warned about the interaction between these agents and anticholinergic antiparkinsonian drugs.

Some controversy has arisen about the appropriateness of prescribing antiparkinsonian medications prophylactically when dopamine blockers

Telegram: @medical_k

www.konkur.in

are started. Reports indicate that 30% to 50% of patients receiving long-term treatment do not need anticholinergics. In 1990, the World Health Organization (WHO) published a consensus statement on the use of anticholinergics in patients receiving long-term antipsychotic treatment. The statement argued against the prophylactic use of these agents because of some of their side effects (e.g., the possible worsening of TD, the risk of anticholinergic toxicity, the impairment in memory, and the possible pharmacokinetic interactions with the primary treatment agent). The consensus group concluded that anticholinergics are overprescribed, that they should be given only as needed, and side effects should be treated first by lowering the antipsychotic dosage or by using other agents. However, reports indicate that anticholinergics may be helpful in managing forms of EPS that may not be obvious to the clinician and side effects. That is, milder forms of akathisia may appear as anxiety or irritability, and milder forms of akinesia may appear as negative symptoms such as decreased motivation and a lack of affect. In these individuals, long-term anticholinergics may be useful for optimal pharmacotherapy.

There are other circumstances in which prophylactic antiparkinsonian medications may be helpful. Because of the discomfort and anxiety associated with acute dystonia, prophylaxis is prudent when there is a substantial risk of this side effect, for example, when young patients are treated with high-potency dopamine blockers. Some patients and staff may interpret dystonia as evidence that they are allergic to a particular drug, which may lead to drug refusal and an “allergy” label in the patient chart. Prudent practice may include using prophylactic antiparkinsonian drugs in high-risk patients, with a gradual lowering of the dosage of this drug with regular evaluations for obvious and subtle manifestations of EPS over a 2- to 3-month period.

The availability of serotonin–dopamine antagonists, provides an important alternative for patients with EPS. Symptoms of acute EPS that cannot be adequately controlled with dosage reduction or an adjunctive medication will probably improve, if they are changed to a serotonin dopamine antagonist.

Neuroleptic Malignant Syndrome. NMS is an uncommon but potentially fatal complication of dopamine-blocking agents. Its main clinical features include (1) hyperthermia; (2) severe muscular rigidity; (3) autonomic instability, including hyperthermia, tachycardia, increased blood

Telegram: @medical_k

www.konkur.in

pressure, tachypnea, and diaphoresis; and (4) changing levels of consciousness. It usually presents as muscular rigidity and progresses to elevated temperature, fluctuating consciousness, and unstable vital signs. These symptoms are often associated with elevations in creatine phosphokinase (CPK) and aldolase. Less common are elevations in liver transaminases, leukocytosis, myoglobinemia, and myoglobinuria. Acute renal failure may also occur. Mortality in well-developed cases ranges from 20% to 30% and may be higher when depot forms are used. More expedient early recognition of NMS has led to a substantially decreased mortality rate. Readers may find the Neuroleptic Malignant Syndrome Information Service (NMSIS) (nmsis.org) website helpful for specific questions or for their physician hotline to aid in the diagnosis of NMS.

NMS is more common when high-potency dopamine blockers are prescribed in high doses and when the dosage is escalated rapidly. The syndrome is twice as common in men as in women and is more likely to be present in younger patients. Clinicians should be concerned about any patient who demonstrates severe muscular rigidity and a rising body temperature because early diagnosis and treatment can be life-saving.

Management of NMS. When NMS is diagnosed or suspected, antipsychotics should be discontinued, and supportive and symptomatic treatment should begin. This may include treating EPS with antiparkinsonian medications, correcting fluid and electrolyte imbalances, treating fevers, and managing cardiovascular complications such as hyper- or hypotension. Dantrolene (Dantrium) may be effective for treating severe NMS. Treatment begins with IV administration of 0.8 to 2.5 mg/kg every 6 hours, with a maximum of 10 mg/kg daily. When the symptoms subside, and the patient can swallow, dantrolene is administered orally in dosages of 100 to 200 mg daily. Bromocriptine can then be added at doses of 20 to 30 mg daily in four divided doses. Amantadine may be helpful, if the other agents are not sufficient. The course of treatment is commonly 5 to 10 days unless a long-acting injectable agent has been used.

Although NMS is considered by some to be an extreme form of EPS, its cause and biologic risk factors are unknown. Most patients will require antipsychotic medications after they recover from NMS. Low-potency drugs may be preferable for patients who have previously had NMS. However, even clozapine has been demonstrated to be a potential cause

Telegram: @medical_k

www.konkur.in

of the syndrome. At this time, there are no data available to indicate whether clozapine or other serotonin–dopamine antagonists are associated with a lower risk of NMS than dopamine D2 antagonists.

CHRONIC EXTRAPYRAMIDAL SYNDROMES

Tardive Dyskinesia

TD is a movement disorder that can follow chronic treatment with antipsychotic medications. Patients with TD may have any or all of a number of abnormal movements, including mouth and tongue movements (lip smacking, sucking, and puckering), as well as facial grimacing. Other movements may include irregular movements of the limbs, particularly choreoathetoid-like movements of the fingers and toes, and slow, writhing movements of the trunk. Although seriously disabling TD is uncommon, a small proportion may affect walking, breathing, eating, and talking.

The differential diagnosis of TD includes a number of disorders of the basal ganglia (including Huntington disease, Wilson disease, and Sydenham chorea), striatal hypercalcifications, hyperthyroidism, hypoparathyroidism, tardive Tourette disorder, and dyskinesias related to other drugs, such as L-dopa and amphetamines. Abnormal movements were also described in patients with schizophrenia before the introduction of antipsychotic medications.

Although dopamine-blocking medications will frequently suppress or reduce TD, dose increases are only appropriate when the movements are severe and incapacitating. If patients have their dosages of antipsychotic medication either decreased or discontinued, abnormal movements may worsen temporarily or appear for the first time and then diminish, termed withdrawal emergent dyskinesias. Antiparkinsonian medications will often worsen TD. However, when patients suffer from combined TD and acute EPS, prescribing antiparkinsonian medication is often unavoidable.

Although the biologic mechanism underlying TD is still controversial, it is likely that the disorder is related to an increased sensitivity of dopamine receptors in the basal ganglia. This is supported by the observation that drugs that block dopamine, such as antipsychotic medications, suppress TD, whereas dopamine agonists worsen the disorder. These observations are consistent with findings from preclinical laboratories indicating that blocking dopamine receptors can result in their upward regulation.

Telegram: @medical_k

www.konkur.in

Approximately 10% to 20% of patients treated with dopamine blockers for more than a year develop TD. In chronically institutionalized patients, the prevalence of TD is between 15% and 20% but increases with each year of treatment. Recent prospective studies indicate that approximately 4% to 5% of patients who are undergoing antipsychotic drug treatment, particularly with dopamine D2 receptor antagonists, will develop TD each year, with this risk markedly compounded in older adult individuals whose first treatment with antipsychotics is after age 65. Certain populations are at a greater risk than others for developing TD. Older adult women are particularly vulnerable. Moreover, TD in older adults is less likely to remit when dopamine blockers are discontinued. Patients with affective disorders may also be at a greater risk of TD when they are treated with dopamine receptor antagonists. Other possible risk factors for TD are the dosage of antipsychotic medications and the duration of treatment. There is also evidence indicating that the presence of acute EPS increases the risk of developing TD later.

TD does not appear to be a progressive disorder for most patients. The disorder seems to develop rather rapidly and then stabilize and often improves with time. The consensus of a number of long-term studies is that the severity of TD in most patients improves, even if their dopamine blockers are continued. Moreover, this improvement can be clinically meaningful in some patients. Individuals who are most likely to remit are those with recent onset and those with an onset prior to age 40. When dopamine blockers are discontinued, a substantial proportion of patients with TD will demonstrate remission. Reinstatement of a dopamine blocker does not mean an automatic reoccurrence. This is particularly likely for those with a rather recent onset of TD. Sometimes, this remission will take several months to occur.

Perioral Tremor

Perioral tremor is an uncommon side effect of dopamine receptor antagonists that appears after months or years of drug treatment. The peculiar tremors of the mouth have led to this disorder being called rabbit syndrome.

Management of TD. Patients receiving dopamine blockers for more than 6 months should have regular and systematic evaluations for TD every 6 months. Although instruments such as the Abnormal Involuntary

Telegram: @medical_k

www.konkur.in

Movement Scale (AIMS) were originally developed as research tools, they also provide a structured system for evaluating and recording abnormal movements.

Once TD is diagnosed, the clinician should evaluate the need for continued antipsychotic treatment. This decision requires consideration of the dangers of both the psychotic illness and TD. It is a decision that, whenever possible, should be made in collaboration with the patient and their family. The results of this discussion should be documented in the patient's medical record. For most patients with chronic schizophrenia, the best decision will probably involve continuing the antipsychotic. If this is the case, there is some evidence that treating patients with the lowest effective dose may minimize the risk of TD. Moreover, prescribing the lowest effective dosage of antipsychotic medication may also decrease the patient's risk of developing the disorder. Patients with severe TD may also be candidates for a trial of clozapine or other dopamine–serotonin antagonists. Most clinical reports indicate that clozapine can suppress TD.

The American Psychiatric Association task force on TD recommended a number of steps for the prevention and management of the disorder, including (1) establishing objective evidence that antipsychotic medications are effective; (2) using the minimum effective dosage for long-term treatment; (3) exercising caution with children, the older adults, and patients with mood disorders; (4) examining patients on a regular basis for evidence of dyskinesia and noting the results of the examination in the medical record; (5) if TD is diagnosed, considering alternatives to antipsychotics, obtaining informed consent, and considering dosage reduction; and (6) if the dyskinesia worsens, considering the discontinuation of the antipsychotic, switching to a different drug, or considering a trial of clozapine.

In addition, there is substantial data indicating that clozapine and other dopamine–serotonin antagonists are less likely to cause the disorder than other antipsychotic medications, and, therefore, it is promising for the long-term management of patients who have developed TD. In addition, studies using animal models indicate that clozapine does not result in the increased sensitivity of striatal D2 receptors, which is associated with typical neuroleptics and has been theorized to result in TD.

Current evidence suggests that dopamine–serotonin antagonists are associated with a lower risk of TD than dopamine D2 receptor agonists. This has been proposed since the decreased tendency of these agents to

Telegram: @medical_k

www.konkur.in

cause acute EPS would predict a lower risk of TD. An accumulation of controlled and uncontrolled studies led a consensus group of experts in the pharmacotherapy of schizophrenia to conclude that dopamine–serotonin antagonists were associated with a lower risk of TD. Because most of these studies were not designed to focus on TD, this remains a controversial issue. A Cochrane review did not find sufficient evidence to conclude that there was an advantage for dopamine–serotonin antagonists, while other meta-analyses concluded that the available evidence supported an advantage. Still, despite the high penetration of dopamine–serotonin antagonists into clinical practice, the incidence and prevalence of TD appear relatively unchanged since the 1980s. Since it would be difficult to perform an adequate study of sufficient duration to prove that there is a difference, this issue remains unresolved.

There are currently two medications approved for the treatment of TD: deutetrabenazine and valbenazine. Both are VMAT2 inhibitors and can be administered in conjunction with antipsychotic treatments. Using these medications is suggested if TD symptoms cannot be controlled with dose reductions or medication changes.

BEHAVIORAL SIDE EFFECTS

Dopamine D2 antagonists may cause a number of subjective and behavioral effects that are not accompanied by obvious motor effects. Subtle parkinsonian side effects may lead to decreases in emotional expressiveness, apathy, and depression. These symptoms can easily be confused with the negative symptoms of schizophrenia. In addition, subjective akathisia may cause feelings of restlessness that can cause anxiety or even agitation. High dosages of dopamine D2 antagonists may also lead to cognitive impairment and attentional deficits. These behavioral symptoms can often be managed by decreasing the antipsychotic dosage.

CARDIOVASCULAR EFFECTS

Cardiac Side Effects

Animal studies have shown that antipsychotic agents may decrease cardiac contractility, disrupt enzyme activity in cardiac cells, decrease tissue levels and increase circulating levels of catecholamines, and

Telegram: @medical_k

www.konkur.in

prolong atrial and ventricular conduction time and refractory periods. Low-potency agents, particularly chlorpromazine and thioridazine, can induce electrocardiogram (ECG) abnormalities, such as prolongation of the QT and PR intervals, blunting of the T-waves, and depression of the ST segment. QT prolongation is a particular concern since this can lead to ventricular arrhythmia (known as torsades de pointes), which can progress to ventricular fibrillation and sudden death. There are indications that these arrhythmias have occurred in patients treated with thioridazine and chlorpromazine. A recent study monitored the QT interval in patients treated with a number of dopamine–serotonin antagonists, as well as haloperidol. The results led the FDA to conclude that the dopamine–serotonin antagonists thioridazine and mesoridazine (which is metabolized to thioridazine) were associated with substantial QTc prolongation and risk of torsades de pointes, with a subsequent high risk of sudden death. As a result, these agents are recommended only for patients who are refractory to other agents. Clinicians should consider obtaining an ECG before and during treatment with thioridazine and mesoridazine. These agents should not be prescribed for patients with prolonged QTc intervals or those who are receiving other agents that tend to prolong the QTc interval or that decrease the metabolism of such agents. Attempts are underway to identify patients at risk of QTc prolongation through pharmacogenomics. Recently the FDA and Johnson & Johnson have informed health care providers of a revision to the prescribing information for haloperidol, haloperidol decanoate, and haloperidol lactate to include a new cardiovascular subsection highlighting the risk of sudden death, QT prolongation, and torsades de pointes, particularly when given intravenously or at dosages higher than those recommended. Pimozide is also associated with QTc problems (and seizures) when given in doses of 20 mg or higher.

Older adult patients and those with dementia are at a greater risk of sudden cardiac death, presumably because of slower metabolism (higher blood levels) and concomitant polypharmacy for multiple aging-related illnesses and symptoms. This polypharmacy may lead to drug–drug interactions.

OTHER DOPAMINE RECEPTOR ANTAGONISTS EFFECTS

Telegram: @medical_k

www.konkur.in

Orthostatic (Postural) Hypotension

Dopamine D2 blockers may cause orthostatic hypotension, particularly when these agents are first prescribed. This side effect can be dangerous when it results in fainting or falls. Both older adult patients and individuals with impaired balance should be monitored carefully for orthostatic changes. Since tolerance may develop gradually, patients should be initially treated with a relatively low dose of these agents (e.g., 25 mg orally twice daily), and the dose should be titrated upward over several days until a target dose is reached. When appropriate, patients should be warned of this side effect and told to sit or stand up slowly, to sit with their feet outside the bed when arising, to wait for as long as a minute, and to sit or lie down if they feel faint, particularly during the first 2 weeks of treatment. Some patients, particularly the older adults, may have persisting orthostatic hypotension and, as a result, may benefit from a change to a high-potency antipsychotic. Younger patients usually adapt to hypotension and may be asymptomatic, even though their blood pressure is low.

Orthostatic hypotension is more likely with IM administration. Thus, clinicians should consider measuring the patient's blood pressure (both lying and standing) before and 1 to 2 hours after the first dose and before subsequent doses during the first days of treatment.

If hypotension does occur, it can usually be managed by having the patient lie down and instructing the individual to arise very slowly. Some patients may benefit from stockings, volume expansion, or pressor agents. The use of epinephrine paradoxically worsens antipsychotic-induced hypotension through β-stimulation and is, therefore, contraindicated. Pure α-adrenergic agents, such as metaraminol (Aramine), and norepinephrine, are the drugs of choice for this condition.

Sudden Unexplained Death

In spite of reports that dopamine receptor antagonists have been associated with sudden unexplained death, no evidence indicates that the incidence of such deaths changed in psychiatric patients after the introduction of antipsychotics. An American Psychiatric Association task force report concluded:

Although a relationship between the use of antipsychotic drugs and sudden death has not been firmly established, it has also not been disproved. From a neurocardiologic perspective, these drugs have the

Telegram: @medical_k

www.konkur.in

potential for both increasing and decreasing the risk of sudden death. The ultimate outcome is probably determined by a multitude of interacting factors, and the role played by the drug in a given individual is difficult, if not impossible to determine.

Reports of sudden death in patients treated with antipsychotics could be explained by cardiac arrhythmias such as torsades de pointes secondary to QTc prolongation or other causes. For example, seizures, asphyxiation, heat stroke, malignant hyperthermia, and NMS could result in relatively sudden death. Individuals who may be more vulnerable to sudden death include older adults, physically debilitated individuals, and agitated patients (particularly those who are physically restrained). Increasing evidence of QTc prolongation caused by antipsychotic agents is surfacing, presumably responsible for torsades de pointes.

Gastrointestinal Tract

The most common GI side effects of dopamine receptor antagonists, although uncommon, are related to their peripheral anticholinergic effects. These include dry mouth, constipation, occasional diarrhea, and urinary retention. Nausea and vomiting are less common. However, these effects can be exacerbated when other anticholinergic drugs such as tricyclic antidepressants are combined with dopamine blockers.

Patients who experience a severe dry mouth should be advised to rinse their mouth frequently and to chew sugarless gum or candy. Sugar-containing candies may lead to fungal infections in the mouth and increase the risk of dental caries. Constipation can be managed with stool softeners or laxatives. Clinicians should manage severe constipation carefully since it can progress to paralytic ileus, a potentially fatal condition.

Liver

Dopamine receptor antagonists may cause transient abnormalities in liver function tests. These are seldom of serious medical concern. Obstructive or cholestatic jaundice is a serious condition that was commonly associated with chlorpromazine treatment, a dopamine–serotonin antagonist, in the past. It is currently very uncommon.

Blood

Telegram: @medical_k

www.konkur.in

Dopamine receptor antagonists may be associated with temporary and transient depression of leukopoiesis. Mild leukopenia may occur for prolonged periods, although it is more common for the leukocyte to eventually return to normal. Agranulocytosis is rare with dopamine receptor antagonists, occurring in less than 1 in 10,000 cases. Thrombocytopenia and pancytopenia may also occur.

Skin and Eye Effects

Cutaneous reactions seen during the first weeks of antipsychotic drug treatment include urticarial, maculopapular, petechial, and edematous reactions. These reactions usually improve when drugs are discontinued and sometimes clear even when drugs are continued. Although uncommon in patients receiving dopamine D2 blockers, chlorpromazine may develop photosensitivity reactions consisting of severe sunburn or rash. Patients should be instructed to avoid direct sunlight or to use sunscreens. Skin discoloration has also been observed, as well as granular deposits in the anterior lens and posterior cornea, especially after long-term treatment. Changing to a dopamine D2 receptor antagonist will usually lead to gradual improvement.

Endocrine Effects

Dopamine receptor antagonists elevate circulating levels of prolactin. In women, elevated prolactin can lead to breast enlargement, galactorrhea, and irregular menses, including anovulatory cycles and infertility, menses with abnormal luteal phases, or frank amenorrhea and hypoestrogenemia. The elevation of prolactin associated with dopamine blockers may also suppress testosterone in men. Prolactin elevation occurs as a direct result of D2 blockade in the tuberoinfundibular dopamine pathway and the pituitary. Since prolactin is under tonic inhibitory control by dopamine, blockade of dopamine receptors will elevate prolactin. Some patients, but not all, develop tolerance to the prolactin-elevating effects of these drugs after several weeks. Dosage reduction may relieve symptoms that are related to prolactin elevation.

Effects on Sexual Function

Dopamine blockers can have important effects on sexual functioning in both men and women. In men, these agents can result in decreased libido

Telegram: @medical_k

www.konkur.in

and ejaculatory and erectile disturbances. Erectile dysfunction has been reported to occur in 23% to 54% of men receiving an antipsychotic. This can be an important cause of medication noncompliance in men, and clinicians should inquire about it. Retrograde ejaculation has been reported. In addition, these agents can affect ejaculatory latency and the quantity of ejaculate. Since sexual functioning is affected by dopamine, serotonergic, and adrenergic systems, it is unclear how sexual dysfunction resulting from pure dopamine D2 antagonists is mediated. Dosage reduction may be helpful in some individuals.

Women who receive dopamine receptor antagonists may experience decreased libido, anorgasmia, and decreased lubrication. Although reports indicate that a number of adjunctive medications have been reported, there is little evidence that any are effective. As with men, reducing the dosage of the antipsychotic may be helpful. Presumably, agents with a high 5-HT_{2A} blockade should be able to counter these effects.

Pregnancy

Although dopamine receptor antagonists cross the placenta, there is very little evidence to suggest that there is an association between prenatal exposure and an increased incidence of congenital malformations. A meta-analysis by Altshuler and colleagues found that the baseline incidence of congenital anomalies is 2% and the incidence with antipsychotics is 2.4%. This meta-analysis found no evidence that dopamine D2-blocking drugs increase the risk to the fetus.

Prenatal exposure to dopamine receptor antagonists in rats may lead to a decreased number of brain dopamine receptors. Other animal studies indicate that prenatal haloperidol exposure may raise cholesterol levels in offspring. It is unclear if these animal findings indicate risks in humans.

In developing a treatment for pregnant patients with schizophrenia, the relatively low risk of congenital abnormalities associated with antipsychotics should be weighed against the dangers of psychotic episodes. Clinicians may attempt to discontinue these medications during the first trimester, if this is feasible and should consider carefully whether the risks of prescribing these drugs during the remainder of a patient's pregnancy are justified by the likely benefits. If patients have a history of relapse when dopamine blockers are discontinued, the drugs are

Telegram: @medical_k

www.konkur.in

relatively safe. If antipsychotics are prescribed, high-potency compounds are probably safer.

Lactation

Dopamine receptor antagonists are secreted in low concentrations with lactation, suggesting that patients should be advised against breastfeeding during antipsychotic treatment.

Seizure Threshold

Dopamine receptor antagonists tend to lower the seizure threshold. As a result, they are associated with an increased risk of seizures. This risk is usually clinically important in individuals with a prior history of seizures.

Temperature Regulation

Some patients become poikilothermic; that is, they become hypothermic in the winter and overheat in the summer with chlorpromazine and other low-potency agents. This indicates that special precautions should be taken for these patients during exposure to extremes in temperature.

Overdose

Overdoses with dopamine D2 receptor antagonists are usually characterized by exaggerations of their usual side effects. Thus, high-potency drugs are associated with severe extrapyramidal reactions, including dystonia and severe rigidity, as well as hypotension and sedation. The clinical picture may also include agitation, restlessness, convulsions, fever, autonomic reactions such as dry mouth and ileus, ECG changes, and cardiac arrhythmias. In severe overdoses with dopamine D2 blockers, the pupils are mydriatic, deep tendon reflexes are decreased, areflexia may occur, tachycardia and hypotension are present, and the EEG shows diffuse slowing and low voltage. This picture may progress to delirium and coma, with respiratory depression and hypotension.

The management of dopamine blocker overdose is symptomatic and supportive since overdoses with these agents are seldom lethal. However, the outcome may be unfavorable when these agents are combined with others, particularly CNS depressants such as alcohol, barbiturates, and benzodiazepines. If the overdose is recent, gastric lavage is helpful. If the

Telegram: @medical_k

www.konkur.in

patient can swallow, activated charcoal is indicated. Emetics should not be administered since their effects may be attenuated by the antipsychotic and because they are associated with a risk of aspiration pneumonia. Aspiration may be a serious risk, if the patient develops a dystonic reaction of the head or neck. Forced diuresis and hemodialysis are not effective because dopamine D2 blockers are highly protein bound and lipophilic.

When hypotension occurs, standard measures for managing circulatory shock should be implemented. The hypotension may occur when, during α-receptor blockade, β-receptors are unopposed. Therefore, the clinician should consider norepinephrine or dopamine. Epinephrine is contraindicated.

Tolerance, Dependence, and Withdrawal Symptoms

Some tolerance develops to the sedative, the anticholinergic, the hypotensive, and some other effects of dopamine blockers. Tolerance does not develop to the antipsychotic effects. Some patients experience a decrease in EPS over time, suggesting tolerance to the motor side effects of these agents. Dopamine receptor antagonists are not addictive. As a result, most patients can be withdrawn from these agents without difficulty, although manifestations of “cholinergic rebound,” including nausea, vomiting, and diarrhea, can occur. Other reported withdrawal symptoms include headache, sweating, restlessness, and insomnia. These symptoms tend to occur within 2 to 3 days of drug withdrawal and may last as long as 2 weeks. However, most patients who are withdrawn from dopamine D2 antagonists do not show withdrawal symptoms.

DRUG INTERACTIONS

Clinicians should be aware of several types of interactions. These include drugs that interact with the metabolism of dopamine blockers; age and gender, which may affect metabolic pathways; medical conditions, which may affect drug-protein binding, absorption, and fecal or renal clearance; individuals who are dehydrated or malnourished or who have impaired liver and kidney function and are at risk of altered sensitivity and metabolism.

Metabolism

Telegram: @medical_k

www.konkur.in

Dopamine D2 antagonists may have clinically important interactions with drugs that are metabolized by the same cytochrome P450 enzymes. Particularly for haloperidol, perphenazine, and others, this involves CYP 2D6. Since some SSRIs—particularly fluoxetine and paroxetine—are potent inhibitors of this enzyme, plasma levels of the dopamine antagonist are likely to be increased when an SSRI is added. This may result in an increase in a worsening of EPS. Other drugs that are substrates for 2D6, including heterocyclic antidepressants, β-blockers, and cimetidine (Tagamet), may also increase antipsychotic plasma concentrations.

Other drugs, particularly phenytoin (Dilantin), carbamazepine, and barbiturates, can reduce antipsychotic plasma concentrations by increasing the metabolism of the dopamine antagonist. Reports indicate that carbamazepine can reduce the plasma concentration of haloperidol by 50%. Cigarette smoking can also reduce the plasma levels of dopamine blockers.

There are other common interactions that should be of concern to clinicians. Antacids, activated charcoal, cimetidine, cholestyramine (Questran), kaolin, and pectin can decrease the absorption of antipsychotics from the gut. Increased absorption may occur with drugs that decrease GI motility, such as digoxin (Digitek) and steroids.

Coffee and tea may precipitate dopamine blockers. Although this has been demonstrated in vitro, its clinical significance is unclear.

Dopamine D2 blockers antagonize the effects of dopamine agonists or levodopa when these drugs are used to treat parkinsonism. Haloperidol can block the antihypertensive effects of guanethidine (Ismelin). Dopamine D2 blockers may also enhance the effects of CNS depressants such as analgesics, anxiolytics, and hypnotics.

Dopamine D2 blockers may enhance the effects of oral hypoglycemics. Phenothiazines enhance the effects of oral anticoagulants, although haloperidol may decrease these effects. Cigarette smoking may lower dopamine antagonist blood levels by enzyme induction.

Side-Effect Interactions

Narcotics, captopril (Capoten), trazodone (Desyrel), heterocyclic antidepressants, hydralazine (Apresoline), and minoxidil (Rogaine) may increase hypotension.

Amoxapine (Asendin), fluoxetine, chloroquine (Aralen), and lithium may increase extrapyramidal symptoms.

Telegram: @medical_k

www.konkur.in

LABORATORY INTERFERENCES

Perphenazine may give false-positive or false-negative results on pregnancy tests and also give inaccurate reports of bilirubin (with reagent test strips) and urobilinogen (with Ehrlich reagent test). Phenothiazines may produce false-positive results in tests for phenylketonuria. Phenothiazines may also interfere with 17-ketosteroids (with the Haltorff-Koch modification of the Zimmermann reaction) and 17-OH corticosteroids (with the modified Glenn-Nelson technique).

TREATMENT OF ACUTE PSYCHOSIS

Initiation of Treatment

Treatment with a dopamine blocker is usually initiated soon after a diagnosis is made. Whenever possible, patients should receive a psychiatric evaluation, including a history and physical examination and a laboratory evaluation that includes complete blood cell count; blood electrolytes; glucose, liver, renal, and thyroid function tests; and other appropriate evaluations (including ECG, pregnancy tests, and screens for alcohol and drugs). The results of this evaluation can be useful in confirming the diagnosis and establishing a pretreatment baseline. Under most conditions, it is not necessary to delay treatment while awaiting the results of these tests. Moreover, because there are few contraindications to receiving FGAs, these evaluations can be postponed when patients refuse an evaluation or when treatment is urgent.

Choice of Agent

There is no evidence for differential effectiveness of dopamine D2 blockers, dopamine–serotonin blockers, or dopamine–serotonin–norepinephrine blockers, with the exception of clozapine, which is the most effective antipsychotic available. Amisulpride may also have a slightly lower EPS risk and does not appear to be as sedating as some of the low-potency SGAs. The choice among the dopamine D2 blockers is based on prior responses, both objective improvement and the patient's subjective response to the drug, available routes of administration and dosage forms, side-effect profiles, and cost.

The introduction of the dopamine–serotonin and dopamine–serotonin–norepinephrine antagonists (risperidone, olanzapine, quetiapine,

Telegram: @medical_k

www.konkur.in

ziprasidone, aripiprazole, iloperidone, lurasidone, zotepine, iloperidone, amisulpride, at this time) has complicated the decision-making process. These agents, in themselves quite heterogeneous, have different side-effect profiles when compared with dopamine blockers. The most important advantage of these “newer agents” is that they cause substantially less EPS. Patients who experience EPS at dosages of dopamine blocker needed to treat their psychosis may or may not experience EPS with an effective dosage of any of these other agents. This was evaluated in a phase of the CATIE trial in which patients who discontinued perphenazine were subsequently randomized to risperidone, olanzapine, or quetiapine.

There is also evidence from a number of well-designed clinical trials indicating that patients who have only partial responses to a dopamine blocker due to lack of efficacy or side effects may improve, if changed to a dopamine–serotonin and dopamine–serotonin–norepinephrine antagonist. The evidence is compelling for clozapine, but there are also some reports supportive of other agents as well. However, most of the studies reporting this advantage of newer drugs were carried out in the late 1980s and 1990s when patients had only been exposed to dopamine D2 blockers. More recently, there are clinical reports of patients who had only received dopamine–serotonin or dopamine–serotonin–norepinephrine antagonists who improved when they were changed to a dopamine D2 blocker. Moreover, cost considerations have become more important, especially in the United States. Many of the newer medications are patent protected and are considerably more expensive than dopamine blockers which are usually available as generics. Risks and benefits need to be considered carefully when choosing antipsychotics, especially in light of the different TD risks.

An additional advantage of some newer medications is that they are less likely to elevate prolactin. As a result, these agents may be helpful for women who experience galactorrhea and irregular menses with dopamine blockers.

Haloperidol and fluphenazine are still commonly prescribed. They are more strongly antidopaminergic and thus more likely to cause EPS than other available medications. However, EPS in some individuals may be easier to manage than the sedation and orthostatic hypotension associated with other medications. Haloperidol and Prolixin can also readily be administered intramuscularly and seldom cause problems with

Telegram: @medical_k

www.konkur.in

blood pressure, and oral doses can often be escalated over a few days without untoward sedation or hypotension.

Route of Administration

Dopamine D2 blocking drugs can be administered orally or as short- or long-acting injectables (Once patients are stabilized on a dosage, most patients can be managed with a single daily dose. Short-acting injectables are administered intramuscularly for calming acutely anxious patients or for administering a drug to patients who refuse oral medication. The clinical effects of an IM dose may appear as soon as 15 minutes after the injection. Since the dopamine D2 blockers are most effective when patients have reached a steady state for several days or even weeks, patients should be changed to oral administration as soon as possible.

Dopamine D2 blockers can also be administered as long-acting injectables. In the United States, haloperidol and fluphenazine are available in long-acting formulations. Long-acting antipsychotics are usually prescribed in stabilized patients during maintenance treatment after tolerance to the oral formulation has been established. It can take several months to reach a steady state, and oral supplementation may be necessary during that time, although the longer the oral medication treatment period and the better the adherence, the shorter time to steady state. For these reasons, long-acting depot dopamine D2-blocking drugs are clearly better suited than oral medications for long-term relapse prevention. They are cost-effective as well, but their TD risk may be higher.

Dosage

Patients demonstrate marked differences in the dosage of a dopamine receptor antagonist that is optimal. For example, some patients will find it difficult to tolerate the side effects of 1 mg of haloperidol, whereas others will tolerate 50 mg without suffering any side effects. Finding the best dosage for a dopamine D2 receptor antagonist is both important and difficult. The importance stems from the tendency of dopamine D2 blockers to cause side effects at their effective dosages. Oftentimes the clinician must weigh the therapeutic advantages of a particular dosage against discomforting or disabling side effects. As many of the dopamine blockers were developed prior to the required rigorous pharmacologic methodology of today, a minimally effective or lowest dose has usually not

Telegram: @medical_k

www.konkur.in

been established. As a result, the most reasonable practice may be to treat a patient with a dosage that is likely to be effective and to wait an adequate amount of time, 4 to 6 weeks at most, to determine if the patient is responding.

Dosage comparison studies provide guidance to clinicians who are making decisions regarding the dosages of dopamine blockers for most patients with schizophrenia or schizoaffective disorder. Doses below 2 mg of haloperidol or 5 mg of fluphenazine are likely to be too low for many psychotic patients. At the same time, doses above 10 mg of haloperidol or 20 mg of fluphenazine are seldom necessary and may lead to substantial side effects and even fewer antipsychotic effects. In other words, most patients will respond to doses between 5 and 20 mg of fluphenazine or 2 and 10 mg of haloperidol. Studies that focused on haloperidol suggest that doses below 8 mg are adequate for most patients and that these doses are associated with less EPS than 20 mg doses. First-episode patients should be treated with lower doses, and children and older adult patients should be treated with much lower doses.

The issue of dosing was recently highlighted by the FDA when it added a “Black Box” warning to the use of dopamine–serotonin and dopamine–serotonin–norepinephrine antagonists in older adult patients with dementia (increased mortality risk). A similar increased mortality risk has been associated with dopamine D2 blockers. Whether this is secondary to higher blood levels and the use of polypharmacy in older adults, exposing them to an increased risk of QTc prolongation, which may lead to torsades de pointes, arrhythmias, and subsequent death, has not been determined but seems likely. As with any condition that requires multiple medications, practitioners need to be aware of potential drug–drug interactions.

Some patients tolerate very high dosages of dopamine D2 blockers, leading some clinicians to raise the prescribed doses in the hope that “more is better.” This resulted in a substantial increase in the average dose of antipsychotics prescribed in the United States during the 1970s and 1980s. However, dosage comparison studies failed to support the routine use of higher doses. For example, when groups of patients were assigned to high doses such as 40 mg of haloperidol, the commensurate improvements were no greater than in those assigned to more moderate doses. Moreover, these higher doses were associated with more EPS. Current evidence does not support the use of excessive doses of antipsychotic medications.

Telegram: @medical_k

www.konkur.in

As-Needed Medication

Prescribing medication as needed is recommended only for the initial phases of treatment. Although dopamine D2 blockers can result in nearly immediate calming for agitated individuals, this response appears to differ from the true antipsychotic effect of these medications, which has a delayed onset. Treating excitement and agitation with the addition of benzodiazepines such as lorazepam (Ativan) has the advantage of calming patients without causing EPS.

Blood Levels and Clinical Activity

Drug response is an interaction between dosage and time on drug and individual pharmacokinetic and dynamic variables. Finding the best dosage of an antipsychotic for an individual patient often requires weeks or months of adjusted treatment. The clinician usually selects a drug dosage that is effective for most patients with the same illness or a dosage that has been effective for the patient at an earlier time. Once a decision is made about the dosage and the plan implemented, the clinician is forced to wait days or weeks until it is clear whether the dosage is effective, toxic, or ineffective. If measuring a patient's plasma or blood level enabled clinicians to select a drug dosage for an individual scientifically, this could decrease the amount of time it takes to arrive at an appropriate dosage.

Early studies of plasma levels indicated that patients who received the same dosage of a drug had large variations in their plasma levels. These findings suggested that studying individual differences in plasma levels would provide information that could be useful to clinicians. However, these early studies were limited to drugs such as chlorpromazine that have complex metabolisms. This creates a problem since some of the antipsychotic activity of these agents could result from metabolites rather than the parent drug. This and other problems, including flawed research methods, may explain why early studies failed to find a reliable relationship.

A number of more recent studies have focused on other dopamine receptor antagonists and have shown more promising results. Haloperidol has received the most attention for the study of relationships between plasma concentration and clinical response. An advantage of haloperidol for these studies is that its metabolism includes only a single important metabolite, reduced haloperidol, which does not have significant

Telegram: @medical_k

www.konkur.in

antipsychotic activity. As a result, measuring the plasma level of haloperidol may provide an accurate representation of the effective amount of the drug. At least five research groups, but not all, have reported a therapeutic window relationship between haloperidol levels and clinical response. Although all of these ranges are supported by one or more high-quality studies, the strongest evidence is for haloperidol.

Studies do not support the routine use of plasma level measurement with the exception of clozapine. Still, a level may be helpful in the patient who is receiving what appears to be an adequate drug dosage but who is not responding. A low level may suggest that the patient is not complying or that poor absorption or extensive drug metabolism is interfering with an adequate level. In other cases, the clinician may find it difficult to interpret anxiety or agitation and may consider whether psychotic agitation could come from an inadequate dosage or whether akathisia may result from an excessive dosage. A high or low plasma level could provide valuable information in these circumstances.

Plasma levels should only be obtained after steady-state levels have been reached, preferably during the late phase of the plasma level curve. This usually means after 5 days on a stable oral dose and 10 to 12 hours after the last dose.

Adjunctive Medications

Antipsychotic medications are frequently supplemented by other psychotropic medications. These are aimed at managing comorbid conditions that frequently occur with schizophrenia. There is substantial evidence indicating that depression is underdiagnosed and undertreated, while antidepressants may be effective for treating depressive symptoms in patients with schizophrenia and schizoaffective disorder. Mood-stabilizing drugs, including lithium, carbamazepine, and valproate (Depakote), are often used for patients with unstable moods. However, carbamazepine may induce the metabolism of antipsychotic agents, lowering plasma concentrations of the parent drug. Benzodiazepines are often effective for treating anxiety, as well as agitation and excitement. Newer sleeping agents may assist patients to sleep better with lower risks than older medications.

MAINTENANCE TREATMENT

Telegram: @medical_k

www.konkur.in

Duration of Treatment

During the maintenance phase of treatment, the treatment goals include preventing psychotic relapse and supporting treatments aimed at improving the patient's level of functioning and quality of life. Although dopamine D2 blockers are effective in delaying or preventing relapse, they are also associated with short- and long-term side effects. For most patients with schizophrenia or schizoaffective illness, the analysis of costs and benefits will favor continuing the patient on an antipsychotic, including depot antipsychotics. Patients who have recovered from a single psychotic episode have a substantial risk of relapse, if they are withdrawn from medications. As a result, first-episode patients should receive at least 1 year of maintenance therapy, if asymptomatic. This is often a substantial point of contention with parents and their families, but the evidence is very clear that relapse will occur in 95% of patients eventually. Patients who have had multiple episodes should continue to receive antipsychotic maintenance for at least 2 to 5 years, potentially indefinitely. Present data indicate that there is a 10% relapse rate per year, often precipitated by nonadherence with medication, suggesting that continuous, moderate dosage maintenance dopamine D2 blockers afford the best chance of avoiding relapse in psychotic patients. Patients with a history of violent, aggressive behavior or serious suicide attempts should receive antipsychotics indefinitely. If a decision is made to discontinue medications, the dosage of medication should gradually be reduced, and the patient should be carefully observed. However, as with many chronic medical diseases, patients do discontinue or take medications irregularly on their own.

Long-Acting Injectable Antipsychotics

There is substantial evidence indicating that long-acting injectable antipsychotics have advantages for patients, including first-episode patients during the maintenance stage of treatment. Depot antipsychotics should be considered for each patient, starting early in the course of illness, because they have been shown to reduce relapse more than oral antipsychotics, potentially improving long-term prognosis, as well as preventing both psychiatric readmissions and arrests. One advantage is that these agents are a partial solution to the problem of poor medication adherence in schizophrenia. Clinicians can administer a drug without depending on patients to take their pills. In addition, because depot drugs

Telegram: @medical_k

www.konkur.in

bypass variations in drug absorption and first-pass hepatic and gut metabolism, drug levels may be more consistent. A number of studies have compared the relative effectiveness of long-acting and oral drugs for preventing relapse in stabilized patients. Studies that closely resemble treatment in the community have found that patients are better protected by depot medications. A number of carefully controlled studies and meta-analyses have compared the risk of psychotic relapse in patients who were randomly assigned to receive either oral or depot medication, with depot antipsychotics reducing relapse rates to a greater extent than oral antipsychotics.

Treatment Strategies During Maintenance

Concerns about the side effects of antipsychotics and the risk of TD have led to a number of proposed strategies for safely managing patients on the lowest possible amount of a dopamine antagonist. A number of studies have found that patients can be safely managed with substantially lower dosages of a long-acting depot antipsychotic than are commonly prescribed. These studies found that most patients did well when their doses were reduced by 80% from doses that are usually prescribed for acute treatment. Patients treated with lower dosages experienced a small increase in the risk of relapse that was balanced in some studies by reductions in side effects, improved compliance, and suggestions of improved community adjustment.

Other studies have focused on a strategy called *targeted* or *intermittent therapy,* in which an antipsychotic is gradually reduced and eventually discontinued. Patients are monitored carefully for early or prodromal signs of relapse. The antipsychotic is reintroduced when these signs appear. A number of studies, including a NIMH collaborative study, have found that targeted treatment is associated with high relapse rates, indicating that this strategy is not advisable.

Mechanism of action	Receptor antagonists (D_2, 5-HT_2), reuptake inhibitor (NET)
Iloperidone	
Pharmacologic Domain	Serotonin, dopamine
Mechanism of action	Receptor antagonists (5-HT_2, D_2)
Asenapine	
Pharmacologic Domain	Serotonin, dopamine, norepinephrine
Mechanism of action	Receptor antagonists (5-HT_2, D_2, α2)
Lumateperone	
Pharmacologic Domain	Serotonin, dopamine
Mechanism of action	Receptor antagonist (5-HT_2, D_2), reuptake inhibitor (SERT)

Telegram: @medical_k

www.konkur.in

Dopamine-serotonin antagonists (DSAs) are the most widely prescribed agents for schizophrenia and other illnesses associated with psychotic symptoms.

This diverse group of compounds can be differentiated from the dopamine receptor antagonists based on their high affinity for serotonin 2A (5-HT_{2A}) as well as dopamine (D_2) receptors. In prior editions of this text, the term second-generation antipsychotics or SGAs was used to refer to these agents. However, this term is inaccurate since decades of studies have failed to support the contention that antipsychotics marketed after clozapine were more effective antipsychotics than older drugs. The adoption of neuroscience-based nomenclature (NbN) provides a preferred method for characterizing antipsychotic medications based on their pharmacology. It is notable that antipsychotics previously considered first-generation antipsychotics—including chlorpromazine, thioridazine, and flupenthixol—are categorized as DSAs, and sulpiride and amisulpride are classified as dopamine antagonists (DAs).

The differentiation of the DSAs from other antipsychotics emerged following the introduction of clozapine (Clozaril), an antipsychotic that was introduced in the United States in 1990, although it had been available in some countries in Europe since the early 1970s. Clozapine was considered an “atypical” antipsychotic because it was an effective agent at doses that caused negligible extrapyramidal symptoms (EPS). Moreover, it had broad effectiveness for a range of mood and anxiety symptoms that were common in schizophrenia. This led to a focus on understanding the mechanism of action of clozapine. Clozapine’s D_2 receptor blockade is lower than that of traditional antipsychotics, while its antagonism of the 5-HT_2 receptor is greater than that of haloperidol. The unique activity at these two receptors led Herbert Meltzer to propose that the distinctive antipsychotic effect of clozapine was related to its low receptor blockade at D_2 relative to 5-HT_2. Clozapine’s affinity for the 5-HT_2 receptor is among the highest for antipsychotic agents.

During the early 1980s, scientists at Janssen Pharmaceutica were interested in developing an antipsychotic that would have a clinical profile similar to clozapine but without a tendency to cause agranulocytosis. The company developed a number of drugs with 5-HT_2 antagonism with and without D_2 activity. One compound, setoperone, had weak dopamine activity and was a relatively weak antipsychotic. Ritanserin was developed

Telegram: @medical_k

www.konkur.in

as a 5-HT_2 antagonist (inverse agonist) that could be added to a D_2 antagonist to decrease the amount of extrapyramidal side effects. Although ritanserin had antinegative symptom effects, improved sleep, and some weak antipsychotic effects, it also had significant effects on QTc interval. The synthesis of risperidone in 1984 led the company to focus on the development of this agent since it combined strong D_2 and 5-HT_2 antagonism. Subsequent safety and efficacy studies with risperidone led to its approval in the United States in 1994. This was followed by the introduction of olanzapine in 1996 and quetiapine in 1997, and others during the subsequent years. This chapter will discuss the DSAs using the following NbN categories:

1. Dopamine, serotonin (chlorpromazine, flupenthixol, loxapine, lurasidone, olanzapine, perospirone, pipotiazine, sertindole, thioridazine, trifluoperazine, zotepine)
2. Dopamine, serotonin NE α2 (clozapine, risperidone, paliperidone)
3. Dopamine, serotonin, NET (quetiapine)
4. Serotonin, dopamine (iloperidone)
5. Serotonin, dopamine, norepinephrine (asenapine)
6. Serotonin, dopamine, serotonin transporter (lumateperone)

The partial agonists, aripiprazole, brexpiprazole, and cariprazine are discussed in the next chapter.

Comparisons of DSAs

A network meta-analysis of randomized controlled trials compared the effectiveness of 32 antipsychotics. The study found that clozapine, amisulpride, zotepine, olanzapine, and risperidone were more effective for improving overall symptoms than other antipsychotics. However, with the exception of clozapine, the differences between the drugs were relatively small, and it was not clear that the DSAs were more effective than the DAs. The differences among the antipsychotics in side effects were substantial. A reasonable conclusion from this and other meta-analyses is that—aside from clozapine—the selection of an antipsychotic will be based on side-effect concerns rather than efficacy.

DOPAMINE, SEROTONIN

Telegram: @medical_k

www.konkur.in

This group of antipsychotics includes a number of older antipsychotics such as chlorpromazine, flupenthixol, thioridazine, trifluoperazine, zotepine, loxapine, perospirone, pipotiazine, as well as newer drugs, including lumateperone, lurasidone, olanzapine, and sertindole,) This section will focus on the most commonly prescribed drugs from this group, including chlorpromazine, olanzapine, ziprasidone, and lurasidone.

The discovery of chlorpromazine's effectiveness for psychosis represents the beginning of modern psychopharmacology in that it indicated that drugs could have specific effects on the symptoms of mental disorders that went beyond sedation. In 1950, Paul Charpentier, at the Rhóne-Poulenc Laboratories in Paris, synthesized chlorpromazine, a drug that appeared notable as a mild antihistaminic that was also sedating. Henri Laborit, a surgeon with an interest in drugs that would decrease preoperative anxiety and prevent postsurgical shock, convinced the Rhóne-Poulenc Laboratories of the importance of identifying compounds that would relax patients and make surgical shock less likely. Chlorpromazine appeared to fulfill these criteria, but it also appeared qualitatively different from other sedating drugs. Patients appeared indifferent toward the environment and more tranquil. These properties led Laborit to convince psychiatrists, including Jean Delay and Pierre Deniker, to administer chlorpromazine to patients with mania and schizophrenia. In 1952, these authors reported their observation that chlorpromazine was effective in treating mania and schizophrenia. Within a year, the atmosphere in Paris's psychiatric hospitals had improved substantially. Moreover, the availability of drugs with direct effects on mental disorders became a powerful tool for laboratory studies with animals, leading to a greater understanding of how drugs affect the brain and information about the nature of the illnesses that were affected. Although reserpine was also an effective antipsychotic, its side effects led clinicians to prefer chlorpromazine, and, as a result, it is no longer used for treating psychosis because of its side effects, such as depression, suicidality, dysphoria, and orthostatic hypotension.

Other DSA antipsychotics—including trifluoperazine, flupenthixol, thioridazine, and loxapine—were introduced prior to 1975. Along with chlorpromazine, these antipsychotics are not commonly prescribed—with the possible exception of the long-acting formulation of flupenthixol which is not available in the United States. This is partly due to their side-effect profiles. Both chlorpromazine and thioridazine can induce

Telegram: @medical_k

www.konkur.in

electrocardiogram (ECG) abnormalities, such as prolongation of the QT and PR intervals, blunting of the T waves, and depression of the ST segment. QT prolongation is a particular concern since this can lead to ventricular arrhythmia (known as torsades de pointes), which can progress to ventricular fibrillation and sudden death. Thioridazine (Mellaril) has the greatest risk of QTc prolongation among all currently available antipsychotics and is rarely prescribed.

Chlorpromazine is also associated with an uncommon discoloration of the skin. Skin areas that are exposed to sunlight, particularly the face and neck, develop blue–gray metallic discoloration. This skin reaction is usually associated with long-term treatment with high drug dosages. Chlorpromazine-treated patients may develop granular deposits in the anterior lens and posterior cornea. These deposits, visualized on slit lamp examination, seldom affect the patient's vision. Changing the patient to another drug will usually result in a gradual improvement in the condition. High doses of thioridazine—above 1,000 mg daily—can result in altered retinal pigmentation (retinitis pigmentosa). This condition can lead to serious visual impairment or blindness. Moreover, this condition may not remit when thioridazine is discontinued. As a result, thioridazine should not be prescribed at doses over 800 mg daily.

Sertindole was approved and marketed in a number of E.U. countries in 1996. However, concerns about QTc prolongation and the risk of cardiac arrhythmias led to its suspension in 1998. This concern also prevented its approval by the U.S. FDA. Currently, sertindole is available in several E.U. countries with cautions regarding patient selection and recommendations for ECG monitoring.

Olanzapine

Eli Lilly and Company formulated olanzapine in Great Britain in 1982. Since olanzapine is similar in structure to clozapine, its early development was encouraged by the hope that it would have similar efficacy with milder side effects. Phase III clinical trials were completed in July 1995, and olanzapine became available in the U.S. and European markets in the fall of 1996.

Olanzapine reached the market in the United States in 1996. It has a mildly sedating, calming effect that has led to its acceptance in many acute psychiatric settings. Olanzapine has shown marginal efficacy advantages when compared with some other antipsychotics in a number

Telegram: @medical_k

www.konkur.in

of meta-analyzes. However, it is also associated with serious side effects, including weight gain, lipid elevation, and an increased risk of diabetes. This has led many clinicians to consider this a second-line antipsychotic.

FIGURE 33.2b–1. Molecular structures of SGAs discussed in the chapter. (Panels a–l by Fuse809, via Wikimedia Commons. Licensed under the Creative Commons Attribution-Share Alike 3.0 Unported license. Panel j in public domain.)

Chemistry. Olanzapine is a thienobenzodiazepine (Fig. 33.2b–1). It can be considered a derivative of clozapine with the substitution of a thieno ring for clozapine's carbonyl ring.

Pharmacologic Action

PHARMACOKINETICS

Telegram: @medical_k

www.konkur.in

Absorption. Olanzapine is well absorbed when administered orally. Peak plasma concentrations are reached in about 6 hours. Food has relatively little influence on its absorption. Olanzapine's half-life is influenced by smoking, gender, and age, with a mean of about 31 hours (range of 21 to 54 hours). This allows for once-daily dosing. Patients reach steady plasma concentrations in about 7 days. IM administration of olanzapine leads to peak plasma concentrations within 15 to 45 minutes.

Distribution. Olanzapine is widely distributed throughout the body. The drug is 93% protein bound to plasma proteins.

Metabolism and Elimination. The primary metabolic pathways for olanzapine are direct glucuronidation and P450-medicated oxidation. None of olanzapine's metabolites are active. Although in vitro studies indicate that CYP1A2 and 2D6 and the flavin-containing mono-oxygenase system are involved in its oxidation, CYP1A2 appears to be the major pathway.

PHARMACODYNAMICS

Mechanism of Action. Olanzapine is a high-affinity antagonist at 5-$HT_{2A/2C}$, 5-HT_6, $D_{1–4}$, H_1, and adrenergic α_1-receptors and a moderate affinity antagonist at $M_{1–5}$ and 5-HT_3 receptors. PET studies indicate that typical doses of olanzapine such as 10 to 20 mg result in 68% to 84% D_2 occupancy. Its 5-HT_2 activity is approximately eight times as strong as its dopamine receptor blockade. Compared with risperidone, quetiapine, and ziprasidone, olanzapine has greater muscarinic and histaminergic receptor antagonism. This histamine activity may explain its tendency to cause weight gain.

Blood Concentrations and Clinical Activity. Consensus guidelines from 2020 strongly recommend therapeutic-level monitoring for patients receiving olanzapine. The recommended therapeutic range is 20 to 80 ng/mL.

Design and Interpretation of Clinical Drug Studies

ACUTE TREATMENT OF SCHIZOPHRENIA. Double-blind studies have compared once-daily olanzapine at dosages ranging from 2.5 to 17.5 mg per day

Telegram: @medical_k

www.konkur.in

with placebo and haloperidol (10 to 20 mg per day). In one study, olanzapine was found to be superior to placebo and comparable to haloperidol in the treatment of overall psychopathology (mean Clinical Global Impression [CGI]-S score) and positive psychotic symptoms (positive Brief Psychiatric Rating Scale [BPRS] and Positive and Negative Syndrome Scale [PANSS] scores) at intermediate (7.5 to 12.5 mg per day) and high (12.5 to 17.5 mg per day) dosages. Olanzapine was also found to be superior to haloperidol in negative psychotic symptom response.

In another 6-week, fixed-dose, double-blind study involving 1,996 patients in North America and Europe, olanzapine showed significantly greater clinical improvement over haloperidol (total BPRS score, $p < .02$). Significant improvement was also seen in both positive symptom and negative symptom scores ($p = .03$) as well as depression rating ($p = .001$).

Double-blind studies have also evaluated the effect of a rapid-acting IM formulation of olanzapine in the treatment of acute agitation in schizophrenia. IM olanzapine was found to be effective against positive symptoms in acutely agitated patients, superior to placebo and similar to IM haloperidol.

OLANZAPINE IN CHILDREN AND ADOLESCENTS. There are relatively few data evaluating the effectiveness of olanzapine for children or adolescents with schizophrenia or bipolar illness. A study in adolescents reported by Kryzhanovskaya and coworkers found that olanzapine was more effective than placebo but associated with somnolence, liver enzyme elevations, prolactin elevation, and weight gain. An 8-week study that compared olanzapine, risperidone, and haloperidol in 50 patients aged 8 to 19 years with psychosis found that the three conditions were equally effective. However, weight gain and EPS on olanzapine and risperidone appeared to be greater than had been reported in adults. A trial by Linmarie Sikich and coworkers compared risperidone and olanzapine to molindone (Moban) in patients between 8 and 19 years of age. The National Institute of Mental Health (NIMH) Data and Safety Monitoring Board closed randomization to the olanzapine arm due to weight gain. These concerns are mirrored in a study of bipolar adolescents (aged 13 to 17 years) who were randomized in a 3-week comparison of olanzapine or placebo. Although olanzapine was effective in reducing symptoms, it was also associated with increases in weight, liver enzymes, fasting cholesterol, prolactin, and fasting glucose.

Telegram: @medical_k

www.konkur.in

Taken together, all of these studies support very serious safety concerns related to treatment with olanzapine in children and adolescents. In the opinion of the authors, olanzapine should be considered for this population only when other antipsychotics have failed.

OLANZAPINE IN FIRST-EPISODE SCHIZOPHRENIA. A study of 263 patients with first-episode schizophrenia reported by Jeffrey Lieberman found that olanzapine had advantages over haloperidol in total PANSS scores and depression. An analysis of data over 2 years found that fewer patients discontinued olanzapine. However, olanzapine was associated with greater weight gain and elevations in liver enzymes. A 1-year double-blind study reported by Joseph McEvoy randomized 400 recent-onset patients to olanzapine, quetiapine, or risperidone. Discontinuation rates were similar on the three drugs. However, there were advantages for olanzapine on positive symptoms. As in other studies, weight gain was highest with olanzapine.

EFFICACY FOR MANIA AND MIXED STATES IN BIPOLAR DISORDER. Two studies found that olanzapine monotherapy at doses between 5 and 20 mg was superior to placebo at reducing manic symptoms as measured by the Young Mania Rating Scale (YMRS). A third study failed to find this advantage for olanzapine. These studies support the use of olanzapine in bipolar patients with mania or in mixed states. A study by Perlis and coworkers compared olanzapine and risperidone and found that the two SGAs had similar effectiveness in reducing manic symptoms. Two trials evaluated the effectiveness of adding olanzapine or placebo to either lithium or valproate when patients had symptoms that were inadequately controlled on the first drug. In both trials, the addition of olanzapine was more effective than the addition of a placebo in reducing manic symptoms.

AGITATION IN SCHIZOPHRENIA AND BIPOLAR DISORDER. Studies of IM olanzapine focused on the short-term reduction in agitation in patients with schizophrenia or bipolar disorder. They were double blind and consisted of patients being assigned to receive up to three injections in the first 24 hours.

Two studies compared IM olanzapine to placebo in patients with schizophrenia who demonstrated symptoms of excitement. Olanzapine at

Telegram: @medical_k

www.konkur.in

doses of 2.5, 5, 7.5, and 10 mg was more effective than placebo at decreasing levels of excitement. The higher olanzapine doses resulted in greater reductions in excitement. The advantage of olanzapine was apparent for all doses at 2 hours and for 5 to 10 mg at 30 minutes. These improvements were similar to those with IM haloperidol or IM lorazepam in separate studies. Another study found that 10 mg of IM olanzapine was more effective than placebo and oral olanzapine for reducing excitement in bipolar patients with mania or mixed states.

Effects on Specific Organs and Systems. Olanzapine is associated with orthostatic hypotension, tachycardia, and possible syncope. This probably results from its α_1-adrenergic antagonistic properties. IM olanzapine has been associated with a syndrome that includes hypotension with bradycardia.

The anticholinergic effects of olanzapine can lead to constipation in some patients.

Therapeutic Indications

SCHIZOPHRENIA. Olanzapine is an effective agent for treating acute psychotic symptoms in schizophrenia. Since it is mildly sedating, psychiatrists in acute settings often favor olanzapine for patients who will benefit from a calming agent.

Olanzapine is also effective for maintaining an antipsychotic response in stabilized patients. In large studies such as Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE), olanzapine patients tended to have lower discontinuation rates when compared with other first- and second-generation drugs. However, weight gain, lipid elevations, and insulin resistance can be serious problems in some patients. As a result, patients who continue in long-term treatment should be carefully monitored for these metabolic effects.

BIPOLAR DISORDER. Olanzapine is effective for the acute treatment of mania and mixed states, both as monotherapy and as adjunctive therapy to lithium or valproate. It is notable that olanzapine is effective for both psychotic and nonpsychotic patients.

Olanzapine is also effective as monotherapy for maintaining response in patients who have been treated for mania or mixed states. As with

Telegram: @medical_k

www.konkur.in

schizophrenia, patients receiving long-term treatment with olanzapine should be carefully monitored for its adverse metabolic effects.

Bipolar I Disorder with Acute Depression and Treatment-Resistant Major Depressive Disorder

Olanzapine combined with fluoxetine is indicated for both of these disorders.

AGITATION ASSOCIATED WITH SCHIZOPHRENIA AND BIPOLAR I MANIA. IM olanzapine is indicated for agitation that can be associated with schizophrenia or mania. The olanzapine product information defines psychomotor agitation as “excessive motor activity associated with a feeling of inner tension.” It should be noted that oral olanzapine in its different formulations, as well as other antipsychotics, are also effective for agitation. The important advantage of the IM route is a more rapid onset of action.

Precautions and Adverse Reactions

BLACK BOX WARNING

Increased Mortality in Older Adult Patients with Dementia. Olanzapine and the other SGAs carry a black box warning for increased mortality in older adult patients with dementia-related psychosis compared with placebo.

WEIGHT GAIN. A large number of studies indicate that olanzapine is associated with greater weight gain than other DSAs, with the possible exception of clozapine. In the NIMH CATIE study, olanzapine patients gained approximately 2 lb per week. Studies during long-term therapy with olanzapine found that 56% of patients gained greater than 7% of baseline weight. Weight gain occurred across all BMI levels indicating that low, normal, overweight, and obese patients were vulnerable to weight gain. As mentioned earlier, children and adolescents are more vulnerable to weight increase with olanzapine treatment.

HYPERLIPIDEMIA. Patients treated with olanzapine may experience serious increases in total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglycerides. Triglycerides are most likely to be elevated, sometimes

Telegram: @medical_k

www.konkur.in

to levels above 500 mg/dL. In the NIMH CATIE study, the mean increase in triglycerides in patients taking olanzapine was 40.5 mg/dL. For comparison, quetiapine was associated with an increase of 21.2, risperidone with a decrease of 2.4, perphenazine with an increase of 9.2, and ziprasidone with a decrease of 16.5. Since some patients were receiving olanzapine at the start of the trial and may have already experience increases, this may be an underestimate of triglyceride elevation on olanzapine. Patients with no prior history of hyperlipidemia were particularly vulnerable to increases during olanzapine treatment. These concerns about hyperlipidemia suggest that patients who are treated with olanzapine should have lipid levels monitored before and after olanzapine treatment is initiated and at regular intervals.

HYPERGLYCEMIA, INSULIN RESISTANCE, DIABETES MELLITUS. Several studies suggest that hyperglycemia and diabetes mellitus are potential side effects that follow treatment with olanzapine. A number of studies, including CATIE, found greater elevations in blood glucose on olanzapine than on other antipsychotics. These effects were apparent in individuals with normal glucose regulation, as indicated by normal fasting blood glucose, as well as in individuals with diabetes mellitus or other evidence of glucose dysregulation. Other studies have found that olanzapine is associated with an increase in insulin resistance in both obese and nonobese patients. This suggests that the effects of olanzapine are not just secondary to weight gain.

There is also substantial evidence indicating that olanzapine treatment is associated with an increased risk of the development of type 2 diabetes mellitus. Using the U.K. General Practice Research Database, Koro and coworkers found that olanzapine was associated with a significantly increased risk of diabetes when compared with patients who were not on antipsychotics (odds ratio 5.8) or taking FGAs. This finding has been supported by other large epidemiologic studies. The increased risk could be related to weight gain, which is highly associated with the development of diabetes. However, there are descriptions of normal-weight patients on olanzapine who develop diabetes.

There is also evidence that olanzapine can result in elevations in blood glucose that are life-threatening. In a retrospective epidemiologic survey of spontaneously reported adverse events related to olanzapine therapy, 237 patients with olanzapine-associated diabetes or hyperglycemia were

Telegram: @medical_k

www.konkur.in

identified. Seventy-three percent of all cases of hyperglycemia appeared within 6 months of initiating olanzapine therapy. Eighty patients had metabolic acidosis or ketosis, 41 had glucose levels of 1,000 mg/dL or greater, and 15 patients died. When olanzapine was discontinued, or the dosage was decreased, 78% of patients had improved glycemic control. Hyperglycemia recurred in 8 of 10 cases with rechallenge.

These concerns regarding glycemic control with olanzapine indicate that other antipsychotics may be preferred for patients who already have diabetes as well as those with risk factors for diabetes such as obesity or a family history of diabetes. In addition, the American Psychiatric Association and Mount Sinai Guidelines recommend that clinicians evaluate fasting blood glucose before and after initiating treatment with olanzapine.

NEUROLEPTIC MALIGNANT SYNDROME AND TARDIVE DYSKINESIA. The product information for olanzapine has the same warnings regarding tardive dyskinesia and neuroleptic malignant syndrome (NMS) as other antipsychotics.

ELEVATED HEPATIC ENZYMES. Placebo-controlled trials of olanzapine found a small incidence of elevated liver enzymes. For example, 2% of olanzapine-treated patients had clinically significant alanine aminotransferase (ALT) elevations, which were defined as three times the upper level of normal. Patients with these elevations did not develop jaundice.

PREGNANCY. Olanzapine is considered pregnancy category C. In a study that compared exposure to all SGAs to no exposure during pregnancy, the authors reported no increased risk of malformation or neonatal complications, except for lower birth weight in the exposed group. A 2018 study using Medicaid data found that the use of olanzapine and quetiapine during pregnancy was associated with an increased risk of gestational diabetes.

NURSING MOTHERS. Olanzapine is excreted in breast milk, but the concentration of olanzapine in breast milk appears to be low. A study was conducted by Gardiner and colleagues that measured the transfer of olanzapine to breast milk and then infant plasma in seven mother–infant pairs. The measured concentration of olanzapine in breast milk was

Telegram: @medical_k

www.konkur.in

approximately 1% of the maternal dose. Olanzapine was undetectable in the plasma of exposed infants, and all infants were healthy without observable side effects. As with any medication used during breastfeeding, mothers should be advised of the risks and benefits of breastfeeding while on medication and the potential consequences of olanzapine exposure to their infant.

Drug Interactions. Agents that induce CYP1A2, such as omeprazole (Prilosec) and rifampin, may decrease olanzapine plasma concentrations. Smoking also induces CYP1A2 and may have similar effects. Carbamazepine can increase the clearance of olanzapine and may also decrease plasma concentrations. Fluvoxamine, an inhibitor of CYP1A2, can cause increases in olanzapine levels.

Laboratory Interference. Olanzapine does not interfere with common laboratory tests.

Dosage and Administration. Olanzapine is available as 2.5-, 5-, 7.5-, 10-, 15-, and 20-mg tablets; as 5-, 10-, 15-, and 20-mg orally disintegrating tablets (Zydis); as vials with 10 mg of olanzapine for IM injection; and as vials with 150-, 210-, 300-, or 450-mg olanzapine pamoate extended release for IM injection (Relprevv).

TREATMENT OF SCHIZOPHRENIA. Olanzapine is effective at dosages between 7.5 and 20.0 mg per day, administered once daily without regard to meals. A single starting dose of 5 to 10 mg is well tolerated in most adult patients. The recommended initial dose is then adjusted as necessary within the range of 5 to 20 mg per day. Although clinical studies suggest that there is no advantage to prescribing doses above 10 mg daily, the impression of many clinicians is that doses of 15 to 25 mg or more are optimal for acute schizophrenia. This is reflected in the CATIE study, where the mean modal daily dose of olanzapine was 20.1 mg daily. In other words, the mean dose was above the maximum dose of 20 mg that is recommended in the product information. In adolescents, the dose range of 2.5 to 20 mg/day demonstrated efficacy, with the mean dose being 11.1 mg/day.

MAINTENANCE IN SCHIZOPHRENIA. Long-term studies indicate that doses of 10 to 20 mg daily of olanzapine are sufficient to prevent psychotic relapse

Telegram: @medical_k

www.konkur.in

in stabilized patients.

TREATMENT OF BIPOLAR DISORDER. Patients with mania or mixed states can usually be started on 10 to 15 mg daily of oral olanzapine. Doses can be increased to 20 or 25 mg daily. Similar doses can be prescribed when olanzapine is added to lithium or valproate. Patients with bipolar disorder who have been stabilized can usually be maintained on 5 to 10 mg of olanzapine daily.

SPECIAL POPULATIONS. Patients who are debilitated or vulnerable to hypotension should be started on 5 mg or less. Doses of 5 to 10 mg orally may be effective for schizophrenia or bipolar disorder in these individuals.

IM OLANZAPINE IN AGITATION ASSOCIATED WITH SCHIZOPHRENIA OR BIPOLAR DISORDER. IM doses of 2.5 to 10 mg have been effective in reducing agitation. In most cases, 10 mg IM is an appropriate initial dose. Lower doses may be appropriate for some patients. Doses of 10 mg may be repeated after 2 hours if the patient remains agitated. As noted earlier, the advantage of IM administration is a more rapid onset of calming. Therefore, cooperative patients may be changed to oral administration with rapid dissolve or regular tablets.

OLANZAPINE PAMOATE LONG-ACTING INJECTABLE. In 2009, the FDA-approved olanzapine pamoate as a long-acting IM injectable agent was indicated for the treatment of schizophrenia. Its efficacy was demonstrated in an 8-week randomized controlled trial (N = 404), in which patients with schizophrenia were discontinued from their prior oral antipsychotics and underwent a 2- to 7-day washout, followed by initiation of olanzapine long-acting injectable 210 mg every 2 weeks, 405 mg every 4 weeks, 300 mg every 2 weeks, or placebo. The primary outcome measure was the change in PANSS total score from baseline to end point. Olanzapine long-acting injectable showed statistically significant improvement over placebo at all three dosages. A subsequent longer-term trial enrolled 1,065 adults with schizophrenia who were stable for 4 to 8 weeks on oral olanzapine. They were randomized to either continue their current oral olanzapine or switch to olanzapine in long-acting injectable form. The primary outcome measure was the time to exacerbation of schizophrenia, which was defined by prespecified increases in BPRS positive symptom score or

Telegram: @medical_k

www.konkur.in

hospitalization. In this study, olanzapine long-acting injectable at dosages of 150 mg every 2 weeks, 405 mg every 4 weeks, and 300 mg every 2 weeks were superior to the lower dose of 45 mg every 4 weeks.

Of particular importance, this medication has a black box warning for postinjection/sedation syndrome, which can present with signs and symptoms similar to an overdose of olanzapine (e.g., may include sedation, delirium, EPS, dysarthria, ataxia, aggression, dizziness, weakness, hypertension, and convulsions). In its most extreme presentation, it can lead to coma and require intubation. This syndrome generally occurs within the first 3 hours after injection but can also occur after this period. The frequency of this syndrome is reported to be <0.1% of injections and in roughly 2% of patients who received injections for up to 46 months.

The FDA mandates that this medication be administered at registered facilities with access to emergency services if needed. After injection, patients must be under observation for at least 3 hours before leaving the site. If this medication is used, the prescriber, health care facility, patient, and pharmacy must be enrolled in a patient care program to facilitate medication distribution.

Patients being prescribed olanzapine long-acting injection should already be taking olanzapine orally to ensure medication tolerability. This medication is recommended to be administered every 2 to 4 weeks by deep IM gluteal injection. The dosage schedules specify the initial dose during the first 8 weeks, followed by maintenance dosing thereafter. To achieve levels roughly equivalent to a 10 mg/day oral dose, patients should be initially administered 210 mg every 2 weeks or 405 mg every 4 weeks, followed by maintenance dosing of 150 mg every 2 weeks or 300 mg every 4 weeks. To achieve levels roughly equivalent to a 15 mg/day oral dose, patients should be initially administered 300 mg every 2 weeks, followed by maintenance dosing of 210 mg every 2 weeks or 405 mg every 4 weeks. To achieve levels roughly equivalent to a 20 mg/day oral dose, patients should be initially administered 300 mg every 2 weeks, followed by maintenance dosing of 300 mg every 2 weeks. Patients who are debilitated or more sensitive to olanzapine should be started at 150 mg every 4 weeks.

Ziprasidone

Telegram: @medical_k

www.konkur.in

Ziprasidone was synthesized in 1987 by Harry Howard of Pfizer Pharmaceuticals. Tom Seeger screened the compound and identified the activity at D_2 and 5-HT_2 receptors. Early on, it was noted that ziprasidone differed from the other agents in this class by not being associated with weight gain and having relatively few sedative side effects. Its approval in the United States was delayed due to concerns regarding its tendency to prolong the QT interval on the ECG. The FDA required Pfizer to document the extent of the problem in a large trial that evaluated the effects of several antipsychotics on the QT interval. The results of this study led to ziprasidone's approval in the United States in 2001.

Concerns about weight gain, diabetes, and lipid elevations led to an increase in the use of ziprasidone. For example, in the NIMH CATIE trial, patients randomized to ziprasidone showed negligible changes in weight, glucose, or lipids. Moreover, patients who gained weight on other antipsychotics were likely to show substantial weight loss when they were switched to ziprasidone.

Chemistry. Ziprasidone is a benzisothiazolyl piperazine (Fig. 33.2b–1) with a structure unlike any of the other SGAs.

Pharmacologic Action

PHARMACOKINETICS OF ORAL ZIPRASIDONE

Absorption. Ziprasidone is well absorbed when orally administered. Bioavailability doubles when ziprasidone is administered with food. Therefore, patients should be instructed to take ziprasidone with a meal. After administration of multiple doses of ziprasidone under fed conditions, peak serum concentrations occur at 6 to 8 hours.

Distribution. Ziprasidone has a mean volume of distribution of 1.5 L/kg. It is more than 99% protein bound.

Metabolism and Elimination. Ziprasidone is extensively metabolized, with less than 1% excreted unchanged in the urine and less than 4% in feces. In vitro studies indicate that the formation of the major metabolites is mediated by CYP3A4, although there is a small contribution from CYP1A2. Ziprasidone's metabolites are, for the most part, inactive, representing less than 1% of the binding affinity of the parent compound

Telegram: @medical_k

www.konkur.in

for D_2 and 5-HT_{2A} receptors. Unmetabolized ziprasidone represents 44% of the circulating drug-related material.

Steady state is attained after 1 to 3 days of dosing. Overall exposure at steady state is relative to the dose over the range of 20 to 80 mg twice a day. The mean terminal plasma half-life for ziprasidone at steady state ranges from 5 to 10 hours in volunteers and in schizophrenia patients. The 0.5- to 1-hour lag in reaching peak plasma concentrations has been attributed to delayed gastric emptying. Age, gender, or mild to moderate renal or hepatic impairment have no significant effect on the pharmacokinetics of ziprasidone, making dosage adjustments unnecessary.

Pharmacokinetics of IM Ziprasidone

ABSORPTION AND DISTRIBUTION. Intramuscularly administered ziprasidone, as with all parenterally administered drugs, is 100% bioavailable. Serum concentrations of ziprasidone reach their peak approximately 1 hour after IM administration, with a half-life from 2 to 5 hours.

METABOLISM AND ELIMINATION. After IM administration, metabolism and elimination are anticipated to occur via the same pathways as with oral administration.

Pharmacodynamics

MECHANISM OF ACTION. In vitro studies show that while ziprasidone is a strong D_2 antagonist, it is an even more potent antagonist at the 5-HT_{2A} receptor, with a very high 5-HT_{2A} to D_2 ratio of 11. PET studies in healthy volunteers confirm that 5-HT_2 occupancy substantially exceeds D_2 occupancy. Ziprasidone also has a potent affinity for the D_3 receptor and moderate affinity for the D_4 receptor, similar to haloperidol; the affinity for the D_1 receptor is 100-fold lower than for other dopamine receptors. Ziprasidone is an agonist at the 5-HT_{1A} receptor and a potent antagonist at 5-HT_{2C} (5 times greater than clozapine and 19 times greater than risperidone) and 5-HT_{1D} receptors. It also moderately affects norepinephrine and serotonin (and dopamine) uptake sites. Ziprasidone has only moderate affinity for the α_1 receptor and low affinity for the H_1

Telegram: @medical_k

www.konkur.in

receptor. Ziprasidone is the only agent providing uptake inhibition of norepinephrine and serotonin. Stimulation of 5-HT_{1A} receptors is shared with clozapine.

BLOOD CONCENTRATIONS AND RELATION TO ACTION. With twice-daily administration of oral ziprasidone, estimates based on systemic exposure and PET scan data predict that 5-HT_2 and D_2 receptor occupancy ranges from 80% to 90% and 45% to 75%, respectively. Ziprasidone at serum concentrations of 30 to 40 ng/mL is likely to be associated with approximately 75% 5-HT_2 and more than 65% D_2 receptor occupancy, as determined from PET scan data.

A consensus statement recommends plasma level monitoring for ziprasidone with a recommended range of 50 to 200 ng/mL.

Design and Interpretation of Clinical Drug Studies

EARLY CLINICAL TRIALS IN SCHIZOPHRENIA. Results from 4- to 6-week, fixed-dosage, double-blind clinical trials indicate that oral ziprasidone is effective in the treatment of positive, negative, and affective symptoms in patients with schizophrenia and schizoaffective disorder. In two separate 4- to 6-week clinical trials in patients with acute psychotic exacerbation of schizophrenia, oral ziprasidone (80 to 160 mg per day) was significantly superior to placebo, and, in a 4-week trial, oral ziprasidone (160 mg per day) was comparable to haloperidol (15 mg per day) in reducing psychotic symptoms. Statistically significant, dose-dependent improvements in negative symptoms, as measured by the PANSS, have been observed with oral ziprasidone (80 and 160 mg per day) compared with placebo in a 6-week trial. Oral ziprasidone (160 mg per day) also significantly improved depressive symptoms in patients with clinically significant symptoms at baseline (Montgomery–Asberg Depression Rating Scale [MADRS] 14 or more; baseline mean, 23.5) compared with placebo at 6 weeks. A statistically significant improvement has also been observed in affective symptoms at 4 weeks in patients with a BPRS anxiety–depression cluster baseline score greater than or equal to 18. Further evidence for efficacy in negative symptoms comes from a 4-week, placebo-controlled trial in which a significant improvement in the BPRS anergia factor was observed with ziprasidone at 120 mg per day. A dose-dependent effect was not

Telegram: @medical_k

www.konkur.in

observed, which suggests that the negative symptom reduction effect may be related to its lack of extrapyramidal side effects.

A careful look at these short-term trials provides valuable information about the dosing of ziprasidone. In most of the fixed-dose studies, less than 40 mg twice daily was not superior to placebo; results for 40 mg twice daily were mixed. This suggests that for most patients, dosing of ziprasidone should be targeted at above 40 mg twice daily.

CATIE TRIAL AND ZIPRASIDONE. In phase I of CATIE, discontinuation rates on ziprasidone were similar to those for patients treated with the other SGAs and perphenazine. Ziprasidone had the best metabolic profile among the phase I agents. Ziprasidone-treated patients showed slight weight loss, as well as small reductions in cholesterol and triglycerides and trivial increases in glucose levels. Among patients who gained more than 7% of their baseline body weight during phase I, 42% of those assigned to ziprasidone during phase II lost 7% of their new weight.

LONG-TERM EFFECTIVENESS IN SCHIZOPHRENIA. Oral ziprasidone appears to be effective in the long-term treatment of stable patients with chronic schizophrenia according to double-blind, randomized studies. Results from a 28-week, fixed-dose comparative study indicate that ziprasidone is comparable to haloperidol in reducing overall psychopathology during long-term treatment of schizophrenia. Ziprasidone, however, demonstrated superior tolerability and control of negative symptoms.

Results from a prospective, 1-year double-blind, fixed-dose ziprasidone study in patients with chronic or subchronic schizophrenia showed that oral ziprasidone (40 to 160 mg per day) is associated with significantly lower relapse rates compared with placebo. This group of stable patients experienced a significant reduction in negative symptoms from baseline compared with placebo, as measured with the negative symptom subscale of the PANSS. This improvement in negative symptoms was maintained throughout 12 months of treatment, with a tendency for continuing improvement in those patients completing the study.

BIPOLAR MANIA. A study reported by Paul Keck and coworkers randomized 210 patients with mania or mixed states to a 3-week trial of ziprasidone or placebo. Dosing was flexible. From day 8 to 14, the mean ziprasidone dose was 139 mg; between days 15 and 21, it was 130.1.

Telegram: @medical_k

www.konkur.in

Ziprasidone-treated patients demonstrated significant improvements compared to placebo-treated patients on a Mania Rating Scale and the CGI. Improvements on ziprasidone emerged by day 2. Advantages of the same instruments were found in a second 3-week controlled study.

AGITATION IN SCHIZOPHRENIA. Two double-blind studies evaluated the efficacy of IM ziprasidone for reducing agitation in schizophrenia during a 24-hour period. Patients could receive up to four injections 4 hours apart. Both studies used the Behavioral Activation Scales (BARS) to evaluate the outcome. One study found that 20 mg was more effective than the 2-mg dose, and the other found that 10 mg was superior to 2 mg. Two other studies were open label and compared 3 days of IM ziprasidone or haloperidol followed by 4 days on the same drug. A 6-week study administered IM ziprasidone or haloperidol for 3 days followed by oral treatment. Each of these studies found that IM ziprasidone had similar or better efficacy against agitation than haloperidol and caused fewer extrapyramidal side effects.

Effects on Specific Organs and Systems. Ziprasidone has substantial α_1-adrenergic antagonist effects, which may explain a tendency to cause orthostatic hypotension, tachycardia, and dizziness in some individuals. Ziprasidone can cause prolongation of the QTc interval (see Precautions and Adverse Reactions).

Therapeutic Indications

SCHIZOPHRENIA. Ziprasidone is effective for the treatment of schizophrenia. The evidence supporting its efficacy is from 4- to 6-week trials indicating greater efficacy than placebo. A large 52-week double-blind trial also found that ziprasidone was more effective than placebo for preventing relapse in stabilized patients with schizophrenia.

BIPOLAR I DISORDER. Ziprasidone is also indicated as monotherapy for the acute treatment of manic or mixed episodes in bipolar I disorder. It is also indicated for the maintenance treatment of bipolar I disorder as an adjunct to lithium or valproate. The efficacy of ziprasidone as monotherapy for maintenance therapy has not been systematically evaluated.

Telegram: @medical_k

www.konkur.in

ACUTE TREATMENT OF AGITATION IN SCHIZOPHRENIA. IM ziprasidone is effective for managing agitation in patients with schizophrenia. The advantage of IM medication is a more rapid onset of effects. The product information for ziprasidone has the following description of the type of individual where ziprasidone may be useful: "Schizophrenic patients experiencing agitation often manifest behaviors that interfere with their diagnosis and care, for example, threatening behaviors, escalating or urgently distressing behavior, or self-exhausting behavior, leading clinicians to the use of IM antipsychotic medications to achieve immediate control of the agitation."

Precautions and Adverse Reactions

BLACK BOX WARNING. Ziprasidone and the other SGAs carry a black box warning for increased mortality in older adult patients with dementia-related psychosis compared with placebo.

QT PROLONGATION. Ziprasidone is associated with a dose-related prolongation of the QT interval on the ECG. This is a concern since a prolonged QT interval can lead to the development of a characteristic ventricular tachycardia known as torsade de pointes. This arrhythmia can result in hypotension or, more seriously, ventricular fibrillation and death. There is a concern that if ziprasidone was administered in combination with other agents associated with QTc prolongation, the effects could be additive. As a result, the product information for ziprasidone warns against combining it with other drugs that may increase the QT interval, including dofetilide (Tikosyn), sotalol (Betapace), quinidine, other class Ia and III antiarrhythmics, mesoridazine (Serentil), thioridazine, chlorpromazine, droperidol (Inapsine), pimozide (Orap), sparfloxacin (Zagam), gatifloxacin (Tequin), moxifloxacin (Avelox), halofantrine (Halfan), mefloquine (Lariam), pentamidine (Nebupent), arsenic trioxide (Trisenox), levomethadyl acetate (Orlaam), dolasetron mesylate (Anzemet), probucol (Lorelco), or tacrolimus (Prograf). Ziprasidone should also not be prescribed for patients with existing QT prolongation. In addition, it should not be prescribed in patients who have conditions such as hypokalemia and hypocalcemia, which can prolong the QT interval.

An interesting study that was required prior to the approval of ziprasidone by the FDA gives a perspective on the amount of QT

Telegram: @medical_k

www.konkur.in

prolongation associated with ziprasidone and other antipsychotics. Patients receiving six antipsychotics had their QT interval measured at their maximal plasma concentration. This was done in the presence and absence of a metabolic inhibitor of the antipsychotic in question (in the presence of an inhibitor, the plasma concentration of the antipsychotic drug increases). Ziprasidone administration resulted in a mean increase in the QTc (i.e., the QT interval corrected for heart rate) of 9 to 14 ms greater than four of the comparator drugs (risperidone, olanzapine, quetiapine, and haloperidol) but 14 ms less than thioridazine. This finding was sufficiently reassuring to lead to the approval of ziprasidone.

USE IN PREGNANCY AND DURING LACTATION. Ziprasidone is considered category C for pregnancy. Although there are no well-controlled studies on the risk of ziprasidone to the fetus, animal studies suggest that there is a potential for teratogenic effects from ziprasidone. Unlike the other older SGAs, little is published on the effects of ziprasidone during pregnancy and lactation. Therefore, ziprasidone should only be taken during pregnancy if the clinical benefits justify the risk to the fetus.

OTHER SIDE EFFECTS. Double-blind comparisons of ziprasidone and placebo have not found a statistically significant difference in EPS or akathisia. However, case reports suggest that some patients experience an increase in the restlessness that may be mild akathisia.

Drug Interactions. Ziprasidone should not be combined with drugs that prolong the QT interval. Otherwise, ziprasidone has a low potential for clinically significant drug interactions. In vitro studies indicate that ziprasidone is not a substrate for CYP2D6, CYP2C9, CYP2C19, or CYP1A2 and has low potential to inhibit CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4. The lack of clinically relevant CYP2D6 inhibition has been confirmed in healthy volunteers, in whom ziprasidone did not inhibit the metabolism of dextromethorphan (Benylin) (a CYP2D6 model substrate) to its major metabolite, dextrorphan. Although ziprasidone is a substrate for CYP3A4, cimetidine (a CYP3A4 inhibitor) does not inhibit its metabolism, suggesting that significant metabolism occurs by an alternative pathway. Carbamazepine induces CYP3A4 and lowers ziprasidone plasma concentrations. In healthy subjects, clinically significant interactions have not been reported with lithium, cimetidine, antacids (aluminum and magnesium hydroxides), ketoconazole, or oral

Telegram: @medical_k

www.konkur.in

contraceptives. Ziprasidone did not affect steady-state lithium concentrations.

Laboratory Interference. Ziprasidone does not affect common laboratory tests.

Dosage and Administration

SCHIZOPHRENIA. For most adult patients, ziprasidone should be initiated at 20 mg twice a day with food. Dosage may be increased every 2 days. As mentioned earlier, trials in schizophrenia indicate that patients receiving a total daily dose of 100 mg or greater are more likely to respond. Daily dosage can be adjusted on the basis of clinical status up to a maximum of 80 mg twice a day.

Duration of Treatment. The benefits of ziprasidone in schizophrenia have been found to be maintained for periods of up to 1 year when given at dosages ranging from 20 to 80 mg twice a day, although, in these studies, no additional benefits were seen at dosages higher than 20 mg twice a day. Ziprasidone has been administered safely for up to 2 years.

BIPOLAR I DISORDER. For the acute treatment of manic or mixed episodes, ziprasidone should be given at an initial dose of 40 mg twice daily with food. It may be increased to 60 mg or 80 mg twice daily on day 2 and titrated according to efficacy and tolerance. In flexible-dose trials, the mean daily dose used was around 120 mg. For maintenance treatment as an adjunct to lithium or valproate, patients should be continued at the same dose as initial stabilization, within the range of 40 to 80 mg twice daily with food.

ACUTE TREATMENT OF AGITATION IN SCHIZOPHRENIA (IM FORMULATION). The recommended IM dosage is 10 to 20 mg administered every 2 hours for the 10-mg dose and every 4 hours for the 20-mg dose, up to a maximum dosage of 40 mg per day. IM administration has not been studied for longer than 3 consecutive days, and it is recommended that oral therapy be initiated if longer-term treatment is necessary.

Lurasidone

Telegram: @medical_k

www.konkur.in

Lurasidone is an antipsychotic that is a potent antagonist at 5-HT_{2A}, D_2, and 5-HT_7 receptors and a partial agonist at the 5-HT_{1A} receptor. It is among the DSAs (along with aripiprazole and ziprasidone) that have a relatively low liability for metabolic side effects. Patients should be cautioned to take lurasidone with food. Its most common side effects include sedation, extrapyramidal side effects (including akathisia), and nausea.

Lurasidone was developed by Dainippon Sumitomo Pharma and marketed by Sunovion in the United States. It was approved by the FDA for the treatment of schizophrenia in adults in 2010. Subsequently, approval was granted in 2013 for the treatment of adults with bipolar depression (as both monotherapy and as an adjunct to lithium or valproate therapy).

Chemistry. Lurasidone belongs to the class of benzisothiazol derivatives, with the full chemical name of (3aR,4S,7R,7aS)-2-[((1R,2R)-2-{[4-(1,2-benzisothiazol-3-yl)-piperazin-1-yl]methyl}cyclohexyl)methyl]hexahydro-1H-4,7-methanisoindol-1,3-dione. Its molecular formula is $C_{28}H_{36}N_4O_2S$, and its molecular weight is 492.676 (free base). It is currently used in the form of its hydrochloride salt.

Pharmacologic Action

PHARMACOKINETICS

Absorption. Lurasidone has a relatively low oral bioavailability of 9% to 19%, and its absorption is affected by food intake. Administration of lurasidone with a meal of at least 350 calories increases drug exposure.

Distribution. Peak serum concentrations are reached in 1 to 3 hours. The volume of distribution is 6,173 L, and lurasidone is highly bound to serum proteins.

Metabolism and Elimination. Lurasidone is metabolized mostly by CYP3A4 and is not a substrate for CYP1A1, CYP1A2, CYP2A6, CYP4A11, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, or CYP2E1. Its major biotransformation pathways are oxidative *N*-dealkylation, hydroxylation of its norbornane ring, and S-oxidation. It has two major active and two major inactive metabolites. Lurasidone is eliminated

Telegram: @medical_k

www.konkur.in

primarily in the feces (80%), with 9% of labeled metabolites recovered in urine. The mean elimination half-life was found to be 18 hours.

PHARMACODYNAMICS

Mechanism of Action. Lurasidone is an antagonist with a high affinity for the dopamine D_2 receptor as well as serotonin 5-HT_{2A} and 5-HT_7 receptors. It has been found to occupy 60% to 70% of D_2 receptors at a 40-mg dose. In addition, it is an antagonist with moderate affinity for α_{2A} and α_{2C} adrenergic receptors and is a partial agonist at the 5-HT_{1A} receptor. It has a low affinity for the serotonin 5-HT_{2C} receptor and negligible affinity for histamine H_1 and muscarinic M_1 receptors.

Design and Interpretation of Clinical Drug Studies

SCHIZOPHRENIA. Efficacy was established for the treatment of schizophrenia by five 6-week randomized controlled trials, with two including active comparators. The studies were conducted on adult patients with DSM-IV schizophrenia. Two of these studies (*N* = 145 and B = 180) used the change in Brief Psychiatric Rating Scale derived (BPRSd) as the primary outcome measure, and lurasidone significantly outperformed placebo at 40, 80, and 120 mg/day dosages. A third study (*N* = 489) used the change in PANSS total score as the primary outcome measure, and lurasidone 80 mg/day was found significantly superior to placebo, but the 40 and 80 mg/day dosages did not separate from placebo. A fourth study (*N* = 473) used olanzapine 15 mg/day as an active comparator. Lurasidone 40 and 120 mg/day, as well as olanzapine 15 mg/day, were significantly more effective than placebo on the primary outcome measure of change in PANSS total score. In the fifth study (*N* = 482), patients were randomized to receive lurasidone 80 mg/day, lurasidone 160 mg/day, quetiapine extended release 600 mg/day, or placebo. The primary outcome measure was the change in PANSS total score. Both doses of lurasidone, as well as quetiapine extended release, were associated with significant improvement in the primary outcome measure as compared to placebo. A sixth study (*N* = 353) involved a random assignment to lurasidone 20, 40, and 80 mg/day or haloperidol 10 mg/day as an active comparator. This study was considered a failure

Telegram: @medical_k

www.konkur.in

because lurasidone at all dosages, as well as haloperidol, did not separate from placebo on the primary outcome measure (BPRSd).

The long-term effectiveness of lurasidone has been assessed in a 52-week controlled trial in which 639 stable outpatients with schizophrenia were randomized to receive lurasidone 40 to 120 mg/day or risperidone 2 to 6 mg/day. The two groups did not statistically differ in relapse rate (defined as a 30% increase in PANSS total score compared to baseline). Both groups also showed statistically equivalent improvement in PANSS total score over the 12 months.

DEPRESSIVE EPISODES ASSOCIATED WITH BIPOLAR I DISORDER

Monotherapy. Efficacy was established in a 6-week randomized controlled trial (*N* = 485) of adults with DSM-IV bipolar I disorder in a major depressive episode, with or without rapid cycling and without psychotic features. Participants were randomized to receive flexible-dose lurasidone 20 to 60, 80 to 120 mg/day, or a placebo. The primary outcome measure was the change in the MADRS score from baseline to week 6. Both dose ranges of lurasidone were superior to placebo, and the effectiveness of the lower- versus higher-range dosing of lurasidone was not statistically different.

Adjunctive Therapy. Efficacy was established in a 6-week randomized controlled trial (*N* = 340) of adults with DSM-IV bipolar I disorder in a major depressive episode, with or without rapid cycling and without psychotic features. Patients who were still symptomatic despite lithium or valproic acid treatment were randomized to receive flexible-dose lurasidone 20 to 120 mg/day or a placebo. The primary outcome measure was the change in MADRS from baseline to week 6. Lurasidone, as an adjunct to valproic acid or lithium, was statistically superior to placebo in the reduction of MADRS score.

Therapeutic Indications

SCHIZOPHRENIA. Lurasidone is indicated for the treatment of adults and adolescents (aged 13 to 17 years) with schizophrenia. Its efficacy was established in five short-term studies of adults with schizophrenia. Lurasidone is not indicated at the time of writing for longer-term use (greater than 6 weeks).

Telegram: @medical_k

www.konkur.in

DEPRESSIVE EPISODES ASSOCIATED WITH BIPOLAR I DISORDER

Monotherapy. Lurasidone is indicated as monotherapy for the treatment of adults and pediatric patients (aged 10 to 17 years) with major depressive episodes associated with bipolar I disorder. Its efficacy for this indication was established in a 6-week monotherapy study of adults with bipolar depression.

Adjunctive Therapy with Lithium or Valproate. Lurasidone is indicated as adjunctive therapy (with either lithium or valproate) for the treatment of patients with major depressive episodes associated with bipolar I disorder. Its efficacy for this indication was established in a 6-week study of adults with bipolar depression who were being treated with lithium or valproate.

Precautions and Adverse Reactions. Lurasidone is contraindicated in individuals with hypersensitivity to lurasidone or any components in the tablets. Lurasidone is also contraindicated in patients using strong CYP3A4 inhibitors (e.g., ketoconazole, clarithromycin, ritonavir, voriconazole, and mibefradil) or CYP3A4 inducers (e.g., rifampin, avasimibe, St. John's wort, phenytoin, and carbamazepine).

BLACK BOX WARNINGS

Increased Mortality in Older Adult Patients with Dementia. Lurasidone and the other SGAs carry a black box warning for increased mortality in older adult patients with dementia-related psychosis compared with placebo.

Suicidal Thoughts and Behaviors. Lurasidone also carries a black box warning for suicidal thoughts and behavior in children, adolescents, and young adults. This warning is associated with all antidepressant medications, including SGAs, with indications for the treatment of depression.

NEUROLEPTIC MALIGNANT SYNDROME. NMS has been associated with the use of antipsychotic medications, including lurasidone. If NMS is suspected, lurasidone and other antipsychotic medications should be discontinued immediately, and the patient should undergo intensive supportive care and medical monitoring.

Telegram: @medical_k

www.konkur.in

TARDIVE DYSKINESIA. Tardive dyskinesia can develop in all patients treated with antipsychotic drugs. Its prevalence is highest among the older adults.

METABOLIC CHANGES. DSAs have been associated with weight gain, lipid elevations, and hyperglycemia, including severe cases with ketoacidosis, hyperosmolar coma, and death. Among available antipsychotics, lurasidone has a low to moderate risk of metabolic changes.

QT PROLONGATION. Lurasidone was evaluated in a randomized controlled QT study in 43 patients with schizophrenia or schizoaffective disorder. Participants were administered lurasidone 120 or 600 mg, and ECGs were assessed 2 to 4 hours after dosing. Patients who received the 120-mg dose experienced a 7.5 ms increase in QTc, and those who received the 600 mg experienced a 4.6 ms increase. There was no observed dose–response relationship. In short-term schizophrenia and bipolar depression clinical trials, no study participants experienced QTc prolongation to greater than 500 ms.

SEIZURES. In short-term premarketing schizophrenia studies, seizures occurred in 0.1% (2/1,508) of patients treated with lurasidone as compared to 0.1% (1/708) of patients treated with placebo. In short-term premarketing bipolar depression studies, no patients experienced seizures.

ORTHOSTATIC HYPOTENSION AND SYNCOPE. Lurasidone may cause orthostatic hypotension and syncope. In pooled premarketing short-term schizophrenia studies, orthostatic hypotension was reported in 0.3% of lurasidone and 0.1% of placebo patients; syncope was reported in 0.1% of lurasidone and no placebo patients. In the premarketing short-term bipolar depression study, there were no reported adverse events of orthostatic hypotension and syncope. However, orthostatic hypotension, as assessed by vital signs, occurred in 0.6% of lurasidone patients as compared to 0% receiving placebo. In the premarketing short-term adjunctive therapy bipolar depression study, there were no reported adverse events of hypotension and syncope. Orthostatic hypotension, as assessed by vital signs, occurred in 1.1% of lurasidone patients and 0.9% of placebo patients.

Telegram: @medical_k

www.konkur.in

HYPERPROLACTINEMIA. As with most antipsychotic medications, lurasidone can increase prolactin levels. In pooled short-term schizophrenia studies, changes in prolactin level with placebo (*N* = 672) and lurasidone 20 (*N* = 70), 40 (*N* = 476), 80 (*N* = 495), 120 (*N* = 284), and 160 mg/day (*N* = 115) were −1.9, −1.1, −1.4, −0.2, +3.3, and +3.3 ng/mL, respectively.

POTENTIAL FOR COGNITIVE AND MOTOR IMPAIRMENT. Lurasidone can cause somnolence, which can impair judgment, thinking, and motor skills.

SERUM CREATININE. In short-term schizophrenia trials, serum creatinine levels increased 0.05 mg/dL in lurasidone-treated participants as compared to 0.02 mg/dL in placebo-treated participants. Changes in creatinine levels appeared to be dose dependent, with 7% of patients receiving lurasidone 160 mg/day (*N* = 121) shifting from normal to abnormally high creatinine levels as compared to 2% of those receiving placebo (*N* = 708).

EXTRAPYRAMIDAL SYMPTOMS. In premarketing schizophrenia studies, EPS (excluding akathisia) was reported in 13.5% of patients receiving lurasidone as compared to 5.8% of patients receiving placebo. Akathisia was reported in 12.9% of patients receiving lurasidone as compared to 3% of patients receiving a placebo. These effects were dose dependent, with the highest percentage of events occurring in the group receiving lurasidone 120 mg/day. EPS were also reported in short-term bipolar depression studies with similar frequencies. Dystonic symptoms occurred in 4.2% of patients in premarketing schizophrenia trials versus 0.8% of those receiving placebo, and 7/1,508 participants (0.5%) discontinued the clinical trial due to dystonic events, which occurred during the first few days of treatment. Dystonia occurred less frequently with lurasidone in bipolar depression studies though it still occurred more often than in the placebo groups. No participants in bipolar depression studies discontinued participation due to dystonic symptoms.

PREGNANCY. Lurasidone is classified as pregnancy category B, which indicates that animal reproductive studies did not identify a specific risk to the fetus, but there are no adequate and well-controlled studies on pregnant women. Lurasidone should only be used in pregnancy if the potential benefit justifies the potential risk to the fetus.

Telegram: @medical_k

www.konkur.in

NURSING MOTHERS. Rat studies demonstrated excretion of lurasidone in milk during lactation. It is unknown whether this also occurs in humans. Mothers should consider discontinuation of nursing due to the potential for adverse reactions in infants.

COMMON AND DRUG-RELATED ADVERSE REACTIONS IN CLINICAL TRIALS. In short-term premarketing schizophrenia studies, the most common adverse reactions associated with lurasidone (defined as incidence ≥5% and at least twice the rate of placebo) were somnolence, akathisia, EPS, and nausea. In the bipolar depression monotherapy study, the most common adverse reactions associated with lurasidone were akathisia, EPS, somnolence, nausea, vomiting, diarrhea, and anxiety. In the bipolar depression adjunctive therapy study, the most common adverse reactions associated with lurasidone were akathisia and somnolence. In premarketing studies for both schizophrenia and bipolar disorder, there were no adverse reactions associated with lurasidone discontinuation (defined as ≥2% occurrence and at least twice the rate of placebo).

Drug Interactions. It is recommended that lurasidone not be used in conjunction with strong CYP3A4 inhibitors (e.g., ketoconazole, clarithromycin, ritonavir, voriconazole, and mibefradil). If lurasidone is used with moderate CYP3A4 inhibitors (e.g., diltiazem, atazanavir, erythromycin, fluconazole, and verapamil), the lurasidone dose should be reduced by half. Grapefruit and grapefruit juice should be avoided in conjunction with lurasidone use.

Lurasidone is contraindicated for use with strong CYP3A4 inducers (e.g., rifampin, avasimibe, St. John's wort, phenytoin, and carbamazepine). If lurasidone is used in conjunction with a moderate CYP3A4 inducer, it may be necessary to increase lurasidone dosage after at least 7 days of treatment with the CYP3A4 inducer.

Lithium and valproic acid dosages do not need to be adjusted if used concomitantly with lurasidone. Dosages of P-glycoprotein substrates (i.e., digoxin) and other CYP3A4 substrates (e.g., midazolam or oral contraceptives) also do not need to be adjusted if used with lurasidone.

Dosage and Administration. Lurasidone is available in 20-, 40-, 60-, 80-, and 120-mg tablets. It is recommended that lurasidone is taken with at least 350 calories of food to improve absorption.

Telegram: @medical_k

www.konkur.in

For the treatment of schizophrenia, it is recommended to start lurasidone at 40 mg once daily. Lurasidone has been found effective for schizophrenia in the dose range of 40 to 160 mg daily, and the maximum recommended dose is 160 mg daily.

For the treatment of bipolar I depression, the recommended starting dose is 20 mg once daily, given as either monotherapy or as an adjunct to lithium or valproate. Lurasidone has been found effective for bipolar I depression in the dose range of 20 to 120 mg daily, and the maximum recommended dose for both monotherapy and adjunct therapy is 120 mg daily.

DOSING IN SPECIAL POPULATIONS

Geriatric Use. There were insufficient numbers of patients aged 65 years and older in lurasidone trials to determine whether they respond differently to the medication than younger adults. In a limited sample of older adult patients with psychosis (65 to 85 years of age), plasma concentrations of lurasidone after 20 mg/day administration were similar to those in younger adults.

Hepatic Impairment. In patients with moderate (Child–Pugh Score of 7 to 9) or severe hepatic impairment (Child–Pugh score of 10 to 15), dose reduction in lurasidone is recommended. The recommended starting dose is 20 mg daily, and the maximum recommended dose in moderate or severe hepatic impairment is 80 and 40 mg/day, respectively.

Renal Impairment. In patients with moderate or severe renal impairment (creatinine clearance less than 50 mL/min), dose reduction in lurasidone is recommended. In this population, the recommended starting dose is 20 mg daily, and the maximum recommended dose is 80 mg daily.

DOPAMINE, SEROTONIN, NOREPINEPHRINE α2

Clozapine

Clozapine was the first of the DSAs. It was discovered in 1958 in Bern, Switzerland, and was first studied in animal experiments in 1960. Soon after clinical trials with clozapine began, the drug appeared to be an effective antipsychotic agent that did not cause extrapyramidal side

Telegram: @medical_k

www.konkur.in

effects. The first studies showed that patients became calmer in the first 5 days, and psychotic excitement decreased from day 5 onward. Day 20 effects on psychosis were substantial, and negative symptoms improved at 40 days. However, early studies with clozapine in Europe were met with skepticism because this agent was inconsistent with the dogma that effective antipsychotic agents were associated with extrapyramidal effects. This dogma was challenged by a number of European authorities, including Hans Hippius, and, as a result, clozapine was eventually approved in several countries in Europe in 1972.

The enthusiasm about clozapine was dampened when it was discovered that the drug was associated with significant hematologic toxicity. In 1975, clozapine was introduced in Finland, where 16 of 1,600 treated patients developed granulocytopenia (1,600 cells or less per mm^3). Eight of the 13 patients in whom granulocytopenia progressed to agranulocytosis died of infectious diseases. After 50 patients around the world had died, clozapine was withdrawn from most European markets, and research with this drug came to a virtual halt. Some patients who were receiving clozapine before its withdrawal from the market continued on the drug because of its clear advantages over prior treatment. Regular monitoring of white blood cell (WBC) counts in these individuals showed that clozapine-induced agranulocytosis was reversible when drug use was stopped. In addition, controlled trials in Europe showed that clozapine was more effective than conventional agents for treating schizophrenic patients who were either severely ill or resistant to other antipsychotic agents.

Discussions with the FDA led to a U.S. multicenter trial to determine whether clozapine was effective for treatment-refractory patients. The effectiveness of clozapine was compared with that of chlorpromazine (Thorazine) in 268 schizophrenia patients with thoroughly documented failure to respond to conventional antipsychotic agents. The study, reported in 1988 by John Kane, Herbert Meltzer, and others, found that clozapine was more effective than chlorpromazine in terms of a number of important outcomes, including psychosis, mood, and anxiety. The results from this study and others led to the approval of clozapine in the United States in 1990 for schizophrenia patients who are resistant to treatment with other antipsychotic drugs or who are unable to tolerate conventional drugs because of extrapyramidal side effects or severe tardive dyskinesia.

Telegram: @medical_k

www.konkur.in

Treatment resistance in schizophrenia is a poorly defined concept that has evolved since clozapine's introduction. At that time, treatment resistance referred to a failure to respond to a conventional dopamine receptor antagonist. Because of clozapine's side-effect profile, it was hoped that other DSAs would replace it as the agent of choice for treatment-resistant schizophrenia. However, studies that compared clozapine to other DSAs for treatment-resistant patients nearly always found that clozapine was superior. Over the years, meta-analyses have consistently identified clozapine as the most effective antipsychotic for schizophrenia.

Chemistry. Clozapine is a five-membered heterocyclic compound, 8-chloro-11-(4-methyl-1-piperazinyl)-5*H*-dibenzo-[*b,e*][1,4-]diazepine. Its chemical formula is $C_{18}H_{19}N_4Cl$, with a molecular weight of 326.8. Substitutions for the A-ring have led to other clinically effective clozapine-like agents; however, loxapine (Loxitane), an antipsychotic with a clozapine-related molecular structure, has a clinical and side-effect profile similar to other traditional antipsychotic drugs. Other clozapine-derived antipsychotic agents are olanzapine and quetiapine, but being a derivative does not translate to similar efficacy. Chemical structures for clozapine and the other SGAs discussed in this chapter are depicted in Figure 33.2b–1.

Pharmacologic Actions

PHARMACOKINETICS. The pharmacokinetic profiles of clozapine and other DSAs are summarized in Table 33.2b–1.

Absorption. Clozapine is only available as an oral preparation. As with other antipsychotic agents, peak plasma levels are reached approximately 2 hours after oral administration (range, 1.1 ± 0.5 to 3.0 ± 1.5 hours). The elimination half-life is approximately 12 hours (between 10 and 16 hours; range, 6 to 33 hours). As a result, twice-daily dosing results in steady-state plasma concentrations in less than 1 week. Based on animal studies, coadministration of highly protein-bound drugs may increase free clozapine concentrations, although the total concentration (free plus bound) may be unchanged.

Telegram: @medical_k

www.konkur.in

Distribution. Clozapine has a large volume of distribution (mean of 2.0 to 5.1 L/kg [range, 1.0 to 10.2 L/kg]), although this is lower than other antipsychotic drugs.

Metabolism and Elimination. Clozapine undergoes extensive first-pass metabolism in the liver and gut. Absolute bioavailability (percentage of clozapine reaching the systemic circulation unchanged) after oral administration varies from 27% to 47%. The primary metabolic routes are demethylation, *N*-oxidation, oxidation of the aromatic ring, and conjugation. Reportedly 80% of administered clozapine appears in the urine or feces as metabolites. Less than 5% of the parent compound is found unchanged in the urine.

The *N*-desmethylclozapine metabolite represents 40% to 80% of the concentration of clozapine. It is a muscarinic type 1 (M_1) receptor agonist, whereas clozapine itself has muscarinic antagonist effects. According to Herbert Meltzer, this metabolite may be a major contributor to clozapine's purported superior effects on cognition and negative symptoms compared to the other agents.

PHARMACODYNAMICS

Mechanism of Action. The explanation for clozapine's unique clinical profile remains controversial. Preclinical studies in rats have shown that clozapine blocks the conditioned avoidance response, indicating that the drug has potential antipsychotic activity. However, it did not produce catalepsy in animals, suggesting that it is unlikely to produce EPS in humans. This made it different from conventional antipsychotic medications, which all cause extrapyramidal side effects as a direct result of their D_2 receptor blockade in the forebrain.

The relatively low affinity for D_2 receptors may explain clozapine's lack of extrapyramidal side effects. In patients treated with most FGAs and SGAs, PET scan studies have shown that, with doses comparable to 10 mg of haloperidol (Haldol), more than 80% of striatal D_2 receptors are occupied. Higher doses do not increase receptor occupancy further. In clinically effective doses, clozapine only occupies 40% to 50% of D_2 receptors. This weak effect at the D_2 receptor site may be related to clozapine's unusual biologic profile that combines a low D_2 affinity with

Telegram: @medical_k

www.konkur.in

activity at a number of other receptor sites, including serotonergic (e.g., 5-HT_2 and 5-HT_{1C}), adrenergic, and cholinergic sites.

As mentioned above, the clozapine metabolite *N*-desmethylclozapine has M_1 agonist activity. Studies suggest that patients who have higher ratios of this metabolite to the parent compound tend to have better clinical outcomes. This suggests that M_1 agonism may contribute to clozapine's unique effectiveness.

Philip Seeman and Shitij Kapur have proposed that the lack of EPS with clozapine and other DSAs is related to their fast dissociation from the D_2 receptor. Conventional dopamine receptor antagonists tend to bind more tightly to dopamine receptors than dopamine itself. Clozapine and nearly all of the other SGAs bind more loosely and tend to come off the receptor more readily in the presence of dopamine. As a result, these newer agents may block these receptors more transiently, coming off the receptor to permit more normal dopamine transmission. Clozapine also has a 10-fold higher affinity for the D_4 receptor than do other antipsychotics. The D_4 receptor is present in the cortex and less so in the striatal areas. However, other agents with a high affinity for D_4 receptors have failed to demonstrate that they are effective antipsychotics.

Blood Concentrations and Relation to Action. As with most antipsychotic drugs, patients display considerable variability in their clozapine plasma concentrations among patients receiving the same daily dose. This probably results from differences in both absorption and metabolism. Variability is also observed within patients, which is presumably related to variable absorption rates rather than changes in hepatic metabolism and clearance. Some reports show that women have slightly higher and smokers slightly lower plasma levels (20% to 30%). The plasma levels of older adults may be twofold higher than those of young adults.

Several investigators have studied the relationship between plasma concentrations of clozapine and clinical response. Their findings suggest that monitoring clozapine plasma concentrations may be useful under certain conditions. A wide range of clozapine concentrations appears to

Telegram: @medical_k

www.konkur.in

be associated with a clinically meaningful response. Plasma concentrations of clozapine average approximately 10 to 80 ng/mL/mg of drug given per kilogram of weight. Thus, a typical daily dosage of 300 to 400 mg (approximately 5 mg/kg) is associated with plasma concentrations ranging from 200 to 400 ng/mL. Studies indicate that patients are more likely to respond when their clozapine plasma concentrations are >350 ng/mL. If patients with a plasma concentration of 250 ng/mL have not responded by 6 weeks, the clinician should consider adjusting the dosage to raise the concentration to approximately 350 ng/mL. The correlations between plasma concentration and clinical improvement or side effects are weak, as is observed with other antipsychotic agents.

Design and Interpretation of Clinical Drug Studies

CLOZAPINE FOR ACUTE SCHIZOPHRENIA. Open-label clinical trials conducted in the early 1970s suggested that clozapine was an effective antipsychotic drug that lacked extrapyramidal side effects. These findings were then reinforced with double-blind trials comparing clozapine with other agents. In 79% of the controlled trials that compared clozapine with another antipsychotic drug, clozapine was superior. In reviewing these studies, Ross Baldessarini cautions that the differences between clozapine and the comparator drug were relatively small. Nevertheless, certain patterns emerge. One comparison with chlorpromazine found a small advantage favoring clozapine when a heterogeneous group of patients was studied, but differences favoring clozapine were clearer when the most severely ill subgroup was studied.

EFFICACY IN TREATMENT-REFRACTORY PATIENTS. Early clinical experience with clozapine suggested that it was more effective than conventional drugs for patients who were unresponsive to conventional antipsychotic agents. Moreover, the studies cited in the previous section suggested that the differences between clozapine and other antipsychotics were greater in patients who were severely ill and refractory to treatment with conventional dopamine receptor antagonists. Before marketing clozapine to these patients, the FDA and the manufacturer of clozapine developed a study comparing clozapine with chlorpromazine plus benztropine (Cogentin). The 268 patients who participated in this trial had previously responded poorly in at least three prior antipsychotic trials and a prospective, single-blind trial of haloperidol. This study compared the

Telegram: @medical_k

www.konkur.in

effectiveness of chlorpromazine and clozapine in 248 patients who had thorough documentation of poor responsiveness to conventional antipsychotic agents. During this 6-week trial, the clozapine-treated patients did better on a range of measures of both positive and negative symptoms. Thirty percent of clozapine-treated patients met a priori criteria for significant improvement, in contrast to only 4% of chlorpromazine-treated patients. Other studies show that this 6-week trial may have significantly underestimated the proportion of patients who respond to clozapine and that up to 60% of patients may display substantial improvement after a 6-month trial. Clozapine in this trial was superior to chlorpromazine on 14 of 18 BPRS items, as well as on the CGI and nursing ratings such as social competence, social interest, personal neatness, irritability, manifest psychosis, and motor retardation. When patients were classified as having improved (by prospective criteria) to a clinically significant extent, 30% of clozapine patients improved within 6 weeks versus only 4% of those receiving chlorpromazine plus benztropine ($p < .001$). Based on this trial, the FDA approved clozapine for limited use in the United States.

The NIMH CATIE study compared clozapine (open label) to double-blind risperidone, olanzapine, or quetiapine in patients who had their phase I medication changed for lack of efficacy. Patients assigned to clozapine had the best outcome, with 56% of clozapine patients being discontinued compared to 71% on olanzapine, 86% on risperidone, and 93% on quetiapine. These results were also supported by a study from the United Kingdom by Shon Lewis that compared clozapine to an SGA selected prior to the randomization and found an advantage for clozapine.

The effectiveness of clozapine in treatment-refractory schizophrenia has also been compared to the use of antipsychotic polypharmacy, which is a nonrecommended strategy that is often used in this population. In this study, the utilization of emergency department and hospital services, as well as cost outcomes, was compared between Medicaid beneficiaries receiving clozapine monotherapy and those receiving two or more antipsychotics. It was found that Medicaid beneficiaries receiving clozapine monotherapy between 2006 and 2009 ($N = 479$) had a lower risk for emergency department use as well as lower Medicaid payments (both all cause and mental disorder related) than patients receiving SGA polypharmacy.

Telegram: @medical_k

www.konkur.in

Altogether, these studies support the view that patients with schizophrenia who continue to demonstrate psychotic symptoms that are bothersome should not be considered refractory to treatment unless they have had an adequate trial with clozapine. An adequate trial is probably at least 3 months of clozapine at an adequate dose.

LONG-TERM EFFECTIVENESS. Long-term studies have supported the concept of maintaining patients on clozapine. A 29-week study reported in 2001 found that 60% of moderately refractory outpatients with schizophrenia treated with clozapine met improvement criteria compared with 12% of haloperidol-treated patients. In a study of patients with schizophrenia in Connecticut state hospitals, those who were discharged on clozapine treatment were more likely to remain out of the hospital when compared with individuals discharged on treatment with other agents. A Department of Veterans Affairs Cooperative Study comparing 1 year of treatment with clozapine to that of haloperidol also found that clozapine was associated with a decreased need for hospitalization. Moreover, patients treated with clozapine demonstrated a greater likelihood of participating in psychosocial treatments and rehabilitation programs. As mentioned in an earlier section, there is evidence that patients who are unresponsive to treatment in adequate trials of conventional dopamine receptor antagonists may respond when treated with SGAs other than clozapine. As a result, patients who respond poorly to conventional dopamine receptor antagonists may benefit from a trial of at least one of these agents before receiving a clozapine trial. Clinicians should also consider that prolonged sequential trials with a number of antipsychotics may take months or even years, thus delaying treatment with an agent that may be effective.

SEVERE TARDIVE DYSKINESIA. Patients with severe tardive dyskinesia should also be considered for a clozapine trial. Most clinical reports indicate that clozapine can suppress abnormal movements in tardive dyskinesia. This is not surprising, as conventional antipsychotic agents are effective for the short-term suppression of tardive dyskinesia. However, clozapine is probably less likely to cause the disorder and, therefore, is promising for the long-term management of patients, particularly those who already have tardive dyskinesia. Although rare cases of tardive dyskinesia have been found in patients who receive

Telegram: @medical_k

www.konkur.in

clozapine, the risk of developing this disorder is substantially reduced. Studies using animal models indicate that clozapine does not result in the increased sensitivity of striatal D_2 receptors that are associated with typical antipsychotic agents and has been theorized to result in tardive dyskinesia. It remains to be established whether a positive effect on tardive dyskinesia results from a direct suppressive effect of clozapine on certain transmitter systems or whether clozapine spares the striatal D_2 receptors, allowing spontaneous remission of tardive dyskinesia. The former interpretation is supported by the reports of a return of tardive dyskinetic movements after clozapine withdrawal.

CLOZAPINE IN HOSTILE AND AGGRESSIVE PATIENTS. Clozapine has also been studied in patients with schizophrenia and other psychotic disorders who display hostile and aggressive behaviors. A study of 157 inpatients by Citrome found that clozapine treatment led to greater reductions in ratings of hostility than other antipsychotics. Similarly, Chengappa found that clozapine led to a reduction in the need for seclusion and restraint. A recent study of physically assaultive patients with schizophrenia found that clozapine was more effective at reducing assaults than olanzapine and haloperidol. A within-subject study of a large population in Sweden found that clozapine was associated with a lower rate of violent offending than olanzapine. These findings suggest that clozapine may be of particular benefit to patients who demonstrate hostile and aggressive behaviors.

PATIENTS AT RISK FOR SUICIDE. Clozapine may also be a preferred agent for patients with schizophrenia who are at a higher risk of suicide. Large epidemiologic studies found what appeared to be a reduction in death from suicide in patients receiving clozapine. This and other observations led Herbert Meltzer and colleagues to design the International Suicide Prevention trial (or InterSePT). The study compared clozapine and olanzapine in 956 patients with schizophrenia or schizoaffective disorder who were considered at risk for suicide. Clozapine was more effective in delaying the time of recurrent suicidal behavior. In addition, over a 2-year period, 24% of clozapine and 32% of olanzapine patients were hospitalized for suicidal risk.

Telegram: @medical_k

www.konkur.in

SCHIZOPHRENIA WITH SUBSTANCE ABUSE. Although the effectiveness of clozapine in patients with comorbid substance abuse has not been demonstrated by randomized controlled trials, there is some supporting evidence from naturalistic studies. A retrospective study by Green and coworkers found that patients treated with clozapine were more likely to abstain from alcohol and cannabis use than patients treated with risperidone. A prospective study by the same investigators found that patients treated with clozapine were better able to reduce their substance abuse.

TREATMENT-RESISTANT MANIA. Clozapine can be an effective treatment of manic symptoms that are not responsive to other agents. Early clinical case reports indicated that clozapine was effective both as monotherapy and as an adjunct to mood-stabilizing agents in this population. An open-label, randomized trial in acutely manic patients found that clozapine had a more rapid onset of effect than chlorpromazine. In another open-label trial involving patients with schizoaffective disorder or bipolar disorder who were randomized to either clozapine or treatment, as usual, clozapine-treated patients demonstrated greater improvements. Although the available data support clozapine's effectiveness in mania, none of these trials have used a double-blind design.

NEUROLOGIC ILLNESSES. Clozapine has also found uses in patients with neurologic disorders. It has been used in idiopathic Parkinson disease as a treatment of psychotic symptoms that are secondary to dopaminergic agents that are used to treat the disease. These patients may respond to relatively low dosages of clozapine (doses of 25 to 75 mg). Higher dosages (e.g., 100 to 250 mg a day) may exacerbate the parkinsonian symptoms. The effectiveness of clozapine in patients with idiopathic Parkinson disease is supported by at least two double-blind studies. A report from the American Academy of Neurology recommends clozapine as a preferred agent for psychosis in Parkinson disease. Patients with benign essential tremor or with Huntington disease have also responded positively to clozapine.

POLYDIPSIA–HYPONATREMIA SYNDROME. Case reports suggest that clozapine may have advantages over other antipsychotic agents in

Telegram: @medical_k

www.konkur.in

patients who tend to intoxicate themselves with water. This syndrome—called *polydipsia–hyponatremia syndrome*—can result in seizures.

Effects on Specific Organs and Systems

GENERAL. Sedation is the most common adverse effect of clozapine treatment. It occurs early in treatment, and tolerance usually develops after the first few days or weeks. Giving the larger part of the daily dose at bedtime may reduce daytime sedation. However, many individuals are still unable to tolerate the sedative effects and should, therefore, be treated with another antipsychotic. Dizziness or vertigo may be related to orthostatic hypotension.

DISTURBANCES IN TEMPERATURE REGULATION. Benign hyperthermia is occasionally observed during the first 3 weeks of clozapine treatment, with a peak incidence on the 10th day. The increase in temperature is usually not more than 1 °F to 2 °F and resolves over a few days. Occasionally, however, temperature readings above 101 °F have been seen, which require temporary interruption of clozapine treatment and frequent hematologic monitoring. Differential diagnoses include drug fever, intercurrent infection, infection secondary to agranulocytosis, dehydration, heat stroke, lethal catatonia, and, possibly, NMS. Patients who develop a high temperature can be given the drug again but with a more gradual increase in dosage. If this strategy does not work, clozapine may need to be discontinued. As is also seen with chlorpromazine, mild hypothermia is frequently observed (87%) after clozapine treatment. This common effect may indicate the poikilotherm effect of antipsychotic agents, presumably mediated by the hypothalamus.

CARDIOVASCULAR. The cardiovascular side effects most frequently observed with clozapine are tachycardia and postural hypotension. The tachycardia is probably a direct effect of the vagolytic properties of the drug. It can be present in the supine position and is thus not the result of orthostatic changes. Increased pulse rates of 20 to 25 beats per minute are encountered when clozapine reaches 300 mg per day or more over a 7-day period (e.g., sinus tachycardia). Tachycardia related to clozapine may be treated with a β-blocker such as atenolol (Tenormin), although patients should then be monitored for hypotension. Propranolol (Inderal)

Telegram: @medical_k

www.konkur.in

should not be prescribed because it may increase the risk of agranulocytosis.

Reversible nonspecific ST-T wave changes, T-wave flattening, or inversions (repolarization effects) are seen infrequently with clozapine and are usually of no clinical significance. These changes are similar to those seen with other antipsychotic agents and are dose dependent. Clozapine can increase the QT interval, although there are very limited data to determine if these increases are associated with a risk of ventricular arrhythmias. Orthostatic hypotension is more likely to occur during the initial titration of clozapine in association with rapid dose escalation but may occur after the first dose. In one report, initial dosages of clozapine as low as 12.5 mg were associated with orthostatic collapse and respiratory arrest. The risk of postural hypotension progressing to orthostatic collapse is substantially greater if the initial dosage of clozapine exceeds 75 mg per day. Tolerance to the hypotensive effects of clozapine often develops over time, and the effects can usually be managed if the initial dosage is low (e.g., 25 mg per day) and is increased gradually. When hypotension occurs, lowering the dosage to the previous level and slowing the rate of upward titration usually limits problems. Support stockings, increased sodium intake, or fludrocortisone (Florinef) may be helpful. Rarely (approximately 1 case per 3,000 or 4,000 patients), orthostatic collapse can be profound, accompanied by respiratory or cardiac arrest.

Clozapine has been associated with idiopathic myocarditis. The section on warnings and precautions below will discuss this further.

GASTROINTESTINAL. Constipation, most probably due to the antimuscarinic effects of clozapine, is the most common gastrointestinal adverse effect and, if left untreated, can progress to intestinal obstruction. Clinicians treating patients with clozapine should monitor the presence of constipation and intervene proactively at the earliest sign that this symptom has developed. Interventions may include modifications in the patient's diet, use of stool softeners, increased fluid intake, and exercise.

Nausea and vomiting may occur during the initial stages of clozapine treatment. Patients who experience the side effects can often, but not always, be managed by dosage reduction.

Telegram: @medical_k

www.konkur.in

UROGENITAL. Urogenital effects include enuresis, frequency and urgency, hesitancy, urinary retention, and impotence. All of these are independent of dose or blood concentrations of clozapine. Urinary incontinence or enuresis can be managed by setting an alarm clock to ring at night or administering intranasal desmopressin (DDAVP) or oxybutynin (Ditropan) (5 to 15 mg per day). So far, a few cases of clozapine treatment-associated priapism have been noted. Because patients may not volunteer these complaints, clinicians should ask about them.

Therapeutic Indications

TREATMENT-RESISTANT SCHIZOPHRENIA. Clozapine is indicated for patients who have failed trials with other antipsychotics. Given the serious side effects associated with clozapine treatment, including seizures and agranulocytosis, most guidelines recommend a trial of a minimum of two other antipsychotics, one of which should be a Second Generation Antipsychotic (SGA). Studies have found that clozapine's advantage, when compared with other antipsychotics, extends from patients who continue to experience severe symptoms to those who have moderate symptoms.

REDUCTION IN THE RISK OF RECURRENT SUICIDAL BEHAVIOR IN SCHIZOPHRENIA OR SCHIZOAFFECTIVE DISORDER. The InterSePT study, as well as epidemiologic data, indicates that clozapine is indicated for those patients who are at risk of suicidal behaviors. It is the only antipsychotic with this particular indication.

Precautions and Adverse Reactions. The only contraindications to the use of clozapine are a history of hypersensitivity to clozapine or tablet components, a WBC count below 3,500 cells per mm^3, a previous bone marrow disorder, a history of agranulocytosis during clozapine treatment, or the concomitant use of another bone marrow suppressant drug such as carbamazepine (Tegretol). The history of myocarditis is not a labeled contraindication, but the authors recommend against the use of clozapine in these patients. Although the mechanism of action is unknown, there is a slight risk of respiratory depression or collapse if treatment is initiated while patients are taking benzodiazepines.

BLACK BOX WARNINGS

Telegram: @medical_k

www.konkur.in

Agranulocytosis. The risk of clozapine-induced agranulocytosis is 0.73% during the first year of treatment and 0.07% in the second year. A review of the clozapine registry indicates that the incidence may be as low as 0.038%. The risk of this adverse effect is greatest during the first 3 months of treatment, but a significant risk remains during the first year of treatment. For neutropenia, the risk is 2.32% in the first year and 0.69% in the second year.

Increased familiarity of clinicians with agranulocytosis (absolute neutrophil count [ANC] less than 500 cells per mm^3 or WBC less than 1,000 cells per mm^3) decreased the incidence of agranulocytosis by more than 50% from before 1995 to after 1997.

Agranulocytosis due to clozapine is a potentially fatal condition that requires immediate medical attention. The risk of agranulocytosis increases with age and is higher in women. Therefore, before treating patients with clozapine, clinicians must register patients with a clozapine monitoring system. The United Kingdom and Australia require, in addition to the 3,500 WBC per mm^3, that granulocyte count (ANC) is 2,000 cells per mm^3 or higher when clozapine is initiated.

Patients who are treated with clozapine in the United States must receive the following monitoring protocol:

- WBC is no longer required to be monitored—only ANC.
- Initial ANC must be ≥1,500/mm^3, and in patients with benign ethnic neutropenia, it must be ≥1,000/mm^3.
- Monitoring is weekly for the first 6 months, every 2 weeks for the second 6 months, and monthly after 12 months. The threshold minimum ANC that is not classified as neutropenia is now 1,500/mm^3 rather than 1,000/m^3.

The requirement for ANC monitoring is continued for as long as patients receive the drug and for at least 1 month after it is discontinued. Current guidelines specify that any fever or sign of infection (e.g., pharyngitis) is an immediate indication for a WBC count, particularly in the first 18 weeks of treatment. The revised requirements indicate that clozapine treatment should be interrupted for ANC <1,000/mm^3. Reports of clozapine re-exposure after hematologic recovery have shown that all such patients again experienced agranulocytosis, but sooner and at lower doses than

Telegram: @medical_k

www.konkur.in

during initial treatment. As a result, patients who develop agranulocytosis should not receive clozapine again. Although a WBC count below 3,500 cells per mm^3 is not a proven risk factor, clozapine should be administered cautiously in patients with such low counts because of the difficulty in the early identification of agranulocytosis. Rechallenge is not dictated by WBC any longer, only ANC. Rechallenge is allowed following recovery from moderate neutropenia (500 to 999/mm^3) but not after recovery from severe neutropenia (<500/mm^3) unless the prescriber determines benefits outweigh risks. Clozapine therapy should be discontinued whenever the total WBC count falls below 3,000 cells per mm^3, or the granulocyte count falls below 1,500 cells per mm^3.

Other hematologic changes have been reported with clozapine, including leukocytosis (0.6%), eosinophilia (1%), leukopenia, neutropenia, decreased WBC count (3%), and, rarely, thrombocytopenia. If the total eosinophil count rises above 4,000, clozapine should be discontinued until the count falls below 3,000.

Orthostatic Hypotension. On rare occasions, clozapine can cause severe episodes with orthostatic hypotension and possible syncope. This has been associated with cardiac or respiratory arrest. These serious events are more likely to occur early in treatment when the dose is increased. Also, these events have been associated with benzodiazepine use and suggest that combining clozapine and benzodiazepines early in treatment should be done cautiously. Dosage should be increased slowly, with divided doses, and clozapine should be used with caution in patients with cardiovascular or cerebrovascular disease or conditions predisposing them to hypotension.

Seizures. Five percent to 10% of patients treated with clozapine will develop seizures. The risk is clearly related to dosage, with an increased risk at dosages greater than 600 mg. The rapid escalation of dosage during the first weeks of clozapine treatment may increase the likelihood of seizures. A pre-existing seizure disorder or head trauma places the patient at even greater risk.

A number of strategies may be effective for managing the risk of seizures. Monitoring clozapine plasma concentrations in patients receiving higher dosages may ensure that concentrations do not become excessive. Patients with a history of head injury should have baseline electroencephalographs (EEG) performed before the initiation of

Telegram: @medical_k

www.konkur.in

clozapine. Clinicians may also consider an EEG before increasing clozapine dosages above 600 mg. In addition, when patients receive higher doses or have abnormal EEGs, adding an anticonvulsant such as sodium valproate (Depakene) may be helpful.

The occurrence of seizures in patients treated with clozapine should not be viewed as a clear reason to stop clozapine. Lowering the dosage and adding an anticonvulsant is usually sufficient to prevent further seizures. Sodium valproate, gabapentin (Neurontin), and topiramate (Topamax) have been effective in treating clozapine-induced seizures. Carbamazepine should not be prescribed because it can also cause neutropenia or granulocytopenia. Once patients have begun anticonvulsant therapy, the dosage of clozapine can be retitrated to an optimal level.

Myocarditis and Cardiomyopathy. Clozapine is associated with an increased risk of myocarditis. Although the incidence of myocarditis is very low (approximately 2.8/100,000 patient-years), it can result in death. Clinicians should consider the possibility of myocarditis when patients receiving clozapine present with unexplained chest pain, tachycardia, palpitations, dyspnea, fever, flu-like symptoms, or hypotension. Unfortunately, some of these symptoms are common in individuals who are in the early stages of clozapine treatment, and 80% of clozapine-induced cases of myocarditis occur during the first 6 weeks of treatment. Because mortality from myocarditis approaches 40%, early detection and treatment are important. If this syndrome is suspected, clozapine should be discontinued, and evaluations including an ECG, creatine kinase level, and erythrocyte sedimentation rate should be performed.

Increased Mortality in Older Adult Patients with Dementia. Clozapine and the other SGAs carry a black box warning for increased mortality in older adult patients with dementia-related psychosis compared with placebo.

OTHER ADVERSE EVENTS

Sialorrhea. Sialorrhea is an uncomfortable adverse effect that develops early in treatment. Hypersalivation is most profound during sleep, and patients may complain that their pillow is wet in the morning. Placing a towel over the pillow may be of some help. Clonidine (Catapres) (0.1- or

Telegram: @medical_k

www.konkur.in

0.2-mg patch once a week), amitriptyline (Elavil, Endep), glycopyrrolate, and atropine sublingual drops at bedtime have been used to treat sialorrhea. Clinical reports also support the injection of botulinum toxin into the salivary glands. Studies suggest that clozapine does not increase saliva flow but decreases swallowing, which becomes more pronounced during sleep.

Peripheral Anticholinergic Effects. Dry mouth, blurred vision, constipation, and urinary retention are commonly observed with clozapine. Constipation can be severe, particularly when patients fail to exercise or drink sufficient fluids. Other side effects of the autonomic nervous system, such as increased sweating, have also been reported.

Weight Gain. Clozapine can be associated with substantial weight gain; a meta-analysis of short-term trials with clozapine found an average weight gain of 4.45 kg over 10 weeks. This exceeded the weight gain observed with all of the other medications evaluated in the trials. Other studies indicate that patients can continue to gain weight over a period of 5 years. The amount of weight that patients gain can be substantial and can result in some patients becoming obese. Younger patients, including adolescents, may be more vulnerable to gaining weight on clozapine.

These observations demonstrate the importance of preventing substantial weight gain for patients receiving clozapine. Physicians should weigh patients frequently during the first months of clozapine treatment and should encourage patients to monitor their own weight. If weight gain is observed, it is important for clinicians to intervene with counseling about nutrition, weight, and exercise. If these interventions are unsuccessful, changing medication to an agent less likely to cause weight gain should be considered.

Diabetes Mellitus. Clozapine, along with many other SGAs, can increase the risk of type 2 diabetes mellitus. In a naturalistic study by David Henderson that monitored 81 patients over a 5-year period, 36.6% developed diabetes. Case reports suggest that new cases of diabetes usually occur during the first 6 months of clozapine treatment. Michael Sernyak and his coworkers examined the records of more than 30,000 veterans and found that the prevalence of diabetes was higher in patients receiving clozapine, olanzapine, or quetiapine. It is also concerning that a number of case reports indicate that patients receiving clozapine

Telegram: @medical_k

www.konkur.in

developed diabetic ketoacidosis. Although these forms of evidence remain inconclusive, they strongly suggest that clinicians should be aware of the possible association of clozapine with an increased risk of diabetes. This may lead clinicians to monitor patients for diabetes, with fasting blood glucose determinations at regular intervals. It may also be helpful to inquire if patients are experiencing clinical signs of diabetes, such as polydipsia, polyuria, or weight loss.

Extrapyramidal Side Effects. Clozapine has a much lower incidence of extrapyramidal side effects than other antipsychotics. Akathisia (6%), tremors (6%), and rigidity (3%) are considerably less frequent with clozapine than with First Generation Antipsychotics (FGA). The authors are not aware of reports of acute dystonia with clozapine. Case reports suggest that tardive dyskinesia may improve with clozapine.

Neuroleptic Malignant Syndrome. Consistent with clozapine's low affinity for D_2 receptors, there have been few reports of NMS developing in patients who were treated solely with clozapine, although case reports of this syndrome developing in patients when concomitantly treated with lithium (Eskalith) exist. Although two patients had experienced NMS with conventional antipsychotics before, one case has been reported of a patient with a history of NMS that was successfully treated with clozapine. The authors recommend, therefore, that lithium should not be used as adjunctive treatment with clozapine in patients who have previously experienced NMS.

Because clozapine treatment is accompanied by side effects that resemble several signs and symptoms of NMS (e.g., hyperthermia, cardiovascular effects, delirium, increased sweating, elevations in creatine phosphokinase, and leukocytosis), clinicians should be alert for the development of a potential NMS during clozapine treatment. Some case reports have described NMS without rigidity in patients treated with clozapine, although the lack of rigidity could preclude the diagnosis of this syndrome.

Pregnancy and Lactation. Clozapine is rated as pregnancy category B. Studies have not revealed evidence that clozapine causes harm to the fetus. However, there are no adequate and well-controlled studies on pregnant women. Studies in animals suggest that clozapine is excreted in breast milk. As a result, women taking clozapine should not breastfeed.

Telegram: @medical_k

www.konkur.in

Discontinuing Clozapine. If a decision is made to change a patient to a different antipsychotic, it should not be made abruptly unless patients have developed agranulocytosis. In some individuals, the sudden discontinuation of clozapine has led to a severe exacerbation of their underlying illness. In addition, withdrawal of a potent antimuscarinic agent such as clozapine can lead to a cholinergic rebound, with symptoms such as nausea and vomiting. For these reasons, the authors recommend that patients are gradually cross-tapered from clozapine to another antipsychotic agent over 2 to 4 weeks.

Drug Interactions. Because the cytochrome P450 (CYP) mitochondrial system is involved in the metabolism of clozapine, ethnic differences and interactions with drugs that inhibit or stimulate this system will affect clozapine plasma concentrations. For instance, caffeine *N*-3-demethylation, which is a measure of CYP isoenzyme 1A2 (CYP1A2) activity, accounts for 70% of the variance in clozapine clearance. This suggests that administration of fluvoxamine (Luvox), a potent inhibitor of CYP1A2, will elevate clozapine concentrations, whereas fluoxetine (Prozac) administration may only lead to changes in higher dosage ranges. Cimetidine (Tagamet), selective serotonin reuptake inhibitors (SSRIs), tricyclic drugs, and valproic acid decrease clearance, presumably through inhibition of CYP1A2 and CYP2D6, whereas phenytoin (Dilantin) and carbamazepine induce CYP2C and CYP3A4 hepatic isoenzymes and may decrease concentrations of clozapine.

Tobacco smoking induces the activity of CYP1A2, which reduces clozapine plasma concentrations by about one-third. When patients stop smoking, there can be a substantial increase in plasma levels resulting in increased side effects. This suggests that clozapine plasma levels should be checked whenever there is a change in smoking behavior.

Dosage and Administration

INITIATING TREATMENT. Clozapine treatment should begin with 12.5 to 25 mg per day and increased to 25 or 50 mg per day on the second day. The daily dose, which should be administered at least twice daily initially, can usually be increased by 25 mg every 1 or 2 days until a target dose of 300 to 450 mg per day is reached. The rate of increase is often limited by sedation and orthostatic hypotension. Because the titration phase for clozapine may require several weeks in some individuals, these patients

Telegram: @medical_k

www.konkur.in

should be continued on their current antipsychotic agent, which should be gradually decreased as the clozapine dosage increases. Patients who fail to respond in the 300 to 450 mg per day range and who do not have serious side effects can be increased gradually to doses as high as 900 mg per day. However, clinicians and patients should be aware of the risk of seizures at higher levels and when doses are escalated more rapidly.

DURATION OF TREATMENT. Once the appropriate dosage has been reached, and the patient improves, the medication should be continued. There is evidence that patients who receive clozapine will continue to improve over a 3- to 6-month period. If there are concerns that patients are experiencing excessive side effects or an inadequate response, measurement of plasma concentration may be helpful. Levels above 350 ng/mL are an indication that patients are receiving adequate dosages of clozapine.

Risperidone and Paliperidone

Risperidone was the first serotonin-dopamine antagonist (SDA) medication to be approved following clozapine. Whereas clozapine was reserved for patients with illnesses that were poorly responsive to available antipsychotic drugs, risperidone was a first-line antipsychotic that could be administered to nearly every patient with a psychotic illness. Following its introduction, it was hoped that risperidone would share clozapine's efficacy for a broad range of psychopathology in schizophrenia and that it would be more effective than the FGAs. Although this promise has not been met, risperidone has been widely accepted and is among the most prescribed antipsychotics worldwide.

Paliperidone is the major active metabolite of risperidone and shares risperidone's receptor profile. Paliperidone extended-release tablets use a pressure-based osmotic release oral system (OROS) delivery system to provide continual drug delivery for over 24 hours (see below). Because paliperidone extended release is gradually released into the plasma without peaks in concentration, it permits treatment initiation without titration. As the primary metabolite of risperidone, paliperidone does not undergo further significant hepatic metabolism. Therefore, it suffers from fewer potential drug–drug interactions.

Telegram: @medical_k

www.konkur.in

Chemistry. Risperidone and paliperidone are benzisoxazole derivatives. Paliperidone is the major metabolite of risperidone.

Pharmacologic Action

PHARMACOKINETICS

Absorption and Distribution. Risperidone has a bioavailability of 70%, and studies show that all oral forms of risperidone are bioequivalent. Risperidone is metabolized in the liver to 9-hydroxyrisperidone (or paliperidone [Invega]), which generally has the same pharmacologic profile as the parent compound. After ingestion, peak plasma levels of the parent compound occur within 1 hour and within 3 hours for 9-OH-risperidone. Steady state is expected to be reached within 5 days (with a range of 1 to 5 days, depending on the CYP2D6 activity in the individual patient). Food does not affect the rate or extent of absorption in the gut.

The volume of distribution is 1 to 2 L/kg. Risperidone is 90% plasma protein bound, and its metabolite is 77% protein bound. However, there is only a slight increase in the free fraction of risperidone and paliperidone with high therapeutic doses of warfarin (Coumadin) and other highly protein-bound medications.

Peak plasma concentration of paliperidone extended release is reached approximately 24 hours after a single dose. The half-life of paliperidone is about 23 hours, which allows for once-a-day dosing. Absorption is increased by approximately 60% when paliperidone extended release is taken with food.

Metabolism and Elimination. Risperidone undergoes extensive metabolism, primarily by CYP2D6 (see the section on drug interactions). The major metabolite is 9-OH-risperidone (or paliperidone), which has similar pharmacologic activity as risperidone. The half-life of risperidone is 3 hours in rapid metabolizers and 20 hours in poor metabolizers. The half-life of paliperidone is 21 hours in rapid metabolizers and 30 hours in poor metabolizers. The combined half-life of risperidone and its metabolites has a mean of 20 hours. Seventy percent of risperidone is excreted in the urine.

PHARMACODYNAMICS

Telegram: @medical_k

www.konkur.in

Mechanism of Action. Risperidone and paliperidone share similar receptor affinities. Both have a high affinity for dopamine D_2 receptors (Table 33.2b–2) and for serotonin 5-HT_{2A} receptors, and potent antagonism at these receptors is thought to mediate their therapeutic effects. They also demonstrate a high affinity for adrenergic α_1- and α_2-receptors and histaminergic H_1 receptors. Although risperidone and paliperidone have a high affinity for D_2 receptors, they have lower rates of EPS than the high-potency FGA medications. This is most likely due to the dopamine-promoting effects of 5-HT_{2A} antagonism. Risperidone blocks 65% of D_2 receptors (the lowest threshold percentage for antipsychotic efficacy) at an average dose of 2 mg per day. At an average of 6 mg per day, 80% of D_2 receptors are blocked, and EPS may occur. At the 2-mg dose, 5-HT_{2A} effects may not be optimal.

Blood Concentrations and Clinical Activity. The clinical activity of risperidone results from the combination of risperidone and 9-OH-risperidone. A consensus statement on therapeutic drug monitoring considers both risperidone and paliperidone as drugs where there is only limited evidence linking plasma concentrations to clinical response. The guidelines indicate that there is a lower likelihood of response when levels of risperidone plus paliperidone are below 20 ng/mL, and adverse effects are more likely above 60 ng/mL.

Design and Interpretation of Clinical Drug Studies

DESIGN. Since risperidone and paliperidone became available, there have been numerous studies evaluating their efficacy, safety, and tolerability. In this section, the focus will mostly be on randomized double-blind, placebo- or active-controlled trials.

Schizophrenia and Psychosis: Acute Treatment. Multiple studies with brief treatment trials have confirmed risperidone's efficacy in treating the acute phase of psychosis associated with schizophrenia, schizoaffective

Telegram: @medical_k

www.konkur.in

disorder, schizophreniform disorder, and acute psychotic disorder. Risperidone has consistently been shown to be superior to placebo, superior or equivalent to FGAs such as haloperidol and perphenazine, and equivalent to other SGAs with the exception of clozapine. Early multicenter trials in the United States and Canada compared risperidone 2, 6, 12, or 16 mg, haloperidol 20 mg, or placebo in a combined total of 513 patients with schizophrenia. The results from the U.S. and Canadian studies were very similar. In the Canadian study, risperidone 2 mg per day was not shown to be superior to placebo on measures of efficacy. Risperidone was superior to placebo at all higher doses and superior to haloperidol on a variety of measures, most noticeably the PANSS. Risperidone 6 mg was as efficacious as the higher doses. In the U.S. sample, there was no significant difference in the rates of EPS between patients on risperidone 6 mg and placebo. There was a linear trend toward more EPS as risperidone doses increased. Another large multicenter, multinational study of 1,362 patients with schizophrenia compared risperidone 1, 4, 8, and 12 mg per day to haloperidol 10 mg for 8 weeks. At doses of 4 and 8 mg, the response rates were 63% and 66%, respectively. There was no significant difference between the response to haloperidol (response rate 59%) and the response to risperidone. Risperidone was associated with lower EPS side effects at all doses compared with haloperidol.

Taken together, these studies indicate that risperidone at doses of 4 to 8 mg has similar effectiveness to other SDAs. This is consistent with the product label. Using group data, the findings suggest that there is little advantage to increasing the dose above 4 to 6 mg. This observation, and the tendency of risperidone to be associated with dose-dependent EPS, has led many clinicians to target risperidone in the 3- to 5-mg range. A 2019 meta-analysis found that 6.3 mg of risperidone was the dose that was 95% effective for symptom reduction (ED95).

Three 6-week randomized, double-blind, placebo-controlled efficacy and safety studies were conducted using fixed doses of paliperidone extended release. Kane and colleagues administered a placebo, 6, 9, or 12 mg of paliperidone extended release to 628 patients with schizophrenia. Davidson and colleagues treated 618 subjects with schizophrenia with placebo or 3, 9, or 15 mg of paliperidone extended release. Marder and colleagues evaluated 444 patients administered placebo, 6, or 12 mg of paliperidone extended release. In all three studies,

Telegram: @medical_k

www.konkur.in

the PANSS total score decreased significantly in all paliperidone arms compared with placebo. In the study by Kane et al., there was a trend toward greater improvement in the 12-mg paliperidone group. Davidson's group reported that as early as day 4, the three paliperidone arms had separated significantly from the placebo on PANSS total score. The study by Marder and colleagues found significant improvement by day 4 for the 6-mg arm and by day 15 for the 12-mg arm. In all three studies, the three paliperidone arms showed significant or trend improvement from baseline compared with placebo on positive, negative, disorganized, hostility or agitation, and anxiety or depression factor scores. The above studies support the product label recommendation of 6 mg as the target dose for schizophrenia. There is evidence of increased efficacy at higher doses. The 2019 meta-analysis found an ED95 of 13.4 mg for paliperidone.

Schizophrenia and Psychosis: Maintenance Treatment. The effectiveness of risperidone for relapse prevention in schizophrenia was demonstrated in a double-blind comparison with haloperidol. Relapse rates were significantly lower in patients randomized to risperidone.

Kramer and colleagues treated 205 patients in a study with an 8-week open-label run-in phase, followed by a 6-week open-label stabilization period before entering a variable duration double-blind treatment phase where patients were randomized to either placebo or paliperidone 3 to 15 mg daily. The primary efficacy variable was time to the first recurrence of schizophrenia symptoms (e.g., hospitalization, changes in symptom scores, aggressive, self-injurious, or suicidal behavior). Time to recurrence was significantly longer in the paliperidone group; in the final analysis, 52% of patients on placebo had a recurrence versus 22% on paliperidone. Twenty-five percent of patients on placebo had a recurrence event by day 23, whereas 25% of paliperidone-treated patients had a recurrence event by day 83.

Schizophrenia and Psychosis: Adolescents. Two trials evaluating the efficacy of risperidone in adolescents aged 13 to 17 years with schizophrenia compared risperidone at doses ranging from 0.15 to 6 mg per day with a placebo. Risperidone treatment significantly improved PANSS total scores. Doses below 0.6 mg per day were less effective than higher doses. Doses above 3 mg per day were not more efficacious and resulted in a greater side-effect burden.

Telegram: @medical_k

www.konkur.in

Bipolar Mania: Adults. In two 3-week studies comparing risperidone treatment with placebo in patients with acute mania, risperidone treatment was associated with significantly greater improvements on the YMRS versus placebo. The time to onset of improvement was as brief as 3 days in the first study. A recent meta-analysis by Scherk et al. was conducted on the effects of SGAs in the treatment of mania. It concluded that risperidone was significantly more efficacious than placebo in the treatment of mania, as efficacious as haloperidol, and more effective when used in combination with a mood stabilizer than was a mood stabilizer alone. A small study of 65 patients compared risperidone with haloperidol and lithium and found all medications were similarly efficacious.

Bipolar Mania: Children and Adolescents. An 8-week open-label trial of 30 children and adolescents (aged 6 to 17 years) found that risperidone monotherapy (mean dose 1.25 mg per day) resulted in clinically significant improvements in the YMRS scores, although at the end point, there were mild residual symptoms present. A double-blind trial of children and adolescents aged 10 to 17 years compared risperidone 0.5 to 2.5 mg per day, risperidone 3 to 6 mg per day, and placebo in the treatment of manic or mixed episodes of bipolar I disorder. Risperidone in both dosage groups significantly improved YMRS scores compared to placebo. Doses above 2.5 mg per day were not more efficacious than lower doses.

Irritability Associated with Autism: Children and Adolescents. A study of 101 children and adolescents aged 5 to 17 years compared risperidone treatment (dose range 0.5 to 3.5 mg per day) with placebo on measures of irritability and global improvement. Sixty-nine percent of risperidone-treated patients versus 12% of placebo-treated patients were classified as responders. Hyperactivity and stereotypy scores also improved significantly in the risperidone group. Patients treated with risperidone gained more weight (mean = 2.7 kg) than did patients on placebo (mean = 0.8 kg) in the 8-week trial. EPS rates were similar, although parents reported a higher incidence of tremor in the risperidone group. Of the risperidone responders who followed in open-label treatment for the next 6 months, 68% maintained those gains. A continuation of the same study followed 63 of the original patient sample for 4 months on open-label risperidone treatment, followed by an 8-week placebo-controlled discontinuation protocol. During the 4-month risperidone continuation phase, 83% of the patients maintained the gains in irritability diminution

Telegram: @medical_k

www.konkur.in

they had achieved during the original 8-week trial. Overall, the mean irritability ratings increased from 9.5 to 10.8, an increase the authors concluded was clinically insignificant. Thirty-eight subjects were enrolled in the placebo-controlled discontinuation phase. The relapse rate was 62.5% in the placebo group versus 12.5% in the risperidone group. A randomized, double-blind, placebo-controlled trial of 40 children with autism (aged 2 to 9 years) found that risperidone 1 mg per day produced improvements of 20% or greater on the Childhood Autism Rating Scale and the Children's Global Assessment Scale in 63% and 89%, respectively, versus 0% and 10% of children treated with placebo. Risperidone was also associated with improvements in social responsiveness, nonverbal communication, hyperactivity, and aggression.

Effects on Specific Organs and Systems

CARDIOVASCULAR SYSTEM. Tachycardia and palpitations are the most commonly reported cardiovascular side effects of risperidone and paliperidone, followed by hypotension and postural hypotension. This is most likely related to α-receptor blockade. Palpitations are noted to be dose related. There have been rare reports of atrioventricular and bundle branch block.

Risperidone and paliperidone are more strongly associated with an increase in prolactin levels than other antipsychotics. These elevations can result in gynecomastia, galactorrhea, menstrual disturbances, and sexual dysfunction.

Therapeutic Indications. Risperidone is indicated for schizophrenia in adults and adolescents and for maintenance therapy. It is also indicated for bipolar mania and irritability associated with autistic disorder.

Paliperidone is indicated for schizophrenia and schizoaffective disorder.

Precautions and Adverse Reactions

BLACK BOX WARNING. Risperidone, paliperidone, and the other SGAs carry a black box warning for increased mortality in older adult patients with dementia-related psychosis compared with placebo.

QT PROLONGATION. Both risperidone and paliperidone have only modest effects on the QT interval.

Telegram: @medical_k

www.konkur.in

NEUROLEPTIC MALIGNANT SYNDROME. Risperidone and paliperidone have been associated with NMS, possibly at rates higher than most other antipsychotic medications. NMS is a serious and potentially life-threatening condition. Patients with suspected cases of NMS should be immediately discontinued from the antipsychotic agent and aggressively treated with supportive measures, symptomatic treatment, and medical monitoring. If the patient requires antipsychotic treatment after recovery from NMS, close monitoring and gradual reintroduction are essential.

CEREBROVASCULAR ADVERSE EVENTS. In placebo-controlled trials, older adult patients with dementia-related psychosis treated with risperidone had significantly higher incidences of cerebrovascular accidents and other related adverse events than did patients treated with placebo.

TARDIVE DYSKINESIA. All antipsychotic medications (with the possible exceptions of clozapine and quetiapine) carry a risk of tardive dyskinesia. Tardive dyskinesia risk is thought to be related to a combination of factors, the most important of which is unopposed D_2 blockade in the basal ganglia. Risperidone has a high affinity for D_2 receptors, but its action at the 5-HT_{2A} receptors may partially mitigate some of the striatal D_2 blockade. In one trial of risperidone treatment, 5 of 453 patients developed symptoms of tardive dyskinesia, and 14 patients with pre-existing tardive dyskinesia improved. In another study of risperidone microspheres, the rate of tardive dyskinesia emergence in 530 patients after 50 weeks of treatment was 1.19%. A review article that considered the second-generation medications together reported a rate of tardive dyskinesia with risperidone, amisulpride (Solian), olanzapine, and quetiapine ranging from 0.5% to 1.5%. The rates of tardive dyskinesia emergence are slightly higher in older adult populations, especially among women. Among 133 older adults administered risperidone, the incidence of persistent tardive dyskinesia was 2.6%, and at doses of 0.75 to 1.5 mg per day, the incidence dropped to 1%.

HYPERCHOLESTEROLEMIA, HYPERGLYCEMIA, AND DIABETES MELLITUS. Risperidone and paliperidone are associated with weight gain, dyslipidemias as well as an increased risk of diabetes mellitus. Results from the CATIE study indicate that risperidone produced changes in glucose level comparable to perphenazine and quetiapine, with an

Telegram: @medical_k

www.konkur.in

increase lower than that with olanzapine treatment and higher than that with ziprasidone treatment.

CHANGES IN WEIGHT. In the CATIE study, patients on risperidone gained an average of 0.8 lb during treatment, and 14% gained more than 7% of their body weight. There was no significant difference between risperidone, quetiapine, perphenazine, and ziprasidone on measures of body weight change. The percentage of patients gaining over 7% of their body weight during the 6- to 8-week trials was 18% versus 9% for placebo.

MOVEMENT SIDE EFFECTS AND DISORDERS. Double-blind trials indicate that risperidone and paliperidone are associated with a dose-dependent increase in extrapyramidal side effects. Although many adult patients may not experience these effects at the recommended daily dosage of 6 mg, dystonic reactions have occurred with dosages between 4 and 16 mg per day, and akathisia has been described. Many patients require only 2 to 4 mg per day of risperidone. In all studies, paliperidone extended release was noted to be associated with higher rates of movement side effects in dosages above 9 mg.

ORTHOSTATIC HYPOTENSION AND SYNCOPE. Risperidone and paliperidone have antagonistic activity at α-receptors, which contributes to their risk of orthostatic hypotension, dizziness, and syncope. In phase II and III trials among adult patients with schizophrenia, 0.2% of patients reported syncope on risperidone. Limiting the initial dose to 2 mg per day, either in a single or divided dose, may minimize these side effects in healthy adults. In patients with hepatic or renal insufficiency or older adult patients, the initial dose should be reduced to 0.5 mg twice a day to reduce the potential for hypotension and syncope.

HYPERPROLACTINEMIA. Risperidone and paliperidone increase prolactin levels. In the CATIE study, risperidone increased prolactin by a mean of 15.4 ng/dL, and it was the only study medication to significantly increase prolactin levels. Hyperprolactinemia suppresses gonadotropin-releasing hormone (GnRH), which reduces gonadotropin release and can impair gonadal steroidogenesis in men and women. This elevation is sometimes but not always associated with inhibited reproductive function and symptoms such as galactorrhea, amenorrhea, gynecomastia, erectile

Telegram: @medical_k

www.konkur.in

dysfunction, and anorgasmia. Long-term hyperprolactinemia may lead to decreased bone density in both sexes when associated with hypogonadism (although no direct evidence exists that would suggest that risperidone decreases bone density, regardless of prolactin level). Approximately one-third of breast cancers are prolactin dependent. A 2021 large cohort study from Finland found an association between prolactin-elevating antipsychotics and the risk of breast cancer in women. These findings suggest that clinicians treating patients with these two medications should inquire about prolactin-related side effects. If there is a concern, prolactin levels can be evaluated. In addition, clinicians should discuss the risk of breast cancer with women when they are treated with risperidone and paliperidone.

PREGNANCY. Risperidone and paliperidone are rated FDA pregnancy category C. A retrospective and prospective case series of 713 pregnancies with risperidone exposure found that in the prospective data, the percentage of congenital malformations (3.6%) and spontaneous abortions (16.9%) was consistent with background rates in the general population. In the retrospectively identified cases, the percentages of congenital malformation (7.6%) and spontaneous abortion (16.7%) were higher, but retrospective reporting is subject to bias. Thirty-seven of 197 pregnancies retrospectively had perinatal syndromes, 21 of which were behavioral or motor disorders. These syndromes involved symptoms of tremor, jitteriness, irritability, somnolence, and feeding problems, consistent with possible risperidone withdrawal or risperidone-induced movement side effects. If risperidone is used during pregnancy, the medication should be slowly titrated down prior to delivery.

LACTATION. Risperidone and paliperidone are excreted in breast milk. The milk/plasma concentration ratio for both agents was less than 0.5. Relative infant doses of risperidone ranged from 2.3% to 4.7% of the maternal dose. In infants who were breastfed, risperidone and paliperidone were not detected in the plasma of the infants. However, the possibility of infant exposure and possible EPS/NMS risk cannot be ruled out. The decision to breastfeed while on risperidone should be made only after a careful risk–benefit analysis.

Telegram: @medical_k

www.konkur.in

FERTILITY. Risperidone and paliperidone increase prolactin, which can decrease fertility in men and women. Meta-analysis of 15 antipsychotic medications across 212 clinical trials found risperidone and its metabolite paliperidone caused the greatest elevation in prolactin level of the drugs studied.

SPECIAL POPULATIONS

Pediatric Use. Risperidone has been approved for use in children aged 5 to 16 years old for irritability associated with autism, aged 10 to 17 years for bipolar disorder, manic, or mixed episodes, and aged 13 to 17 years for schizophrenia. As a metabolite of risperidone, paliperidone has similar effectiveness. Overall, over 1,850 pediatric patients have been treated with risperidone in industry-sponsored clinical trials. The rate of tardive dyskinesia in this population was 0.1%, and it resolved with the discontinuation of risperidone. In a review of studies lasting more than 11 months, Correll and Kane reported an annual tardive dyskinesia incidence in children and adolescents of 0.3%. Weight gain among children and adolescents must be monitored with regard to expected weight gain for the appropriate age group. Risperidone is associated with larger-than-expected levels of weight gain in these populations. In a study of 103 adolescents with diagnoses of schizophrenia, the average weight gain was 9.0 kg over 8 months. In several studies of children with autistic disorder or other disorders, there was an average weight gain of 7.5 kg over 1 year, compared to the expected gains of 3 to 3.5 kg per year, depending on age. Risperidone increases prolactin in children and adolescents, as it does in adults. Rates of prolactin elevation vary from 49% to 87% of pediatric patients taking risperidone compared to 2% to 7% of patients on placebo. Galactorrhea was reported in 0.8% of pediatric patients on risperidone, and gynecomastia was reported in 2.3% of risperidone users in the pediatric population. The long-term effects of risperidone treatment on growth and sexual maturation have not been assessed. Transient somnolence lasting a median of 16 days after treatment initiation was reported frequently in the child and adolescent population.

Geriatric Use. Risperidone and paliperidone use in the older adults should be initiated cautiously. Older adult patients are more prone to orthostatic hypotension, which can put them at greater risk of falls.

Telegram: @medical_k

www.konkur.in

Furthermore, older adult patients tend to have reduced pharmacokinetic clearance, higher rates of hepatic or renal insufficiency, and a greater likelihood of polypharmacy. Older adult patients started on risperidone should be given a lower initial dose of 0.5 once or twice daily, and titration should be slower than in the adult population. Potential drug interactions should be carefully monitored, and any medications significantly metabolized by CYP2D6 should be coadministered with caution. In particular, two placebo-controlled trials found that concomitant administration of risperidone and furosemide (Lasix) increased mortality in older adult patients with dementia-related psychosis compared to patients treated with risperidone or furosemide alone. Furosemide should not be combined with risperidone in the older adults.

Drug Interactions. Risperidone is extensively metabolized by the CYP 2D6 enzyme, where it is converted to its major metabolite, 9-OH-risperidone (paliperidone). There are identified genetic polymorphisms for the CYP2D6 enzyme, and some percentage of people (6% to 8% in Caucasians; higher in African Americans) have little to no 2D6 activity. These people are poor metabolizers of drugs hydroxylated through the 2D6 pathway. Similarly, some individuals are rapid metabolizers at this enzyme site. Risperidone metabolism can also be affected by drugs that are inhibitors (paroxetine [Paxil], fluoxetine, quinidine [Cardioquin]) or inducers (carbamazepine, phenytoin, rifampin [Rifadin], phenobarbital [Bellatal]) of the 2D6 enzyme. Medications that inhibit the 2D6 enzyme (Table 33.2b–3) increase plasma levels of risperidone and decrease the rate of conversion to 9-OH-risperidone. Dosing of 20 mg each of fluoxetine and paroxetine (strong inhibitors of 2D6) raised plasma levels of risperidone by 2.5 times and 3.9 times, respectively. Because risperidone and its major metabolite have similar if not identical pharmacologic effects, the result of 2D6 inhibition may not be clinically meaningful. However, risperidone dosage should be reassessed whenever a medication with 2D6 inhibition is initiated, discontinued, or changed. Medications that induce 2D6 metabolism can substantially decrease the steady-state levels of risperidone and 9-OH-risperidone. Carbamazepine (a strong 2D6 inducer) lowers the steady-state concentrations of risperidone and its metabolite by up to 50%. Patients coadministered risperidone and any 2D6 inducer, like carbamazepine, should be closely monitored when the inducing medication is initiated, titrated, or

Telegram: @medical_k

www.konkur.in

discontinued. In particular, if a 2D6-inducing medication is discontinued, risperidone may need to be decreased to avoid plasma concentration increases to toxic levels.

Other potential drug interactions include up to 20% higher levels of valproic acid with risperidone coadministration and the additive effects of medications with the potential to cause orthostatic hypotension.

Dosage and Administration

SCHIZOPHRENIA. For adults starting oral risperidone (available as tablets, fast-dissolve tablets, or a solution), the initial dose should be no higher than 2 mg daily in a single or divided dose. Higher starting dosages are associated with tachycardia and orthostatic hypotension. Dose increases of 1 to 2 mg per day are acceptable but should not be spaced less than 24 hours apart. Most patients are evaluated on 4 to 6 mg for the first 4 to 6 weeks. Many patients may be optimally treated with an average 4 mg daily dose, but doses ranging from 2 to 16 mg have been found effective. Several studies have concluded that doses above 6 mg per day in divided doses were not more effective than lower doses and were associated with higher rates of EPS and other dose-dependent side effects.

For paliperidone extended release, an initial dose of 6 mg daily is recommended. Some patients may require doses up to 12 mg, and others may respond to 3 mg.

Adolescents with schizophrenia should be started on no more than 0.5 mg once daily of risperidone. Dose increases should be made in increments of 0.5 to 1 mg per day, no less than 24 hours apart. The recommended daily dosage for adolescents with schizophrenia is 3 mg per day. Although a dose range of 1 to 6 mg per day has demonstrated efficacy, doses higher than 3 mg per day did not provide additional benefit and were associated with higher rates of side effects. If side effects are experienced, tolerability may be improved by dividing the dose into twice-daily dosing. There is only limited data on doses of paliperidone for children and adolescents. For 12 to 17 year olds, a starting dose of 3 mg is recommended.

Older adult and Parkinson disease patients should start with 0.5 mg once or twice daily of risperidone. Doses should be divided into twice-daily dosing to reduce the risk of orthostatic hypotension. Dose increases should be spaced 2 to 3 days apart, and dose increases above 1.5 mg

Telegram: @medical_k

www.konkur.in

twice a day should be made no sooner than 1 week after the last dosage change. This population may need maintenance doses of 1 mg or less to prevent other side effects. There is only limited information on paliperidone doses for older adult and Parkinson disease patients. As with risperidone, starting patients on a low dose such as 3 mg daily of paliperidone with monitoring for hypotension is recommended.

Long-Acting Formulations. Both risperidone and paliperidone are available as long-acting injectable formulations. The long-acting preparation of risperidone is an aqueous suspension, with risperidone contained in a matrix of glycolic acid–lactate polymer "microspheres" (25 to 150 μm). This preparation minimizes pain and inflammation at the injection site. Gradual hydrolysis of the copolymer at the site of injection ensures slow, steady, and smooth release of risperidone over several weeks. Paliperidone is available in three different formulations: Sustenna, a monthly formulation; Trinza, an every 3-month formulation; and Hafyera, an every 6-month formulation. The process for initiating these formulations is discussed in Table 33.2b–4.

BIPOLAR MANIA. Adults with acute bipolar mania should be started at a dose of 2 to 3 mg per day of risperidone with once-daily dosing. Dose increments should not be higher than 1 mg per day or spaced less than 24 hours apart. In this population, doses higher than 6 mg per day have not been fully evaluated. Paliperidone should be started at a dose of 6 mg daily. Doses can be increased to 12 mg or decreased to 3 mg depending on side effects and effectiveness.

Children and adolescents with bipolar mania should be started at doses of 0.5 mg once daily of risperidone and titrated up by 0.5 to 1 mg per day no less than 24 hours apart to a recommended dose of 2.5 mg per day. Doses as high as 6 mg per day have been studied in this population, but efficacy was no greater at doses above 2.5 mg per day. The dose can be divided to reduce side effects, should they emerge. Given the unknown long-term impact of risperidone on the neurologic, endocrinologic, and sexual maturation of children, clinicians should strive to find the lowest effective dose and regularly re-evaluate risperidone's efficacy and appropriateness for each patient.

IRRITABILITY ASSOCIATED WITH AUTISM. Children and adolescents with autistic disorder should be initiated on 0.25 mg per day for patients under

Telegram: @medical_k

www.konkur.in

20 kg and 0.5 mg per day for patients over 20 kg. No further dose increase should be initiated for a minimum of 4 days, after which time the dose can be titrated up to 0.5 mg per day for patients under 20 kg and 1 mg per day for patients over 20 kg. This dose should be maintained for 2 weeks. If there is no or partial response at that dose, increases of 0.25 mg per day for patients below 20 kg and 0.5 mg per day for patients over 20 kg should occur at intervals no briefer than 2 weeks. In clinical trials of children and adolescents with autistic disorder, 90% of the medication responders responded to doses between 0.5 and 2.5 mg per day. In patients over 45 kg, the optimal dose may be slightly higher, approximately 3 mg per day. As in the pediatric bipolar population, given the unknown long-term impact of risperidone on the neurologic, endocrinologic, and sexual maturation of children, clinicians should strive to find the lowest effective dose and regularly re-evaluate risperidone's efficacy and appropriateness for each patient.

OVERDOSE. Reports of an overdose of up to 360 mg of risperidone are associated with signs and symptoms such as sedation, tachycardia, hypotension, EPS, prolonged QT interval, and convulsions. A study evaluating the symptoms associated with overdose has shown that risperidone is associated with fewer side effects than clozapine and olanzapine (particularly anticholinergic side effects like agitation, confusion, and dysarthria).

Table 33.2b–3. Overview of Potential Cytochrome P450 Interactions with Antipsychotics

Drug	Major P450 Pathway[a]	Drugs that ↑ Antipsychotic Levels[b]	Drugs that ↓ Antipsychotic Levels[b]	Effect on Other Med Levels[b]	Comments
Clozapine (Clozaril)	1A2, 2D6, 3A4	Fluvoxamine (paroxetine, fluoxetine, bupropion, other 2D6 → modest ↑), cimetidine, caffeine, ciprofloxacin, erythromycin	Nicotine, carbamazepine, modafinil, St. John's wort, omeprazole, phenytoin, rifampin	Mild 2D6 inhibitor. Caution advised with other meds metabolized by 2D6. Levels of both may be ↑.	May decrease tobacco use, which can ↑ clozapine level; caution when patients change tobacco use; due to high toxicity and multiple P450 pathways, check all coadministered medicines for interactions and monitor clozapine levels with medicine changes.
Risperidone (Risperdal)	2D6	Fluoxetine, paroxetine, bupropion, quinidine	Carbamazepine, phenytoin, phenobarbital, rifampin	Valproate ↑ by 20%	Risperidone and its metabolite (paliperidone) are both active.
Olanzapine (Zyprexa)	1A2	Fluvoxamine, ciprofloxacin, fluoxetine (small)	Nicotine, carbamazepine, modafinil, omeprazole, rifampin	N/A	
Quetiapine (Seroquel)	3A4	Divalproex (small), cimetidine (small), nefazodone, ketoconazole, clarithromycin, erythromycin, ritonavir	Carbamazepine, thioridazine, phenytoin, modafinil, St. John's wort	Slight decrease in lorazepam clearance; Slight decrease in valproic acid exposure	
Ziprasidone (Geodon)	3A4	Nefazodone, ketoconazole, clarithromycin, erythromycin, protease inhibitors	Carbamazepine, phenytoin, modafinil, St. John's wort	N/A	Concomitant Rx of medicines that ↑ QTc is contraindicated or should be used with caution.
Aripiprazole (Abilify)	2D6, 3A4	Fluoxetine, paroxetine, bupropion, quinidine, nefazodone, ketoconazole, clarithromycin, erythromycin, protease inhibitors	Carbamazepine, rifampin, phenytoin, modafinil, St. John's wort	N/A	
Paliperidone (Invega)	N/A	Paroxetine (small), divalproex	N/A	N/A	As the metabolite of risperidone, paliperidone undergoes only limited P450 metabolism.
Iloperidone (Fanapt)	2D6, 3A4	Fluoxetine, paroxetine, ketoconazole, itraconazole	Carbamazepine, rifampin, phenytoin, modafinil, St. John's wort	N/A	Recommend not using with other drugs which prolong QTc interval.
Asenapine (Saphris)	1A2	Fluvoxamine, imipramine (small)	Paroxetine (small), carbamazepine (small)	Weak 2D6 inhibitor → double paroxetine exposure	
Lurasidone (Latuda)	3A4	Ketoconazole, clarithromycin, ritonavir, voriconazole, mibefradil, diltiazem, atazanavir, erythromycin, fluconazole, verapamil, grapefruit juice	Rifampin, avasimibe, St. John's wort, Phenytoin, carbamazepine	Small increase in midazolam exposure (CYP3A4 substrate)	
Cariprazine (Vraylar)	3A4, 2D6	Ketoconazole, erythromycin	Carbamazepine, phenytoin, modafinil, St. John's wort		
Brexpiprazole (Rexulti)	2D6, 3A4	Fluoxetine, paroxetine, bupropion, ketoconazole, quinidine, erythromycin	Carbamazepine, phenytoin, rifampin, modafinil, St. John's wort		
Lumateperone (Caplyta)	3A4, 2C8, 1A2	Amprenavir ciprofloxacin cyclosporin diltiazem erythromycin fluconazole fluvoxamine verapamil clarithromycin ritonavir nelfinavir itraconazole	Carbamazepine phenytoin efavirenz modafinil armodafinil pioglitazone nafcillin prednisone rifampin St. John's wort Bosentan		

Rx, prescription; N/A, not available.
[a]Medications primarily metabolized by only one cytochrome system, especially CYP2D6, are subject to more numerous and more significant potential drug–drug interactions than medications with multiple pathways.
[b]This is not a comprehensive list of potential interactions. Clinicians should check for possible drug interactions whenever patients' medication regimens are changed, including by other providers.

Table 33.2b–4. Comparison of Usual Dosing[a] for the Commonly Used Antipsychotics in Schizophrenia

Antipsychotic	Typical Starting Dosage	Maintenance Therapy Dose Range	Titration/Notes	Maximum Recommended Dosage
Clozapine (tablets) (Clozaril)	12.5 mg once or twice a day	150–450 mg per day in divided doses or as a single bedtime dose	The dosage should be increased to 25–50 mg on the second day. Further increases may be made in daily increments of 25–50 mg to a target dose of 300–450 mg per day. Subsequent dosage increases should be made no more than once or twice weekly in increments of no more than 100 mg.	900 mg per day
Risperidone (tablets, orally disintegrating tablets, and oral solution) (Risperdal)	1 mg twice a day or 2 mg at night	2–8 mg per day, in divided doses or as a single bedtime dose	Increase by increments of 1–2 mg per day. In some patients (older adults, hepatic or renal impairment), a slower titration may be appropriate.	16 mg per day
Risperidone IM long-acting (Consta)	25 mg every 2 weeks	25–50 mg every 2 weeks	Continue oral antipsychotic for 3 weeks. Titrate by 12.5 mg every 4 weeks.	50 mg every 2 weeks
Risperidone SQ long-acting (Perseris)	90 mg or 120 mg every 4 weeks	90–120 mg every 4 weeks	Initiate with 90 or 120 mg SQ injection. No loading dose or oral supplementation required	120 mg every 4 weeks
Olanzapine (tablets and orally disintegrating tablets) (Zyprexa)	5–10 mg per day	10–20 mg per day	Dosage increments of 5 mg, at change intervals of not less than 1 week.	20 mg per day
Olanzapine IM long-acting (Relprevv)	210 mg/2 weeks or 405 mg/4 weeks (for target 10 mg/day); 300 mg/2 weeks (for target 15–20 mg/day)	150 mg/2 weeks or 300 mg/4 weeks (for target 10 mg/day); 210 mg/2 weeks or 405 mg/4 weeks (for target 15 mg/day); 300 mg/2 weeks (for target 20 mg/day) Requires a 3-hour observation period after injections.	Adjust dosage at intervals of 2 or 4 weeks, depending on dosing schedule and maintenance therapy target dose.	300 mg IM every 2 weeks
Quetiapine (tablets) (Seroquel)	25 mg twice a day	400–800 mg per day	Increase by 25–50 mg in divided doses for first several days, to target of 300–400 mg per day by day 4. Adjustments can be made by 25–50 mg twice daily, every 2 days	800 mg per day
Quetiapine extended release (Seroquel XR)	300 mg nightly	400–800 mg per day	Can increase by up to 300 mg per day at intervals as short as 1 day	800 mg per day
Ziprasidone (capsules) (Geodon)	20 mg twice a day with food	20–80 mg twice a day with food	Adjust at intervals not less than 2 days	80 mg twice a day
Ziprasidone (intramuscular)	For acute agitation: 10–20 mg, as required, up to a maximum of 40 mg per day	N/A	For acute agitation: Dosages of 10 mg may be administered every 2 hours, and dosages of 20 mg may be administered every 4 hours up to a maximum of 40 mg per day.	For acute agitation: 40 mg per day, for not more than 3 consecutive days
Aripiprazole (tablets) (Abilify)	10–15 mg once per day	10–30 mg per day	Dosage increases should not be made at intervals less than every 2 weeks	30 mg per day
Aripiprazole IM long acting (Maintena)	400 mg IM monthly	300–400 mg IM monthly	Continue oral antipsychotic for 14 days before discontinuing.	400 mg IM monthly
Aripiprazole lauroxil IM (Aristada and Aristada Initio)	Can be started at any of the available monthly, every 6 weeks, or every 2-month doses	Monthly: 441 mg, 662 mg, or 882 mg. Every 6 weeks: 882 mg. Every 2 months: 1,064 mg	2 options for initiation: (1) 675 mg IM Aristada Initio plus single dose oral aripiprazole 30 mg plus Aristada IM. (2) Aristada IM plus 21 days of oral aripiprazole	882 mg every month
Paliperidone (tablets) (Invega)	6 mg once per day	3–12 mg per day	Efficacy beyond 6 mg per day has not been shown. Dose increases of 3 mg should occur at intervals no less than 5 days.	12 mg per day
Paliperidone palmitate (Invega Sustenna)	234 mg IM on day 1, then 156 mg IM 1 week later	39–234 mg IM monthly (117 mg recommended)	Make adjustments no more frequently than monthly	234 mg IM monthly
Paliperidone palmitate (Trinza)	Initiate only after at least 4 months of Invega Sustenna treatment	273–819 mg every 3 months	Trinza started only after adequate treatment with Invega Sustenna (1-month paliperidone) for at least 4 months	819 mg IM every 3 months

Telegram: @medical_k

www.konkur.in

Paliperidone Palmitate (Hafyera)	Initiate only after at least 4 months on Invega Sustenna or 3 months on Invega Trinza	1,092–1,560 mg every 6 months	Hafyera dose based on previous Invega or Trinza dose. Dose adjust every 6 months. Patient response to dose changes may not be apparent for several months.	1,560 mg IM every 6 months
Iloperidone (Fanapt)	1 mg twice daily	6–12 mg twice daily	Can make dose increases no more frequently than by 2 mg twice daily every day	12 mg twice daily
Asenapine (Saphris)	5 mg twice daily	5–10 mg twice daily	Can increase to 10 mg twice daily after 1 week	10 mg twice daily
Asenapine transdermal system (Secuado)	3.8 mg every 24 hours	3.8–7.6 mg every 24 hours	Can increase to 5.7 mg/24 hours or 7.6 mg/24 hours after 1 week at 3.8 mg	7.6 mg every 24 hours
Lurasidone (Latuda)	40 mg daily with food	40–160 mg daily with food	Not specified; tablets are available in 20, 40, 60, 80, and 120 mg strengths	160 mg daily
Cariprazine (Vraylar)	1.5 mg once per day	1.5–6 mg once daily	Start with 1.5 mg for 1 day with increases in 1.5 mg increments; due to the long half-life of cariprazine and its active metabolites, changes in dose will not be fully reflected in plasma for several weeks	6 mg
Brexpiprazole (Rexulti)	1 mg once per day	2–4 mg daily for schizophrenia; 2–3 mg daily for adjunctive treatment of depression	For schizophrenia, start 1 mg QD for 4 days, then 2 mg for 3 days, then 4 mg QD. For adjunctive treatment of depression, start 0.5–1 mg QD, then increase dose to 2 mg QD after 1 week.	4 mg for schizophrenia; 3 mg for adjunctive treatment of depression
Lumateperone (Caplyta)	42 mg once per day	42 mg daily	No titration required Start with 42 mg Only 42-mg dose approved	42 mg

Information taken from U.S. Prescribing Information for individual agents.
[a]Dosage adjustments may be required in special populations.

DOPAMINE, SEROTONIN, NET (NE TRANSPORTER) INHIBITOR (METABOLITE)

Quetiapine

Quetiapine was developed by Zeneca Laboratories. Its new drug application was filed with the FDA in 1996 and approved in 1998.

Chemistry. Quetiapine is a dibenzothiazepine with more potent 5-HT_2 than D_2 receptor-blocking properties. Its molecular formula is $C_{42}H_{50}N_6O_4S_2 \cdot C_4H_4O_4$. Quetiapine is related to the clozapine, olanzapine (Fig. 33.2b–1), and fluperlapine molecules.

Pharmacologic Action

PHARMACOKINETICS

Absorption. The time to maximum concentration (T_{max}) after oral intake is 1.5 hours, with an estimated half-life of 6 hours. No difference was found between twice- and three-times-daily dosing, in spite of a steady-state half-life of 6.9 hours.

Distribution. Steady-state levels are reached in 48 hours. Quetiapine has a wide volume of distribution, approximately 10 L/kg.

Telegram: @medical_k

www.konkur.in

Metabolism and Elimination. Quetiapine is extensively metabolized by the liver. It has many metabolites, although only a small percentage of these are active. The primary metabolic pathway is CYP3A4. Ninety-five percent of [^{3}H] quetiapine is recovered as metabolites in urine and feces, but only 1% is recovered as quetiapine itself.

PHARMACODYNAMICS

Mechanism of Action. Quetiapine is a multitransmitter antipsychotic agent: It has a high affinity for 5-HT_2, histamine H_1, α_1, and α_2 receptors; a moderate affinity for 5-HT_{1A} receptors; a moderate affinity for D_2; and a low affinity for D_1 receptors. Quetiapine has a very low affinity for cholinergic M_1 and D_4 receptors (despite its low affinity for cholinergic receptors, quetiapine is associated with several typically anticholinergic side effects, such as dry mouth and constipation). In addition, norquetiapine, the major metabolite of quetiapine, has a high affinity for the norepinephrine transporter (NET).

Quetiapine's low incidence of EPS may be explained by its relatively high 5-HT_{2A} binding compared to its activity at D_2 receptors, according to Meltzer. An early PET study demonstrated that 2 hours after a single clinical dose, quetiapine occupies 44% of D_2 receptors and 72% of 5-HT_2 receptors. Other PET studies demonstrate rapid dissociation of quetiapine from the D_2 receptor. In one study, D_2 receptor occupancy 2 hours postdose ranged from 58% to 64% and fell to 20% to 0% 12 to 24 hours postdose for single doses of 400 and 450 mg, respectively. This supports the hypothesis of Kapur and colleagues, who propose that quetiapine's "fast dissociation" (i.e., a high D_2 occupancy which decreases to low levels by the end of the dosing interval) may be sufficient to induce antipsychotic response while minimizing EPS. Further, there is evidence that the clinical effectiveness of quetiapine is related to both the low occupancy of D_2 receptors and inhibition of the NET.

Design and Interpretation of Clinical Drug Studies

SCHIZOPHRENIA: ACUTE TREATMENT. The earliest clinical trials demonstrated that quetiapine is significantly superior to placebo at reducing positive, negative, and depressive symptoms of schizophrenia. A post hoc analysis

Telegram: @medical_k

www.konkur.in

of early placebo-controlled trials found that quetiapine separated from placebo on multiple clinical measures by the end of the first week of treatment. Later trials compared quetiapine to other FGAs and SGAs. Some of the early comparison trials suffered from quetiapine underdosing, with some study doses as low as 150 to 300 mg per day. These studies generally found quetiapine to have comparable efficacy to haloperidol in reducing positive symptoms but slightly less efficacy in reducing negative symptoms. Later studies began assessing quetiapine treatment at higher doses, up to 800 mg per day. Such studies mostly found comparable efficacy between quetiapine and haloperidol on positive and negative symptoms and virtually no EPS or persistent prolactin elevation with quetiapine. In two separate 6- to 8-week, double-blind comparative studies, quetiapine (300 to 600 mg per day) had comparable efficacy to haloperidol in reducing psychotic symptoms. Both quetiapine and haloperidol produced clear reductions in mean PANSS scores, with more quetiapine-treated patients showing a clinical response (greater than 20% reduction in total PANSS score, $p = .043$). In addition, patients treated with quetiapine had a greater reduction in EPS ($p = .005$) and fewer treatment-emergent extrapyramidal-related adverse events ($p < .001$) compared with haloperidol-treated patients. In another study comparing multiple fixed doses of quetiapine to haloperidol and placebo, a dose range of 150 to 750 mg per day of quetiapine was comparable to haloperidol 12 mg per day in reducing positive symptoms, and doses of quetiapine above 300 mg per day were comparable in reducing negative symptoms. A post hoc analysis of this data concluded that patients treated with quetiapine had significantly greater reductions of hostility and agitation compared to both placebo- and haloperidol-treated patients that were independent of the improvements in psychotic symptoms. An 8-week double-blind trial of 673 patients comparing quetiapine (mean dose 525 mg per day) and risperidone treatment (mean dose 5.2 mg per day) found that overall treatment efficacy did not differ between the two drugs, although there were some data to support greater positive symptom reduction with risperidone. Quetiapine had significantly lower rates of EPS and prolactin elevation but higher rates of somnolence. Another 6-week, double-blind trial in recently hospitalized patients with schizophrenia found that treatment with risperidone, but not quetiapine, was associated with statistically significant separation from placebo by week 2 of treatment.

Telegram: @medical_k

www.konkur.in

Patients on quetiapine required higher rates of antipsychotic polypharmacy to control symptom exacerbation.

SCHIZOPHRENIA: MAINTENANCE TREATMENT. Quetiapine does not have FDA approval for the maintenance treatment of schizophrenia. However, quetiapine is frequently used off-label for maintenance treatment. Studies of quetiapine treatment in schizophrenia have followed patients for up to 18 months and found continued symptomatic improvement of positive, negative, and affective symptoms on par with improvements seen in acute treatment with quetiapine and the maintenance effects of other FGAs and SGAs. A small open-label study of 25 patients compared treatment with oral quetiapine (mean dose 493 mg per day) to treatment with haloperidol decanoate (mean dose 170 mg per injection). Quetiapine treatment was associated with comparable prevention of symptom exacerbation over 48 weeks, less rigidity and akathisia, and greater improvement in negative symptoms over haloperidol decanoate treatment. There have been few direct comparisons between quetiapine and the other SGA medications. A large multinational naturalistic prospective study of 5,883 participants compared the efficacy of haloperidol, olanzapine, risperidone, and quetiapine at 6 months of treatment. Quetiapine was found to have comparable efficacy to haloperidol but was less efficacious than olanzapine and risperidone. However, quetiapine was likely underdosed, with a mean study dose of 200 mg per day at baseline and 300 mg per day by 6 months.

An open-label study of 728 patients with schizophrenia compared quetiapine to risperidone treatment for 4 months. Quetiapine- and risperidone-treated patients showed similar improvements on positive and negative symptoms scales, and quetiapine-treated patients had greater improvements on depressive symptom scales. Quetiapine was not associated with any extrapyramidal side effects but had higher rates of dry mouth, somnolence, and dizziness. A 6-month study comparing treatment with quetiapine or olanzapine in 346 patients found that both medications demonstrated similar efficacy in the treatment of negative symptoms but that olanzapine therapy was associated with significantly greater positive symptom reduction, improvements in measures of functional outcome, and reduced rates of medication discontinuation. Finally, a 1-year study comparing olanzapine, risperidone, and quetiapine in the treatment of 400 patients with early-onset psychosis found no differences in the all-cause

Telegram: @medical_k

www.konkur.in

discontinuation rate among the drugs. However, positive symptom reductions were greater in the olanzapine and risperidone groups at some (but not all) time points.

These studies suggest that when appropriately dosed, quetiapine has equivalent or near equivalent efficacy compared with FGAs or other SGAs. Quetiapine appears to demonstrate a tendency toward slightly weaker symptom control but a better movement disorder profile than most other antipsychotic medications.

CATIE TRIAL. Quetiapine did not separate from fluphenazine, risperidone, or ziprasidone on the primary measure of time to discontinuation in the first phase of CATIE. Treatment with quetiapine (mean dose 543.4 mg per day) was associated with higher rates of side effects like dry mouth and constipation. In phase II, patients who had discontinued an SGA due to lack of efficacy had a significantly longer time to discontinuation on olanzapine and risperidone than on quetiapine or ziprasidone. However, in patients who had discontinued the first-generation medication due to lack of efficacy, the time to discontinuation was longer in the quetiapine and olanzapine groups than in the risperidone group. This latter finding suggests that quetiapine, because of its low incidence of EPS, may have advantages for patients who have difficulty tolerating FGAs.

BIPOLAR DEPRESSION. Two 8-week, placebo-controlled trials of identical design evaluated treatment response to quetiapine at 300 mg per day and 600 mg per day fixed doses in 542 and 509 outpatients with bipolar I or bipolar II depression. The results of both studies were similar. Both fixed doses demonstrated significant improvements in depressive symptoms, which separated from placebo by the first week of treatment. There were no statistically significant differences between the dosage groups. There was no difference between quetiapine- and placebo-treated patients in terms of manic switch rate. A subanalysis of one of the studies examined patients with a rapid-cycling course and concluded that quetiapine 300 or 600 mg per day was significantly more efficacious than placebo at reducing symptoms of depression, anxiety, and related symptoms in this patient population.

BIPOLAR MANIA. Two identical studies comparing adjunctive quetiapine treatment versus adjunctive placebo treatment in 191 and 402 bipolar

Telegram: @medical_k

www.konkur.in

manic patients on lithium or valproate found that adjunctive quetiapine treatment (mean dose 584 mg per day and 492 mg per day, respectively) was associated with significantly greater reductions in manic symptoms and significantly higher rates of remission than adjunctive treatment with placebo. In the second study, a statistically greater degree of improvement in manic symptoms was evident in the adjunctive quetiapine group by the end of the first week of treatment. A study of 302 patients randomized to quetiapine, lithium, or placebo monotherapy treatment concluded that quetiapine was significantly more effective at reducing manic symptoms than placebo. Although the study was not powered to detect differences between lithium and quetiapine treatment, a post hoc analysis found no significant differences in symptom reduction between patients treated with quetiapine versus lithium. Another placebo-controlled study using haloperidol as the active control found that quetiapine was slightly less effective at reducing symptoms and achieving remission than haloperidol. The comparative analysis was post hoc, and some differences between the medications were not statistically significant. A placebo-controlled trial of 403 patients with mania concluded that quetiapine was associated with higher rates of symptom remission than placebo at both 3 and 12 weeks.

OTHER DIAGNOSES. Quetiapine was found to be effective for treating generalized anxiety disorder in three randomized controlled trials.

Quetiapine is used off-label for a number of other diagnoses and symptoms, despite limited controlled data. Three small open-label studies have evaluated the effects of treatment with quetiapine for chronic post-traumatic stress disorder (PTSD). In all three studies, quetiapine significantly reduced the severity of PTSD symptoms in patients with and without psychotic features.

There are several small trials of quetiapine treatment of Obsessive-Compulsive Disorder (OCD). A small single-blind, placebo-controlled study found that adjunctive treatment with quetiapine and an SSRI was more efficacious at reducing symptoms of OCD than placebo and SSRI.

There are a few case reports and small open-label trials of quetiapine in the treatment of borderline personality disorder. The dose ranges in these studies varied from about 200 to 800 mg per day. Overall, the studies reported that treatment with quetiapine improved multiple symptom clusters, most notably mood, impulsivity, and aggression. There have

Telegram: @medical_k

www.konkur.in

been no randomized, double-blind, controlled trials in this population to date.

Anecdotally, quetiapine is considered the antipsychotic drug of choice to treat psychosis in Parkinson disease. Although quetiapine does not appear to worsen parkinsonism, two placebo-controlled trials failed to show efficacy in treating the psychotic symptoms associated with the dopaminergic treatment of Parkinson disease. One study comparing quetiapine to clozapine (the only antipsychotic medication with proven efficacy and tolerability in Parkinson psychosis) found comparable levels of efficacy between the two drugs. Because of the high 5-HT_{2A} blockade and relatively low D_2 binding, quetiapine has been used off-label as a first-line treatment for psychosis in Parkinson disease. Quetiapine is more easily administered than clozapine in patients with Parkinson disease, but treatment efficacy has not been sufficiently established. The sedating effects and potential EPS are treatment limiting in this population.

QUETIAPINE EXTENDED RELEASE FORMULATION. A study comparing quetiapine Extended-release (XR) (once daily dosing) to quetiapine immediate release (twice daily dosing) and placebo found comparable improvements with both forms of quetiapine preparation compared to placebo. There were no adverse events specific to the XR formulation.

Effects on Specific Organs and Systems

CARDIOVASCULAR SYSTEM. Postural hypotension, likely due to quetiapine's high affinity for adrenergic α_1 receptors, is the most common cardiovascular effect. Tachycardia also occurs at rates above placebo; whether the tachycardia is secondary to postural hypotension or a separate effect is not clear. Quetiapine is not associated with clinically important increases in the QTc interval.

RESPIRATORY AND EAR, NOSE, AND THROAT SYSTEM. Dyspnea, cough, pharyngitis, rhinitis, and nasal congestion have been reported with rates slightly above placebo, which is observed with all SGAs.

GASTROINTESTINAL SYSTEM. Dry mouth, constipation, and dyspepsia are commonly reported side effects of quetiapine, with dry mouth being an

Telegram: @medical_k

www.konkur.in

especially frequent side effect. Abdominal pain is less common, but it (along with dyspepsia) is a dose-related effect.

HEMATOLOGIC AND LYMPHATIC SYSTEM. Leukopenia and neutropenia in conjunction with quetiapine therapy have been observed. Very rare cases of agranulocytosis, including fatal cases, have also been described.

CENTRAL NERVOUS SYSTEM. Sedation, somnolence, and dizziness are frequently reported effects, with lethargy slightly less so. Headache and, to a lesser degree, asthenia are also commonly reported.

METABOLIC AND NUTRITIONAL SYSTEM. Peripheral edema has been described with quetiapine and other antipsychotics. Hyperlipidemia, hypertriglyceridemia, and hyperglycemia are common effects of quetiapine. These have been attributed to the H_1 and 5-HT_{2C} binding as in other multireceptor antipsychotics.

Therapeutic Indications

SCHIZOPHRENIA. Quetiapine is indicated for the acute treatment of schizophrenia, although in clinical practice, it is used both acutely and for maintenance treatment.

BIPOLAR DISORDER. Quetiapine is indicated for the acute treatment of manic episodes in bipolar I disorder, either as monotherapy or as adjunctive treatment with lithium or valproate. It is also indicated for monotherapy for the acute treatment of depressive episodes associated with bipolar I or II disorder. Quetiapine is indicated for the maintenance treatment of bipolar I disorder as an adjunct to lithium or divalproex.

OFF-LABEL USES. Quetiapine is used in clinical practice to treat a number of symptoms. Typically, in these cases, clinicians are taking advantage of quetiapine's sedative and somnolent properties to treat insomnia, anxiety, and agitation. Usually, the doses used for such symptomatic indications are between 12.5 and 100 mg per day, and insomnia will often respond to a dose range of 25 to 50 mg at bedtime. Sleep induction may be mediated by H_1 blockade, while improvement in sleep maintenance insomnia (i.e., decreased slow-wave sleep) may be caused by 5-HT_{2A} antagonism. This

Telegram: @medical_k

www.konkur.in

mechanism in insomnia is similar to the effects of low-dose doxepin (Sinequan). Although quetiapine benefits from having limited abuse potential, the possible metabolic risks of quetiapine use must be weighed against the benefits of a nonaddictive medication. Having lower doses for these indications means that the metabolic risks are also lower but still require regular assessment.

Quetiapine is used to treat nonpsychotic disorders such as major depressive disorder, OCD, and borderline personality disorder.

Anecdotally, quetiapine is considered the antipsychotic drug of choice to treat psychosis in Parkinson disease, although efficacy failed to be established in two placebo-controlled trials.

Precautions and Adverse Reactions

BLACK BOX WARNINGS

Increased Mortality in Older Adult Patients with Dementia-Related Psychosis. Quetiapine and the other SGAs carry a black box warning for increased mortality in older adult patients with dementia-related psychosis compared with placebo.

Suicidal Thoughts and Behaviors. After quetiapine received an indication for the treatment of depression in bipolar disorder, it received the same black box warning as other antidepressant medications. In 2004, the FDA issued a warning about suicidal ideation and antidepressant therapy in the pediatric and young adult population. Although quetiapine was not one of the agents included in the 24 trials that led to the FDA black box warning, the impact of quetiapine on suicidal ideation in patients with depression or anxiety has not been assessed. Any patient, especially patients younger than 24 years, treated with medication for depression or severe anxiety, should be monitored for the emergence or worsening of suicidal ideation. Emergent or worsening symptoms of anxiety, panic attacks, agitation, irritability, hostility, aggressiveness, impulsivity, akathisia, insomnia, hypomania, and mania may precede the onset of suicidal ideation and should be evaluated carefully at each visit. Patients started on treatment for depression, or severe anxiety should be monitored frequently for the first 2 to 3 months of treatment or until remission occurs.

Telegram: @medical_k

www.konkur.in

NEUROLEPTIC MALIGNANT SYNDROME. Despite quetiapine's very low rate of EPS, rare cases of NMS have been reported with quetiapine use. Physicians should remain aware that even medications with low to nonexistent EPS risk can still occasionally cause NMS. Furthermore, several cases of high creatine kinase levels in the absence of clear NMS have been reported with quetiapine.

TARDIVE DYSKINESIA. Quetiapine has a very low rate of tardive dyskinesia. Although there are some reported cases of presumed quetiapine-induced tardive dyskinesia, there are many more reports of quetiapine being an effective treatment of tardive dyskinesia, much like clozapine. However, the data supporting quetiapine as a treatment of tardive dyskinesia are equivocal.

MOVEMENT SIDE EFFECTS AND DISORDERS. Since its release in 1998, most studies suggest that quetiapine, along with clozapine, has the lowest rate of extrapyramidal side effects of all the SGAs. This is thought to be the result of quetiapine's low and transient D_2 occupancy and its relatively high 5-$HT_{2A/2C}$ binding.

HYPERCHOLESTEROLEMIA AND HYPERTRIGLYCERIDEMIA. In the industry-sponsored efficacy and safety trials of quetiapine, 16% of patients with schizophrenia and 9% of patients with bipolar disorder developed hypercholesterolemia, compared with 7% and 6% of placebo-treated patients. The rates of hypertriglyceridemia were higher; 23% of people with schizophrenia and 14% of people with bipolar disorder, versus placebo rates of 16% and 9%. In phase I of the CATIE trial, quetiapine-treated patients experienced exposure-adjusted mean increases in cholesterol and triglycerides of 6.6 and 21.2 mg/dL, respectively. These increases were second only to olanzapine and clinically significantly higher than those seen with risperidone or perphenazine. Severe cases of hypertriglyceridemia, with levels above 400 mg/dL, are not uncommon with quetiapine therapy. Patients on quetiapine should be monitored regularly (at baseline and every 6 months) for changes in lipid parameters.

HYPERGLYCEMIA AND DIABETES MELLITUS. Quetiapine is associated with increases in plasma glucose and an increased risk of diabetes, but the

Telegram: @medical_k

www.konkur.in

degree of glucose increase is less dramatic than that of lipid and triglyceride increases with quetiapine. In two long-term treatment studies, 10.7% of patients on quetiapine developed fasting glucose measurements greater than 126 mg/dL versus 4.6% of placebo-treated patients. During phase I of the CATIE trial, patients treated with quetiapine had exposure-adjusted mean increases in blood glucose of 7.5 mg/dL, an increase that was not significantly larger than that seen with risperidone or perphenazine. Patients treated with quetiapine should be monitored regularly for increases in fasting glucose above 100 mg/dL.

CHANGES IN WEIGHT. Quetiapine is associated with significant increases in weight, likely related in part to its high affinity for histaminergic H_1 receptors. In four 3- to 6-week trials of patients with schizophrenia, 23% of quetiapine-treated patients and 6% of placebo-treated patients gained more than 7% of their body weight. Similar rates were seen in patients with bipolar disorder treated with either quetiapine or placebo. However, the increases are not as extreme as those seen with olanzapine or clozapine. In phase I of the CATIE study, 16% of patients treated with quetiapine gained over 7% of their body weight. The mean weight gain for quetiapine-treated patients was 1.1 l from baseline to last observation.

ORTHOSTATIC HYPOTENSION AND SYNCOPE. Quetiapine is a potent antagonist at the α_1-adrenergic receptor, contributing to its risk of orthostatic hypotension and syncope. Other related effects include dizziness and tachycardia. These symptoms are most pronounced during the initial dose titration and are minimized by starting doses of 25 mg twice a day or less. In the older adults, even lower initial doses may be indicated. Patients with known cardiovascular disease, cerebrovascular disease, or conditions that increase the risk of hypotension should be initiated on quetiapine with caution and frequent monitoring.

CATARACTS. Studies on dogs at quetiapine doses four times the maximum human dose found associations between long-term (6- or 12-month) quetiapine use and cataracts. Studies in humans have failed to find similar associations between cataracts and quetiapine use. The product insert for quetiapine recommends slit lamp examinations at treatment initiation and every 6 months thereafter; it is unclear if these recommendations are followed regularly in clinical care or whether the

Telegram: @medical_k

www.konkur.in

health care costs of such frequent assessment are justified by the hypothetical human risk of cataracts.

THYROID HORMONE CHANGES. Quetiapine affects total and free thyroxine (T_4) levels in a dose-dependent manner. At the high therapeutic dose range of quetiapine, T_4 levels may be decreased by as much as 20%. These changes are generally not clinically significant, nor do they typically result in changes to thyroid stimulating hormone (TSH) or thyroid-binding globulin (TBG). Less than 1% of patients had changes in TSH while on quetiapine. T_4 levels generally return to baseline with discontinuation of quetiapine. Patients on lithium therapy who are started on adjunctive treatment with quetiapine are likely at greater risk of thyroid hormone fluctuation than those not started on quetiapine adjunctively.

ELEVATED TRANSAMINASES. Quetiapine has been associated with transient and asymptomatic elevations in serum transaminases, especially Alanine Transaminase (ALT). In 3- to 6-week trials of patients with schizophrenia, 6% of people on quetiapine had elevations in transaminases of over three times the normal limit, compared with 1% of people on placebo. The transaminase elevations typically occurred by the third week of treatment, and levels returned to baseline with continued quetiapine administration.

SOMNOLENCE AND SEDATION. Quetiapine can cause significant sedation and somnolence, especially during initial dose titration. In industry-sponsored studies, the rates of somnolence in the schizophrenia, bipolar mania, and bipolar depressed groups ranged from 18% to 34% of patients treated with quetiapine versus 7% to 9% of patients treated with placebo. The percentage of patients on quetiapine reporting somnolence in the CATIE trial was 31%, but this was not significantly different from the other antipsychotic treatment groups. The sedation and somnolence are likely secondary to quetiapine's high affinity for histaminergic H_1 receptors.

PREGNANCY. Quetiapine is rated pregnancy category C. Three case studies of pregnant women treated with quetiapine throughout all or part of their pregnancies reported no noticeable effects of quetiapine treatment on the neonates.

Dosage and Administration

Telegram: @medical_k

www.konkur.in

SCHIZOPHRENIA. Quetiapine dosages should be titrated to avoid excessive somnolence, postural hypotension, and syncope. The manufacturer's recommended dosing schedule is as follows: 25 mg twice daily on day 1, 75 to 100 mg in divided doses by day 2 or 3, for a total dose of 300 to 400 mg in divided doses by day 4. Dose increments above day 4 should occur no more rapidly than every 2 days (however, other studies have shown that a more aggressive titration is well tolerated and associated with good response). The target dose range is 150 to 800 mg per day. All efficacy studies occurred with twice or three times a day dose schedules, but in the community, quetiapine is frequently administered once daily at bedtime. Dosages above 800 mg have not been systematically evaluated, but doses up to 1,200 mg per day have been used clinically.

MANIA. In acute mania, the manufacturer recommends an initial dose of 100 mg in a divided dose, with rapid titration of up to 100 mg increases per day in divided doses, to a total dose of 400 mg by day 4. The dose can be escalated by up to 200 mg increases on day 5 and 6, for a total dose of 800 mg by day 6. Children and adolescents (aged 10 to 17 years) should start with 25 mg twice daily and should reach a total dose of 400 mg by day 5. Patients should be monitored for orthostatic hypotension and syncope. The effective dose range for mania is 400 to 800 mg per day (400 to 600 mg per day in children and adolescents). Inpatients may benefit from the daytime sedative effects of twice-daily dosing, and as an outpatient, community practice is once a day at bedtime dosing.

DEPRESSION. The recommended titration schedule for bipolar depression is as follows: day 1, 50 mg at bedtime; day 2, 100 mg at bedtime; day 3, 200 mg at bedtime; day 4, 300 mg at bedtime. Patients being titrated beyond 300 mg can receive 400 mg by day 5 and 600 mg by day 8. In efficacy trials, no additional antidepressant benefit was noted above doses of 300 mg. The efficacy trials for bipolar depression dosed quetiapine once daily at night.

The manufacturer's recommended titration schedules should be modified for people who demonstrate significant orthostatic hypotension, somnolence, or have episodes of syncope.

Telegram: @medical_k

www.konkur.in

QUETIAPINE EXTENDED RELEASE. The extended-release formulation of quetiapine is intended for once-daily dosing at bedtime. The recommended initial dose is 300 mg. The dose can be titrated up to 800 mg as rapidly as by day 3. The tablets should not be crushed or cut. It is recommended that quetiapine extended release be taken without food or with no more than 300 calories at the time of administration, as high calorie or high fat meals cause increased plasma concentrations.

DOSING IN SPECIAL POPULATIONS

Older Adults. Older adult patients are generally more sensitive to quetiapine's effect on blood pressure. In this population, orthostatic hypotension or syncope can increase the risk of falls. Furthermore, the metabolism of all drugs is slowed in geriatric populations. The titration schedule in the older adults should be slowed and the target doses lower. Initial doses should be 12.5 to 25 mg per day, and increments of no more than 25 mg should occur every 1 to 3 days, depending on tolerability. Quetiapine is not indicated for patients with psychosis due to dementia.

Hepatic Impairment. Patients with hepatic impairment should be initiated at doses no higher than 25 mg per day. The dose can be increased daily by 25 to 50 mg to an effective dose.

Drug Interactions. Quetiapine is metabolized by the CYP system. CYP 3A4 is the major metabolic pathway, and CYP 2D6 is a minor pathway. Quetiapine is neither an inhibitor nor an inducer of any CYP enzyme system. Cimetidine (a nonspecific enzyme inhibitor) did not inhibit quetiapine metabolism. Phenytoin, a strong inducer of CYP3A4, caused a fivefold increase in quetiapine clearance. Similarly, ketoconazole, a strong CYP3A4 inhibitor, increased quetiapine levels by 335%. Valproic acid increased quetiapine plasma levels by a clinically insignificant amount. Lithium, lorazepam (or other benzodiazepines), risperidone, haloperidol, fluoxetine, and imipramine (Tofranil) had no effects on the pharmacokinetics of quetiapine and vice versa (i.e., did not require dose adjustments). Concomitant administration of thioridazine (Mellaril), however, increased oral clearance of quetiapine by 65%.

Overdose. Quetiapine is relatively safe in overdose. Acute nonfatal overdoses up to 30 g have been described. One fatal overdose involved

Telegram: @medical_k

www.konkur.in

ingestion of over 13 g of quetiapine. The effects of overdose are exaggerations of the medication's side-effect profile: Sedation and somnolence, hypotension, and tachycardia.

SEROTONIN, DOPAMINE

Iloperidone

Iloperidone is the only antipsychotic in this NbN category. It has a high affinity for 5-HT_{2A} and D_2 receptors. Important clinical properties include a low liability to cause EPS but a risk of orthostatic hypotension requiring a titration period of several days.

Initial research and development of iloperidone occurred in the early to middle 1990s. FDA approval for the treatment of schizophrenia was finally granted in 2009 after an initial new drug application submitted in 2007 was denied due to the need for additional clinical trial support.

Chemistry. Iloperidone belongs to the class of piperidinyl-benzisoxazole derivatives (Fig. 33.2b–1). The chemical name of iloperidone is 4′-[3-[4-(6-Fluoro-1,2-benzisoxazol-3-yl)piperidino]propoxy]-3′-methoxyacetophenone. Its molecular formula is $C_{24}H_{27}FN_2O_4$, and its molecular weight is 426.48.

Pharmacologic Action

PHARMACOKINETICS. The mean elimination half-lives for iloperidone and its two major metabolites (P88 and P95) are 18, 26, and 23 hours, respectively, in CYP2D6 extensive metabolizers. In poor metabolizers, the half-lives are 33, 37, and 31 hours. Steady-state concentrations in plasma are reached after 3 to 4 days of dosing.

Absorption. Iloperidone is well absorbed with oral administration, with peak plasma levels occurring 2 to 4 hours after ingestion. Administration with a high-fat meal delayed T_{max} for iloperidone by 1 hour and its major metabolites, P88 and P95, by 2 and 6 hours, respectively. As a high-fat meal does not significantly affect the maximum concentration or area under the curve (AUC) of iloperidone or its major metabolites, product labeling indicates it can be administered without regard to meals.

Telegram: @medical_k

www.konkur.in

Distribution. Iloperidone has an apparent volume of distribution of 1,340 to 2,800 L, and it, as well as its major metabolites, is approximately 95% serum protein bound.

Metabolism and Elimination. Iloperidone is metabolized by three pathways: CYP2D6-mediated hydroxylation, CYP3A4-mediated O-demethylation, and carbonyl reduction. There are two major metabolites of iloperidone, P95 and P88, with P95 exposure being greater in CYP2D6 extensive metabolizers and P88 being greater in CYP2D6 poor metabolizers. Elimination of metabolites is primarily through the urine, with feces accounting for a lesser proportion.

PHARMACODYNAMICS

Mechanism of Action. Iloperidone functions as an antagonist with high affinity at 5-HT_{2A}, D_2, D_3, α_{1-}, and α_{2c}-adrenergic receptors; intermediate affinity at D_4, 5-$HT_{6,}$ and 5-HT_7 receptors; and low affinity for 5-HT_{1A}, D_1, and H_1 receptors. Iloperidone possesses a negligible affinity for muscarinic receptors. Its metabolite P88 has receptor affinities “generally equal or less than that of the parent compound,” according to product labeling. Its metabolite P95 possesses a high affinity for 5-HT_{2A}, α_{1A}, α_{1B}, α_{1D}, and α_{2C} receptors only.

Design and Interpretation of Clinical Drug Studies

ACUTE TREATMENT TRIALS. The efficacy of iloperidone was supported by two large trials—one 4 weeks and one 6 weeks in duration. In the 4-week trial, 604 participants with DSM-IV schizophrenia were randomized to receive iloperidone 24 mg daily (titrated over the course of 1 week, with twice-daily dosing), ziprasidone (160 mg daily), or placebo. The primary endpoint was the change in PANSS total score from baseline to end of treatment (day 28). In this study, both iloperidone and ziprasidone were statistically superior to placebo in improving PANSS scores. Iloperidone was noted to have a different adverse event profile than ziprasidone, with iloperidone having less sedation, somnolence, EPS, akathisia, agitation, and restlessness and causing more weight gain, tachycardia, orthostatic hypotension, dizziness, and nasal congestion. In the 6-week trial, 706 participants with DSM-IV schizophrenia were randomized to receive either

Telegram: @medical_k

www.konkur.in

one of two flexible-dose ranges of iloperidone (12 to 16 mg/day or 20 to 24 mg/day), risperidone (6 to 8 mg/day), or placebo. The primary endpoint was the change in BPRS total score from baseline to end of treatment (day 42). Both dose ranges were superior to placebo in improving BPRS scores. While the efficacy of risperidone appeared greater than iloperidone within the first 2 weeks of treatment, the efficacy between treatments was similar in patients who remained on the treatment for at least 2 weeks. This differential efficacy in the first 2 weeks was attributed to the slower dose titration schedule necessary for iloperidone.

Two additional large short-term studies were performed to assess the efficacy of iloperidone for the treatment of schizophrenia or schizoaffective disorder. In the first study (6 weeks), iloperidone 12 mg/day (but not 4 mg or 8 mg/day) statistically improved the PANSS and BPRS total scores as compared to placebo. In the second 6-week study, both iloperidone 4 to 8 and 10 to 16 mg/day outperformed placebo for improving the BPRS total score. For the PANSS, the 4 to 8 mg/day group outperformed placebo only on the positive symptom subscale, while the 10 to 16 mg/day group outperformed placebo on the PANSS total as well as positive and negative symptom subscales.

MAINTENANCE TREATMENT TRIALS. While iloperidone is currently only indicated "for the treatment of adults with schizophrenia," based on two large short-term studies, limited long-term maintenance studies have been performed. Kane et al. reported the data from three trials. Subjects from three short-term studies (*N* = 1,644), who had experienced at least a 20% reduction in PANSS total score in the initial 6-week study, were randomized to receive iloperidone 4 to 16 mg/day or haloperidol 5 to 20 mg/day for 46 weeks. The primary outcome measure was the time to relapse, defined as a ≥25% increase in PANSS total score, discontinuation due to lack of efficacy, aggravated psychosis with hospitalization, or a 2-point increase on the CGI-C after week 6. Iloperidone was found to be statistically equivalent to haloperidol for relapse prevention.

Therapeutic Indications

SCHIZOPHRENIA. Iloperidone is indicated for the treatment of schizophrenia, with efficacy established based on two short-term studies.

Precautions and Adverse Reactions

BLACK BOX WARNING. Iloperidone and the other SGAs carry a black box warning for increased mortality in older adult patients with dementia-related psychosis compared with placebo.

QT PROLONGATION. Iloperidone, at the dose of 12 mg twice daily, was found to increase the QTc interval by 9 ms in an open-label study of 160 individuals. This QTc prolongation was increased to 19 ms in the presence of a CYP2D6 inhibitor (paroxetine) or CYP3A4 inhibitor (ketoconazole). It is recommended that iloperidone be avoided in combination with other medications known to increase the QTc interval in individuals with congenital long QT syndrome, history of cardiac arrhythmias, or histories of significant cardiovascular illness. It is also recommended that individuals at risk of electrolyte disturbances have potassium and magnesium levels monitored periodically, as low levels can increase the risk of QTc prolongation and arrhythmia. Iloperidone should be discontinued if QTc is found to be greater than 500 ms.

NEUROLEPTIC MALIGNANT SYNDROME. NMS has been associated with the use of antipsychotic medications, including iloperidone. If NMS is suspected, iloperidone and other antipsychotic medications should be discontinued immediately, and the patient should undergo intensive supportive care and medical monitoring.

EXTRAPYRAMIDAL SYMPTOMS. Iloperidone is associated with a low risk of EPS, including akathisia, bradykinesia, dyskinesia, dystonia, parkinsonism, and tremor. When considering all EPS events in four short-term trials, 15.1% of subjects taking iloperidone 20 to 24 mg/day (N = 391), 13.5% of subjects taking 10 to 16 mg/day (N = 483), and 11.6% of subjects taking placebo (N = 587) reported any type of EPS. Parkinsonism was reported in 0.3% of subjects taking iloperidone 20 to 24 mg/day as compared to 0% in subjects taking placebo.

TARDIVE DYSKINESIA. The propensity of iloperidone to cause tardive dyskinesia is not known but is expected to be low due to the minimal extrapyramidal side effects of this medication.

METABOLIC CHANGES. Iloperidone has been associated with hyperglycemia, dyslipidemia, and weight gain, and patients should be monitored accordingly. In a pooled analysis of longer-term trials, iloperidone 10 to 16 mg/day was associated with a 1.8 mg/dL glucose increase at 3 to 6 months (*N* = 773) and a 5.4 mg/dL glucose increase at >12 months (*N* = 425). Iloperidone 10 to 16 mg/day was associated with a −3.9 mg/dL change in total cholesterol and −8.9 mg/dL change in triglycerides at 3 to 6 months (*N* = 783) and −7.7 mg/dL change in total cholesterol and −17.7 mg/dL change in triglycerides at >12 months (*N* = 428). Of note, the observed decrease in lipid parameters could be a consequence of the participants switching to iloperidone from another antipsychotic with a higher propensity for dyslipidemia. Iloperidone has also been associated with weight gain in a dose-dependent manner, with 18% of subjects taking iloperidone 20 to 24 mg/day and 12% of those taking 10 to 16 mg/day gaining ≥7% of body weight at 4 to 6 weeks.

SEIZURES. In 4- to 6-week placebo-controlled trials, iloperidone was associated with a seizure in 1 of 1,344 patients treated with iloperidone (0.1%) and 2 of 587 patients treated with placebo (0.3%).

ORTHOSTATIC HYPOTENSION AND SYNCOPE. Iloperidone has been associated with orthostatic hypotension with dizziness, tachycardia, and syncope, and this is thought to be related to its property as an α1-antagonist. In short-term studies where the dose was increased slowly, as per label recommendations, orthostatic hypotension occurred in 5% of patients taking iloperidone 20 to 24 mg/day, 3% taking iloperidone 10 to 16 mg/day, and 1% of patients taking placebo. It is noted that more rapid increases in iloperidone dose would be expected to increase the risk of orthostatic hypotension and syncope.

HYPERPROLACTINEMIA. In a 4-week placebo-controlled trial of iloperidone, prolactin increased by 2.6 ng/mL in the group taking iloperidone 24 mg/day, as compared to a decrease of 6.3 ng/mL in the placebo group. In longer-term trials (*N* = 3,210), 0.1% of males taking iloperidone developed gynecomastia as compared to 0% in the placebo group, and 0.2% of females taking iloperidone developed galactorrhea as compared to 0.5% in the placebo group.

www.konkur.in

PRIAPISM. Three cases of priapism were observed in the drug development process, according to the manufacturer's prescribing information. This is thought to be related to the α-antagonist properties of iloperidone.

PREGNANCY. Iloperidone is currently designated "category C" for use in pregnant women, meaning that animal studies have shown an adverse effect on the fetus, there are no adequate and well-controlled studies in humans, and potential benefits may warrant use despite potential risks. In pregnant rat studies, a dose of iloperidone 26 times the maximum recommended human daily dose (MRHD) (in mg/kg/day) caused increased intrauterine deaths, decreased fetal weight and length, decreased fetal skeletal ossification, and increased incidence of minor fetal skeletal anomalies. In pregnant rabbits, a dose of iloperidone 20 times the MRHD increased early intrauterine deaths and decreased fetal viability at term. In pregnant rats, doses of 1.6 to 4.8 times the MRHD caused no adverse effects on the pups except for an increase in stillbirth rates at the dose of 1.6 times MRHD. The iloperidone metabolite P95 was given to pregnant rats at 20, 80, and 200 mg/kg/day during the period of organogenesis, and no teratogenic effects were seen; however, delayed skeletal ossification occurred.

NURSING MOTHERS. While iloperidone has been found to be excreted in the milk of lactating rats, it is not known if this occurs in humans. It is currently recommended that women taking iloperidone should not breastfeed.

Drug Interactions. Iloperidone dose should be reduced by half when administered along with strong CYP2D6 inhibitors (e.g., fluoxetine and paroxetine), CYP3A4 inhibitors (e.g., ketoconazole and clarithromycin), or poor CYP2D6 metabolizers. If CYP2D6 or CYP3A4 inhibitors are discontinued, the iloperidone dose can be increased accordingly.

Dosage and Administration. Iloperidone is available in tablets of 1, 2, 4, 6, 8, 10, and 12 mg. Iloperidone should be uptitrated slowly to minimize orthostatic hypotension side effects, given its α-adrenergic antagonist properties. It is recommended to start at 1 mg twice daily, increasing the dose (by no more than 4 mg total/day) to a target dose of 6 to 12 mg twice daily (12 to 24 mg total/day). Efficacy in pivotal trials is demonstrated in

Telegram: @medical_k

the range of 6 to 12 mg twice daily. Iloperidone does not need to be administered with meals.

DOSING IN SPECIAL POPULATIONS

Pediatric Use. Safety and efficacy data supporting the use of iloperidone in child and adolescent patients have not been established.

Geriatric Use. Safety and efficacy data supporting the use of iloperidone in geriatric populations has not been established. Only 25 of 3,210 participants of iloperidone premarketing trials were 65 years old or greater.

Renal Impairment. Iloperidone undergoes almost total hepatic metabolism, with <1% excreted unchanged. Creatinine clearance <30 mL/min had minimal effect on C_{max} of iloperidone or its P88 and P95 metabolites. However, the AUC of iloperidone increased by 24%, P88 decreased by 6%, and P95 increased by 52%, so prescribers should monitor patients with renal impairment with greater vigilance.

Hepatic Impairment. No dosing adjustments to iloperidone are needed for patients with mild hepatic impairment. It is recommended that prescribers exercise caution when administering iloperidone to patients with moderate hepatic impairment and not prescribe iloperidone to patients with severe hepatic impairment. Specifically, in patients with mild hepatic impairment, there were no significant differences in the pharmacokinetics of iloperidone or its major metabolites as compared to healthy controls. With moderate hepatic impairment, a twofold higher exposure to the P88 metabolite was observed as compared to healthy controls. Adequate data is not available for patients with severe hepatic impairment.

SEROTONIN, DOPAMINE, NOREPINEPHRINE

Asenapine

Asenapine is an antipsychotic with a high affinity for 5-HT_{2A} and D_2 receptors, as well as several other serotonergic, dopaminergic, and adrenergic receptors. Important clinical properties include sublingual
