The cardinal signs and symptoms of peritonitis are acute, typically severe, abdominal pain with tenderness and fever. How patients' complaints of pain are manifested depends on their overall physical health and whether the inflammation is diffuse or localized. Elderly and immunosuppressed patients may not respond as aggressively to the irritation. Diffuse, generalized peritonitis is most often recognized as diffuse abdominal tenderness with guarding, rigidity, and other evidence of parietal peritoneal irritation. Physical findings may only be identified in a specific region of the abdomen if the intraperitoneal inflammatory process is limited or otherwise contained as may occur in patients with uncomplicated appendicitis or diverticulitis. Bowel sounds are usually absent to hypoactive but are not reliable as a physical finding.

Most patients present with tachycardia and signs of volume depletion with hypotension. Laboratory testing typically reveals a significant leukocytosis, and patients may be severely acidotic. Radiographic studies may show dilatation of the bowel and associated bowel wall edema. Free air or other evidence of leakage requires attention and could represent a surgical emergency. In stable patients in whom ascites is present, diagnostic paracentesis is indicated, where the fluid is tested for protein and lactate dehydrogenase and the cell count is measured.

THERAPY AND PROGNOSIS

Whereas mortality rates can be <10% for reasonably healthy patients with relatively uncomplicated, localized peritonitis, mortality rates >40% have been reported for the elderly or immunocompromised. Successful treatment depends on correcting any electrolyte abnormalities, restoration of fluid volume and stabilization of the cardiovascular system, appropriate antibiotic therapy, and surgical correction of any underlying abnormalities.

Acknowledgment

The wisdom and expertise of Dr. William Silen are gratefully acknowledged in this updated chapter on acute appendicitis and peritonitis.

Section 2 Nutrition

343 Nutrient Requirements and Dietary Assessment

Johanna T. Dwyer

Nutrients are substances that are essential but not synthesized in sufficient amounts in the body and therefore must be supplied by the diet. Nutrient requirements for groups of healthy persons have been determined experimentally. The absence of essential nutrients leads to growth impairment, organ and metabolic dysfunction, and failure to maintain nitrogen balance or adequate status of protein and other nutrients. For good health, we require energy-providing nutrients (protein, fat, and carbohydrate), vitamins, minerals, and water. Requirements for organic nutrients include 9 essential amino acids, several fatty acids, glucose, 4 fat-soluble vitamins, 10 water-soluble vitamins, dietary fiber, and choline. The inorganic nutrients include 4 minerals, 7 trace minerals, 3 electrolytes, and the ultra trace elements that must also be supplied by diet. Individuals of different ages and physiologic states differ in the amounts of nutrients they require.

Conditionally essential nutrients are not required in the diet but must be supplied to certain individuals such as those with genetic defects; pathologies such as infection, disease, or trauma with nutritional implications; and some developmentally immature infants who need them because they do not synthesize inositol, taurine, arginine, and/or glutamine in adequate amounts. Many other organic and inorganic bioactive compounds that are present in foods and dietary supplements may also have health effects, including pesticides, heavy metals like lead, phytochemicals, zoochemicals, and microbial products.

ESSENTIAL NUTRIENT REQUIREMENTS

Energy The estimated energy requirement (EER) is the predicted average requirement to maintain energy balance and health in an adult of a defined age, sex, weight, height, level of physical activity, and life stage. For weight to remain stable, energy intake must match total energy expenditure (TEE). The major components of TEE are resting energy expenditure (REE) and the physical activity level (PAL), and minor components include the energy cost of metabolizing food (thermic effect of food, or specific dynamic action) and cold-induced (shivering) thermogenesis. The average energy intake is ~2600 kcal/d for American men and ~1800 kcal/d for American women, but individuals vary with body size and activity level. Although estimates introduce considerable error, energy intakes are usually calculated from formulas rather than measuring TEE directly. In individuals whose weights are stable, for males, REE = 900 + 10*m*, and for females, REE = 700 + 7*m*, where *m* is mass in kilograms. The calculated REE is then multiplied by the appropriate PAL to account for physical activity that ranges from 1.4 (inactive) for individuals who perform only essential activities of daily living (e.g., 30 minutes walking and 90 minutes light to moderate activity) to 1.6 (low active), 1.75 (active), and 2.05 (very active). The result is the estimated energy (EER) or intake. When describing their PALs, sedentary, inactive, and low active individuals tend to overestimate, and so in practice, use of PALs of 1.2 to 1.4 may be closer to their actual activity levels. The EER provides a rough target for planning caloric needs for a person of a certain age, sex, weight, height, and physical activity level who is neither gaining nor losing weight. **For further discussion of energy balance in health and disease, see Chap. 345.**

Protein Dietary protein consists of both "essential" (e.g., not synthesized endogenously and must be supplied by diet) and "nonessential" (e.g., synthesized endogenously or obtained from diet) amino acids that are all required for protein synthesis. The nine essential amino acids are histidine, isoleucine, leucine, lysine, methionine/cystine, phenylalanine/tyrosine, threonine, tryptophan, and valine. Several amino acids, such as alanine, arginine, aspartic acid, glutamic acid, glutamine, and glycine can also be converted to glucose and used for energy and gluconeogenesis. When energy intake is inadequate, protein intake must be increased, because ingested amino acids are diverted into pathways of glucose synthesis and oxidation. In extreme energy deprivation, protein-calorie malnutrition may ensue **(Chap. 345)**.

For adults, the recommended dietary allowance (RDA) for protein is ~0.8 g/kg desirable body mass per day, assuming that energy needs are met and that the protein is of relatively high biological value. Current recommendations for a healthy diet call for at least 10–14% of calories from protein. Most American diets provide at least those amounts. Biologic value tends to be highest for animal proteins, followed by proteins from legumes (beans), cereals (rice, wheat, corn), and roots. Combinations of plant proteins that complement one another in their essential amino acid profiles or combinations of animal and plant proteins can increase biologic value and lower total protein intakes necessary to meet requirements. In healthy people with adequate diets, the timing of protein intake over the course of the day has little effect.

Protein needs increase during growth, pregnancy, lactation, and rehabilitation after injury or undernutrition. Tolerance to dietary protein is decreased in renal insufficiency (with consequent uremia) and in liver failure. Usual protein intakes can precipitate encephalopathy in patients with cirrhosis of the liver.

Fat and Carbohydrate Carbohydrate (4 kcal/g), fat (9 kcal/g), and protein (4 kcal/g) all provide energy. So does alcohol (ethanol) (7 kcal/g), but it is not a nutrient. Fats are a concentrated source of energy and constitute, on average, 34% of calories in U.S. diets. However, for optimal health, fat intake should total no more than 30% of calories. Saturated fat and trans-fat should be limited to <10% of calories and polyunsaturated fats to <10% of calories, with monounsaturated fats accounting for the remainder of fat intake. At least 45–55% of total calories should be derived from carbohydrates, with <10% and preferably <6% from added sugars. The brain requires ~100 g of glucose per day for fuel; other tissues use ~50 g/d. Some tissues (e.g., brain and red blood cells) rely on glucose supplied either exogenously or from muscle proteolysis. Over time, during hypocaloric states, adaptations that lower carbohydrate needs are possible.

Water For adults, 1–1.5 mL of water per kilocalorie of energy expenditure is sufficient under usual conditions to allow for normal variations in physical activity, sweating, and the diet's solute load. Water losses include 50–100 mL/d in the feces; 500–1000 mL/d by evaporation or exhalation; and, depending on the renal solute load, ≥1000 mL/d in the urine. If external losses increase, intakes must increase accordingly to avoid underhydration. Fever increases water losses by ~200 mL/d per °C; diarrheal losses vary but may be as great as 5 L/d in severe diarrhea. Heavy sweating, vigorous exercise, and

vomiting also increase water losses. When renal function is normal and solute intakes are adequate, the kidneys can adjust to increased water intake by excreting up to 18 L of excess water per day **(Chap. 393)**. However, obligatory urine outputs can compromise hydration status when there is inadequate water intake or when losses increase in disease or kidney damage.

Infants have high requirements for water because of their large surface area to volume ratios, their inability to communicate their thirst, and the limited capacity of the immature kidney to handle high renal solute loads. Increased water needs during pregnancy are ~30 mL/d. During lactation, milk production increases daily water requirements so that ~1000 mL of additional water is needed, or 1 mL for each milliliter of milk produced. Special attention must also be paid to the water needs of the elderly, who have reduced total-body water, blunted thirst sensation, and frequently use medications such as diuretics.

Other Nutrients **See Chap. 344 for detailed descriptions of vitamins and minerals.**

DIETARY REFERENCE INTAKES AND RDAS

Fortunately, human life and well-being can be maintained within a fairly wide range of most nutrient intakes. However, the capacity for adaptation is not infinite—too much, as well as too little, intake of a nutrient can have adverse effects itself or decrease health benefits conferred by another nutrient. Therefore, benchmark recommendations regarding nutrient intakes have been developed to guide menu development and clinical practice. They are referred to in the United States and Canada as the *dietary reference intakes* (DRIs) and are set by National Academy of Medicine's (formerly Institute of Medicine [IOM]) Food and Nutrition Board and Health Canada. The recommendations apply to the general population, including those with or at risk for chronic diseases, overweight, and obesity. Exceptions may be needed for individuals with severe comorbidities, diseases, disabilities, or use of medications known to alter energy or some nutrient requirements. The DRIs supplanted the recommended dietary allowances (RDAs)—the single reference values used in the United States until the early 1990s. DRIs now include an *estimated average requirement* (EAR) as well as other reference values used for dietary planning: the RDA, the *adequate intake* (AI), the *chronic disease risk reduction intake* (CDRR), and the tolerable *upper level* (UL). The DRIs also include acceptable macronutrient distribution ranges (AMDRs) for protein, fat, and carbohydrate. The types of evidence and criteria used to establish nutrient requirements vary by nutrient, age, and physiologic group. The current DRIs for vitamins and elements are provided in **Tables 343-1** and **343-2**, respectively. **Table 343-3** provides DRIs for water and macronutrients. Energy has neither an RDA nor a UL because intakes above or below requirements lead to weight gain or loss; **EERs are used instead and are discussed in Chap. 345 on energy balance in health and disease.**

Estimated Average Requirement (EAR) When florid manifestations of the classic dietary-deficiency diseases such as rickets (deficiency of vitamin D and calcium), scurvy (deficiency of vitamin C), xerophthalmia (deficiency of vitamin A), and protein-calorie malnutrition were common, nutrient adequacy was inferred from the absence of their clinical deficiency signs. Later, biochemical and other earlier changes were used that appeared long before the deficiency was clinically apparent. Today, criteria of adequacy are based on biologic markers when they are available, and to sensitive biochemical, physiologic, or behavioral tests that reflect early changes in regulatory processes; maintenance of body stores of nutrients; or, if available, the amount of a nutrient that minimizes the risk of chronic degenerative disease. However, relevant biomarkers of disease risk are often not available, and the long time lags between intake and disease outcomes further complicate the picture.

The EAR is the amount of a nutrient estimated to be adequate for half of the healthy individuals of a specific age and sex. It is not an effective estimate of nutrient adequacy in individuals because it is a median requirement for a group, with 50% of individuals in a group falling below and 50% falling above the requirement. Thus, a person with a usual intake at the EAR has a 50% risk of inadequate intake. For these reasons, the other standards described below are more useful for clinical purposes.

Recommended Dietary Allowances The RDA is the nutrient intake goal for planning diets of individuals. It is the average daily dietary intake level that meets the nutrient requirements of nearly all healthy persons of a specific sex, age, life stage, or physiologic condition (e.g., pregnancy or lactation). The RDA is set two standard deviations above the EAR to ensure that the needs of virtually any individual are met. The risk of dietary inadequacy increases as one's intake falls below the RDA. However, the RDA is an overly generous criterion for evaluating nutrient adequacy because, by definition, the RDA exceeds the actual requirements of all but ~2–3% of the population. Therefore, many people whose intake falls below the RDA are still getting enough of the nutrient.

The RDAs are used to formulate food guides such as the U.S. Department of Agriculture's (USDA) MyPlate Plan for individuals (*https://www.choosemyplate.gov/resources/MyPlatePlan*), as well as to create food-exchange lists for therapeutic diet planning. An online tool, available at *https://www.nal.usda.gov/fnic/dri-calculator/*, allows health professionals to calculate individualized daily nutrient recommendations for dietary planning based on the DRIs.

The RDAs are also used as a standard for labels describing the nutritional content of foods and nutrient-containing dietary supplements. On food labels, the nutrient content in a food is stated by weight and/or as a percentage of the daily value (DV), a variant of the RDA used on the nutrition facts panel that, for an adult, represents the highest RDA for an adult consuming 2000 kcal.

Adequate Intake (AI) Some nutrients lack an EAR and so an RDA cannot be set. In this circumstance, the AI is used, based on observed or experimentally determined approximations of nutrient intakes in healthy people. In the DRIs, AIs rather than RDAs are proposed for nutrients consumed by infants (up to age 1 year) as well as for chromium, fluoride, manganese, sodium, potassium, pantothenic acid, biotin, choline, fiber, and water consumed by persons of all ages.

Tolerable Upper Levels (UL) Healthy individuals derive no established benefit from consuming nutrient levels above the RDA or AI. In fact, excessive nutrient intake can disturb body functions and cause acute, progressive, or permanent disabilities. The tolerable UL is the highest level of chronic (usually daily) nutrient intake that is unlikely to pose a risk of adverse health effects for most of the population. Data on the adverse effects of large amounts of many nutrients are unavailable or too limited to establish a UL and so the lack of a UL does *not* mean that the risk of adverse effects from high intake is nonexistent. Nutrient levels in commonly eaten foods rarely exceed the UL, although very highly fortified foods and dietary supplements provide more concentrated amounts of nutrients per serving and thus pose a potential risk of toxicity. Dietary supplements have Supplement Facts panels on labels that express the amount of nutrients present in absolute units or as the percentage of the DV provided per recommended serving size. Total nutrient intakes, including that from foods, supplements, and over-the-counter medications (e.g., antacids), should not exceed RDA levels.

Chronic Disease Risk Reduction Intake (CDRR) The CDRR is the level above which a reduction in intake is expected to lower chronic disease risk is the CDRR. For example, the sodium CDRR for adults is 2300 mg/d; this is the lowest level of intake for which there is sufficiently strong evidence to characterize a CDRR. CDRRs are not available for potassium or other nutrients, but note that the AI for potassium was recently reduced to 2500 mg/d.

Acceptable Macronutrient Distribution Ranges (AMDRs) AMDRs are estimated ranges from epidemiologic data of energy-providing macronutrient intakes (protein, carbohydrate, and fat) considered to be healthful. These ranges are 10–35% of calories for protein, 20–35% of calories for fat, and 45–65% of calories for carbohydrate. Alcohol, which also provides energy, is not a nutrient; therefore, no recommendations for it are provided. The latest DRI committee

Note: This table (taken from the DRI reports; see *www.nap.edu*) presents recommended dietary allowances (RDAs) in **bold type** and adequate intakes (AIs) in ordinary type followed by an asterisk (*). An RDA is the average daily dietary intake level sufficient to meet the nutrient requirements of nearly all healthy individuals (97–98%) in a group. The RDA is calculated from an estimated average requirement (EAR). If sufficient scientific evidence is not available to establish an EAR and thus to calculate an RDA, an AI is usually developed. For healthy breast-fed infants, an AI is the mean intake. The AI for other life-stage and sex-specific groups is believed to cover the needs of all healthy individuals in those groups, but lack of data or uncertainty in the data makes it impossible to specify with confidence the percentage of individuals covered by this intake.

[a]As retinol activity equivalents (RAEs). 1 RAE = 1 μg retinol, 12 μg β-carotene, 24 μg α-carotene, or 24 μg β-cryptoxanthin. The RAE for dietary provitamin A carotenoids is twofold greater than the retinol equivalent (RE), whereas the RAE for preformed vitamin A is the same as the RE. [b]As cholecalciferol. 1 μg cholecalciferol = 40 IU vitamin D. [c]Under the assumption of minimal sunlight. [d]As α-tocopherol. α-Tocopherol includes *RRR*-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the *2R*-stereoisomeric forms of α-tocopherol (*RRR-*, *RSR-*, *RRS-*, and *RSS*-α-tocopherol) that occur in fortified foods and supplements. It does not include the *2S*-stereoisomeric forms of α-tocopherol (*SRR-*, *SSR-*, *SRS-*, and *SSS*-α-tocopherol) also found in fortified foods and supplements. [e]As niacin equivalents (NEs). 1 mg of niacin = 60 mg of tryptophan; 0–6 months = preformed niacin (not NE). [f]As dietary folate equivalents (DFEs). 1 DFE = 1 μg food folate = 0.6 μg of folic acid from fortified food or as a supplement consumed with food = 0.5 μg of a supplement taken on an empty stomach. [g]Although AIs have been set for choline, there are few data to assess whether a dietary supply of choline is needed at all stages of the life cycle, and it may be that the choline requirement can be met by endogenous synthesis at some of these stages. [h]Because 10–30% of older people may malabsorb food-bound B_{12}, it is advisable for those >50 years of age to meet their RDA mainly by consuming foods fortified with B_{12} or a supplement containing B_{12}. [i]In view of evidence linking inadequate folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 μg of folate from supplements or fortified foods in addition to intake of food folate from a varied diet. [j]It is assumed that women will continue consuming 400 μg from supplements or fortified food until their pregnancy is confirmed and they enter prenatal care, which ordinarily occurs after the end of the periconceptional period—the critical time for formation of the neural tube.

Note: This table (taken from the DRI reports; see *www.nap.edu*) presents recommended dietary allowances (RDAs) in **bold type** and adequate intakes (AIs) in ordinary type followed by an asterisk (*). An RDA is the average daily dietary intake level sufficient to meet the nutrient requirements of nearly all healthy individuals (97–98%) in a group. The RDA is calculated from an estimated average requirement (EAR). If sufficient scientific evidence is not available to establish an EAR and thus to calculate an RDA, an AI is usually developed. For healthy breast-fed infants, an AI is the mean intake. The AI for other life-stage and sex-specific groups is believed to cover the needs of all healthy individuals in those groups, but lack of data or uncertainty in the data makes it impossible to specify with confidence the percentage of individuals covered by this intake.

recommended that the CDRR method be used instead of the AMDR for establishing DRIs for macronutrients in the future.

FACTORS ALTERING NUTRIENT NEEDS

The DRIs are affected by age, sex, growth rate, pregnancy, lactation, physical activity level, concomitant diseases, drugs, and dietary composition.

Physiologic Factors Growth, strenuous physical activity, pregnancy, and lactation all increase needs for energy and several essential nutrients. Energy needs rise during pregnancy due to fetal growth demands and increased energy required for milk production during lactation. Energy needs decrease with loss of lean body mass, the major determinant of REE. The energy needs of older persons, especially those aged >70 years, tend to be lower than those of younger persons because lean tissue, physical activity, and health often decline with age.

Dietary Composition Dietary composition affects the biologic availability and use of nutrients. For example, iron absorption may be impaired by large amounts of calcium or lead; likewise, non-heme iron uptake may be impaired by a lack of ascorbic acid and amino acids in the meal. Bodily protein may be decreased when essential amino acids are not present in sufficient amounts—a rare scenario in U.S. diets. Animal foods, such as milk, eggs, and meat, have high biologic values, with most of the needed amino acids present in adequate amounts. Plant proteins in corn (maize), soy, rice, and wheat have lower biologic values and must be combined with other plant or animal proteins or fortified with the amino acids that are deficient to achieve optimal use by the body.

Route of Intake The RDAs apply only to oral intakes. When nutrients are administered parenterally, similar values can sometimes be used for amino acids, glucose (carbohydrate), fats, sodium, chloride, potassium, and most vitamins because their intestinal absorption rate is nearly 100%. However, the oral bioavailability of most mineral elements may be only half that obtained by parenteral administration. For some nutrients that are not readily stored in the body or that cannot be stored in large amounts, timing of administration may also be important. For example, amino acids cannot be used for protein synthesis if they are not supplied together intravenously; instead, they will be used for energy production. In contrast, among healthy individuals eating adequate diets, the distribution of protein intake over the course of the day has little effect on health.

Disease Dietary deficiency diseases include protein-calorie malnutrition, iron-deficiency anemia, goiter (due to iodine deficiency), rickets and osteomalacia (vitamin D deficiency), xeropthalmia (vitamin A deficiency), megaloblastic anemia (vitamin B_{12} or folic acid deficiency), scurvy (vitamin C/ascorbic acid deficiency), beriberi (thiamin deficiency), and pellagra (niacin and tryptophan deficiency) **(Chaps. 344 and 345)**. Each deficiency disease is characterized by imbalances at the cellular level between the supply of nutrients or energy and the body's nutritional needs for growth, maintenance, and other functions. Imbalances and excesses in nutrient intakes are recognized as risk factors for certain chronic degenerative diseases, such as saturated/trans-fat and cholesterol in coronary artery disease; sodium in hypertension; obesity in hormone-dependent cancers (endometrial and breast); and ethanol in alcohol addiction. These disorders are multifactorial in their etiology and pathogenesis, and diet is only one of the many risk factors for their occurrence. Osteoporosis, for example, is sometimes associated with calcium deficiency secondary to vitamin D deficiency, as well as with environment-related risk factors (e.g., smoking, sedentary lifestyle), physiology (e.g., estrogen deficiency), genetic determinants (e.g., defects in collagen metabolism), and drug use (chronic steroids and aromatase inhibitors) **(Chap. 423)**.

DIETARY ASSESSMENT

Nutrition assessment in clinical situations is an iterative process involving screening for malnutrition risk; assessing the diet and other biomarkers to determine if malnutrition is present and if so its possible causes; planning and implementing appropriate dietary intakes and medical nutrition therapy; and reassessing to make sure that intakes have been consumed. Disease states affecting the bioavailability, requirements, use, or excretion of specific nutrients may require specific measurements of certain nutrients or their biomarkers to assess status and ensure that nutrient replacement is adequate **(Chap. 344)**.

The Joint Commission, which accredits and certifies health care organizations in the United States, requires most health care facilities to perform nutrition screening for identifying possible malnutrition risk within 24 h after hospital admission. However, a single universally recognized or validated standard is not used yet. The Global Leadership Initiative on Malnutrition (GLIM) proposes that in acute care settings a tool be used that evaluates weight loss, low body mass index (BMI), reduced muscle mass, reduced food intake or absorption, and increased disease burden or inflammation. Other screens usually include these and also abnormal weight for height or body mass index (e.g., BMI <19 or >25); reported weight change (involuntary loss or gain of >5 kg in the past 6 months) **(Chap. 50)**; diagnoses with known nutritional implications (e.g., metabolic disease, any disease affecting the gastrointestinal tract, alcohol abuse); present therapeutic dietary prescription; chronic poor appetite; presence of dental, chewing, and swallowing problems; major food allergies or intolerances; need for assistance with preparing or shopping for food, eating, or other aspects of self-care; and social isolation. The nutritional status of hospitalized patients should be reassessed periodically—at least once every week.

Patients who exhibit frank malnutrition or a high risk of it on nutritional screening need more complete dietary assessment that varies with the clinical setting, the severity of the patient's illness, and the stability of the patient's condition.

Acute-Care Settings The goal is to identify and avoid inadequate intake, assure intake is appropriate, and gather enough information to determine if malnutrition is due to poor dietary intake or other causes and whether nutritional therapy is indicated **(Chap. 346)**. In acute-care settings, anorexia, various diseases, test procedures, and medications can further compromise dietary intake. Dietary assessment focuses on what patients are currently eating, whether or not they are able and willing to eat, and whether or not they experience any problems with eating. Simple observations may suffice to suggest inadequate oral intake. These include dietitians' and nurses' notes; observation of a patient's frequent refusal to eat or the amount of food served versus that eaten on trays; the frequent performance of tests and procedures that are likely to cause meals to be skipped; consumption limited to nutritionally inadequate diet orders (e.g., clear liquids or full liquids) for more than a few days; the occurrence of fever, dehydration, gastrointestinal distress, vomiting, diarrhea, or a comatose state; and the presence of diseases or use of treatments that involve any part of the alimentary tract. Acutely ill patients with diet-related diseases such as diabetes and chronic renal failure are in particular need of assessment because an inappropriate diet may exacerbate these conditions and adversely affect other therapies. Abnormal biochemical values (serum albumin levels <35 g/L [<3.5 mg/dL]; serum cholesterol levels <3.9 mmol/L [<150 mg/dL]) are nonspecific but may indicate a need for further nutritional assessment.

Most therapeutic diets offered in hospitals are calculated to meet individual nutrient requirements and the RDA *if they are eaten*. Exceptions include clear liquids, some full-liquid diets, and test diets (such as those adhered to in preparation for gastrointestinal procedures), which are inadequate in several nutrients and should not be used, if possible, for >24 h. However, because as much as half of the food served to hospitalized patients is not eaten, it cannot be assumed that the intakes of hospitalized patients are adequate. Dietary assessment should compare how much and what kinds of food the patient has consumed with the diet that has been provided. Major deviations in intakes of energy, protein, fluids, or other nutrients of special concern for the patient's illness should be noted and corrected, especially for long-staying patients.

Nutritional monitoring is especially important for patients who are very ill, who have extended lengths of hospital stay, or who are discharged home with diagnoses involving the gastrointestinal tract, end-stage renal disease, and insulin-dependent diabetes. Patients who are fed by enteral and parenteral routes and those receiving home chemotherapy infusions also require special nutritional assessment and monitoring by physicians and/or dietitians with certification in nutritional support **(Chap. 346)**.

Ambulatory Settings The aim of dietary assessment in the outpatient setting is to determine whether or not the patient's usual diet is a health risk in itself, if it contributes to existing chronic disease–related problems, and if medical nutrition therapy is required. The information is used to plan an eating pattern that fulfills therapeutic goals while ensuring patient adherence. Dietary assessment should review the adequacy of present and usual food intakes, including vitamin and mineral supplements, oral nutritional supplements, medical foods, other dietary supplements, medications, and alcohol, because all of these may affect the patient's nutritional status. Assessment should focus on the dietary constituents that are most likely to be involved or compromised by the specific diagnosis as well as on any comorbidities that are present. A diet history of several days of intake or a food-frequency questionnaire can be used and reviewed to provide a representation of the usual diet and assess the adequacy of the patient's habitual diet. The Automated Self-Administered 24-Hour Dietary Assessment Tool (ASA24) (which is a web-based, self-administered, 24-h recall tool), a diet history questionnaire (DHQ), a daily food checklist, and validated short dietary instruments are all available at the National Institute of Health's National Cancer Institute webpage at *https://epi.grants.cancer.gov/dietary-assessment/resources.html*. The Nutritools interactive website (*www.nutritools.org*) guides clinicians and researchers to choose among suitable validated dietary assessment tools used in North America and elsewhere. Assessment findings are used to craft dietary recommendations for changes in healthier directions. These may be as simple as a food guide, a food-exchange list, or more personalized and detailed recommendations by a dietitian that are tailored to the patient's food preferences and medical nutrition therapy needs. Therapeutic dietary prescriptions and menu plans for most diseases are available in the diet manuals of most hospitals and from the Academy of Nutrition and Dietetics for many other diseases. For persons on therapeutic diets, counseling using food-exchange lists such as those available from the American Diabetes Association for diabetes and from the Academy of Nutrition and Dietetics or the National Kidney Foundation's Council on Renal Nutrition for renal disease is helpful. Patients who follow ethnic or unusual dietary

TABLE 343-4 Choose My Plate: A Guide to Individualized Dietary Planning

DIETARY FACTOR, UNIT OF MEASURE (ADVICE)	EXAMPLES OF STANDARD PORTION SIZES AT INDICATED ENERGY LEVEL		
	LOWER: 1600 kcal	MODERATE: 2200 kcal	HIGHER: 2800 kcal
Fruits, cups (Focus on fruits.)	1.5	2	2.5
Vegetables, cups (Vary vegetables.)	2	3	3.5
Grains, oz eq (Make at least half of grains whole.)[a]	5	7	10
Protein foods, oz eq (Go lean with protein.)[b]	5	6	7
Dairy, cups or oz[c] (Choose calcium-rich foods.)	3	3	3
"Empty" calories, kcal[d]	120	260	400
Sodium, mg	<2300 at all energy levels		
Physical activity, min	At least 150 min vigorous physical activity per week at all energy levels		

Note: Oils (formerly listed with portions of 5, 6, and 8 teaspoons for the lower, moderate, and higher energy levels, respectively) are no longer singled out in Choose My Plate, but rather are included in the empty calories/added sugar category with SOFAS (calories from solid fats and added sugars). The limit is the remaining number of calories in each food pattern above after intake of the recommended amounts of the nutrient-dense foods.

[a]For example, 1 serving equals 1 slice bread, 1 cup ready-to-eat cereal, or 0.5 cup cooked rice, pasta, or cooked cereal. [b]For example, 1 serving equals 1 oz lean meat, poultry, or fish; 1 egg; 1 tablespoon peanut butter; 0.25 cup cooked dry beans; or 0.5 oz nuts or seeds. [c]For example, 1 serving equals 1 cup milk or yogurt, 1.5 oz natural cheese, or 2 oz processed cheese. [d]Formerly called "discretionary calorie allowance." Portions are calculated as the number of calories remaining after all of the above allotments are accounted for.

Abbreviation: oz eq, ounce equivalent.

Source: Data from U.S. Department of Agriculture (*http://www.Choosemyplate.gov*).

patterns need extra instruction on how to categorize their foods and on the appropriate portion sizes that constitute a serving.

For healthy persons who do not require medical nutrition therapy, a rough guide for avoiding inadequate nutrient intakes as well as excessive intakes of fat (especially saturated and trans fats), sodium, sugar, and alcohol is the USDA's Choose My Plate **(Table 343-4)**. The Choose My Plate graphic emphasizes a balance between calories and nutritional needs, encouraging increased intake of fruits and vegetables, whole grains, and low-fat milk in conjunction with reduced intake of sodium and high-calorie sugary drinks. The guide provides a web-based calculator that tailors the number of servings suggested for healthy people of different weights, sexes, ages, and life-cycle stages to meet their needs while avoiding excess (*https://www.myplate.gov/myplate-plan* and *www.ChooseMyPlate.gov*). Reviewing the guide with patients helps them identify food groups eaten in insufficient amounts or in excess and aids the transition to healthier dietary patterns.

NUTRITIONAL STATUS ASSESSMENT

Full nutritional status assessment is reserved for seriously ill patients and those at very high nutritional risk when the cause of malnutrition is still uncertain after initial clinical evaluation and dietary assessment. It involves multiple dimensions, including documentation of dietary intake, health history, anthropometric measurements, biochemical measurements of blood and urine, clinical examination, and functional status evaluation. **For further discussion of nutritional assessment, see Chap. 345.**

GLOBAL CONSIDERATIONS

Several DRIs (e.g., the EAR, the UL, and energy needs) are estimates of physiologic requirements based on experimental evidence that apply globally to healthy individuals when adjusted for age, sex, body size, and physical activity level. However, the AIs, AMDRs, and CDRRs are not exportable and should be used with caution in other countries. AIs for micronutrients are based on epidemiologic observations of customary and adequate intakes in healthy U.S. and Canadian populations. The AMDRs are not based on direct experimental evidence but represent expert opinion on potentially healthy intakes of energy-providing nutrients in North American populations. The CDRR may also vary in other populations. Nutrient-based standards like the DRIs have also been developed by the World Health Organization/Food and Agricultural Organization of the United Nations. They are available at *https://www.who.int/activities/establishing-global-nutrient-requirements*. The European Food Safety Authority (EFSA) Panel on Dietetic Products, Nutrition, and Allergies periodically publishes its recommendations in the *EFSA Journal* (*https://efsa.onlinelibrary.wiley.com/journal/18314732*). Other countries have also promulgated recommendations similar to the DRI. The different standards have many similarities in their basic concepts, definitions, and nutrient recommendation levels, but some differ from the DRIs as a result of the functional criteria chosen for nutrient requirements, environmental differences, the timeliness of the evidence reviewed, and expert judgment. There is a growing trend toward global harmonization of these recommendations.

344 Vitamin and Trace Mineral Deficiency and Excess

Paolo M. Suter

Vitamins are required constituents of the human diet because they are synthesized inadequately or not at all in the human body. Only small amounts of these substances are needed to carry out essential biochemical reactions (e.g., by acting as coenzymes or prosthetic groups). Overt vitamin or trace mineral deficiencies are rare in Western countries because of a plentiful, varied, and inexpensive food supply; food fortification; and use of supplements. However, multiple nutrient deficiencies may appear together in persons who are chronically ill, alcoholic, on specific medications (see below), or living in poverty. After bariatric surgery, patients are at high risk for multiple nutrient deficiencies. Moreover, subclinical vitamin and trace mineral deficiencies (often designated as "hidden hunger"), as diagnosed by laboratory testing, are quite common in the normal population, especially in the geriatric age group and socioeconomically deprived individuals due to the lack of nutrient-dense foods. Conversely, because of the widespread use of nutrient supplements and food fortification, nutrient toxicities are gaining pathophysiologic and clinical importance.

Victims of famine, emergency-affected and displaced populations, refugees, and camp populations are at increased risk for protein-energy malnutrition and classic micronutrient deficiencies (vitamin A, iron, zinc, iodine) as well as for overt deficiencies in thiamine (beriberi), riboflavin, vitamin C (scurvy), and niacin (pellagra).

Body stores of vitamins and minerals vary tremendously. For example, stores of vitamins B_{12} and A are large, and an adult may not become deficient until ≥1 year after beginning to eat a deficient diet. However, folate and thiamine may become depleted within weeks among those eating a deficient diet. Therapeutic modalities can deplete essential nutrients from the body; for example, hemodialysis or diuretics remove water-soluble vitamins, which must be replaced by supplementation.

Vitamins and trace minerals play several roles in diseases: (1) deficiencies of vitamins and minerals may be caused by disease states such as malabsorption; (2) either deficiency or excess of vitamins and minerals can cause disease in and of itself (e.g., vitamin A intoxication and liver disease); and (3) vitamins and minerals in high doses may be used as drugs (e.g., niacin for hypercholesterolemia). Since they are covered elsewhere, the hematologic-related vitamins and minerals **(Chaps. 102 and 104)** either are not considered or are considered only briefly in this chapter, as are the bone-related vitamins and minerals (vitamin D, calcium, phosphorus, magnesium; **Chap. 421**).

VITAMINS

See also Table 344-1 and Fig. 344-1.

THIAMINE (VITAMIN B_1)

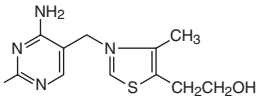
Thiamine was the first B vitamin to be identified and therefore is referred to as vitamin B_1. Thiamine functions in the decarboxylation of α-ketoacids (e.g., pyruvate α-ketoglutarate) and branched-chain amino acids and thus is essential for energy generation. In addition, thiamine pyrophosphate acts as a coenzyme for a transketolase reaction that mediates the conversion of hexose and pentose phosphates. It has been postulated that thiamine plays a role in peripheral nerve conduction, although the exact chemical reactions underlying this function are not known.

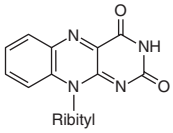
Food Sources The median intake of thiamine in the United States from food alone is ~2 mg/d. Primary food sources for thiamine include yeast, organ meat, pork, legumes, beef, whole grains, and nuts. Milled rice and grains contain little thiamine. Thiamine deficiency is therefore more common in cultures that rely heavily on a milled polished rice-based diet. Certain foods contain antithiamine factors such as heat-labile thiaminases (raw fish, shellfish), which destroy the vitamin, or heat-stable polyhydroxyphenols (tannins; in coffee, tea, Brussels sprouts, or betel nuts), which inactivate the vitamin. Thus, drinking large amounts of tea or coffee could theoretically lower thiamine body stores.

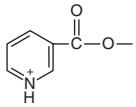
TABLE 344-1 Principal Clinical Findings of Vitamin Malnutrition

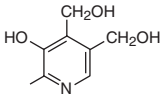
NUTRIENT	CLINICAL FINDING	DIETARY LEVEL PER DAY ASSOCIATED WITH OVERT DEFICIENCY IN ADULTS	CONTRIBUTING FACTORS TO DEFICIENCY
Thiamine	Beriberi: neuropathy, muscle weakness and wasting, cardiomegaly, edema, ophthalmoplegia, confabulation	<0.3 mg/1000 kcal	Alcoholism, chronic diuretic use, bariatric surgery, hyperemesis, thiaminases in food
Riboflavin	Magenta tongue, angular stomatitis, seborrhea, cheilosis, ocular symptoms, corneal vascularization	<0.4 mg	Alcoholism, individuals with poor diets and low intake of milk products
Niacin	Pellagra: pigmented rash of sun-exposed areas, bright red tongue, diarrhea, apathy, memory loss, disorientation	<9.0 niacin equivalents	Alcoholism, vitamin B_6 deficiency, riboflavin deficiency, tryptophan deficiency
Vitamin B_6	Seborrhea, glossitis, convulsions, neuropathy, depression, confusion, microcytic anemia	<0.2 mg	Alcoholism, isoniazid
Folate	Megaloblastic anemia, atrophic glossitis, depression, ↑ homocysteine	<100 μg/d	Alcoholism, sulfasalazine, pyrimethamine, triamterene
Vitamin B_{12}	Megaloblastic anemia, loss of vibratory and position sense, abnormal gait, dementia, impotence, loss of bladder and bowel control, ↑ homocysteine, ↑ methylmalonic acid	<1.0 μg/d	Gastric atrophy (pernicious anemia), terminal ileal disease, strict vegetarianism, acid-reducing drugs (e.g., H_2 blockers), metformin
Vitamin C	Scurvy: petechiae, ecchymosis, coiled hairs, inflamed and bleeding gums, joint effusion, poor wound healing, fatigue	<10 mg/d	Smoking, alcoholism
Vitamin A	Xerophthalmia, night blindness, Bitot's spots, follicular hyperkeratosis, impaired embryonic development, immune dysfunction	<300 μg/d	Fat malabsorption, infection, measles, alcoholism, protein-energy malnutrition
Vitamin D	Rickets: skeletal deformation, rachitic rosary, bowed legs; osteomalacia	<2.0 μg/d	Aging, lack of sunlight exposure, fat malabsorption, deeply pigmented skin
Vitamin E	Peripheral neuropathy, spinocerebellar ataxia, skeletal muscle atrophy, retinopathy	Not described unless underlying contributing factor is present	Occurs only with fat malabsorption or genetic abnormalities of vitamin E metabolism/transport
Vitamin K	Elevated prothrombin time, bleeding	<10 μg/d	Fat malabsorption, liver disease, antibiotic use

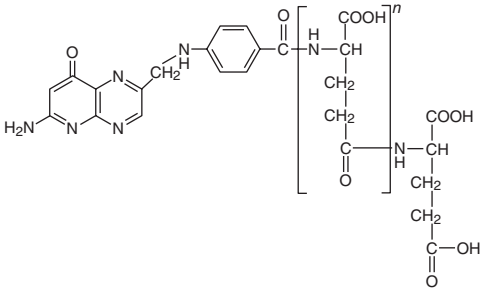
Deficiency Most dietary deficiency of thiamine worldwide is the result of poor dietary intake due to the lack of food or disproportionate reliance on highly processed staple crops. Food processing removes thiamine, and high-heat or long-duration cooking destroys it. In Western countries, the primary causes of thiamine deficiency are alcoholism and chronic illnesses such as cancer. Alcohol interferes directly with the absorption of thiamine and with the synthesis of thiamine pyrophosphate, and it increases urinary excretion. Thiamine should always be replenished when a patient with alcoholism is being refed, as carbohydrate repletion without adequate thiamine can precipitate acute thiamine deficiency with lactic acidosis. Other at-risk populations are women with prolonged hyperemesis gravidarum, anorexia (including eating disorders), patients with overall poor nutritional status who are receiving parenteral glucose, patients who have had

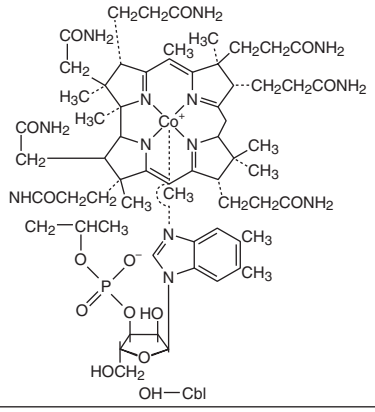












Vitamin	Active derivative or cofactor form	Principal function
Thiamine (B_1) 	Thiamine pyrophosphate	Coenzyme for cleavage of carbon-carbon bonds; amino acid and carbohydrate metabolism
Riboflavin (B_2) 	Flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD)	Cofactor for oxidation, reduction reactions, and covalently attached prosthetic groups for some enzymes
Niacin 	Nicotinamide adenine dinucleotide phosphate (NADP) and nicotinamide adenine dinucleotide (NAD)	Coenzymes for oxidation and reduction reactions
Vitamin B_6 	Pyridoxal phosphate	Cofactor for enzymes of amino acid metabolism
Folate 	Polyglutamate forms of (5, 6, 7, 8) tetrahydrofolate with carbon unit attachments	Coenzyme for one carbon transfer in nucleic acid and amino acid metabolism
Vitamin B_{12} 	Methylcobalamine Adenosylcobalamin	Coenzyme for methionine synthase and L-methylmalonyl-CoA mutase

FIGURE 344-1 Structures and principal functions of vitamins associated with human disorders.

bariatric/metabolic surgery (*bariatric Wernicke*), and patients receiving chronic diuretic therapy (e.g., in hypertension or systolic heart failure) due to increased urinary thiamine losses. Different drugs (e.g., metformin, verapamil) could inhibit intestinal thiamine transporters (ThTR-2), thereby increasing the risk of deficiency for this vitamin. Maternal thiamine deficiency can lead to infantile beriberi in breast-fed children. Thiamine deficiency could be an underlying factor in motor vehicle accidents and could be overlooked in the setting of head injury.

Thiamine deficiency in its early stage is challenging to identify. It causes anorexia and nonspecific symptoms (e.g., irritability, decrease in short-term memory). Prolonged thiamine deficiency causes *beriberi*, which is classically categorized as wet or dry, although there is considerable overlap between the two categories. In either form of beriberi, patients may complain of pain and paresthesia. *Wet beriberi* presents primarily with cardiovascular symptoms that are due to impaired myocardial energy metabolism and dysautonomia; it can occur after 3 months of a thiamine-deficient diet. Patients present with an enlarged heart, tachycardia, high-output congestive heart failure, peripheral edema, and peripheral neuritis. Patients with *dry beriberi* present with a symmetric peripheral neuropathy of the motor and sensory systems, with diminished reflexes. The neuropathy affects the legs most markedly, and patients have difficulty rising from a squatting position.

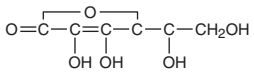
Alcoholic patients with chronic thiamine deficiency also may have central nervous system (CNS) manifestations known as *Wernicke's encephalopathy*, which consists of horizontal nystagmus, ophthalmoplegia (due to weakness of one or more extraocular muscles), cerebellar ataxia, and mental impairment **(Chap. 464)**. When there is an additional loss of memory and a confabulatory psychosis, the syndrome is known as *Wernicke-Korsakoff syndrome*. Despite the typical clinical picture and history, Wernicke-Korsakoff syndrome is underdiagnosed.

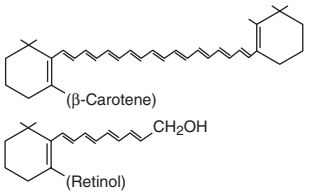
The laboratory diagnosis of thiamine deficiency usually is made by a functional enzymatic assay of transketolase activity measured before and after the addition of thiamine pyrophosphate. A >25% stimulation in response to the addition of thiamine pyrophosphate (i.e., an activity coefficient of 1.25) is interpreted as abnormal. Thiamine or the phosphorylated esters of thiamine in serum or blood also can be measured by high-performance liquid chromatography to detect deficiency.

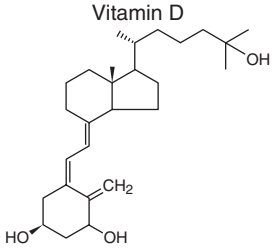
TREATMENT

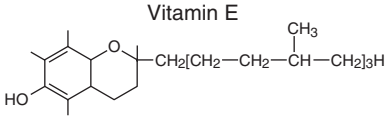
Thiamine Deficiency

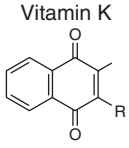
In acute thiamine deficiency with either cardiovascular or neurologic signs, 200 mg of thiamine three times daily should be given intravenously until there is no further improvement in acute symptoms; oral thiamine (10 mg/d) should subsequently be given until recovery is complete. Cardiovascular and ophthalmoplegic improvement occurs within 24 h. Other manifestations gradually clear, although psychosis in Wernicke-Korsakoff syndrome may be permanent or may persist for several months. Other nutrient deficiencies should be corrected concomitantly (e.g., magnesium, required for thiamine activation). In view of the widespread, often unrecognized (subclinical) deficiency, a more generous











Vitamin	Active derivative or cofactor form	Principal function
Vitamin C 	Ascorbic acid and dehydroascorbic acid	Participation as a redox ion in many biologic oxidation and hydrogen transfer reactions
Vitamin A 	Retinol, retinaldehyde, and retinoic acid	Formation of rhodopsin (vision) and glycoproteins (epithelial cell function); also regulates gene transcription
Vitamin D 	1,25-Dihydroxyvitamin D	Maintenance of blood calcium and phosphorus levels; antiproliferative hormone
Vitamin E 	Tocopherols and tocotrienols	Antioxidants
Vitamin K 	Vitamin K hydroquinone	Cofactor for posttranslation carboxylation of many proteins including essential clotting factors

FIGURE 344-1 (*Continued*)

supplementation of this vitamin in the emergency care setting and in all patients with any alcohol use disorder is warranted.

Toxicity Although hypersensitivity/anaphylaxis has been reported after high intravenous doses of thiamine, no adverse effects have been recorded from either food or supplements at high doses.

RIBOFLAVIN (VITAMIN B_2)

Riboflavin is important for the metabolism of fat, carbohydrate, and protein, acting as a respiratory coenzyme and an electron donor in energy production. Enzymes that contain flavin adenine dinucleotide (FAD) or flavin mononucleotide (FMN) as prosthetic groups are known as *flavoenzymes* (e.g., succinic acid dehydrogenase, monoamine oxidase, glutathione reductase). FAD is a cofactor for methyltetrahydrofolate reductase and therefore modulates homocysteine metabolism. The vitamin also plays a role in drug and steroid metabolism, including detoxification reactions.

Although much is known about the chemical and enzymatic reactions of riboflavin, the clinical manifestations of riboflavin deficiency are nonspecific and are similar to those of other deficiencies of B vitamins. Riboflavin deficiency is manifested principally by lesions of the mucocutaneous surfaces of the mouth and skin. In addition, corneal vascularization, anemia, and personality changes have been described with riboflavin deficiency.

Deficiency and Excess Riboflavin deficiency is rare and almost always due to dietary deficiency. Milk, other dairy products, and enriched breads and cereals are the most important dietary sources of riboflavin in the United States, although lean meat, fish, eggs, broccoli, and legumes are also good sources. Riboflavin is extremely sensitive to light, and milk should be stored in containers that protect against photodegradation. Laboratory diagnosis of riboflavin deficiency can be made by determination of red blood cell or urinary riboflavin concentrations or by measurement of erythrocyte glutathione reductase activity, with and without added FAD. Because of the limited capacity of the gastrointestinal tract to absorb riboflavin (~27 mg after one oral dose or meal) as well as the instantaneous urinary excretion, riboflavin toxicity has not been described.

NIACIN (VITAMIN B_3)

The term *niacin* refers to nicotinic acid and nicotinamide and their biologically active derivatives. Nicotinic acid and nicotinamide serve as precursors of two coenzymes, nicotinamide adenine dinucleotide (NAD) and NAD phosphate (NADP), which are important in numerous oxidation and reduction reactions in the body. In addition, NAD and NADP are active in adenine diphosphate–ribose transfer reactions involved in DNA repair and calcium mobilization.

Metabolism and Requirements Nicotinic acid and nicotinamide are absorbed well from the stomach and small intestine. The bioavailability of niacin from beans, milk, meat, and eggs is high; bioavailability from cereal grains is lower. Since flour is enriched with "free" niacin (i.e., the non-coenzyme form), bioavailability is excellent. Median intakes of niacin in the United States considerably exceed the recommended dietary allowance (RDA).

The amino acid tryptophan can be converted to niacin with an efficiency of 60:1 by weight. Thus, the RDA for niacin is expressed in niacin equivalents. A lower-level conversion of tryptophan to niacin occurs in vitamin B_6, riboflavin, and/or iron deficiencies, and in the presence of isoniazid. The urinary excretion products of niacin include 2-pyridone and 2-methyl nicotinamide, measurements of which are used in the diagnosis of niacin deficiency.

Deficiency Niacin deficiency causes *pellagra*, which is found mostly among people eating corn-based diets in parts of China, Africa, and India. Pellagra in North America is found mainly among alcoholics; among patients with congenital defects of intestinal and kidney absorption of tryptophan (Hartnup disease); and among patients with carcinoid syndrome, in which there is increased conversion of tryptophan to serotonin. The antituberculosis drug isoniazid is a structural analogue of niacin and can precipitate pellagra. This also occurs in the setting of mass scale-up of isoniazid tuberculosis preventive therapy in low-income countries. In the setting of famine or population displacement, pellagra results from the absolute lack of niacin but also from the deficiency of micronutrients required for the conversion of tryptophan to niacin (e.g., iron, riboflavin, and pyridoxine). The early symptoms of pellagra include loss of appetite, generalized weakness and irritability, abdominal pain, and vomiting. Bright red glossitis then ensues and is followed by a characteristic skin rash that is pigmented and scaling, particularly in skin areas exposed to sunlight. This rash is known as *Casal's necklace* because it forms a ring around the neck; it is seen in advanced cases. Vaginitis and esophagitis also may occur. Diarrhea (due in part to proctitis and in part to malabsorption), depression, seizures, and dementia are also part of the pellagra syndrome. The primary manifestations of this syndrome are sometimes referred to as "the four Ds": *d*ermatitis, *d*iarrhea, and *d*ementia leading to *d*eath. Aging is characterized by a decline in cellular NAD^+, and it seems plausible that maintaining and/or reestablishing cellular NAD^+, might have beneficial effects (e.g., metabolic disorders).

TREATMENT

Pellagra

Treatment of pellagra consists of oral supplementation with 100–200 mg of nicotinamide or nicotinic acid three times daily for up to 4 weeks. High doses of nicotinic acid (2 g/d in a time-release form) may be used for the treatment of elevated cholesterol and triglyceride levels and/or low high-density lipoprotein cholesterol levels, but without proven evidence to prevent cardiovascular disease. Nevertheless, nicotinic acid may be useful in patients with statin intolerance or severe hypertriglyceridemia **(Chap. 419)**.

Toxicity Prostaglandin-mediated flushing due to binding of the vitamin to a G protein–coupled receptor has been observed at daily nicotinic acid doses as low as 30 mg taken as a supplement or as therapy for dyslipidemia. There is no evidence of toxicity from niacin that is derived from food sources. Flushing always starts in the face and may be accompanied by skin dryness, itching, paresthesia, and headache. Flushing is subject to tachyphylaxis and often improves with time; premedication with aspirin may alleviate these symptoms. Nausea, vomiting, and abdominal pain also occur at similar doses of niacin. Hepatic toxicity is the most serious toxic reaction caused by sustained-release niacin and may present as jaundice with elevated aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels. A few cases of fulminant hepatitis requiring liver transplantation have been reported at doses of 3–9 g/d. Other toxic reactions include glucose intolerance, hyperuricemia, macular edema, and macular cysts. The combination of nicotinic acid preparations for dyslipidemia plus 3-hydroxy-3-methylglutaryl–coenzyme A (HMG-CoA) reductase inhibitors may increase the risk of rhabdomyolysis. The upper limit for daily (nontherapeutic) niacin intake has been set at 35 mg.

PYRIDOXINE (VITAMIN B_6)

Vitamin B_6 refers to a family of compounds that includes pyridoxine, pyridoxal, pyridoxamine, and their 5′-phosphate derivatives. 5′-Pyridoxal phosphate (PLP) is a cofactor for >100 enzymes involved in amino acid metabolism. Vitamin B_6 also is involved in heme and neurotransmitter synthesis and in the metabolism of glycogen, lipids, steroids, sphingoid bases, and several vitamins, including the conversion of tryptophan to niacin.

Dietary Sources Plants contain vitamin B_6 in the form of pyridoxine, whereas animal tissues contain PLP and pyridoxamine phosphate. The vitamin B_6 contained in plants is less bioavailable than that in animal tissues. Rich food sources of vitamin B_6 include legumes, nuts, wheat bran, and meat, although it is present in all food groups.

Deficiency Symptoms of vitamin B_6 deficiency include epithelial changes, as seen frequently with other B vitamin deficiencies. In

addition, severe vitamin B_6 deficiency can lead to peripheral neuropathy, abnormal electroencephalograms, and personality changes that include depression and confusion. In infants, diarrhea, seizures, and anemia have been reported. Microcytic hypochromic anemia is due to diminished hemoglobin synthesis, since the first enzyme involved in heme biosynthesis (aminolevulinate synthase) requires PLP as a cofactor **(Chap. 102)**. In some case reports, platelet dysfunction has been reported. Since vitamin B_6 is necessary for the conversion of homocysteine to cystathionine, it is possible that chronic low-grade vitamin B_6 deficiency may result in hyperhomocysteinemia, which has been associated with vascular dysfunction and an increased risk of cardiovascular disease; however, so far, there is only limited randomized controlled trial evidence **(Chap. 431)**. Independent of homocysteine, low levels of circulating vitamin B_6 have been associated with inflammation and elevated levels of C-reactive protein.

Certain medications, such as isoniazid, L-dopa, penicillamine, and cycloserine, interact with PLP due to a reaction with carbonyl groups. Pyridoxine should be given concurrently with isoniazid to avoid neuropathy. The increased ratio of AST to ALT seen in alcoholic liver disease reflects the relative vitamin B_6 dependence of ALT. Vitamin B_6 dependency syndromes that require pharmacologic doses of vitamin B_6 are rare; they include cystathionine β-synthase deficiency, pyridoxine-responsive (primarily sideroblastic) anemias, and gyrate atrophy with chorioretinal degeneration due to decreased activity of the mitochondrial enzyme ornithine aminotransferase. In these situations, 100–200 mg/d of oral vitamin B_6 is required for treatment.

Severe nausea and vomiting in pregnancy might respond to pyridoxine combined with doxylamine. High doses of vitamin B_6 have been used to treat carpal tunnel syndrome, premenstrual syndrome, schizophrenia, autism, and diabetic neuropathy but have not been found to be effective.

The laboratory diagnosis of vitamin B_6 deficiency is generally based on low plasma PLP values (<20 nmol/L). Vitamin B_6 deficiency is treated with 50 mg/d; higher doses of 100–200 mg/d are given if the deficiency is related to medication use. Vitamin B_6 should not be given with L-dopa, since the vitamin interferes with the action of this drug.

Toxicity The safe upper limit for vitamin B_6 has been set at 100 mg/d, although no adverse effects have been associated with high intakes of vitamin B_6 from food sources only. When toxicity occurs, it causes severe sensory neuropathy, leaving patients unable to walk; however, in most cases, this is reversible upon cessation of the high intake. Medication safety monitoring suggests a rather high prevalence of vitamin B_6–induced neuropathy. Accordingly, long-term high-dose vitamin B_6 supplementation should be discouraged. Some cases of photosensitivity and dermatitis have been reported.

FOLATE (VITAMIN B_{12})

See Chap. 104.

VITAMIN C

Both ascorbic acid (only the L-isomer) and its oxidized product dehydroascorbic acid are biologically active. Actions of vitamin C include antioxidant activity, promotion of nonheme iron absorption, carnitine biosynthesis, conversion of dopamine to norepinephrine, tyrosine catabolism, histone and DNA demethylation, and synthesis of many peptide hormones. Vitamin C is also important for connective tissue metabolism and cross-linking (proline hydroxylation), and it is a component of many drug-metabolizing enzyme systems, particularly the mixed-function oxidase systems.

Absorption and Dietary Sources Vitamin C is almost completely absorbed if <100 mg is administered in a single dose; however, only ≤50% is absorbed at doses >1 g. Enhanced degradation and fecal and urinary excretion of vitamin C occur at higher intake levels.

Good dietary sources of vitamin C include citrus fruits, green vegetables (especially broccoli), tomatoes, and potatoes. Consumption of five servings of fruits and vegetables a day provides vitamin C in excess of the RDA of 90 mg/d for men and 75 mg/d for women. In addition, ~40% of the U.S. population consumes vitamin C as a dietary supplement in which "natural forms" of the vitamin are no more bioavailable than synthetic forms. Smoking (including "passive" smoking), hemodialysis, pregnancy, lactation, and stress (e.g., infection, trauma) appear to increase vitamin C requirements.

Deficiency Vitamin C deficiency causes scurvy. In the United States, this condition is seen primarily among the poor and the elderly, in alcoholics who consume <10 mg/d of vitamin C, and in young adults who eat severely unbalanced diets. In addition to generalized fatigue, symptoms of scurvy primarily reflect impaired formation of mature connective tissue and include bleeding into the skin (petechiae, ecchymoses, perifollicular hemorrhages); inflamed and bleeding gums; and manifestations of bleeding into joints, the peritoneal cavity, the pericardium, and the adrenal glands. In children, vitamin C deficiency may cause impaired bone growth. Laboratory diagnosis of vitamin C deficiency is based on low plasma or leukocyte levels.

Administration of vitamin C (200 mg/d) improves the symptoms of scurvy within several days. High-dose vitamin C supplementation (e.g., 0.2 g up to several grams per day) may slightly decrease the symptoms and duration of upper respiratory tract infections. Vitamin C supplementation has also been reported to be useful in Chédiak-Higashi syndrome **(Chap. 67)** and osteogenesis imperfecta **(Chap. 425)**. Diets high in vitamin C have been claimed to lower the incidence of certain cancers, particularly esophageal and gastric cancers. If proven, this effect may be because vitamin C can prevent the conversion of nitrites and secondary amines to carcinogenic nitrosamines. Emerging evidence suggests a therapeutic effect of intravenous parenteral (*not oral*) pharmacologic doses of up to 1 g/kg body weight of ascorbic acid in the treatment of cancers (e.g., metastatic pancreatic, ovarian, glioblastoma, and non-small-cell lung cancers). The mechanism of pharmacologic ascorbate in cancer treatment (as a stand-alone agent or with other therapeutic agents) appears to be pro-oxidative, either synergistic (e.g., gemcitabine, programmed cell death protein 1 [PD-1] inhibitors, radiation) or additive with other agents.

Toxicity Taking >2 g of vitamin C in a single dose may result in abdominal pain, diarrhea, and nausea. Since vitamin C may be metabolized to oxalate, it is feared that chronic high-dose vitamin C supplementation could result in an increased prevalence of kidney stones. However, except in patients with preexisting renal disease, this association has not been borne out in several trials. Nevertheless, it is reasonable to advise patients with a history of kidney stones (especially oxalate renal stones) and renal insufficiency not to take large doses of vitamin C. There is also an unproven but possible risk that chronic high doses of vitamin C could promote iron overload and iron toxicity (e.g., in patients with hemochromatosis or thalassemia major). High doses of vitamin C can induce hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency, and doses >1 g/d can cause false-negative guaiac reactions and interfere with tests for urinary glucose. High doses may interfere with the activity of certain drugs and diagnostic tests (e.g., false-negative results of guaiac-based fecal occult blood tests). Parenteral high-dose vitamin C in patients with severe infections or sepsis has no beneficial effects and may increase mortality.

BIOTIN

Biotin (also known as vitamin B_7 or vitamin H) is a water-soluble vitamin that plays a role in gene expression, gluconeogenesis, and fatty acid synthesis and serves as a carbon dioxide (CO_2) carrier on the surface of both cytosolic and mitochondrial carboxylase enzymes. The vitamin also functions in the catabolism of specific amino acids (e.g., leucine) and in gene regulation by histone biotinylation. Excellent food sources of biotin include organ meat such as liver or kidney, soy and other beans, yeast, and egg yolks; however, egg white contains the protein avidin, which strongly binds the vitamin and reduces its bioavailability.

Biotin deficiency due to low dietary intake is rare; rather, deficiency is due to inborn errors of metabolism (e.g., biotinidase deficiency). Biotin deficiency has been induced by experimental feeding of egg white diets and by biotin-free parenteral nutrition in patients with short bowels. In adults, biotin deficiency results in mental changes (depression, hallucinations), paresthesia, anorexia, and nausea. A

scaling, seborrheic, and erythematous rash may occur around the eyes, nose, and mouth as well as on the extremities. In infants, biotin deficiency presents as hypotonia, lethargy, and apathy. In addition, infants may develop alopecia and a characteristic rash that includes the ears. At present, evidence does not support a therapeutic role of high-dose biotin in multiple sclerosis. The laboratory diagnosis of biotin deficiency can be established on the basis of a decreased concentration of urinary biotin (or its major metabolites), increased urinary excretion of 3-hydroxyisovaleric acid after a leucine challenge, or decreased activity of biotin-dependent enzymes in lymphocytes (e.g., propionyl-CoA carboxylase). Treatment requires pharmacologic doses of biotin, that is, up to 10 mg/d. No toxicity is known. High-dose biotin supplements could interfere with different immunoassay platforms based on streptavidin-biotin technology (e.g., biotinylated antibodies), resulting in false-positive (e.g., free T_4 or T_3) or false-negative tests (e.g., thyroid-stimulating hormone, troponin, β-human chorionic gonadotropin pregnancy test).

PANTOTHENIC ACID (VITAMIN B_5)

Pantothenic acid is a component of coenzyme A and phosphopantetheine, which are involved in fatty acid metabolism and the synthesis of cholesterol, steroid hormones, and all compounds formed from isoprenoid units. In addition, pantothenic acid is involved in the acetylation of proteins. The vitamin is excreted in the urine, and the laboratory diagnosis of deficiency is based on low urinary vitamin levels.

The vitamin is ubiquitous in the food supply. Liver, yeast, egg yolks, whole grains, and vegetables are particularly good sources. Human pantothenic acid deficiency has been demonstrated only by experimental feeding of diets low in pantothenic acid or by administration of a specific pantothenic acid antagonist. The symptoms of pantothenic acid deficiency are nonspecific and include gastrointestinal disturbance, depression, muscle cramps, paresthesia, ataxia, and hypoglycemia. Pantothenic acid deficiency is believed to have caused the "burning feet syndrome" seen in prisoners of war during World War II. No toxicity of this vitamin has been reported.

CHOLINE

Choline is a precursor for acetylcholine, phospholipids, and betaine. Choline is necessary for the structural integrity of cell membranes, cholinergic neurotransmission, lipid and cholesterol metabolism, methyl-group metabolism, and transmembrane signaling. Recently, a recommended adequate intake was set at 550 mg/d for men and 425 mg/d for women, although certain genetic polymorphisms can increase an individual's requirement. Choline is thought to be a "conditionally essential" nutrient in that its de novo synthesis occurs in the liver and results in lesser-than-used amounts only under certain stress conditions (e.g., alcoholic liver disease). The dietary requirement for choline depends on the status of other nutrients involved in methyl-group metabolism (folate, vitamin B_{12}, vitamin B_6, and methionine) and thus varies widely. Choline is widely distributed in food (e.g., egg yolks, wheat germ, organ meat, milk) in the form of lecithin (phosphatidylcholine). Choline deficiency has occurred only in experimental conditions or in patients receiving parenteral nutrition devoid of choline and rarely in specific inborn errors of choline metabolism. Deficiency results in fatty liver, elevated aminotransferase levels, and skeletal muscle damage with high creatine phosphokinase values. The diagnosis of choline deficiency is currently based on low plasma levels, although nonspecific conditions (e.g., heavy exercise) may also suppress plasma levels.

Toxicity from choline results in hypotension, increased sweating, diarrhea, salivation, and a fishy body odor. The upper limit for choline intake has been set at 3.5 g/d. Because of its ability to lower cholesterol and homocysteine levels, choline treatment has been suggested for patients with dementia and patients at high risk of cardiovascular disease. However, the benefits of such treatment have not been firmly documented; recently, signals for an increased cardiovascular risk have been reported. Choline- and betaine-restricted diets are of therapeutic value in trimethylaminuria ("fish odor syndrome") or in decreasing the production of the gut microbiome-derived trimethylamine *N*-oxide (TMAO) as a potential cardiovascular risk modulator.

FLAVONOIDS

Flavonoids constitute a large family of polyphenolic phytochemicals that contribute to the aroma, taste, and color of fruits and vegetables. Major groups of dietary flavonoids include anthocyanidins in berries; flavanols (catechins) in green tea and chocolate; flavonols (e.g., quercetin) in broccoli, kale, leeks, onions, and the skins of grapes and apples; and isoflavones (e.g., genistein) in legumes. Isoflavones have a low bioavailability and are partially metabolized by the intestinal flora. The dietary intake of flavonoids is highly variable and estimated at 10–400 mg/d; this figure is almost certainly an underestimate attributable to a lack of information on their concentrations in many foods. Several flavonoids have antioxidant activity and affect cell signaling. From observational epidemiologic studies and limited clinical (human and animal) studies, flavonoids have been postulated to play a role in the prevention of several chronic diseases, including neurodegenerative disease, diabetes, and osteoporosis. The ultimate importance and usefulness of these compounds against human disease have not been consistently demonstrated. Nevertheless, a dietary pattern with high intake of fruits, vegetables, and legumes should be encouraged to assure a higher intake of these and others nonnutritive bioactives.

VITAMIN A

Vitamin A, in the strictest sense, refers to retinol and retinyl esters. However, the oxidized metabolites retinaldehyde and retinoic acid are also biologically active compounds. The term *retinoids* includes all molecules (including synthetic molecules) that are chemically related to retinol. Retinaldehyde (11-*cis*) is the form of vitamin A that is required for normal vision, whereas retinoic acid is necessary for normal morphogenesis, growth, and cell differentiation. Retinoic acid does not function directly in vision and, in contrast to retinol, is not involved in reproduction. Vitamin A also plays a role in iron utilization, humoral immunity, T cell–mediated immunity, natural killer cell activity, and phagocytosis.

Vitamin A is found in the human food supply in two forms: preformed as retinyl esters and provitamin A carotenoids. There are >700 carotenoids in nature, ~50 of which can be metabolized to vitamin A. β-Carotene is the most prevalent carotenoid with provitamin A activity in the food supply. In humans, significant fractions of carotenoids are absorbed intact and are stored in liver and fat. It is estimated that in healthy humans ≥12 μg (range, 4–27 μg) of dietary all-*trans* β-carotene is equivalent to 1 μg of retinol activity, whereas the figure is ≥24 μg for other dietary provitamin A carotenoids (e.g., β-cryptoxanthin, α-carotene). The vitamin A equivalency for a β-carotene supplement in an oily solution is 2:1.

Metabolism The liver contains ~90% of the vitamin A reserves in healthy individuals and secretes vitamin A in the form of retinol, which is bound in the circulation to retinol-binding protein. Once binding has occurred, the retinol-binding protein complex interacts with a second protein, transthyretin. This trimolecular complex functions to prevent vitamin A from being filtered by the kidney glomerulus, thus protecting the body against the toxicity of retinol and allowing retinol to be taken up by specific cell-surface receptors that recognize retinol-binding protein. A certain amount of vitamin A enters peripheral cells even if it is not bound to retinol-binding protein. After retinol is internalized by the cell, it becomes bound to a series of cellular retinol-binding proteins, which function as sequestering and transporting agents as well as co-ligands for enzymatic reactions. Certain cells also contain retinoic acid–binding proteins, which have sequestering functions but also shuttle retinoic acid to the nucleus and enable its metabolism.

Vitamin A metabolites (retinoids) such as retinoic acid are potent regulators of gene transcription through nuclear receptor signaling, thus playing a key role in many cellular and metabolic pathways. Two families of receptors (retinoic acid receptors [RARs] and retinoid X receptors [RXRs]) are active in retinoid-mediated gene transcription. Retinoid receptors regulate transcription by binding as dimeric complexes to specific DNA sites—the retinoic acid response elements—in target genes (Chap. 389). The receptors can either stimulate or repress gene expression in response to their ligands. RARs bind all-*trans*

retinoic acid and 9-*cis*-retinoic acid, whereas RXRs bind only 9-*cis*-retinoic acid.

The retinoid receptors play an important role in controlling cell proliferation and differentiation. RXRs dimerize with other nuclear receptors to function as coregulators of genes responsive to retinoids, but also to thyroid hormone and calcitriol. RXR agonists induce insulin sensitivity experimentally, perhaps because RXRs are cofactors for the peroxisome proliferator-activated receptors, which also mediate fatty acid and carbohydrate metabolism and are targets for different drugs including thiazolidinedione drugs (e.g., rosiglitazone and pioglitazone) **(Chap. 416)**.

Dietary Sources The retinol activity equivalent (RAE) is used to express the vitamin A value of food: 1 RAE is defined as 1 μg of retinol (0.003491 mmol), 12 μg of β-carotene, and 24 μg of other provitamin A carotenoids. In older literature, vitamin A often was expressed in international units (IUs), with 1 μg of retinol equal to 3.33 IU of retinol and 20 IU of β-carotene. Although these IUs are no longer in scientific use, they can still be found in reports of the food industry and in public health interventions in low-income countries.

Liver, fish, and eggs are excellent food sources for preformed vitamin A; vegetable sources of provitamin A carotenoids include dark green and deeply colored fruits and vegetables. Moderate cooking of vegetables enhances carotenoid release for uptake in the gut. Carotenoid absorption is also aided by some fat in a meal. Exclusive breast-feeding can cover the vitamin A needs of infants if the mother has an adequate vitamin A status and a large enough volume of milk. If the nursing mother has inadequate vitamin A intake or concomitant diseases or her infant was a preterm delivery, breast milk probably will not supply enough vitamin A to prevent deficiency. In developing countries, chronic dietary deficiency is the main cause of vitamin A deficiency and is exacerbated by infection. In early childhood, low vitamin A status results from inadequate intakes of animal food sources and edible oils, both of which are expensive, coupled with seasonal unavailability of vegetables and fruits and lack of marketed fortified food products. Factors that interfere with vitamin A metabolism may also affect status or function. For example, concurrent zinc deficiency can interfere with the mobilization of vitamin A from liver stores. Alcohol interferes with the conversion of retinol to retinaldehyde in the eye by competing for alcohol (retinol) dehydrogenase. Drugs that interfere with the absorption of vitamin A include mineral oil, neomycin, and bile acid sequestrants (e.g., cholestyramine).

Deficiency Vitamin A deficiency is endemic in areas where diets are chronically poor, especially in southern Asia, sub-Saharan Africa, some parts of Latin America, and the western Pacific, including parts of China. Vitamin A status is usually assessed by measuring serum retinol (normal range, 1.05–3.50 μmol/L [30–100 μg/dL]) or via dose-response tests or tests of dark adaptation. To assure a correct biochemical assessment of vitamin A status, a simultaneous assessment of the inflammatory status is needed (in analogy to the assessment of iron status); not doing so may result in an overestimation of vitamin A deficiency. Correction factors to adjust the measured plasma vitamin A levels to account for the influence of C-reactive protein and α_1-acid glycoprotein are available. Stable isotopic or invasive liver biopsy methods are available to estimate total-body stores of vitamin A. As judged by deficient serum retinol (<0.70 μmol/L [20 μg/dL]), vitamin A deficiency worldwide is present in 190 million preschool-age children, among whom >5 million have an ocular manifestation of deficiency termed *xerophthalmia*. This condition includes milder stages of night blindness and conjunctival *xerosis* (dryness) with *Bitot's spots* (white patches of keratinized epithelium appearing on the sclera) that may affect 1–5% of children in deficient populations as well as rare, potentially blinding corneal ulceration and necrosis. *Keratomalacia* (softening of the cornea) leads to corneal scarring that blinds an estimated quarter of a million children each year and is associated with fatality rates of 4–25%. However, vitamin A deficiency severe enough to cause any clinical stage poses an increased risk of death from diarrhea, dysentery, measles, malaria, or respiratory disease. This is because vitamin A deficiency can compromise barrier, innate, and acquired immune defenses to infection. In areas where deficiency is widely prevalent, vitamin A supplementation can markedly reduce the risk of childhood mortality (by 23–34%, on average). About 10% of pregnant women in undernourished settings also develop night blindness (assessed by history) during the latter half of pregnancy; this level of moderate to severe vitamin A deficiency is associated with an increased risk of maternal infection and death. Maternal vitamin A deficiency may also exacerbate already low vitamin A nutrition and associated risks for the newborn. In South Asia, where maternal deficiency is prominent, giving infants a single oral dose (50,000 IU) of vitamin A shortly after birth has reduced infant mortality by ≥10%, whereas in African settings less affected by maternal vitamin A deficiency, no effect has been noted, revealing differences in risk of deficiency and benefit of supplementation across regions. However, the World Health Organization does not recommend high-dose supplementation to newborns.

TREATMENT

Vitamin A Deficiency

Vitamin A is commercially available for treatment and prevention in esterified forms (e.g., acetate, palmitate), which are more stable than other forms. Any stage of xerophthalmia should be treated with 60 mg (or RAE) or 200,000 IU of vitamin A in oily solution, usually contained in a soft-gel capsule. The same dose is repeated 1 and 14 days later. Doses should be reduced by half for patients 6–11 months of age. Mothers with night blindness or Bitot's spots should be given vitamin A orally 3 mg daily for at least 3 months. These regimens are efficacious, and they are far less expensive and more widely available than injectable water-miscible vitamin A. A common approach to prevention is to provide vitamin A supplementation every 4–6 months to young children 6 months to 5 years of age (both HIV-positive and HIV-negative) in high-risk areas. For prevention, infants 6–11 months of age should receive 30 mg of vitamin A; children 12–59 months of age should receive 60 mg. For reasons that are not clear, although early neonatal vitamin A may reduce infant mortality, vitamin A given between 1 and 5 months of age has not proven effective in improving survival in high-risk settings.

Uncomplicated vitamin A deficiency is rare in industrialized countries. One high-risk group—extremely low-birth-weight (<1000-g) infants—is likely to be vitamin A deficient and should receive a supplement of 1500 μg (or RAE) three times a week for 4 weeks. Severe measles in any society can lead to secondary vitamin A deficiency. Children hospitalized with measles should receive two 60-mg doses of vitamin A on 2 consecutive days. Vitamin A deficiency most often occurs in patients with malabsorptive diseases (e.g., celiac sprue, short-bowel syndrome) who have abnormal dark adaptation or symptoms of night blindness without other ocular changes. Typically, such patients are diagnosed in advanced care settings where they are treated for 1 month with 15 mg/d of a water-miscible preparation of vitamin A. This treatment is followed by a lower maintenance dose, with the exact amount determined by monitoring serum retinol. Finding application elsewhere in medicine, retinoic acid is useful in the treatment of promyelocytic leukemia **(Chap. 109)** and also is used in the treatment of cystic acne because it inhibits keratinization, decreases sebum secretion, and possibly alters the inflammatory reaction **(Chap. 60)**.

No specific signs or symptoms result from carotenoid deficiency. It was postulated that β-carotene would be an effective chemopreventive agent for cancer because numerous epidemiologic studies had shown that diets high in β-carotene were associated with lower incidences of cancers of the respiratory and digestive systems. However, intervention studies in smokers found that treatment with high doses of β-carotene actually resulted in more lung cancers than did treatment with placebo. Non–provitamin A carotenoids such as lutein and zeaxanthin have been suggested to confer protection against macular degeneration, and one large-scale intervention study did not show a beneficial effect except in those with a low

lutein status. The use of the non–provitamin A carotenoid lycopene to protect against prostate cancer has been proposed. However, the effectiveness of these agents has not been proved by intervention studies, and the mechanisms underlying these purported biologic actions are unknown.

Selective plant-breeding techniques that lead to a higher provitamin A carotenoid content in staple foods may decrease vitamin A malnutrition in low-income countries. Moreover, a recently developed genetically modified food (Golden Rice) had a β-carotene–to–vitamin A conversion ratio of ~3:1 in children.

Toxicity The acute toxicity of vitamin A was first noted in Arctic explorers who ate polar bear liver and has also been seen after administration of 150 mg to adults or 100 mg to children. Acute toxicity is manifested by increased intracranial pressure, vertigo, diplopia, bulging fontanels (in children), seizures, and exfoliative dermatitis; it may result in death. Among children being treated for vitamin A deficiency according to the protocols outlined above, transient bulging of fontanels occurs in 2% of infants, and transient nausea, vomiting, and headache occur in 5% of preschoolers. Chronic vitamin A intoxication is largely a concern in industrialized countries and has been seen in otherwise healthy adults who ingest 15 mg/d and children who ingest 6 mg/d over a period of several months. Manifestations include dry skin, cheilosis, glossitis, vomiting, alopecia, bone demineralization and pain, hypercalcemia, lymph node enlargement, hyperlipidemia, amenorrhea, and features of pseudotumor cerebri with increased intracranial pressure and papilledema. Liver fibrosis with portal hypertension may also result from chronic vitamin A intoxication. Provision of vitamin A in excess to pregnant women has resulted in spontaneous abortion and in congenital malformations, including craniofacial abnormalities and valvular heart disease. In pregnancy, the daily dose of vitamin A should not exceed 3 mg. Also, topical retinoids should be avoided during pregnancy. Commercially available retinoid derivatives are also toxic, including 13-*cis*-retinoic acid, which has been associated with birth defects. Thus, contraception should be continued for at least 1 year and possibly longer in women who have taken 13-*cis*-retinoic acid.

In malnourished children, vitamin A supplements (30–60 mg), in amounts calculated as a function of age and given in several rounds over 2 years, are considered to amplify nonspecific effects of vaccines. However, for unclear reasons, in one African setting, there has been a negative effect on mortality rates in incompletely vaccinated girls.

High doses of supplemental carotenoids do not result in toxic symptoms but should be avoided in smokers due to an increased risk of lung cancer. Very high doses of β-carotene (~200 mg/d) have been used to treat or prevent the skin rashes of erythropoietic protoporphyria. Carotenemia, which is characterized by a yellowing of the skin (in creases of the palms and soles) but not the sclerae, may follow ingestion of >30 mg of β-carotene daily. Hypothyroid patients are particularly susceptible to the development of carotenemia due to impaired breakdown of carotene to vitamin A. Reduction of carotenes in the diet results in the disappearance of skin yellowing and carotenemia over a period of 30–60 days.

VITAMIN D

The metabolism of the fat-soluble vitamin D is described in detail in **Chap. 421.** The biologic effects of this vitamin are mediated by vitamin D receptors, which are found in most tissues; binding with these receptors potentially expands vitamin D actions to many different cell systems and organs (e.g., immune cells, brain, breast, colon, and prostate) in addition to the classic endocrine effects on calcium and phosphate metabolism and bone health. Vitamin D is thought to be important for maintaining normal function of many nonskeletal tissues such as muscle (including heart muscle), for immune function, and for inflammation as well as for cell proliferation and differentiation. Older studies have shown that vitamin D may be useful as adjunctive treatment for tuberculosis, psoriasis, and multiple sclerosis or for the prevention of certain cancers. Vitamin D insufficiency may increase the risk of type 1 diabetes mellitus, cardiovascular disease (insulin resistance, hypertension, or low-grade inflammation), or brain dysfunction (e.g., depression). However, the exact physiologic roles of vitamin D in these nonskeletal diseases and the importance of these roles have so far not been clarified. Recent placebo-controlled studies did not show a therapeutic benefit of vitamin D for cancer prevention, control of cardiovascular disease, or risk of type 2 diabetes, depression, tuberculosis infection, or other respiratory infections. Presently, it is not known whether these effects of vitamin D supplements (with or without calcium) might be different according to the baseline status (normal vs severely deficient) of patients.

The skin is a major source of vitamin D, which is synthesized upon skin exposure to ultraviolet B radiation (UV-B; wavelength, 290–320 nm). Except for fish, food (unless fortified) contains only limited amounts of vitamin D. Vitamin D_2 (ergocalciferol) is obtained from plant sources and is the chemical form found in some supplements.

Deficiency Vitamin D status is assessed by measuring serum levels of 25-dihydroxyvitamin D (25[OH] vitamin D); however, there is no consensus on a uniform assay, on optimal serum levels, or on the real benefit of biochemical screening in asymptomatic adults. The optimal level might, in fact, differ according to the targeted disease entity. Epidemiologic and experimental data indicate that a 25(OH) vitamin D level of >20 ng/mL (≥50 nmol/L; to convert ng/mL to nmol/L, multiply by 2.496) is sufficient for good bone health. The latter 25(OH) vitamin D plasma concentration would cover the requirements of 97.5% of the population. Some experts, however, advocate higher serum levels (e.g., >30 ng/mL) for other desirable endpoints of vitamin D action. There is insufficient evidence to recommend combined vitamin D and calcium supplementation as a primary preventive strategy (as opposed to secondary prevention) for reduction of the incidence of fractures in healthy men and premenopausal women.

Risk factors for vitamin D deficiency are old age, lack of sun exposure, dark skin (especially among residents of northern latitudes), fat malabsorption, and obesity; deficiency can also occur after gastric bypass surgery. In addition, in African populations, the prevalence of vitamin D deficiency might be high (especially in women, newborn babies, urban populations, and those living in northern African countries). *Rickets* represents the classic disease of vitamin D deficiency. Signs of deficiency are muscle soreness, weakness, and bone pain. Some of these effects are independent of calcium intake. To *prevent* glucocorticoid-induced osteoporosis, treatment with calcium (1000–1200 mg/d) and vitamin D (600–800 IU/d) through diet and/or supplements in combination with weight-bearing exercise is recommended.

The U.S. National Academy of Sciences recently advised that the majority of adult North Americans should receive 600 IU/d of vitamin D (RDA = 15 μg/d or 600 IU/d; **Chap. 343**). However, for people aged >70 years, the RDA is set at 20 μg/d (800 IU/d). The consumption of fortified or enriched foods as well as suberythemal sun exposure should be encouraged for people at risk for vitamin D deficiency. If adequate intake is impossible, vitamin D supplements should be taken, especially during the winter months. Vitamin D deficiency can be treated by oral administration of 50,000 IU/week for 6–8 weeks followed by a maintenance dose of 800 IU/d (20 μg/d) from food and supplements once normal plasma levels have been attained. There is still uncertainty regarding the optimal therapeutic dosage (high vs low) for elderly at risk of falls. The physiologic effects of vitamin D_2 and vitamin D_3 are similar when these vitamins are ingested over long periods.

Toxicity The upper limit of intake has been set at 4000 IU/d. Contrary to earlier beliefs, acute vitamin D intoxication is rare and usually is caused by the uncontrolled and excessive ingestion of supplements or by faulty food fortification practices. High plasma levels of $1,25(OH)_2$ vitamin D and calcium are central features of toxicity and mandate discontinuation of vitamin D and calcium supplements; in addition, treatment of hypercalcemia may be required.

VITAMIN E

Vitamin E is the collective designation for all stereoisomers of tocopherols and tocotrienols, although only the α-tocopherols meet human requirements. Vitamin E acts as a chain-breaking antioxidant and is an efficient peroxyl radical scavenger that protects low-density

lipoproteins and polyunsaturated fats in membranes from oxidation. A network of other antioxidants (e.g., vitamin C, glutathione) and enzymes maintains vitamin E in a reduced state. Vitamin E also inhibits prostaglandin synthesis and the activities of protein kinase C and phospholipase A_2.

Absorption and Metabolism After absorption, vitamin E is taken up from chylomicrons by the liver, and a hepatic α-tocopherol transport protein mediates intracellular vitamin E transport and incorporation into very-low-density lipoprotein. The transport protein has a particular affinity for the RRR isomeric form of α-tocopherol; thus, this natural isomer has the most biologic activity.

Requirement Vitamin E is widely distributed in the food supply, with particularly high levels in sunflower oil, safflower oil, and wheat germ oil; γ-tocotrienols are notably present in soybean and corn oils. Vitamin E is also found in meats, nuts, and cereal grains, and small amounts are present in fruits and vegetables. Vitamin E pills containing doses of 50–1000 mg are ingested by ~10% of the U.S. population. The RDA for vitamin E is 15 mg/d (34.9 μmol or 22.5 IU) for all adults. Diets high in polyunsaturated fats may necessitate a slightly higher intake of vitamin E.

Dietary deficiency of vitamin E does not exist in developed countries but can occur in developing countries due to inadequate intake. Vitamin E deficiency is seen only in severe and prolonged malabsorptive diseases, such as celiac disease, chronic cholestatic liver disease, or after small-intestinal resection or bariatric surgery. Children with cystic fibrosis or prolonged cholestasis may develop vitamin E deficiency characterized by areflexia and hemolytic anemia. Children with abetalipoproteinemia cannot absorb or transport vitamin E and become deficient quite rapidly. A familial form of isolated vitamin E deficiency also exists; it is due to a defect in the α-tocopherol transport protein. Vitamin E deficiency causes axonal degeneration of the large myelinated axons and results in posterior column and spinocerebellar symptoms. Peripheral neuropathy is initially characterized by areflexia, with progression to an ataxic gait, and by decreased vibration and position sensations. Ophthalmoplegia, skeletal myopathy, and pigmented retinopathy may also be features of vitamin E deficiency. A deficiency of either vitamin E or selenium in the host has been shown to increase certain viral mutations and, therefore, virulence. The laboratory diagnosis of vitamin E deficiency is based on low blood levels of α-tocopherol (<5 μg/mL, or <0.8 mg of α-tocopherol per gram of total lipids).

TREATMENT

Vitamin E Deficiency

Symptomatic vitamin E deficiency should be treated with 800–1200 mg of α-tocopherol per day. Patients with abetalipoproteinemia may need as much as 5000–7000 mg/d. Children with symptomatic vitamin E deficiency should be treated orally with water-miscible esters (400 mg/d); alternatively, 2 mg/kg per d may be administered intramuscularly. Vitamin E in high doses may protect against oxygen-induced retrolental fibroplasia and bronchopulmonary dysplasia as well as intraventricular hemorrhage of prematurity. Vitamin E has been suggested to increase sexual performance, treat intermittent claudication, and slow the aging process, but convincing evidence for these properties is lacking. When given in combination with other antioxidants, vitamin E may help prevent macular degeneration. Vitamin E may have favorable therapeutic effects in noncirrhotic nondiabetic patients with nonalcoholic steatohepatitis. High doses (60–800 mg/d) of vitamin E have been shown in controlled trials to improve parameters of immune function and reduce colds in nursing home residents, but intervention studies using vitamin E to prevent cardiovascular disease or cancer have not shown efficacy, and at doses >400 mg/d, vitamin E may even increase all-cause mortality rates and prostate cancer risk (especially in combination with selenium supplements).

Toxicity All forms of vitamin E are absorbed and could contribute to toxicity; however, the toxicity risk seems to be rather low as long as liver function is normal. High doses of vitamin E (>800 mg/d) may reduce platelet aggregation and interfere with vitamin K metabolism and are therefore contraindicated in patients taking warfarin and antiplatelet agents (such as aspirin or clopidogrel). Nausea, flatulence, and diarrhea have been reported at doses >1 g/d.

VITAMIN K

There are two natural forms of vitamin K: vitamin K_1, also known as *phylloquinone*, from vegetable sources, and vitamin K_2, or *menaquinones*, which are synthesized by bacterial flora and found in hepatic tissue. Phylloquinone can be converted to menaquinone in some organs.

Vitamin K is required for the posttranslational carboxylation of glutamic acid, which is necessary for calcium binding to γ-carboxylated proteins such as prothrombin (factor II); factors VII, IX, and X; protein C; protein S; and proteins found in bone (osteocalcin) and vascular smooth muscle (e.g., matrix Gla protein). However, the importance of vitamin K for bone mineralization and prevention of vascular calcification in different patient groups (including chronic kidney disease) is unclear. Warfarin-type drugs inhibit γ-carboxylation by preventing the conversion of vitamin K to its active hydroquinone form.

Dietary Sources Vitamin K is found in green leafy vegetables such as kale and spinach, and appreciable amounts are also present in margarine and liver. Vitamin K is present in vegetable oils; olive, canola, and soybean oils are particularly rich sources. The average daily intake by Americans is estimated to be ~100 μg/d.

Deficiency The symptoms of vitamin K deficiency are due to hemorrhage; newborns are particularly susceptible because of low fat stores, low breast milk levels of vitamin K, relative sterility of the infantile intestinal tract, liver immaturity, and poor placental transport. Intracranial bleeding as well as gastrointestinal and skin bleeding can occur in vitamin K–deficient infants 1–7 days after birth. Thus, vitamin K (0.5–1 mg IM) is given prophylactically at delivery.

Vitamin K deficiency in adults may be seen in patients with chronic small-intestinal disease (e.g., celiac disease, Crohn's disease), in those with obstructed biliary tracts, or after small-bowel resection. Broad-spectrum antibiotic treatment can precipitate vitamin K deficiency by reducing numbers of gut bacteria, which synthesize menaquinones, and by inhibiting the metabolism of vitamin K. In patients with warfarin therapy, the antiobesity drug orlistat can lead to changes in international normalized ratio due to vitamin K malabsorption. The assessment of the vitamin K status can be done by measurement of phylloquinone (vitamin K_1) concentration in serum (deficiency <0.15 μg/L); the cellular utilization of vitamin K can be assessed by the serum or plasma concentration of undercarboxylated prothrombin (protein induced by vitamin K absence/antagonism [PIVKA-II]). An elevated prothrombin time or activated partial thromboplastin time or reduced clotting factors are useful markers in severe deficiency but are otherwise nonspecific and lack sensitivity. Vitamin K deficiency is treated with a parenteral dose of 10 mg. For patients with chronic malabsorption, 1–2 mg/d should be given orally or 1–2 mg per week can be taken parenterally. Patients with liver disease may have an elevated prothrombin time because of liver cell destruction as well as vitamin K deficiency. If an elevated prothrombin time does not improve during vitamin K therapy, it can be deduced that this abnormality is not the result of vitamin K deficiency.

Toxicity Toxicity from dietary phylloquinones and menaquinones has not been described. High doses of vitamin K can impair the actions of oral vitamin K antagonist anticoagulants.

MINERALS

See also Table 344-2.

CALCIUM

See Chap. 421.

TABLE 344-2 Deficiencies and Toxicities of Metals

ELEMENT	DEFICIENCY	TOXICITY	TOLERABLE UPPER (DIETARY) INTAKE LEVEL
Boron	No biologic function determined	Developmental defects, male sterility, testicular atrophy	20 mg/d (extrapolated from animal data)
Calcium	Reduced bone mass, osteoporosis	Renal insufficiency (milk-alkali syndrome), nephrolithiasis, impaired iron absorption, thiazide diuretics	2500 mg/d (milk-alkali)
Copper	Anemia, growth retardation, defective keratinization and pigmentation of hair, hypothermia, degenerative changes in aortic elastin, osteopenia, mental deterioration	Nausea, vomiting, diarrhea, hepatic failure, tremor, mental deterioration, hemolytic anemia, renal dysfunction	10 mg/d (liver toxicity)
Chromium	Impaired glucose tolerance	*Occupational:* Renal failure, dermatitis, pulmonary cancer	Not determined
Fluoride	↑ Dental caries	Dental and skeletal fluorosis, osteosclerosis	10 mg/d (fluorosis)
Iodine	Thyroid enlargement, ↓ T_4, cretinism	Thyroid dysfunction, acne-like eruptions	1100 µg/d (thyroid dysfunction)
Iron	Muscle abnormalities, koilonychia, pica, anemia, ↓ work performance, impaired cognitive development, premature labor, ↑ perinatal maternal death	Gastrointestinal effects (nausea, vomiting, diarrhea, constipation), iron overload with organ damage, acute and chronic systemic toxicity, increased susceptibility to malaria, increased risk association with certain chronic diseases (e.g., diabetes)	45 mg/d of elemental iron (gastrointestinal side effects)
Manganese	Impaired growth and skeletal development, reproduction, lipid and carbohydrate metabolism; upper body rash	*General:* Neurotoxicity, Parkinson-like symptoms *Occupational:* Encephalitis-like syndrome, Parkinson-like syndrome, psychosis, pneumoconiosis	11 mg/d (neurotoxicity)
Molybdenum	Severe neurologic abnormalities	Reproductive and fetal abnormalities	2 mg/d (extrapolated from animal data)
Selenium	Cardiomyopathy, heart failure, striated muscle degeneration	*General:* Alopecia, nausea, vomiting, abnormal nails, emotional lability, peripheral neuropathy, lassitude, garlic odor to breath, dermatitis *Occupational:* Lung and nasal carcinomas, liver necrosis, pulmonary inflammation	400 µg/d (hair, nail changes)
Phosphorus	Rickets (osteomalacia), proximal muscle weakness, rhabdomyolysis, paresthesia, ataxia, seizure, confusion, heart failure, hemolysis, acidosis	Hyperphosphatemia	4000 mg/d
Zinc	Growth retardation, ↓ taste and smell, alopecia, dermatitis, diarrhea, immune dysfunction, failure to thrive, gonadal atrophy, congenital malformations	*General:* Reduced copper absorption, gastritis, sweating, fever, nausea, vomiting *Occupational:* Respiratory distress, pulmonary fibrosis	40 mg/d (impaired copper metabolism)

ZINC

Zinc is an integral component of many metalloenzymes in the body; it is involved in the synthesis and stabilization of proteins, DNA, and RNA and plays a structural role in ribosomes and membranes. Zinc is necessary for the binding of steroid hormone receptors and several other transcription factors to DNA. Zinc is essential for normal spermatogenesis, fetal growth, and embryonic development.

Absorption The absorption of zinc from the diet is inhibited by dietary phytate, fiber, oxalate, iron, and copper as well as by certain drugs, including penicillamine, sodium valproate, and ethambutol. Protein-containing foods, i.e., meat, shellfish, nuts, and legumes, are good sources of bioavailable zinc, whereas zinc in grains and legumes is less available for absorption. Grains and legumes contain phytate that binds zinc in the intestine and reduces its availability for absorption.

Deficiency Mild zinc deficiency has been described in many diseases, including diabetes mellitus, HIV/AIDS, cirrhosis, alcoholism, inflammatory bowel disease, malabsorption syndromes, and sickle cell disease. In these diseases, mild chronic zinc deficiency can cause stunted growth in children, decreased taste sensation (*hypogeusia*), and impaired immune function. Severe chronic zinc deficiency has been described as a cause of hypogonadism and dwarfism in several Middle Eastern countries. In these children, hypopigmented hair is also part of the syndrome. Acrodermatitis enteropathica is a rare autosomal recessive disorder characterized by abnormalities in zinc absorption. Clinical manifestations include diarrhea, alopecia, muscle wasting, depression, irritability, and a rash involving the extremities, face, and perineum. The rash is characterized by vesicular and pustular crusting with scaling and erythema. Occasional patients with Wilson's disease have developed zinc deficiency as a consequence of penicillamine therapy (Chap. 427).

Zinc deficiency is prevalent in many developing countries and usually coexists with other micronutrient deficiencies (especially iron deficiency). Zinc (20 mg/d until recovery) may be an effective adjunctive therapeutic strategy for diarrheal disease and pneumonia in children ≥6 months of age.

The diagnosis of zinc deficiency is usually based on a serum zinc level <12 µmol/L (<70 µg/dL). Pregnancy and birth control pills may cause a slight depression in serum zinc levels, and hypoalbuminemia from any cause can result in hypozincemia. In acute stress situations (illness, but also postexercise recovery), zinc may be redistributed from serum into tissues. Zinc deficiency may be treated with 60 mg of elemental zinc taken by mouth twice a day. Zinc gluconate lozenges (13 mg of elemental zinc every 2 h while awake) have been reported to reduce the duration and symptoms of the common cold in adults, but study results are conflicting.

Toxicity Acute zinc toxicity after oral ingestion causes nausea, vomiting, and fever. Zinc fumes from welding may also be toxic and cause fever, respiratory distress, excessive salivation, sweating, and headache. Chronic large doses of zinc (ranging from 150 to 450 mg/d) may depress immune function and cause hypochromic anemia as a result of a secondary copper deficiency. Intranasal zinc preparations should be avoided because they may lead to irreversible damage of the nasal mucosa and anosmia.

COPPER

Copper is an integral part of numerous enzyme systems, including amine oxidases, ferroxidase (ceruloplasmin), cytochrome c oxidase, superoxide dismutase, and dopamine hydroxylase. Copper is also a component of ferroprotein, a transport protein involved in the basolateral transfer of iron during absorption from the enterocyte. As such,

copper plays a role in iron metabolism, melanin synthesis, energy production, neurotransmitter synthesis, and CNS function; the synthesis and cross-linking of elastin and collagen; and the scavenging of superoxide radicals. Dietary sources of copper include shellfish, liver, nuts, legumes, bran, and organ meats.

Deficiency Dietary copper deficiency is relatively rare, although it has been described in premature infants who are fed milk diets and in infants with malabsorption (Table 344-2). Copper-deficiency anemia (refractory to therapeutic iron) has been reported in patients with malabsorptive diseases and nephrotic syndrome and in patients treated for Wilson's disease with chronic high doses of oral zinc, which can interfere with copper absorption. *Menkes kinky hair syndrome* is an X-linked metabolic disturbance of copper metabolism characterized by intellectual disability, hypocupremia, and decreased circulating ceruloplasmin **(Chap. 425)**. This syndrome is caused by mutations in the copper-transporting *ATP7A* gene. Children with this disease often die within 5 years because of dissecting aneurysms or cardiac rupture. Aceruloplasminemia is a rare autosomal recessive disease characterized by tissue iron overload, mental deterioration, microcytic anemia, and low serum iron and copper concentrations.

The diagnosis of copper deficiency is usually based on low serum levels of copper (<65 μg/dL) and low ceruloplasmin levels (<20 mg/dL). Serum levels of copper may be elevated in pregnancy or stress conditions since ceruloplasmin is an acute-phase reactant and 90% of circulating copper is bound to ceruloplasmin. It has been suggested that mild or subclinical copper deficiency is more common than expected; at-risk individuals include patients with cholestasis or chronic diarrheal diseases, dialysis patients, and people on long-term zinc supplements. The role of copper in cardiovascular disease, immune function, bone health, or neurodegenerative diseases is still unclear.

Toxicity Copper toxicity is usually accidental (Table 344-2). In severe cases, kidney failure, liver failure, and coma may ensue. In Wilson's disease, mutations in the copper-transporting *ATP7B* gene lead to accumulation of copper in the liver and brain, with low blood levels due to decreased ceruloplasmin **(Chap. 427)**. A potential negative role of copper in the pathogenesis of Alzheimer's disease has been reported.

SELENIUM

Selenium, in the form of selenocysteine, is a component of the enzyme glutathione peroxidase, which serves to protect proteins, cell membranes, lipids, and nucleic acids from oxidant molecules. As such, selenium is being actively studied as a chemopreventive agent against certain cancers, such as prostate cancer. However, it remains unclear whether selenium is effective as a chemopreventive agent or whether it increases cancer risk (e.g., prostate cancer). Convincing evidence for a protective effect of selenium on cognitive decline or cardiovascular disease risk is presently lacking. Selenocysteine is also found in the deiodinase enzymes, which mediate the deiodination of thyroxine to triiodothyronine **(Chap. 394)**. Rich dietary sources of selenium include seafood, muscle meat, and cereals, although the selenium content of cereal is determined by the soil concentration. Countries with low soil concentrations include parts of Scandinavia, China, and New Zealand. *Keshan disease* is an endemic cardiomyopathy found in children and young women residing in regions of China where dietary intake of selenium is low (<20 μg/d). Concomitant deficiencies of iodine and selenium may worsen the clinical manifestations of cretinism. Chronic ingestion of large amounts of selenium leads to selenosis, characterized by hair and nail brittleness and loss, garlic breath odor, skin rash, myopathy, irritability, and other abnormalities of the nervous system.

CHROMIUM

Chromium potentiates the action of insulin in patients with impaired glucose tolerance, presumably by increasing insulin receptor–mediated signaling, although its usefulness in treating type 2 diabetes is uncertain. In addition, improvement in blood lipid profiles has been reported in some patients. The usefulness of chromium supplements in muscle building has not been substantiated. Rich food sources of chromium include yeast, meat, and grain products. Chromium in the trivalent state is found in supplements and is largely nontoxic; however, chromium-6 is a product of stainless steel welding and is a known pulmonary carcinogen as well as a cause of liver, kidney, and CNS damage.

MAGNESIUM

See Chap. 421.

FLUORIDE, MANGANESE, AND ULTRATRACE ELEMENTS

An essential function for fluoride in humans has not been described, although it is useful for the maintenance of structure in teeth and bones. Adult fluorosis results in mottled and pitted defects in tooth enamel as well as brittle bone (skeletal fluorosis).

Manganese and molybdenum deficiencies have been reported in patients with rare genetic abnormalities and in a few patients receiving prolonged total parenteral nutrition. Several manganese-specific enzymes have been identified (e.g., manganese superoxide dismutase). Deficiencies of manganese have been reported to result in bone demineralization, poor growth, ataxia, disturbances in carbohydrate and lipid metabolism, and convulsions.

Ultratrace elements are defined as those needed in amounts <1 mg/d. Essentiality has not been established for most ultratrace elements, although selenium, chromium, and iodine are clearly essential **(Chap. 394)**. Molybdenum is necessary for the activity of sulfite and xanthine oxidase, and molybdenum deficiency may result in skeletal and brain lesions.

345 Malnutrition and Nutritional Assessment

Charles Chin Han Lew, Charlene W. Compher

Malnutrition occurs in 30–50% of hospitalized patients depending on the setting, the patient's diagnosis, and the criteria that are used to diagnose malnutrition. Notable adverse outcomes associated with malnutrition include poor wound healing, compromised immune status, and impaired organ function. These can lead to increased length of hospital stay, readmissions, higher mortality, and increased health care costs. It is now widely appreciated that acute or chronic inflammation

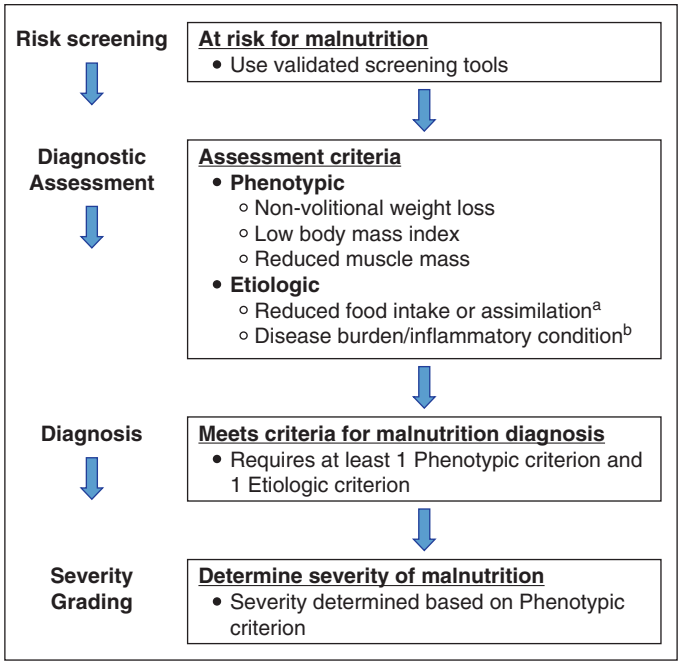

FIGURE 345-1 Global Leadership Initiative on Malnutrition (GLIM) diagnostic scheme for screening, assessment, diagnosis, and grading of malnutrition. [a]≤50% of energy requirement >1 week, or any reduction for >2 weeks, or any chronic gastrointestinal condition that adversely impacts food assimilation or absorption. [b]Acute disease/injury (e.g., major infection, burns, trauma or closed head injury) or chronic disease (e.g., malignant disease, chronic obstructive pulmonary disease, congestive heart failure, chronic renal disease or any disease with chronic or recurrent inflammation) or C-reactive protein may be used as a supportive laboratory measure (mild inflammation: 3.0-9.9 mg/L, moderate inflammation: 10-50 mg/L, severe inflammation: >50 mg/L). *(Reproduced with permission from Jensen GL et al: GLIM criteria for the diagnosis of malnutrition: A consensus report from the global clinical nutrition community. JPEN J Parenter Enteral Nutr 43:32, 2019, Figure 1.)*

contributes to the pathophysiology of malnutrition. The presence of inflammation can also render historic nutrition parameters, like albumin and prealbumin, unreliable. In patients with high levels of inflammation, nutrition care is supportive. At moderate or low levels of inflammation, nutrition care may be therapeutic in reducing the nutritional deficits and improving clinical outcomes.

MALNUTRITION DIAGNOSIS IN CLINICAL SETTINGS

Several tools have been used to diagnose malnutrition, such as the Subjective Global Assessment, Mini Nutrition Assessment, and the Academy of Nutrition and Dietetics and American Society for Parenteral and Enteral Nutrition Indicators of Malnutrition. These tools use common parameters such as dietary intake and weight history, muscle and fat loss, body mass index (BMI), and/or physical function to diagnose malnutrition. However, nuances between them lead to incomparable malnutrition prevalence rates in the literature.

In 2019, four international nutrition societies introduced the Global Leadership Initiative on Malnutrition (GLIM) consensus criteria for diagnosing malnutrition in adults **(Fig. 345-1)**. GLIM incorporates broadly available nutrition parameters that are commonly used in other diagnostic tools to enable data from these earlier assessment methods to be described in the GLIM framework. To diagnose malnutrition and its severity, GLIM requires one etiologic criterion (inflammation/disease burden or reduced food intake/assimilation) and one phenotypic criterion (weight loss, low BMI, or reduced muscle mass) **(Table 345-1)**. To facilitate the diagnosis of malnutrition in settings with variable availability and expertise of personnel and equipment across clinical settings, several options are suggested for the phenotypic criterion. The phenotypic criterion is used to define the severity of malnutrition. Recent publications highlight GLIM's widespread adoption in hospitals and clinical settings, showing predictive value for adverse outcomes.

NUTRITION ASSESSMENT FOR PROTEIN-CALORIE MALNUTRITION

The Nutrition Care Process in the hospital setting involves screening for malnutrition risk, comprehensive nutrition assessment of patients at malnutrition risk, development of a nutrition care plan, and monitoring for needed adjustments to the plan. Screening for the risk of malnutrition is typically undertaken by the bedside nurse or by a clinical dietitian using validated tools such as the Malnutrition Screening Tool, Malnutrition Universal Screening Tool, Nutritional Risk Screening 2002, or other in-house tools. A comprehensive nutrition assessment includes a review of medical, surgical, and social history; dietary intake and weight history; medication profile; available laboratory, diagnostic tests, body composition, and anthropometric measures; and nutrition-focused physical examination. The clinical dietitian designs an individualized intervention and monitoring plan for the patient. The nutrition assessment findings and care plan are shared with the physician who may make a malnutrition diagnosis and prescribe the recommended nutrition care plan. The response to nutrition therapy is monitored with adjustments to the care plan as needed. Micronutrient deficiencies of clinical relevance may be detected in association with malnutrition, but a detailed discussion of their assessment is beyond the scope of this chapter **(see Chap. 344)**.

In ambulatory clinic settings, physicians may have less access to dietitian support than in inpatient settings. However, the GLIM criteria are designed to be feasible even in an outpatient setting. Nurses can obtain measures of height and weight (for BMI) and calf or arm circumference to assess muscle mass. A diagnosis of malnutrition can be made in the clinic with referral of the patient to a dietitian for a detailed nutrition assessment and development of a care plan.

COMPONENTS OF A DETAILED NUTRITIONAL ASSESSMENT

Medical/Surgical History and Clinical Diagnosis The risk of malnutrition varies widely across medical/surgical diagnoses and clinical settings. During the early stages of diseases, malnutrition may be less likely than with disease progression. Knowledge of a patient's

TABLE 345-1 Thresholds for Severity Grading of Malnutrition Into Stage 1 (Moderate) and Stage 2 (Severe) Malnutrition

	PHENOTYPIC CRITERIA[a]		
	WEIGHT LOSS (%)	LOW BODY MASS INDEX (kg/m²)[b]	REDUCED MUSCLE MASS[c]
Stage 1/moderate malnutrition (requires 1 phenotypic criterion that meets this grade)	5%–10% within the past 6 months, or 10%–20% beyond 6 months	<20 if <70 years, <22 if ≥70 years	Mild-to-moderate deficit (per validated assessment methods; see below)
Stage 2/severe malnutrition (requires 1 phenotypic criterion that meets this grade)	>10% within the past 6 months, or >20% beyond 6 months	<18.5 if <70 years, <20 if ≥70 years	Severe deficit (per validated assessment methods; see below)

[a]Severity grading is based on the noted phenotypic criteria, whereas the etiologic criteria described in the text and Figure 345-1 are used to provide the context to guide intervention and anticipated outcomes. [b]Further research is needed to secure consensus reference body mass index for Asian populations in clinical settings. [c]For example, appendicular lean mass index (kg/m²) by dual-energy absorptiometry or corresponding standards using other body composition methods such as bioelectrical impedance analysis, computed tomography, or magnetic resonance imaging. When not available or by regional preference, physical examination or standard anthropometric measures such as mid-arm muscle or calf circumferences may be used. Functional assessments such as hand-grip strength may be used as a supportive measure.

medical/surgical history and associated clinical diagnoses is especially helpful in discerning the likelihood of malnutrition and inflammation. Several conditions or diseases are characterized by severe acute inflammatory response (e.g., critical illness), whereas others are more typically associated with a chronic inflammatory response that is mild to moderate in severity (e.g., chronic cardiometabolic, oncologic, or gastrointestinal disease, or organ failure) and may be relapsing and remitting. It is common for acute inflammatory events to be superimposed on patients with chronic conditions; for example, a patient with chronic renal disease may be admitted to the hospital with sepsis, such that the acute increase in inflammation should be time-limited while the chronic inflammation will continue.

The inflammatory milieu, especially when severe, may modify nutrient requirements by elevating resting energy expenditure and promoting anabolic resistance and catabolism in muscle. Inflammation also promotes anorexia, decreases food intake, and further compromises nutritional status. A deteriorating course may result because severe inflammation may reduce the benefit of nutritional interventions to being supportive rather than therapeutic, and the associated malnutrition may diminish the effectiveness of medical therapies.

It is also imperative to recognize medical/surgical conditions that place patients at increased risk of becoming malnourished because they have increased nutritional requirements or compromised intake or assimilation. Chronic gastrointestinal disease, even if relapsing and remitting, may limit nutrient assimilation. Therefore, patients with seemingly adequate oral intake may still be at risk of malnutrition due to compromised nutrient assimilation.

Clinical Signs and Physical Examination Nonspecific clinical indicators of inflammation include fever, hypothermia, and tachycardia. The nutrition-focused physical examination should identify edema as well as physical signs of weight gain/loss. Physical findings of weight loss associated with decreased muscle and subcutaneous fat mass should be noted. If edema is present, an estimation of dry weight may be needed to identify actual weight loss.

Anthropometric Data Nonvolitional weight loss is a well-validated nutrition parameter associated with underlying disease or inflammation. The degree and duration of nonvolitional weight loss determine its clinical significance. A 5–10% loss of body weight over 6 months is clinically relevant, whereas >10% loss over the same duration is severe.

The trend in body weight may be obtained from patients, their family or caregivers, and the medical record. Obtaining body weight at each clinic, emergency department, and hospital visit will support efforts to detect changes in this important parameter. Training staff members to weigh patients consistently without shoes and heavy outer garments and maintaining scales and stadiometers in good calibration facilitate acquisition of trustworthy weight data. Clinical sites may maintain chair or bed scales for patients who cannot stand. Height may be estimated by doubling the arm span measurement from the sternal notch to the end of the longest finger or by measurement of knee height using a caliper.

BMI, defined as weight (kg)/height (m^2), is used primarily to screen for overweight or obesity. The National Institutes of Health/World Health Organization BMI categories for adults are as follows: BMI <18.5 kg/m^2 = underweight, BMI 18.5–24.9 kg/m^2 = desirable, BMI 25.0–29.9 kg/m^2 = overweight, and BMI ≥30 kg/m^2 = obese. Note that patients of any BMI status can be malnourished. Overweight or obese patients can be malnourished due to weight loss or loss of muscle mass (e.g., sarcopenic obesity). Similarly, being underweight does not equate to malnutrition. BMI <18.5 kg/m^2 is infrequent in economically developed countries.

Classical anthropometric measurements such as arm and calf circumference can be helpful. However, measuring the calf circumference may be more accessible as it requires less specialized training in comparison to measuring the arm circumference. Additionally, calf circumference has established cutoff values validated for various BMI ranges and ethnicities. Clinically available body composition measures include bioelectrical impedance analysis (BIA), dual-energy x-ray absorptiometry (DXA), and air displacement plethysmography (Table 345-2). BIA has the advantage of being portable and is used for patients in diverse clinical settings. Abdominal computed tomography (CT) and magnetic resonance imaging (MRI) taken for disease diagnostic purposes can be interpreted to measure muscle mass, though they are not routinely used to aid in the diagnosis of malnutrition.

Laboratory Indicators There is, unfortunately, no biomarker descriptive of comprehensive nutritional status. Laboratory findings (Table 345-2) should be evaluated in combination with other assessment parameters to appropriately diagnose malnutrition. Albumin and prealbumin are often available in patients with suspected malnutrition; however, these measures have poor sensitivity and specificity as indicators of malnutrition. Albumin and prealbumin are negative acute-phase reactants with levels that are reduced by the systemic response to injury, disease, or inflammation. C-reactive protein, a positive acute-phase reactant, may be useful to identify the presence of inflammation, particularly if the clinical context is unclear about the extent of inflammation. Trends in repeated levels of C-reactive protein over time may help to clarify the extent and trajectory of the inflammatory challenge. Research suggests that interleukin 6, and perhaps other cytokines, may offer promise as indicators of inflammatory status. Nonspecific laboratory indicators that are often associated with inflammatory response include leukocytosis and hyperglycemia. Additional tests that may be obtained to help confirm the presence of inflammatory response include 24-h urine urea nitrogen and indirect calorimetry to measure energy expenditure. In the setting of a severe acute systemic inflammatory response, negative nitrogen balance and elevated resting energy expenditure are anticipated.

Diet History Brief diet surveys are available to target specific aspects of the diet, such as food patterns, to prevent disease or track intake of nutrients of key importance such as calcium, vitamin D, and phosphorus for bone disease management. However, more specific information about the adequacy of intake of key nutrients or food patterns relative to estimated requirements is most often obtained by consultation with a clinical dietitian. Since patients often present to health care practitioners with acute medical events superimposed upon chronic health conditions, it is common for patients to have had decreased food intake and progressive malnutrition for extended periods prior to assessment. Therefore, compromised dietary intake must not be overlooked so that appropriate intervention may be undertaken.

Assessment of the adequacy of nutritional intake must include oral nutrition supplements, enteral tube feedings, and parenteral nutrition both during hospitalization and as a component of home nutrition support. Ongoing reassessment of actual intake received by the patient is undertaken in hospital settings, most commonly by the clinical dietitian, the bedside nurse, and the nutrition support team if available. Changes in the adequacy of oral intake, body weight, or tolerance to enteral or parenteral feedings would all require adjustment of the feedings to optimize patient care.

A comprehensive assessment should also include a review of medications, vitamin/mineral supplements, or herbal remedies with attention to undesirable nutrition-sensitive side effects such as anorexia, dysgeusia, oral mucositis, nausea, vomiting, diarrhea, and constipation. Potential drug–nutrient interactions should also be identified to enable alternative therapeutic options.

Functional Outcomes Advanced malnutrition is accompanied by declines in muscle mass and function that can be detected by various functional test outlined in Table 345-2. Among them, handgrip strength may have better clinical utility since it is easily assessed and helps to identify which patients benefit most from individualized nutritional support.

In summary, malnutrition puts patients at risk of adverse outcomes. Therefore, timely diagnosis and treatment of malnutrition should be provided to improve patient outcome. Robust evidence exists demonstrating that a multipronged approach to malnutrition intervention reduces mortality and holds promise to improve the quality of life of patients.

TABLE 345-2 Common Body Composition Studies, Laboratories, and Other Studies Used in Nutrition Assessment

TEST	NOTES
Body Composition Studies (Recommended)	
Air plethysmography	May be used to assess body composition. It comprises a dual-chamber, sealed compartment containing an oscillating diaphragm, which allows it to measure body volume using Poisson's law, and compute fat mass and fat-free mass. However, its validity in a racially diverse population needs further studies, and it is not readily available in most hospitals.
Bioelectrical impedance analysis (BIA)	A promising method to assess body composition as the equipment is easily portable. It uses the opposition of an electrical current through body tissues (i.e., impedance) and population-specific equations to estimate total body water and body composition. BIA equations are highly device and population specific. Fever, some medications, and fluid/electrolyte disturbances can influence its precision and accuracy.
Calf circumference	A practical and valid clinical estimate of skeletal muscle mass, in which low calf circumference indicates muscle loss. Ethnic specific reference ranges are available, and measurements should be adjusted in persons with body mass index different from the normal range (underweight, overweight, or obese). The technique requires less training than mid-upper arm circumference.
Dual energy x-ray absorptiometry (DXA)	May be used to assess regional and total fat mass in a diverse group of adult clinical patients. However, its validity in assessing muscle mass is unclear.
Imaging with computed tomography (CT) or magnetic resonance imaging (MRI)	May be used to quantify fat and fat-free mass when scans are taken for other diagnostic purposes. Both are costly, and CT entails x-ray exposure.
Mid-upper arm circumference	Mid-upper arm circumference is the circumference of the upper arm measured at the midpoint between the olecranon process and the acromion process. It estimates both muscle and subcutaneous fat stores, but references are population specific. Take note that this measurement technique requires reliability training.
Ultrasound	A promising method to assess body composition as the equipment is easily portable. It uses high-frequency sound waves to capture live images of muscle tissues. Since most studies examined a single muscle, it is unclear if results can be extrapolated to reflect overall nutritional status. More research is needed to establish standardization of measurement protocol.
Laboratory Tests and Other Studies (Recommended)	
Complete blood count with differential	May be used to screen for nutritional anemias (iron, B_{12}, and folate deficiencies) and thrombocytopenia (vitamin C and folate deficiencies).
C-reactive protein (CRP)	May be used to confirm systemic inflammation. While inflammation may be associated with malnutrition, CRP lacks specificity as a biomarker for diagnosing malnutrition. Nevertheless, when combined with other nutrition assessment methods, CRP can complement the diagnostic process for malnutrition. In addition, elevated levels may be associated with reduced food intake and a lack of response to nutritional interventions.
Indirect calorimetry	May be used to determine resting energy expenditure (REE) to aid in determining caloric intake goal. Predictive equations that were based on REE measures in specific populations are also used to estimate REE, especially when indirect calorimetry is not available.
Nitrogen balance (NB)	May be used to reflect the degree of catabolism and adequacy of protein replacement delivery in patients with normal renal and liver function. Method requires collection of 24-h urine. Nitrogen balance = (protein delivery [g]/6.25) – (urinary urea nitrogen + 4 insensible losses).
Specific micronutrients	May be used to validate clinical symptoms of micronutrient deficiencies. Exercise caution with interpretation since levels can be influenced by acute illness.
Laboratory Tests and Other Studies (Not Recommended)	
Blood urea nitrogen (BUN), serum creatinine	Not recommended as malnutrition indicators. Although low BUN and serum creatinine may reflect reduced muscle mass, their levels are influenced by factors unrelated to malnutrition (e.g., renal and hepatic insufficiency).
Cholesterol	Not recommended as a malnutrition indicator. While becoming hypocholesterolemic (<120 mg/dL) during hospitalization may be linked to poorer clinical outcomes, insufficient evidence supports its use for diagnosing malnutrition and evaluating nutritional interventions.
Creatinine height index (CHI)	Not recommended as a malnutrition indicator. CHI = (24-h urinary creatinine excretion/ideal urinary creatinine for gender and height) × 100. Although urinary creatinine excretion reflects muscle mass, it can be influenced by renal insufficiency, meat consumption, physical activity, and trauma. Requires accurate 24-h urine collection.
Cytokines	Not recommended as malnutrition indicators. Their cutoff values and role as an indicator of inflammatory status are still being studied.
Electrocardiogram	Not recommended as a malnutrition indicator. Although prolonged QT interval may be present in severely malnourished patients, the former can be influenced by factors unrelated to malnutrition.
Fecal fat test	May be used to validate clinical symptoms of fat malabsorption. It reflects the percentage of dietary fat that the body does not absorb. Requires stool samples collected over 72 h during ingestion of high-fat diet.
Serum proteins (albumin, prealbumin, transferrin, and retinol-binding protein)	Not recommended as a malnutrition indicator. Their levels are influenced by factors other than malnutrition (e.g., systemic inflammation, hepatic and renal insufficiency, protein-losing enteropathies, corticosteroids, hydration, and iron status), reducing their specificity in diagnosing malnutrition and evaluating nutritional interventions. However, they remain valuable for predicting clinical outcomes.
Skin testing—recall antigens	Not recommended as a malnutrition indicator. Although delayed hypersensitivity is associated with malnutrition, the former can be influenced by factors unrelated to malnutrition.
Total lymphocyte count	Not recommended as malnutrition indicator. Low levels are influenced by factors unrelated to malnutrition.
Urine 3-methylhistidine	Not recommended as a malnutrition indicator. Although it reflects muscle mass, its level is influenced by meat intake and poorly reflects changes in body protein stores. Requires accurate 24-h urine collection

(*Continued*)

TABLE 345-2 Common Body Composition Studies, Laboratories, and Other Studies Used in Nutrition Assessment (Continued)	
TEST	**NOTES**
Functional tests (Recommended)	
Clinical Frailty Scale	A tool that measures frailty, which is defined as a state of increased vulnerability to adverse health outcomes due to reduced physiologic reserves. It uses various self-reported factors (e.g., physical mobility, cognitive function, and the ability to perform daily activities) to classify frailty into nine classifications, ranging from very fit (level 1) to severely frail (level 9). Patients who score ≥5 are considered frail.
Sit-to-Stand Test	Assesses lower limb strength, balance control, and functional mobility by measuring the time required for a person to transfer from a seated to a standing position and back to sitting five times.
Handgrip strength	A measure of muscular strength generated by one's forearm muscles to screen for upper body strength. Low grip strength is associated with poorer clinical outcomes. Patients with low grip strength may benefit most from personalized nutritional support.
SARC-F	A screening tool that determines the risk of sarcopenia, which is defined as a progressive and generalized loss of skeletal muscle mass and strength. It uses self-reported deficiencies in strength, walking, rising from a chair, climbing stairs, and experiencing falls to provide a score from 0 to 10, and a score ≥4 is considered at risk of sarcopenia.
6-Meter Walk Test	Assesses walking speed (meter/sec) over a 6-m distance to determine functional mobility, gait, and vestibular function.

346 Enteral and Parenteral Nutrition

L. John Hoffer, Bruce R. Bistrian

There are three kinds of specialized nutritional support (SNS): (1) optimized voluntary nutritional support, which is indicated when a patient's barriers to adequate nutrition can be overcome by special attention to the details of how their food is constituted, prepared, and served and its consumption optimized; (2) instrumental enteral nutrition (EN), in which a liquid nutrient formula is delivered through a tube placed in the stomach or small intestine; and (3) parenteral nutrition (PN), in which a nutritionally complete mixture of crystalline amino acids, glucose, lipid emulsions, minerals, electrolytes, and micronutrients is infused directly into the bloodstream.

When does a hospitalized adult patient need SNS, and when it's indicated, how should it be provided? This chapter summarizes the physiologic principles that guide the correct use of SNS and offers practical information about the diagnosis and management of nutritional disorders in adult hospitalized patients.

The management of in-hospital nutritional disorders follows three steps: (1) screening and diagnosis; (2) determination of the severity and urgency of treating a diagnosed nutritional disorder in its overall clinical context; and (3) selection of the kind of SNS to provide, its composition, and the details of providing it. To follow these steps properly, physicians require a general understanding of nutritional physiology, nutrient requirements, the pathophysiology and diagnosis of the nutritional disorders, and familiarity with the indications, advantages, risks, and administration of the different kinds of SNS. Because most physicians lack formal clinical nutrition training, they should, in general, collaborate with clinical dietitians and specialized pharmacists in this process.

NUTRITIONAL PHYSIOLOGY

(See Chaps. 343–345.)

Energy The total daily energy expenditure of a healthy sedentary adult is ~36 kcal/kg. Resting energy expenditure accounts for ~75% of this total. Resting energy expenditure can be measured by indirect calorimetry or estimated using a variety of predictive equations that input weight, height, age, sex, and sometimes, disease-related factors. Fever and some diseases increase resting energy expenditure; prolonged semi-starvation triggers an adaptive reduction in resting and total energy expenditure. Total energy expenditure determines how much dietary energy must be consumed to maintain an existing store of body fat and protein. The amount of energy a patient actually *requires* may be less than their total energy expenditure, as in obesity therapy or during temporary periods of exogenous energy intolerance, or greater than total energy expenditure during recovery from starvation disease.

Protein and Amino Acids Dietary protein provides the 23 essential and nonessential amino acids required for protein synthesis. Protein must be consumed throughout life, because endogenous protein turnover entails a minimum obligatory rate of amino acid catabolism. Amino acid catabolism is regulated, appropriately increasing and decreasing in response to variations in protein intake, but it cannot fall below a certain minimum rate—the "protein minimum"—that determines an individual's minimum dietary protein requirement. The average daily minimum protein requirement for a healthy adult consuming an otherwise adequate diet is 0.65 g/kg; the "safe" or "recommended" intake is 0.80 g/kg. Average protein consumption in wealthy societies is approximately twice the average minimum requirement.

Energy balance affects the minimum protein requirement. Positive energy balance, when achieved by greater carbohydrate consumption,

can improve body protein retention. Negative energy balance, such as during therapeutic weight reduction, reduces the efficiency of protein turnover and increases the dietary protein requirement. Some diseases (or their treatments) increase the protein requirement, by (1) increasing amino acid loss from the body (as in malabsorption and protein loss via wound exudates, fistulas, or inflammatory diarrhea), removing amino acids from the circulation (renal replacement therapy), or (2) increased muscle protein catabolism, which occurs as an adverse effect of high-dose glucocorticoid therapy and, most commonly, as part of the metabolic response to the systemic inflammation that accompanies major injury, serious infections, and intense immune system activation. A highly protein-catabolic patient may excrete 15 g N (nitrogen)/d or more in their urine in the absence of dietary protein provision: this is more than three times faster than occurs with simple fasting. Since 1 g N lost from the body reflects the loss of 6.25 g formed protein, 15 g N loss/d implies the loss of 15 × 6.25 = 94 g protein per day. Since the body's hydrated metabolically active tissue mass (also called body cell mass) is ~20% protein, one may calculate that 94 g protein loss/d indicates a loss from the body of ~470 g (1 lb) of active tissue mass per day. Sufficiently generous protein provision can mitigate this kind of active tissue loss. The extent to which protein-catabolic disease increases the protein requirement is debated, but a common recommendation for critically ill patients is 1.2–2.0 g protein/kg of normal body weight per day—close to the habitual protein intake of healthy people in wealthy societies.

Protein-Energy Interactions Both energy deficiency and systemic inflammation increase the dietary protein requirement; how do these factors interact? The loss of body protein caused by energy deficiency can be prevented or minimized by increased protein consumption. Systemic inflammation reduces the benefit of increased protein provision under hypocaloric conditions but does not eliminate it. Some evidence suggests that a minimum energy dose, such as 50% of total energy expenditure, may help preserve the active tissue store during severe systemic inflammation. It is clear, however, that energy doses >70% of total energy expenditure do not have any greater protein-sparing effect, and the additional amounts of glucose and fluid volume required to deliver them can have adverse effects that include hyperglycemia, dyslipidemia, and extracellular volume expansion.

Permissive Underfeeding and Hypocaloric Nutrition These terms have different meanings, and they should not be conflated. Permissive underfeeding refers to the deliberate underprovision of all nutrients including protein, whereas hypocaloric nutrition refers to reduced energy provision combined with increased protein to compensate for the known protein-wasting effect of negative energy balance.

Micronutrients Minimum amounts of the nine water-soluble vitamins (the B vitamins and vitamin C), four fat-soluble vitamins (A, D, E, and K), eight minerals (calcium, phosphorus, potassium, sodium, chloride, magnesium, zinc, and iron), essential fatty acids, and several essential trace elements are required to avoid deficiency diseases. Overt deficiencies of potassium, sodium, magnesium, and phosphorus are so common in hospitalized patients that it is standard practice to monitor for and correct them. Some drugs cause renal potassium, magnesium, or zinc losses that require increased provision. Gastrointestinal losses from nasogastric drainage tubes or intestinal losses from fistulas or diarrhea incur losses of potassium, sodium, calcium, magnesium, and zinc.

Less investigated, but common, are subclinical deficiencies of zinc, vitamin C, vitamin D, and possibly other micronutrients. Physicians often assume that consumption of a regular hospital diet protects patients from micronutrient deficiencies. This assumption is unwarranted when the patient's nutritional status is deficient upon admission and remains so during their hospital stay.

Systemic inflammation can complicate the clinical laboratory evaluation of micronutrient status. It increases the requirements for certain micronutrients, partially redistributing them from the extracellular compartment into tissue stores, as occurs with iron, selenium, zinc, and perhaps other nutrients. This effect reduces the reliability of many standard laboratory tests of micronutrient status. The evaluation of a patient's micronutrient status should begin with a determination of their previous and current intake and health status, including the identification of potential routes of excessive micronutrient loss. In acute-care clinical settings, the intensity of systemic inflammation should be determined using clinical criteria and by measuring serum concentrations of albumin or C-reactive protein, an acute-phase protein whose wide dynamic range and short half-life make it particularly useful in this situation,

MACRONUTRIENT MALNUTRITION SYNDROMES

The decision to embark on SNS must be justified by a well-formulated nutritional diagnosis and a clearly defined therapeutic goal. This chapter focuses on the diagnosis, treatment, and prevention of in-hospital adult starvation-related malnutrition (SRM) and two related conditions: chronic disease–related malnutrition (CDM) and acute disease–related malnutrition (ADM). As explained in **Chap. 345**, SRM is the disease brought about by prolonged semi-starvation. Synonyms for this disease are "starvation-induced protein-energy malnutrition" and "starvation disease." CDM can be understood as SRM (simple starvation disease) that is combined and compounded by moderately severe systemic inflammation. SRM and CDM are anatomically similar but etiologically and metabolically different, as elaborated upon below. ADM refers to an injury-induced metabolic condition that creates a high risk of severe body protein deficiency, rather than to an already-existing anatomic starvation disease.

Starvation-Related Malnutrition The pathologic features that make SRM a disease, and distinguish it from the semi-starvation that precedes it, emerge when the patient's active tissue mass has been depleted enough to impair specific physiologic functions.

The body normally adapts to sustained inadequate energy provision by reducing energy expenditure and net protein catabolism, partly through hormone- and nervous system–regulated alterations in cellular metabolism, but mostly from loss of muscle, which is the major generator of energy expenditure. (Visceral organ mass and function have a higher priority for protection during starvation.) These adaptations permit prolonged survival, although at a cost that includes muscle loss (including cardiac and respiratory muscle), skin thinning, lethargy, a tendency to hypothermia, and functional disability. The cardinal anatomic features of SRM—generalized muscle loss and subcutaneous adipose tissue depletion—are easy to detect by simple physical examination.

SRM always manifests as weight loss, but weight loss alone may not reveal its full severity. Semistarvation increases the extracellular fluid (ECF) volume, sometimes seriously enough to cause edema. Starvation-associated edema may occur even in the absence of its known common causes (it is termed "starvation edema"). In adults with initially normal body composition, starvation-induced weight loss linearly tracks the loss of active tissue mass; this occurs because the weight loss caused by the depletion of adipose tissue is counterbalanced by increased ECF volume. A 25% reduction in body weight (and active tissue mass) significantly compromises physiologic function; a 50% reduction places otherwise uncompromised young adults on the cusp of thermodynamic survival; older people with comorbidities are at even greater risk. People with SRM are frail, feel unwell, lack strength and emotional range, and are at risk of hypothermia.

The main cause of SRM worldwide is involuntary food deprivation. Its causes in hospitalized patients are many: inadvertent or physician-ordered food deprivation; psychological depression or distress; anorexia nervosa; poorly controlled pain or nausea; badly presented unappealing food; communication barriers; physical or sensory disability; dysphagia and other mechanical difficulties ingesting food; partial obstruction of the esophagus, stomach, or intestines; thrush; intestinal angina; and most commonly, combinations of these causes.

Chronic Disease–Related Malnutrition and Cachexia These terms refer to SRM combined with and complicated by chronic systemic inflammation. CDM is common among patients suffering from chronic infection; inflammatory autoimmune disease; chronic severe

hepatic, renal, cardiac, or pulmonary disease; and neoplastic diseases that induce a systemic inflammatory response or cause tissue injury. CDM induces anorexia—a strong disinclination to eat even when there is no physical barrier to it—and is worsened by it. Its features include muscle loss, weakness, fatigue, and impaired adaption to starvation, all of which contribute to a vicious cycle of worsening starvation disease. Fortunately, the nutritional deficit on the input side of this equation (anorexia-driven inadequate food consumption) is usually the strongest driver of the patient's CDM, making it amenable to a well-organized nutritional intervention while an effective treatment plan for the primary disease is identified and implemented.

Cachexia is an older term now used with varying meanings. It generally refers to a metabolic syndrome of moderate systemic inflammation, unrelenting generalized muscle loss, and their associated symptoms, including anorexia, fatigue, frailty, and mood disturbance. For the purpose of this chapter, it may be considered as roughly synonymous with CDM.

Acute Disease–Related Malnutrition Other terms for ADM are "injury-induced malnutrition" and "protein-catabolic critical illness." The metabolic-inflammatory response to severe tissue injury and sepsis mobilizes muscle amino acids and leads to rapid and severe generalized muscle loss and increased resting energy expenditure under conditions in which voluntary food intake is usually impossible. SRM or CDM may be absent at the onset of a patient's critical illness, but muscle loss will rapidly develop unless the inciting medical or surgical disease is rapidly and effectively treated and SNS provided. Death from simple starvation of nonobese adults typically occurs within ~8 weeks, whereas death from untreated starvation in patients with sustained ADM will occur much sooner.

NUTRITIONAL DIAGNOSIS

The cardinal anatomic features of starvation disease (either SRM or CDM) are generalized muscle loss and diminished body fat. Routine physical examination will immediately reveal these features, but, perhaps surprisingly, what ought to be an easy diagnosis is often overlooked. This section explains the details and pitfalls of diagnosing SRM and CDM.

Muscle Mass Muscle tissue normally accounts for ~80% of an adult's active tissue mass. It is easy to detect loss of muscle mass, and its severity is determinable almost at a glance. But generalized muscle loss has many causes: (1) old age–related muscle loss (sarcopenia); (2) disuse muscle atrophy; (3) high-dose glucocorticoid therapy and certain endocrine diseases (uncontrolled diabetes mellitus, adrenocortical insufficiency, hyperthyroidism, androgen deficiency, hypopituitarism); and (4) primary muscle or neuromuscular diseases. The guiding principle is that SRM and CDM are very common treatable causes of muscle loss. Whenever generalized muscle loss is identified, its potential causes should be considered and the treatable ones addressed. Old age is irreversible, but adequate protein and energy provision, combined with physical rehabilitation, can be lifesaving.

Generalized muscle loss of any cause is especially dangerous in ADM, because the combination of ADM and preexisting muscle loss places patients at the cliff edge of lethal depletion of their active tissue store. A diminished muscle mass is less able to release adequate amounts of amino acids into the circulation for protein synthesis at sites of tissue injury and healing and to the central protein pool to regulate the immunoinflammatory response.

Subcutaneous Adipose Tissue Severe adipose tissue depletion almost always indicates starvation disease, but it is not required to make the diagnosis. The current obesity epidemic has created a population of obese patients with SRM or CDM in whom muscle loss has outpaced fat loss. A conscientious physical examination will easily identify the patient's diminished muscle mass beneath their residual subcutaneous fat.

ECF Volume The ECF compartment normally represents ~20% of body weight. SRM moderately increases ECF volume. CDM is associated with additional edema-promoting conditions, especially the hypoalbuminemia associated with systemic inflammation. The effect of increased ECF volume to increase body weight and distort physical appearance should be borne in mind, for it may conceal the severity of muscle loss.

Body Mass Index Body mass index (BMI) is defined as body weight (kg) divided by the square of height (m^2). The normal reference range is 20–25 kg/m^2. BMI <19–20 usually indicates nonpathologically reduced muscle and fat mass. BMI <15 indicates severe starvation disease, and BMI <13 is usually thermodynamically incompatible with life, especially in older patients with comorbidities. Some guidelines and clinical trial enrollment criteria have defined what they term as "malnutrition"—meant as starvation disease—as a BMI <16 or 17. But it is wrong to rely on BMI as the sole basis for diagnosing starvation disease. A BMI <17 certainly implies starvation disease, for the body composition required for such a BMI can only develop by jettisoning a large fraction of the body's active tissue and adipose tissue store. But a BMI >17 does not rule out starvation disease. Many patients with starvation disease have a normal or above-normal BMI, despite important muscle loss, because of residual obesity or an expanded ECF volume.

Visual BMI With some practice, clinicians can learn to accurately predict the BMI of nonobese, nonedematous patients by systematically examining their muscle groups. This skill enables them to evaluate the severity of starvation disease even in obese or edematous patients—for whom measured BMI is unreliable—simply by evaluating their muscle groups while consciously discounting their subcutaneous fat and edema. Visual BMI can be used to estimate a patient's "normalized dry body weight"—what their body weight would be without obesity, edema, or ascites. For example, the normalized dry body weight of a 1.75-m adult with a visual BMI of 17 is $1.75^2 \times 17 = 52$ kg.

Laboratory and Technical Assessment Clinical laboratory measurements have three main purposes in the evaluation and management of starvation disease.

MUSCLE MASS Bedside ultrasound is proving to be a valuable technique for quantifying muscle mass at specific body sites. However, it need not and should not replace the immediate information provided by the eyes, hands, and mind of an astute clinician.

SYSTEMIC INFLAMMATION The absence or presence of systemic inflammation is what fundamentally distinguishes SRM from CDM. The most useful laboratory indicators of systemic inflammation are a reduced serum albumin concentration and increased serum C-reactive protein concentration. Systemic inflammation increases the permeability of capillary walls to large molecules, and the resulting osmotic shift increases ECF volume. As intravascular albumin redistributes in this larger volume, its serum concentration decreases. Variably increased albumin catabolism and reduced liver albumin synthesis also contribute. Dietary protein deficiency and muscle loss perpetuate inflammation-induced hypoalbuminemia, because the amino acids required for hepatic albumin synthesis come from the diet and endogenous muscle protein.

Hypoalbuminemia and a reduced serum prealbumin concentration are often considered as indicators of "malnutrition." This is incorrect. These serum proteins are negative acute-phase reactants that indicate the presence of systemic inflammation. Systemic inflammation induces anorexia and increases muscle catabolism, effects that increase the risk of CDM, but the disease itself may or not exist at the time, and it may never develop. Serum acute-phase reactants will remain abnormal as long as systemic inflammation persists. Appropriate nutrition can mildly improve serum albumin concentration, but it will not fully normalize until after the systemic inflammation subsides. Even then, full normalization may require several weeks because of albumin's serum half-life of at least 2 weeks.

PROTEIN-CATABOLIC INTENSITY The defining feature of protein-catabolic disease is generalized muscle loss. Situations of greatly increased protein loss can be identified by measuring body N loss. Most N leaves the body in the urine (almost all of it in urea, ammonium, and creatinine). Total N is not usually measured in hospital

laboratories, but urinary urea N (which normally accounts for ~85% of urinary N) can be measured and is routinely available. A recent, validated formula estimates daily total N loss as follows: N loss (g) = g N in urinary urea/0.85 + 2.

Net muscle protein catabolism follows approximately first-order kinetics; this means that the rate of N loss from muscle is proportional to the amount of N available to be lost. Protein-catabolic muscle-depleted patients will lose less body N per day than equally catabolic patients with a preserved muscle store, but they are at greater risk of succumbing to their disease because they are closer to lethal depletion. Rate of N loss always has to be interpreted in the context of existing muscle mass.

Instrumental Nutritional Assessment Many nutritional assessment instruments claim to identify "malnutrition" by enumerating and summing a list of risk factors, laboratory results, and physical findings. These tools are often hindered by ambiguity about their definition of malnutrition and by failure to distinguish between screening and diagnosis. Correct clinical diagnosis is the identification of a known pathologic entity—SRM or CDM, for example—by considering the patient's medical history, pertinent findings on physical examination, and laboratory or imaging reports. Diagnosis also involves an estimation of the probability that the diagnosis is correct and a judgment of its severity. By contrast, screening is the application of a simple test that identifies people at sufficiently high risk of a certain disease to warrant definitive procedures to establish the diagnosis or rule it out or that identifies people at sufficiently high risk of developing it to warrant specific preventive interventions. Screening tools and risk predictors are extremely useful, but they should not be confused with clinical diagnosis.

SPECIALIZED NUTRITIONAL SUPPORT

Optimized Voluntary Nutritional Support When feasible, this is the approach of choice because it engages and empowers the patient, encourages mobilization and reconditioning, is consistent with the objectives of patient-centered medicine, and is risk-free. Its disadvantage is that it is time-consuming and labor-intensive, and it demands astute attention to the specific needs of individual patients.

Enteral Nutrition This is nutrition provided through a feeding tube placed through the nose into the stomach or beyond it into the duodenum, by insertion of a tube through the abdominal wall into the stomach or beyond it into the jejunum, or by a surgical approach to access the stomach or small intestine. EN is usually the treatment of choice when optimized voluntary nutritional support is impossible or has failed. It is relatively simple, safe, and inexpensive, and it maintains the digestive, absorptive, and immunologic barrier functions of the gastrointestinal tract. EN is appropriate when optimized voluntary nutrition is not feasible or has failed and the patient's gastrointestinal tract is functioning and can be accessed.

EN Products The most common forms of EN are commercially manufactured formulas.

STANDARD POLYMERIC FORMULAS These are the most widely used EN products. They are available in a wide variety of formats designed to meet the nutritional requirements of a normal, healthy person. Carbohydrates provide most of the energy. The proteins are intact and of high biologic value (casein, whey, or soy) and require adequate pancreatic and intestinal enzyme function for digestion and absorption. They are isotonic or nearly so and provide 1000–2000 kcal and 50–70 g protein/L.

POLYMERIC FORMULAS WITH FIBER The addition of dietary fiber to formulas sometimes improves bowel function and feeding tolerance. Fermentable (soluble) fibers such as pectin and guar are metabolized by colonic bacteria, yielding short-chain fatty acids that fuel colonocytes. Nonfermentable (insoluble) fibers increase fecal bulk, improve peristalsis, and may improve diarrhea.

ELEMENTAL AND SEMI-ELEMENTAL FORMULAS The macronutrients in these formulas are partially or completely hydrolyzed. They were designed for patients with known maldigestion and malabsorption but are sometimes used empirically for patients intolerant of a standard polymeric formula, especially when acutely ill, although without strong evidence of superiority.

IMMUNE-ENHANCING FORMULAS In addition to providing macronutrients and conventional amounts of micronutrients, these EN products contain large amounts of certain nutrients designed to favorably modulate the immune response: arginine and n-3 fatty acids especially have some clinical experimental support, but also various combinations of glutamine, nucleotides, and antioxidants for which evidence of benefit is limited or lacking.

PROTEIN-ENRICHED FORMULAS Most EN products provide energy and protein in a ratio appropriate for a healthy person. Protein-enriched formulas provide ~90 g protein and 1000 kcal/L. Originally marketed to meet the increased protein requirement of weight-reducing obese patients, these products are increasingly used to provide protein-catabolic patients with a more generous amount of protein without energy overfeeding. EN can be further protein-enriched by adding flushes of water-soluble powdered protein supplements.

OTHER FORMULAS Various disease-specific EN products are available for patients with diabetes or hepatic, renal, or pulmonary disease. Their use can improve some metabolic endpoints, without clear evidence that they improve clinical outcomes.

Parenteral Nutrition PN delivers a complete nutritional regimen directly into the bloodstream in the form of crystalline amino acids, glucose, triglyceride emulsions, minerals (calcium, phosphate, magnesium, and zinc), electrolytes, and micronutrients. Because of its high osmolarity (>1200 mOsm/L) and often large volume, PN is infused into a central vein in adults. Ready-to-use PN admixtures typically containing 4–7% hydrated amino acids and 20–25% glucose (with or without electrolytes) are available in two-chamber (amino acids and glucose) or three-chamber (amino acids, glucose, and lipid) bags that are intermixed with vitamins, trace minerals, and additional electrolytes then added just prior to infusion. Although convenient and cost-effective, these products have fixed nutrient compositions and are dosed according to the volume required to meet a patient's energy requirement but not necessarily their protein requirement. In some situations—especially ADM—a more sophisticated approach is justified that uses a computer-controlled sterile compounder to create combinations of amino acids and glucose that precisely meet the protein, energy, fluid, and acid-base regulatory requirements of individual patients.

Amino Acids The amino acids in PN admixtures provide sufficient amounts of the essential amino acids and total nonessential amino acid N. Unlike protein-bound amino acids, which are connected by peptide bonds, free amino acids are hydrated. This reduces their energy density from 4.0 (in formed protein) to 3.3 kcal/g and reduces the amount of protein substrate they provide by ~17%. Thus, 100 g of free mixed amino acids provides 83 g protein substrate.

Carbohydrate and Lipids The glucose in PN is dextrose monohydrate; this hydration state reduces its energy concentration from 4.0 kcal/g (as in formed carbohydrate) to 3.4 kcal/g. Lipid emulsions provide energy (~10 kcal/g) and the essential n-6 and n-3 fatty acids. Traditional lipid emulsions based solely on soybean oil are giving way to mixed emulsions that include medium-chain triglycerides, n-9 monounsaturated fatty acids, and n-3 fatty acids. Emulsions of pure soybean oil; or a mixture of 80% olive oil and 20% soybean oil; or a mixture of 30% soybean oil, 30% medium-chain triglycerides, 25% olive oil, and 15% fish oil are available in the United States.

Fish oil (either as a component of a mixed emulsion or administered separately) may reduce the risk of infections and length of stay in critically ill patients. Some complex lipid emulsions are more highly enriched in n-3 fatty acids and/or contain fewer n-6 polyunsaturated fatty acids than soybean lipid, which is more prone to lipid peroxidation and could promote the formation of the proinflammatory n-6 derivatives. Standard lipid infusion rates should not exceed 8 g/h,

equivalent to 175 g (1925 kcal)/d for a 70-kg patient. Because of their longer chain length and slower tissue uptake, pure fish oil emulsions are infused at lower rates.

Minerals, Micronutrients, and Trace Elements The default concentrations of electrolytes, minerals, and micronutrients in PN solutions are designed to meet the requirements of a healthy adult. These starting doses must be adjusted to meet the frequently abnormal and often-changing requirements of individual patients. Being unstable, multivitamin mixtures are injected into PN bags just prior to their delivery to the medical unit. Parenteral water-soluble vitamin requirements are greater than standard oral requirements, because hospitalized patients often have vitamin deficiencies or increased requirements and because intravenous administration of vitamins increases their loss in the urine. Ascorbic acid degrades spontaneously in PN solutions, even when protected from light.

APPROACH TO THE PATIENT

Indications, Selection, and Provision of Specialized Nutritional Support

Most hospitalized patients do not require SNS because they can and will eat enough with appropriate management of their primary disease. Others may have a terminal disease whose downward course will not be mitigated by SNS. Patients who are unable to eat and digest enough of the standard hospital diet and have or are at high risk of developing SRM or CDM are candidates for optimized voluntary nutritional support. Instrumental SNS is indicated when optimized voluntary nutritional support is inappropriate, impractical, or has failed. The decision to provide EN or PN is based on a combination of four factors: (1) the determination that nutrient ingestion will likely continue to be inadequate for many days; (2) there is important muscle loss (of any cause); (3) the patient's nutrient requirements are increased (as from inflammatory diarrhea, enterocutaneous fistulas or exudates, or an inflammatory protein-catabolic state); and (4) the reasoned judgment that SNS has a reasonable prospect of improving the patient's clinical outcome or quality of life.

EN THERAPY

EN is indicated when the patient is unable to eat enough food and is unlikely to do so for a long time, their gastrointestinal tract is functional and accessible, and optimized voluntary nutrition is impossible or inappropriate. EN is commonly used for patients with impaired consciousness, severe dysphagia, or severe upper gastrointestinal tract dysfunction or obstruction, or who need mechanical ventilation. Equally commonly, situations arise in which a patient's voluntary food intake is seriously curtailed by anorexia, unappealing food, nausea, vomiting, pain, distress, delirium, depression, chewing difficulties, mild dysphagia, physical and sensory disability (including dysgeusia), or undiagnosed thrush. In these complicated and difficult situations, the clinical diagnosis of SRM or CDM will tip the decision toward EN or PN.

EN is contraindicated by intestinal ischemia, mechanical obstruction, peritonitis, and gastrointestinal hemorrhage. High-dose pressor therapy is a relative contraindication because of the rare but lethal risk of intestinal ischemic injury. Severe coagulopathy, esophageal varices, absent gag reflex, hypotension, paralytic ileus, diarrhea, and nausea and vomiting are not absolute contraindications, but they increase the risk of complications and make it less likely that EN will succeed in achieving its nutritional goal. In general, intensive EN is best avoided under conditions of very grave and unstable illness.

Initiation, Progression, and Monitoring Nasogastric tube feeding may proceed when the patient's gastrointestinal function is adequate with respect to gastric contractility (e.g., nasogastric tube output <1200 mL/d) and intestinal function (no known or suspected intraabdominal pathologic process and a nondistended abdomen—mere absence of bowel sounds is not, by itself, a contraindication). After consent has been obtained and the appropriate feeding tube (usually a nasogastric tube for short-term feeding) has been placed and its position verified, the head of the patient's bed is raised to at least 30° and kept there to reduce the risk of regurgitation. The clinical dietitian ordinarily orders the formula and adjusts its rate. When a standard polymeric formula is infused, it normally commences at 50 mL/h and is advanced by 25 mL/h every 4–8 h until the goal rate is attained. Elemental formulas begin at a slower rate and progress more slowly. Intragastric bolus feeding is an option (200–400 mL feeding solution infused over 15–60 min at regular intervals with verification of residual gastric contents every 4 h).

Complications The common complications of EN are aspiration of regurgitated or vomited formula, diarrhea, fluid volume and electrolyte derangements, hyperglycemia, nausea, abdominal pain, constipation, and failure to achieve the nutritional goal.

Aspiration Patients with delayed gastric emptying, impaired gag reflex, and ineffective cough are at high risk of aspiration pneumonia. Ventilator-associated pneumonia is most often caused by aspiration of microbial pathogens in the mouth and throat past the cuff of an endotracheal or tracheostomy tube. Tracheal suctioning can induce coughing and gastric regurgitation. Ventilator-associated pneumonia can be prevented by elevating the head of the bed, good mouth hygiene and gastrointestinal decontamination, nurse-directed algorithms for formula advancement, and sometimes postpyloric feeding. EN need not be suspended for gastric residual volumes <300–400 mL in the absence of other signs of gastrointestinal intolerance (nausea, vomiting, abdominal pain, abdominal distention). Continuous EN is often tolerated better than bolus feeding and is the only option during jejunal feeding.

Diarrhea Diarrhea commonly occurs when the patient's bowel function is compromised by disease or drugs (most often, broad-spectrum antibiotics). Once infection and inflammatory causes have been ruled out, EN-associated diarrhea may be controlled by using a fiber-containing formula or adding an antidiarrheal agent to it. H_2 blockers or proton pump inhibitors may help reduce the net volume of fluid presented to the colon. Luminal nutrients exert trophic effects on intestinal mucosa, so it is often appropriate to continue tube feeding despite moderate but tolerable diarrhea, even if it necessitates supplemental parenteral fluid support. Except in cases of impaired small-intestinal absorptive function, there are no well-established indications for elemental formulas; nevertheless, they may be tested empirically when diarrhea persists despite the use of fiber-enriched formulas and antidiarrheal drugs.

Gastrointestinal Intolerance Abnormally high gastric residual volumes, abdominal distention, pain, and nausea are greatly distressing for patients, increase nursing workload, and slow the progression of EN. These problems can be avoided or minimized by ensuring that the patient is in normal fluid and electrolyte balance, by preventing severe hyperglycemia, and, when nausea, vomiting, or abdominal distention develop, by the judicious prescription of antiemetic and prokinetic drugs (and sometimes proton pump inhibitors) on a regular—rather than as-needed—basis. Patients with gastroparesis require postpyloric feeding.

Fluid Volume, Electrolyte, and Blood Glucose Abnormalities EN's essential purpose is to provide macronutrients at an appropriate rate. EN also provides standard amounts of fluid, electrolytes, minerals, and micronutrients. Standard EN products are not designed to manage abnormal fluid volume, electrolyte, and mineral requirements, which vary considerably and can change rapidly. Blood glucose concentrations should be monitored regularly, and additional measures—including intravenous fluid, electrolyte, and insulin therapy—may be required to maintain homeostasis.

Failure to Reach the Nutritional Goal EN is frequently delayed or interrupted by intolerance to the administered formula,

by diagnostic tests and procedures (including dialysis), physical or occupational therapy, or a clogged or pulled out tube. The result can be a long delay in the progression of EN and ultimate failure to meet the patient's nutrient requirements.

EN in the Intensive Care Unit Most critically ill patients cannot eat anything and hence depend entirely on SNS. EN serves two purposes in this setting. The first is to meet the patient's macronutrient requirements, especially their increased protein requirement. The second purpose is to infuse sufficient nutrients into the intestines to maintain their barrier and immunologic functions in the face of a systemic inflammatory response that threatens them. Current guidelines recommend starting EN soon after a critically ill patient has been fluid resuscitated and stabilized. Once EN is underway, its rate of delivery is gradually increased toward the nutritional goal. EN frequently falls far short of its protein provision target, even after a week or longer in the intensive care unit. Newer, high-protein EN products (and sometimes the addition of powdered protein supplements) can correct this protein shortfall. There is uncertainty about the timing and macronutrient composition of EN early in ADM. We continue to recommend early EN as a platform and preparation for later, more generous nutrient provision and to maintain intestinal function.

PN THERAPY

PN is more resource-intensive and requires more expertise than EN. It is used when invasive SNS is indicated and EN is impossible, inappropriate, or insufficient to meet the patient's nutritional needs. The risks of PN are those of inserting and maintaining a central venous catheter (traumatic injury from the insertion, serious infection, and venous thrombosis); allergy to some of its components; glucose, electrolyte, magnesium, phosphate, and acid-base balance abnormalities; and the adverse effects of the large intravenous fluid volumes. When prolonged for many weeks—and especially when it delivers excess energy—PN may cause or contribute to hepatic dysfunction.

Initiation, Progression, Monitoring, and Discontinuation When indicated, PN should begin soon after the patient has been hemodynamically stabilized; glucose, electrolyte, and acid-base homeostasis has been established; and they are able to tolerate the fluid volume required to deliver it. Newer evidence indicates that the provision of energy equal to total energy expenditure in the first week of PN is not, in general, beneficial and can be harmful under certain conditions. The high osmolarity of adult PN solutions and the need for strict sterility require that they be infused through a dedicated port in a central venous catheter. Jugular or femoral vein catheters should not be used because of the difficulty maintaining a dry, sterile dressing over the insertion site and the higher rate of complications. The initial dose of glucose should not exceed 200 g/d to avoid hyperglycemia (and—in susceptible patients with adapted SRM—the refeeding syndrome).

Most non–critically ill patients do not require >500 g glucose (1700 kcal)/d—assuming in this example a normalized dry body weight of 70 kg. Patients with ADM should, in general, not receive >350 g glucose (1200 kcal)/d during the intense phase of their critical illness. A glucose infusion rate of ~200 g/d is physiologic and rarely needs to be exceeded. When it eventually becomes appropriate to provide energy equal to total energy expenditure, this may be achieved by infusing a lipid emulsion.

We recommend hypocaloric nutrition (limited in glucose, lipid, and fluid volume but generous in amino acids) for the first 2 weeks of SNS in fat-sufficient or obese patients with ADM. Energy provision may increase, if indicated, after the catabolic storm has abated. Lipids are commonly introduced after the first week of PN to make up energy shortfalls. Serum triglyceride concentrations are measured before commencing lipid infusions to detect preexisting hypertriglyceridemia (>400 mg/dL), a relative contraindication. Lipids may be infused daily or two or three times weekly. Lipid infusions are not necessary to prevent essential fatty acid deficiency during hypocaloric nutrition of patients with a normal or excessive fat store, because the endogenous fat mobilized during energy deficiency provides essential fatty acids to the rest of their body.

Capillary blood glucose concentrations are monitored several times daily. Subcutaneous regular insulin is added to the PN admixture as required to maintain average serum glucose concentrations <140 mg/dL and >80 mg/dL. (Upper and lower limits of 180 and 100 mg/dL appear to be appropriate for critically ill patients with diabetes mellitus.) The dose of regular insulin required on a given day can be added to the following day's PN solution. The insulin dose increases roughly proportionately to the glucose dose. Certain benchmarks are useful. Basal endogenous insulin secretion is ~30 units/d in normal people. When insulin is required for nondiabetic, noncatabolic patients, 10 units of regular insulin roughly cover 100 g infused glucose. Patients with non-insulin-dependent diabetes require ~20 units/100 g glucose. Noncatabolic patients with insulin-dependent diabetes usually require approximately twice their at-home insulin dose, because parenteral glucose stimulates insulin release more potently than oral carbohydrate and because some insulin adheres to the infusion bag.

Biochemical Monitoring Serum urea, creatinine, electrolytes, glucose, magnesium, phosphate, calcium, and albumin concentrations are determined prior to commencing PN and most of them (not albumin) monitored for the first few days, then twice weekly or as required. Serum triglycerides and liver function indicators are measured at baseline and after PN is underway to verify tolerance to lipid infusions. An N balance determination may be useful at the outset to evaluate the severity of protein catabolism in patients with CDM or ADM, to identify patients who will benefit from more generous amino acid provision, and during the course of PN to determine whether N balance is improving with therapy.

Discontinuation PN is tapered and discontinued when the patient can be adequately nourished by the enteral route. The PN dose is proportionately reduced as food intake increases. Once a patient can tolerate one-half to two-thirds of their requirement by the enteral route and there is no mechanical or other barrier to further increases, PN should be terminated. The transition to oral nutrition can be difficult for some patients. In this situation, optimized voluntary nutrition, although labor-intensive, is much preferred to replacing PN with EN, for it is safe, effective, fosters well-being, and prepares the patient for discharge home. It is tempting to discontinue PN in hopes of stimulating the patient's appetite, but this impulse should be resisted. PN does not cause anorexia nor does discontinuing it stimulate appetite. Too-early discontinuation of PN may delay a patient's progression to full voluntary food consumption by inducing anxiety and recreating starvation conditions. A patient is most successfully weaned from PN by optimizing their voluntary nutrition (including food brought from home), providing emotional support, encouraging physical activity, and being patient. Some patients on the cusp of adequate oral nutrition will benefit from discharge to the security and pleasure of home life and homemade food; these patients are identified by observing, asking, and listening.

Complications Patients receiving PN are at higher risk of bloodstream infections than other patients with central venous catheters. Rigorously aseptic insertion technique, meticulous dressing care, one port dedicated solely to PN, and careful glycemic control reduce this risk. EN and PN carry equivalent overall risks and complication rates, apart from gastrointestinal side effects of EN. PN is much more prone to the error of inadvertent toxic overfeeding.

Hyperglycemia The most frequent metabolic complication of PN is hyperglycemia in patients with insulin resistance due to non-insulin-dependent diabetes mellitus, high-dose glucocorticoid therapy, or severe systemic inflammation; the problem is exacerbated by excessive rates of glucose provision. Glucose

concentrations are most easily kept <140 mg/dL and with the least risk of hypoglycemia by infusing hypocaloric amounts of glucose and, when necessary, meeting the patient's energy requirement with intravenous lipid. In ADM, the benefits of using the lowest possible insulin dose—minimal hyperinsulinemia and a reduced risk of hypoglycemia—almost always outweigh the doubtful goal of rapidly matching energy provision to energy expenditure.

Hypoglycemia Reactive hypoglycemia is uncommon but can occur immediately after high-glucose, non-insulin-containing PN is abruptly discontinued. It is prevented by slowing the PN infusion rate to 50 mL/h for 1 or 2 h prior to stopping, replacing it with 10% glucose, or when the oral route is available, providing a snack. More often, hypoglycemia occurs when the intensity of the patient's metabolic stress (or their glucocorticoid dose) decreases without an appropriate downward adjustment of the insulin dose. This problem is avoided by frequent capillary glucose determinations and careful attention to medication doses and the patient's general condition.

Artefactual Hyperglycemia and Hyperkalemia Blood samples must be meticulously collected from a dual-port central venous catheter. The intermixing of sample with even a tiny volume of PN solution will falsely indicate hyperglycemia and hyperkalemia and can result in treatment error. This error is identified when the patient's apparent serum glucose (and potassium) concentration abruptly increases without reason, and the high glucose concentration is contradicted by a concurrent capillary glucose reading.

Volume Overload Volume overload causes substantial morbidity and increases mortality. Total fluid provision should not normally exceed 2 L/d in the absence of abnormally high losses. Hypertonic intravenous glucose triggers a more intense insulin response than oral glucose, and it can increase urinary sodium and water retention. Volume overload can be prevented by using a compounder to prepare PN solutions, infusing glucose at the lowest appropriate rate, avoiding energy overfeeding, and monitoring the patient's volume balance.

Hypertriglyceridemia This complication occurs when the rate of lipid infusion exceeds plasma triglyceride clearance capacity. Sepsis, renal failure, diabetes mellitus, high-dose glucocorticoid therapy, and multiple-organ failure reduce triglyceride clearance. An impaired immune response, increased risk of acute pancreatitis, and altered pulmonary hemodynamics are potential, but not well documented, complications of PN-induced severe hypertriglyceridemia. Lipid infusion rates should not usually exceed ~50 g (500 kcal)/d in ADM.

Liver Disease Mild elevations of serum liver enzyme concentrations may occur within 2–4 weeks of initiating PN, but in most cases, they will return to normal even when PN is continued. Clinically important hepatic dysfunction, although common in children, is uncommon in adults for whom energy overfeeding with resultant fatty liver is avoided. Intrahepatic cholestasis occasionally develops after many weeks of continuous PN; it is most often multifactorial in origin. Cyclic PN—in which PN is infused for only 12 h of the day—may prevent or reduce the severity of this complication.

PN in the Intensive Care Unit Current guidelines recommend starting EN soon after a critically ill patient has been resuscitated and stabilized and enteral access to an adequately functioning gastrointestinal tract has been established. If the protein goal has not been achieved after 7–10 days, PN may be added, especially if the protein-catabolic state has not yet abated. Soy-based lipid emulsions should be avoided during the first week of PN; alternative lipid emulsions may prove to be safe and beneficial.

SPECIAL CLINICAL SITUATIONS

The Critical Illness–Nutrition Paradox There is now good clinical trial evidence that confirms what was long indicated by a combination of physiologic reasoning, biologic plausibility, and formal clinical observation—namely, that personalized nutritional interventions improve the clinical outcomes of starving, non–critically ill patients. The case for SNS would seem to be much stronger for patients with ADM, which induces rapid muscle loss and maintains or increases energy expenditure in people rendered incapable of eating voluntarily. Yet well-designed large-enrollment clinical trials have repeatedly failed to demonstrate short-term clinical benefits from nutritional interventions in critical illness. In fact, there is good evidence that, unlike in noncritical illness, early energy provision at a rate near or above the rate of energy expenditure not only fails to improve clinical outcomes but may be deleterious. The failure of formal clinical trials to show benefits from SNS in critical illness has several possible explanations: severe prolonged starvation is so obviously harmful that it is unethical to intentionally include such a treatment arm in a randomized clinical trial; critical illness is extremely heterogeneous, and not every critically ill patient is, or remains, severely protein-catabolic for long; and owing to generous admission criteria and thanks to the high quality of modern intensive care, many patients admitted to intensive care units rapidly improve and are discharged in a handful of days, while others are so mortally ill when admitted to the intensive care unit that their outcome is virtually predetermined. For these reasons, clinical trials that enroll and report the outcomes of all patients admitted to an intensive care unit could well fail to demonstrate an average benefit from SNS. More than that, in current practice, standard EN regimens prescribed for most critically ill patients commonly fail to deliver more than one-half the currently recommended amount of protein, and the low protein-to-energy ratio of most standard EN and PN products can make it impossible to provide critically ill patients sufficiently generous amounts of protein or amino acids without subjecting them to harmful energy overfeeding. We await the publication of large-enrollment clinical trials in which critical illness is diagnosed, not by where the patient is being treated, but using anatomic and pathophysiologic criteria and in which current standard care is compared with treatment arms that provide personalized SNS appropriate to patients' anatomy and pathophysiology. For now, along with other experts, we continue to recommend EN and PN for critically ill patients. Attempts to match energy provision to energy expenditure should be avoided as long as systemic inflammation remains severe. The dose of protein or amino acids should be guided by physiologic reasoning and a personalized evaluation of each patient's anatomic and metabolic condition. We recommend bearing in mind that people who survive critical illness become non–critically ill people for whom the benefit of appropriate nutrition, together with other components of medical and surgical care, is not in question. Accordingly, we recommend a long-view approach to the design of nutritional support regimens for critically ill patients that aims both to increase their likelihood of short-term survival and anticipates their post–critical illness phase, which will be improved by measures that mitigate muscle loss, avoid toxic energy overfeeding, and prevent or correct micronutrient deficiencies.

Iron and PN Iron deficiency is common in hospitalized patients. It has many causes: preexisting deficiency, insufficient food, macro- or microscopic gastrointestinal blood loss, and repeated blood sampling. Even though it is common, the diagnosis is often missed because the anemia of systemic inflammation is even more common, and it confounds interpretation of the usual indicator of iron deficiency, serum ferritin. Serum ferritin and fasting serum transferrin saturation should be part of the patient's initial nutritional evaluation. Current evidence suggests that a fasting transferrin saturation <20% is the most reliable indicator of functional iron deficiency, even in the absence of anemia. In principle, all micronutrient deficiency states should be prevented and corrected. In-hospital iron deficiency causes and prevents recovery from anemia and increases postoperative blood transfusion requirements. Subclinical iron deficiency could contribute to cognitive and immune dysfunction.

Iron is not added to PN mixtures. Iron dextran is incompatible with lipid emulsions, and although it appears to be chemically compatible with aqueous solutions of amino acids and glucose, there is realistic concern that interactions between iron molecules and certain vitamins and amino acids in PN solutions could catalyze the formation of free radicals that degrade vitamins and exert subtle adverse systemic effects.

Intravenous iron is usually necessary to treat in-hospital iron deficiency, but it should be delayed if there is known or suspected bacterial infection, and possibly not during the intense phase of ADM. A substantial rise in the serum iron concentration could increase susceptibility to gram-negative (and possibly other microbial) infections, as well as catalyze the formation of free radicals that increase the intensity of the catabolic response to major tissue injury.

Zinc One liter of secretory diarrhea contains ~12 mg of zinc. Patients with intestinal fistulas or high-volume chronic diarrhea require this amount of zinc in addition to their daily requirement of 15 mg to avoid zinc deficiency. Zinc may be provided parenterally or enterally. Because of its low bioavailability, 12 mg of parenteral zinc is equivalent to 30 mg of oral zinc.

Old Age In addition to their other frailties, elderly people commonly suffer from age-related muscle loss (sarcopenia) compounded by disuse muscle atrophy. These factors place them at high risk of the consequences of starvation disease and make them candidates for earlier SNS.

Inactivity Physical activity and adequate nutrition interact intimately. Reduced physical activity reduces appetite, and physical rehabilitation and its associated emotional benefits restore optimism and appetite. Full nutrient provision will maintain or normalize many physiologic functions in bedridden patients, but without exercise, they will not increase their muscle mass.

Renal Failure Protein provision should not be reduced in patients with renal failure unless renal replacement therapy is unavailable. Renal replacement therapy removes large amounts of amino acids, vitamins, and trace elements from the circulation, so protein and micronutrient provision should be increased to compensate for these losses.

Liver Failure Patients with severe hepatic disease are relatively intolerant to starvation and commonly have CDM when admitted to hospital, so they are prime candidates for SNS. Their SNS should be generous both in energy and protein, despite an increased risk of hepatic encephalopathy. The risk of encephalopathy can be reduced by meticulous attention to fluid balance, acid-base balance, and electrolyte status and by spreading protein provision over the day to accommodate the liver's reduced capacity to clear amino acid–derived ammonia.

Perioperative SNS Patients with SRM or CDM awaiting elective major surgery will benefit from 7–10 days of preoperative SNS. Optimized voluntary nutrition is always preferred, but when a patient has been admitted to hospital in a semi-urgent condition, EN or PN is usually required to quickly meet the patient's nutritional goal. Preoperative SNS improves immunity and reduces postoperative complications, but it will not increase serum albumin concentrations, and it should not be provided for >7–10 days with the expectation that it will do so. More prolonged preoperative EN or PN may confer slight additional nutritional benefits, but they are counterbalanced by their risks and the consequences of prolonged hospitalization and delayed surgery. Surgery should not be delayed for starving patients whose muscle mass is normal or only mildly depleted and who are not experiencing systemic inflammation, for they are well able to withstand the trauma of even major uncomplicated surgery. The need for urgent surgery often precludes otherwise indicated preoperative SNS. Early postoperative PN is usually indicated for these patients, for they are at increased risk of postoperative complications and are unlikely to consume much food over the next many days. Patients with only mild muscle loss, no systemic inflammation, and no postoperative complications do not require postoperative PN unless (1) adequate feeding by mouth has not been achieved by day 5–7 after surgery or (2) there are indications that voluntary feeding will be further delayed. There is evidence that perioperative immune-enhancing EN reduces morbidity in patients undergoing major elective gastrointestinal surgery.

Cancer SNS plays a crucial role in cancer therapy. Many malignant neoplasms (especially those that involve the gastrointestinal tract or induce systemic inflammation) and their cytotoxic therapies create the conditions for starvation and commonly lead to SRM or CDM. The prevention or treatment of these starvation diseases will improve patients' quality of life and their tolerance to anticancer therapy. EN and PN are generally not prescribed to patients with advanced cancer for which effective anticancer therapy is unavailable, because the side effects and complications of instrumental SNS are not counterbalanced by an improved disease trajectory. In some cases, the disease progresses so slowly that the patient will die of starvation long before they succumb to their primary disease. EN or PN is obviously appropriate in such cases.

Advanced Dementia Optimized voluntary nutrition is the key approach in this situation, and it can be used to deal with problems such as disability and dysphagia in patients who get pleasure from eating. There is no evidence that EN or PN improves quality or length of life in patients with advanced dementia who show little or no interest in food, and the side effects and complications are unpleasant and sometimes dangerous.

REFEEDING SYNDROME

The refeeding syndrome can occur in patients with successfully adapted SRM during the first week of nutritional repletion when carbohydrate and sodium are introduced too rapidly. Carbohydrate stimulates insulin secretion, which, owing to its antinatriuretic effect, expands the ECF volume, especially when excessive sodium is provided. Refeeding edema can be minimized by severely limiting sodium provision and increasing carbohydrate provision slowly. Carbohydrate refeeding may stimulate intracellular glucose-6-phosphate and glycogen synthesis sufficiently to seriously lower serum phosphate concentrations, impairing skeletal and cardiac muscle function, and can trigger hemolysis. Abrupt carbohydrate provision increases the downregulated metabolic rate of patients with adapted SRM and stimulates N retention, new cell synthesis, and cellular rehydration. Because phosphorus, potassium, and magnesium deficiencies occur and are dangerous during refeeding, their serum concentrations should be measured frequently and appropriate supplements provided. Left heart failure may occur in predisposed patients; it has three causes: (1) an abrupt increase of intravascular volume due to the administration of fluids and of glucose, which stimulates insulin-mediated renal sodium retention; (2) increased cardiac demand on an atrophic left ventricle created by an insulin-mediated increase of resting energy expenditure; and (3) myocardial deficiencies of potassium, phosphorus, or magnesium. Cardiac arrhythmias may occur. Acute thiamine deficiency encephalopathy is a devastating preventable complication of refeeding, even with simple glucose infusions.

Section 3 Liver and Biliary Tract Disease

347 Approach to the Patient with Liver Disease

Marc G. Ghany, Jay H. Hoofnagle

A diagnosis of liver disease usually can be made accurately by careful elicitation of the patient's history, physical examination, and application of a few laboratory tests. In some circumstances, radiologic examinations are helpful or, indeed, diagnostic. Liver biopsy is considered the criterion standard in evaluation of liver disease but is now needed less for diagnosis than for grading (activity) and staging (fibrosis) of disease. Noninvasive means of assessing fibrosis stage have become increasingly helpful and may allow for avoidance of biopsy in an increasing proportion of patients. This chapter provides an introduction to diagnosis and management of liver disease, briefly reviewing the structure and function of the liver; the major clinical manifestations of liver disease; and the use of clinical history, physical examination, laboratory tests, imaging studies, and liver biopsy.

LIVER STRUCTURE AND FUNCTION

The liver is the largest organ of the body, weighing 1–1.5 kg and representing 1.5–2.5% of the lean body mass. The size and shape of the liver vary and generally match the general body shape—long and lean or squat and square. This organ is located in the right upper quadrant of the abdomen under the right lower rib cage against the diaphragm and projects for a variable extent into the left upper quadrant. It is held in place by ligamentous attachments to the diaphragm, peritoneum, great vessels, and upper gastrointestinal organs. The liver receives a dual blood supply; ~20% of the blood flow is oxygen-rich blood from the hepatic artery, and 80% is nutrient-rich blood from the portal vein arising from the stomach, intestines, pancreas, and spleen.

The majority of cells in the liver are hepatocytes, which constitute two-thirds of the organ's mass. The remaining cell types are Kupffer cells (members of the reticuloendothelial system), stellate (Ito or fat-storing) cells, endothelial and blood vessel cells, bile ductular cells, and cells of supporting structures. Viewed by light microscopy, the liver appears to be organized in lobules, with portal areas at the periphery and central veins in the center of each lobule. However, from a functional point of view, the liver is organized into acini, with both hepatic arterial and portal venous blood entering the acinus from the portal areas (zone 1) and then flowing through the sinusoids to the terminal hepatic veins (zone 3); the intervening hepatocytes constitute zone 2. The advantage of viewing the acinus as the physiologic unit of the liver is that this perspective helps to explain the morphologic patterns and zonality of many vascular and biliary diseases not explained by the lobular arrangement.

Portal areas of the liver consist of small veins, arteries, bile ducts, and lymphatics organized in a loose stroma of supporting matrix and small amounts of collagen. Blood flowing into the portal areas is distributed through the sinusoids, passing from zone 1 to zone 3 of the acinus and draining into the terminal hepatic veins ("central veins"). Secreted bile flows in the opposite direction—that is, in a countercurrent pattern from zone 3 to zone 1. The sinusoids are lined by unique endothelial cells that have prominent fenestrae of variable sizes, allowing the free flow of plasma but not of cellular elements. The plasma is thus in direct contact with hepatocytes in the subendothelial space of Disse.

Hepatocytes have distinct polarity. The basolateral side of the hepatocyte lines the space of Disse and is richly lined with microvilli; it exhibits endocytotic and pinocytotic activity, with passive and active uptake of nutrients, proteins, and other molecules. The apical pole of the hepatocyte forms the canalicular membranes through which bile components are secreted. The canaliculi of hepatocytes form a fine network, which fuses into the bile ductular elements near the portal areas. Kupffer cells usually lie within the sinusoidal vascular space and represent the largest group of fixed macrophages in the body. The stellate cells are located in the space of Disse but are not usually prominent unless activated, whereupon they produce collagen and matrix. Red blood cells stay in the sinusoidal space as blood flows through the lobules, but white blood cells can migrate through or around endothelial cells into the space of Disse and from there to portal areas, where they can return to the circulation through lymphatics.

Hepatocytes perform numerous and vital roles in maintaining homeostasis and health. These functions include the synthesis of most essential serum proteins (albumin, carrier proteins, coagulation factors, many hormonal and growth factors), the production of bile and its carriers (bile acids, cholesterol, lecithin, phospholipids), the regulation of nutrients (glucose, glycogen, lipids, cholesterol, amino acids), and the metabolism and conjugation of lipophilic compounds (bilirubin, anions, cations, drugs) for excretion in the bile or urine. Measurement of these activities to assess liver function is complicated by the multiplicity and variability of these functions. Commonly used liver "function" tests are measurements of serum bilirubin, serum albumin, and prothrombin time. The serum bilirubin level is a measure of hepatic conjugation and excretion; the serum albumin level and prothrombin time are measures of protein synthesis. Abnormalities of bilirubin, albumin, and prothrombin time are typical of hepatic dysfunction. Frank liver failure is incompatible with life, and the functions of the liver are too complex and diverse to be subserved by a mechanical pump; a dialysis membrane; or a concoction of infused hormones, proteins, and growth factors.

LIVER DISEASES

While there are many causes of liver disease **(Table 347-1)**, these disorders generally present clinically in a few distinct patterns and are usually classified as hepatocellular, cholestatic (obstructive), or mixed. In hepatocellular diseases (such as viral hepatitis and alcoholic liver disease), features of liver injury, inflammation, and necrosis predominate. In cholestatic diseases, such as gallstone or malignant obstruction, primary biliary cholangitis (previously referred to as primary biliary cirrhosis), and some drug-induced liver diseases, features of inhibition of bile flow predominate. In a mixed pattern, features of both hepatocellular and cholestatic injury are present (such as in cholestatic forms of viral hepatitis and many drug-induced liver diseases). The pattern of onset and prominence of symptoms can rapidly suggest a diagnosis, particularly if major risk factors are considered, such as the age and sex of the patient and a history of exposure or risk behaviors.

Typical presenting symptoms of liver disease include jaundice, fatigue, itching, right-upper-quadrant pain, nausea, poor appetite, abdominal distention, and intestinal bleeding. At present, however, many patients are diagnosed with liver disease who have no symptoms and who have been found to have abnormalities in biochemical liver tests as a part of a routine physical examination or screening for blood donation or for insurance or employment. The wide availability of batteries of liver tests makes it relatively simple to demonstrate the presence of liver injury as well as to rule it out in someone in whom liver disease is suspected.

Evaluation of patients with liver disease should be directed at determining (1) the etiologic diagnosis, (2) disease severity (grading), and (3) disease stage (staging). Diagnosis should focus on the pattern of

TABLE 347-1 Liver Diseases

Inherited hyperbilirubinemia	**Liver involvement in systemic diseases**
Gilbert syndrome	Sarcoidosis
Crigler-Najjar syndrome, types I and II	Amyloidosis
Dubin-Johnson syndrome	Glycogen storage diseases
Rotor syndrome	Celiac disease
Viral hepatitis	Tuberculosis
Hepatitis A	*Mycobacterium avium-intracellulare* infection
Hepatitis B	**Cholestatic syndromes**
Hepatitis C	Benign postoperative cholestasis
Hepatitis D	Jaundice of sepsis
Hepatitis E	Total parenteral nutrition–induced jaundice
Others (Epstein-Barr virus [mononucleosis] herpesvirus, cytomegalovirus, adenovirus hepatitis)	Cholestasis of pregnancy
Cryptogenic hepatitis	Cholangitis and cholecystitis
Immune and autoimmune liver diseases	Extrahepatic biliary obstruction (stone, stricture, cancer)
Primary biliary cholangitis	Biliary atresia
Autoimmune hepatitis	Caroli disease
Sclerosing cholangitis	Cryptosporidiosis
Overlap syndromes	**Drug-induced liver disease**
Graft-versus-host disease	Hepatocellular patterns (isoniazid, acetaminophen)
Allograft rejection	Cholestatic patterns (methyltestosterone)
Genetic liver diseases	Mixed patterns (sulfonamides, phenytoin)
α_1 Antitrypsin deficiency	Micro- and macrovesicular steatosis (methotrexate, fialuridine)
Hemochromatosis	**Vascular injury**
Wilson disease	Sinusoidal obstruction syndrome
Benign recurrent intrahepatic cholestasis	Budd-Chiari syndrome
Progressive familial intrahepatic cholestasis, types I–III	Ischemic hepatitis
Others (galactosemia, tyrosinemia, cystic fibrosis, Niemann-Pick-disease, Gaucher's disease)	Passive congestion
Alcohol-related liver disease	Portal vein thrombosis
Acute fatty liver	Nodular regenerative hyperplasia
Acute alcoholic hepatitis	**Mass lesions**
Laënnec cirrhosis	Hepatocellular carcinoma
Nonalcoholic fatty liver[a]	Cholangiocarcinoma
Steatosis	Adenoma
Steatohepatitis	Focal nodular hyperplasia
Acute fatty liver of pregnancy	Metastatic tumors
	Abscess
	Cysts
	Hemangioma

[a]Also known as metabolic dysfunction–associated steatotic liver disease (MASLD).

disease presentation (hepatocellular, cholestatic, or mixed injury) as well as on the specific etiologic diagnosis. Grading refers to assessment of the severity or activity of disease—active or inactive as well as mild, moderate, or severe. Staging refers to estimation of the point in the course of the natural history of the disease, whether early or late; or precirrhotic, cirrhotic, or end-stage. This chapter introduces general, salient concepts in the evaluation of patients with liver disease that help lead to the diagnoses discussed in subsequent chapters.

CLINICAL HISTORY

The clinical history should focus on the symptoms of liver disease—their nature, patterns of onset, and progression—and on potential risk factors for liver disease. The manifestations of liver disease include constitutional symptoms such as fatigue, weakness, nausea, poor appetite, and malaise and the more liver-specific symptoms of jaundice, dark urine, light stools, itching, abdominal pain, and bloating. Symptoms can also suggest the presence of cirrhosis, end-stage liver disease, or complications of cirrhosis such as portal hypertension. Generally, the constellation of symptoms and their patterns of onset, rather than a specific symptom, point to an etiology.

Fatigue is the most common and most characteristic symptom of liver disease. It is variously described as lethargy, weakness, listlessness, malaise, increased need for sleep, lack of stamina, and poor energy. The fatigue of liver disease typically arises after activity or exercise and is rarely present or severe after adequate rest; that is, it is "afternoon" rather than "morning" fatigue. Fatigue in liver disease is often intermittent and variable in severity from hour to hour and day to day. In some patients, it may not be clear whether fatigue is due to the liver disease or due to other problems such as stress, anxiety, sleep disturbance, or a concurrent illness.

Nausea occurs with more severe liver disease and may accompany fatigue or be provoked by smelling food odors or eating fatty foods. Vomiting can occur but is rarely persistent or prominent. Poor appetite with weight loss occurs frequently in acute liver disease but is rare in chronic disease except when cirrhosis is present and advanced. Diarrhea is uncommon in liver disease except with severe jaundice, in which a lack of bile acids reaching the intestine can lead to steatorrhea.

Right-upper-quadrant discomfort or ache ("liver pain") occurs in many liver diseases and is usually marked by tenderness over the liver area. The pain arises from stretching or irritation of Glisson's capsule, which surrounds the liver and is rich in nerve endings. Severe pain is most typical of gallbladder disease, liver abscess, and severe sinusoidal obstruction syndrome (previously known as venoocclusive disease) but is also an occasional accompaniment of acute hepatitis.

Itching occurs with acute liver disease, appearing early in obstructive jaundice (from biliary obstruction) or drug-induced cholestasis and somewhat later in hepatocellular disease (acute hepatitis). Itching also occurs in chronic liver diseases—typically the cholestatic forms such as primary biliary cholangitis and sclerosing cholangitis, in which it is often the presenting symptom, preceding the onset of jaundice. However, itching can occur in any liver disease, particularly once cirrhosis develops.

Jaundice is the hallmark symptom of liver disease and perhaps the most reliable marker of severity. Patients usually report darkening of the urine before they notice scleral icterus. Jaundice is rarely detectable with a bilirubin level <43 μmol/L (2.5 mg/dL). With severe cholestasis, there will also be lightening of the color of the stools and steatorrhea. Jaundice without dark urine usually indicates indirect (unconjugated) hyperbilirubinemia and is typical of hemolytic anemia and the genetic disorders of bilirubin conjugation, the common and benign form being Gilbert syndrome and the rare and severe form being Crigler-Najjar syndrome. Gilbert syndrome affects up to 5% of the general population; the jaundice in this condition is more noticeable after fasting and with stress.

Major risk factors for liver disease that should be sought in the clinical history include details of alcohol use, medication use (including herbal compounds, birth control pills, and over-the-counter medications), personal habits, sexual activity, travel, exposure to jaundiced or other high-risk persons, injection drug use, recent surgery, remote or recent transfusion of blood or blood products, occupation, accidental exposure to blood or needlestick, and familial history of liver disease.

For assessing the risk of viral hepatitis, a careful history of sexual activity is of particular importance and should include the number of lifetime sexual partners and, for men, a history of having sex with men. Sexual exposure is a common mode of spread of hepatitis B and D but is uncommon for hepatitis C. A family history of hepatitis, liver disease, and liver cancer is also important. Maternal-infant transmission occurs with both hepatitis B and C. Vertical spread of hepatitis B can now be prevented by passive and active immunization of the infant at birth. Additionally, antiviral therapy administered in the second or third trimester of pregnancy is now recommended for mothers with levels of hepatitis B virus DNA >200,000 IU/mL. Vertical spread of hepatitis C is uncommon, but there are no reliable means of prevention. Transmission is more common among HIV-co-infected mothers and is also linked to prolonged and difficult labor and delivery, early rupture of membranes, internal fetal monitoring, and a high maternal

viral load. A history of injection drug use, even in the remote past, is of great importance in assessing the risk for hepatitis B, C, and D. Injection drug use is the single most common risk factor for hepatitis C. Transfusion with blood or blood products is no longer an important risk factor for acute viral hepatitis due to screening of blood products. However, blood transfusions received before the introduction of sensitive enzyme immunoassays for antibody to hepatitis C virus in 1992 is an important risk factor for chronic hepatitis C. Blood transfusion before 1986, when screening for antibody to hepatitis B core antigen was introduced, is also a risk factor for hepatitis B. Travel to a developing area of the world, exposure to persons with jaundice, and exposure to young children in day-care centers are risk factors for hepatitis A. Tattooing and body piercing (for hepatitis B, C, and D) and eating shellfish (for hepatitis A) are frequently mentioned but are actually types of exposure that rarely lead to infection.

Hepatitis E is one of the more common causes of jaundice in Asia and Africa but is uncommon in developed nations. In endemic areas, transmission is usually through exposure to fecally contaminated water. Non-travel-related (autochthonous) cases of hepatitis E have been described in developed countries, including the United States. These cases appear to be due to strains of hepatitis E virus that are endemic in swine and some wild animals (genotypes 3 and 4). While occasional cases are associated with eating raw or undercooked pork or game (deer and wild boars), most cases of hepatitis E occur without known exposure, predominantly in elderly men without typical risk factors for viral hepatitis. Hepatitis E infection can become chronic in immunosuppressed individuals (such as transplant recipients, patients receiving chemotherapy, or patients with HIV infection), in whom it presents with abnormal serum enzymes in the absence of markers of hepatitis B or C.

A history of alcohol intake is important in assessing the cause of liver disease and in planning management and recommendations. In the United States, for example, at least 70% of adults drink alcohol to some degree, but significant alcohol intake is less common; in population-based surveys, only 5% of individuals have more than two drinks per day, the average drink representing 11–15 g of alcohol. Alcohol consumption associated with an increased rate of alcoholic liver disease is probably more than two drinks (22–30 g) per day in women and three drinks (33–45 g) in men. Most patients with alcoholic cirrhosis have a much higher daily intake and have drunk excessively for ≥10 years before onset of liver disease. In assessing alcohol intake, the history should also focus on whether alcohol abuse or dependence is present. Alcoholism is usually defined by the behavioral patterns and consequences of alcohol intake, not by the amount. Abuse is defined by a repetitive pattern of drinking alcohol that has adverse effects on social, family, occupational, or health status. Dependence is defined by alcohol-seeking behavior, despite its adverse effects. Many alcoholics demonstrate both dependence and abuse, and dependence is considered the more serious and advanced form of alcoholism. A clinically helpful approach to diagnosis of alcohol dependence and abuse is the use of the CAGE questionnaire **(Table 347-2)**, which is recommended for all medical history-taking.

Family history can be helpful in assessing liver disease. Familial causes of liver disease include Wilson disease; hemochromatosis and α_1 antitrypsin deficiency; and the less common inherited pediatric liver diseases—that is, familial intrahepatic cholestasis, benign recurrent intrahepatic cholestasis, and Alagille syndrome. Onset of severe liver disease in childhood or adolescence in conjunction with a family history of liver disease or neuropsychiatric disturbance should lead to investigation for Wilson disease. A family history of cirrhosis, diabetes, or endocrine failure and the appearance of liver disease in adulthood suggest hemochromatosis and should prompt investigation of iron status. Abnormal iron studies in adult patients warrant genotyping of the *HFE* gene for the C282Y and H63D mutations typical of genetic hemochromatosis. In children and adolescents with iron overload, other non-*HFE* causes of hemochromatosis should be sought. A family history of emphysema should lead to investigation of α_1 antitrypsin levels and, if low, for protease inhibitor (Pi) genotype.

TABLE 347-2 CAGE Questions[a]

ACRONYM	QUESTION
C	Have you ever felt you ought to *c*ut down on your drinking?
A	Have people *a*nnoyed you by criticizing your drinking?
G	Have you ever felt *g*uilty or bad about your drinking?
E	Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (*e*ye-opener)?

[a]One "yes" response should raise suspicion of an alcohol use problem, and more than one is a strong indication of abuse or dependence.

PHYSICAL EXAMINATION

The physical examination rarely uncovers evidence of liver dysfunction in a patient without symptoms or abnormal laboratory findings, nor are most signs of liver disease specific to one diagnosis. Thus, the physical examination complements rather than replaces the need for other diagnostic approaches. In many patients, the physical examination is normal unless the disease is acute or severe and advanced. Nevertheless, the physical examination is important in that it can yield the first evidence of hepatic failure, portal hypertension, and liver decompensation. In addition, the physical examination can reveal signs—related either to risk factors or to associated diseases or findings—that point to a specific diagnosis.

Typical physical findings in liver disease are icterus, hepatomegaly, hepatic tenderness, splenomegaly, spider angiomata, palmar erythema, and skin excoriations. Signs of advanced disease include muscle wasting, ascites, edema, dilated abdominal veins, hepatic fetor, asterixis, mental confusion, stupor, and coma. In male patients with cirrhosis, particularly that related to alcohol use, signs of hyperestrogenemia such as gynecomastia, testicular atrophy, and loss of male-pattern hair distribution may be found.

Icterus is best appreciated when the sclera is inspected under natural light. In fair-skinned individuals, a yellow tinge to the skin may be obvious. In dark-skinned individuals, examination of the mucous membranes below the tongue can demonstrate jaundice. Jaundice is rarely detectable if the serum bilirubin level is <43 μmol/L (2.5 mg/dL) but may remain detectable below this level during recovery from jaundice (because of protein and tissue binding of conjugated bilirubin).

Spider angiomata and palmar erythema occur in both acute and chronic liver disease; these manifestations may be especially prominent in persons with cirrhosis but can develop in normal individuals and are frequently found during pregnancy. Spider angiomata are superficial, tortuous arterioles, and—unlike simple telangiectasias—typically fill from the center outward. Spider angiomata occur only on the arms, face, and upper torso; they can be pulsatile and may be difficult to detect in dark-skinned individuals.

Hepatomegaly is not a very reliable sign of liver disease because of variability in the liver's size and shape and the physical impediments to assessment of liver size by percussion and palpation. Marked hepatomegaly is typical of cirrhosis, sinusoidal obstruction syndrome, infiltrative disorders such as amyloidosis, metastatic or primary cancers of the liver, and alcoholic hepatitis. Careful assessment of the liver edge may also reveal unusual firmness, irregularity of the surface, or frank nodules. Perhaps the most reliable physical finding in the liver examination is hepatic tenderness. Discomfort when the liver is touched or pressed upon should be carefully sought with percussive comparison of the right and left upper quadrants.

Splenomegaly, which occurs in many medical conditions, can be a subtle but significant physical finding in chronic liver disease and suggests underlying cirrhosis. The availability of ultrasound (US) methods for assessment of the spleen allows confirmation of the physical finding.

Signs of advanced liver disease include muscle wasting and weight loss as well as hepatomegaly, bruising, ascites, and edema. Ascites is best appreciated by attempts to detect shifting dullness by careful percussion. US examination will confirm the finding of ascites in equivocal cases. Peripheral edema can occur with or without ascites. In patients with advanced liver disease, other factors frequently contribute

to edema formation, including hypoalbuminemia, venous insufficiency, heart failure, and medications.

Hepatic failure is defined as the occurrence of signs or symptoms of hepatic encephalopathy in a person with severe acute or chronic liver disease. The first signs of hepatic encephalopathy can be subtle and nonspecific—change in sleep patterns, change in personality, irritability, and mental dullness. Thereafter, confusion, disorientation, stupor, and eventually coma supervene. In acute liver failure, excitability and mania may be present. Physical findings include asterixis and flapping tremors of the body and tongue. Fetor hepaticus refers to the slightly sweet, ammoniacal odor that can develop in patients with liver failure, particularly if there is portal-venous shunting of blood around the liver. Other causes of coma and disorientation should be excluded, mainly electrolyte imbalances, sedative use, and renal or respiratory failure. The appearance of hepatic encephalopathy during acute hepatitis is the major criterion for diagnosis of acute liver failure and indicates a poor prognosis. In chronic liver disease, encephalopathy is usually triggered by a medical complication such as gastrointestinal bleeding, overdiuresis, uremia, dehydration, electrolyte imbalance, infection, constipation, or use of narcotic analgesics.

A helpful measure of hepatic encephalopathy is a careful mental status examination and use of the trail-making test, which consists of a series of 25 numbered circles that the patient is asked to connect as rapidly as possible using a pencil. The normal range for the connect-the-dot test is 15–30 s; it is considerably longer in patients with early hepatic encephalopathy. Other tests include drawing of abstract objects or comparison of a signature to previous examples. More sophisticated testing—for example, with electroencephalography and visual evoked potentials—can detect mild forms of encephalopathy but are rarely clinically useful.

Other signs of advanced liver disease include umbilical hernia from ascites, hydrothorax, prominent veins over the abdomen, and caput medusa, a condition that consists of collateral veins radiating from the umbilicus and results from recanulation of the umbilical vein. Widened pulse pressure and signs of a hyperdynamic circulation can occur in patients with cirrhosis as a result of fluid and sodium retention, increased cardiac output, and reduced peripheral resistance. Patients with long-standing cirrhosis and portal hypertension are prone to develop the hepatopulmonary syndrome, which is defined by the triad of liver disease, hypoxemia, and pulmonary arteriovenous shunting. The hepatopulmonary syndrome is characterized by platypnea and orthodeoxia: shortness of breath and oxygen desaturation that occur paradoxically upon the assumption of an upright position. Measurement of oxygen saturation by pulse oximetry is a reliable screening test for hepatopulmonary syndrome.

Several skin disorders and changes are common in liver disease. Hyperpigmentation is typical of advanced chronic cholestatic diseases such as primary biliary cholangitis and sclerosing cholangitis. In these same conditions, xanthelasma and tendon xanthomata occur as a result of retention and high serum levels of lipids and cholesterol. Slate-gray pigmentation of the skin is also seen with hemochromatosis if iron levels are high for a prolonged period. Mucocutaneous vasculitis with palpable purpura, especially on the lower extremities, is typical of cryoglobulinemia of chronic hepatitis C but can also occur in chronic hepatitis B.

Some physical signs point to specific liver diseases. Kayser-Fleischer rings occur in Wilson disease and consist of a golden-brown copper pigment deposited in Descemet's membrane at the periphery of the cornea; they are best seen by slit-lamp examination. Dupuytren contracture and parotid enlargement are suggestive of alcohol use disorder and alcohol-related liver disease. In metastatic liver disease or primary hepatocellular carcinoma (HCC), signs of cachexia and wasting as well as firm hepatomegaly and a hepatic bruit may be prominent.

DIAGNOSIS OF LIVER DISEASE

The key diagnostic tests of major causes of acute and chronic liver disease are outlined in **Table 347-3**, and an algorithm for evaluation of the patient with suspected liver disease is shown in **Fig. 347-1**. Specifics of diagnosis are discussed in later chapters. The most common causes of acute liver disease are viral hepatitis (particularly hepatitis A, B, and C), drug-induced liver injury, cholangitis, and alcohol-related liver disease. Liver biopsy usually is not needed for the diagnosis and management of acute liver disease, exceptions being situations where the diagnosis remains unclear despite thorough clinical and laboratory investigation. Liver biopsy can be helpful in diagnosing drug-induced liver disease and acute alcoholic hepatitis.

TABLE 347-3 Important Diagnostic Tests in Common Liver Diseases

DISEASE	DIAGNOSTIC TEST
Hepatitis A	Anti-HAV IgM
Hepatitis B	
Acute	HBsAg and anti-HBc IgM
Chronic	HBsAg and HBeAg and/or HBV DNA
Hepatitis C	Anti-HCV and HCV RNA
Hepatitis D (delta)	HBsAg and anti-HDV
Hepatitis E	Anti-HEV IgM and HEV RNA
Autoimmune hepatitis	ANA or SMA, elevated IgG levels, and compatible histology
Primary biliary cholangitis	Mitochondrial antibody, elevated IgM levels, and compatible histology
Primary sclerosing cholangitis	P-ANCA, cholangiography
Drug-induced liver disease	History of drug ingestion
Alcohol-related liver disease	History of excessive alcohol intake and compatible histology
Nonalcoholic steatohepatitis[a]	Ultrasound or CT evidence of fatty liver and compatible histology
α_1 Antitrypsin disease	Reduced α_1 antitrypsin levels, phenotype PiZZ or PiSZ
Wilson disease	Decreased serum ceruloplasmin and increased urinary copper; increased hepatic copper level
Hemochromatosis	Elevated iron saturation and serum ferritin; genetic testing for *HFE* gene mutations
Hepatocellular cancer	Elevated α-fetoprotein level (to >500 ng/mL); ultrasound or CT image of mass

[a]Also known as metabolic dysfunction–associated steatohepatitis (MASH).

Abbreviations: ANA, antinuclear antibody; anti-HBc, antibody to hepatitis B core (antigen); CT, computed tomography; HAV, HBV, HCV, HDV, HEV, hepatitis A, B, C, D, E virus; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; P-ANCA, peripheral antineutrophil cytoplasmic antibody; SMA, smooth-muscle antibody.

The most common causes of chronic liver disease, in general order of frequency, are chronic hepatitis C, alcoholic liver disease, nonalcoholic steatohepatitis (also called metabolic dysfunction–associated steatohepatitis), chronic hepatitis B, autoimmune hepatitis, sclerosing cholangitis, primary biliary cholangitis, hemochromatosis, and Wilson disease. Hepatitis E virus is a rare cause of chronic hepatitis, with cases occurring mostly in persons who are immunosuppressed or immunodeficient. Strict diagnostic criteria have not been developed for most liver diseases, but liver biopsy plays an important role in the diagnosis of autoimmune hepatitis, primary biliary cholangitis, nonalcoholic and alcoholic steatohepatitis, and Wilson disease (with a quantitative hepatic copper level in the last instance).

Laboratory Testing Diagnosis of liver disease is greatly aided by the availability of reliable and sensitive tests of liver injury and function. A typical battery of blood tests used for initial assessment of liver disease includes measurement of levels of serum alanine (ALT) and aspartate (AST) aminotransferases, alkaline phosphatase (AlkP), direct and total serum bilirubin and albumin, and prothrombin time. The pattern of abnormalities generally points to hepatocellular versus cholestatic liver disease and helps determine whether the disease is acute or chronic and whether cirrhosis and hepatic failure are present. Based on these results, further testing over time may be necessary. Other laboratory tests may be helpful, such as γ-glutamyl transpeptidase (γGT) to define whether AlkP elevations are due to liver disease; hepatitis serology to define the type of viral hepatitis; and autoimmune markers to diagnose primary biliary cholangitis (antimitochondrial

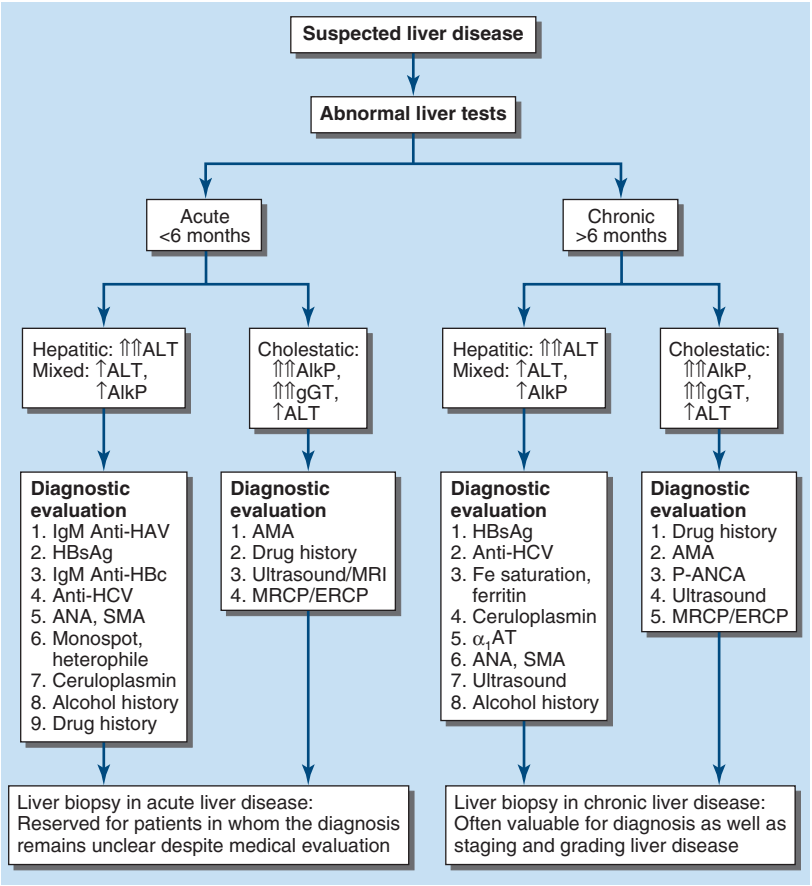

FIGURE 347-1 Algorithm for evaluation of abnormal liver tests. For patients with suspected liver disease, an appropriate approach to evaluation is initial routine liver testing—for example, measurement of serum bilirubin, albumin, alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase (AlkP). These results (sometimes complemented by testing of γ-glutamyl transpeptidase [γGT]) will establish whether the pattern of abnormalities is hepatic, cholestatic, or mixed. In addition, the duration of symptoms or abnormalities will indicate whether the disease is acute or chronic. If the disease is acute and if history, laboratory tests, and imaging studies do not reveal a diagnosis, liver biopsy is appropriate to help establish the diagnosis. If the disease is chronic, liver biopsy can be helpful not only for diagnosis but also for grading of the activity and staging the progression of disease. This approach is generally applicable to patients without immune deficiency. In patients with HIV infection or recipients of bone marrow or solid organ transplants, the diagnostic evaluation should also include evaluation for opportunistic infections (e.g., with adenovirus, cytomegalovirus, *Coccidioides*, hepatitis E virus) as well as for vascular and immunologic conditions (venoocclusive disease, graft-versus-host disease). α_1AT, α_1 antitrypsin; AMA, antimitochondrial antibody; ANA, antinuclear antibody; anti-HBc, antibody to hepatitis B core (antigen); ERCP, endoscopic retrograde cholangiopancreatography; HAV, hepatitis A virus; HBsAg, hepatitis B surface antigen; HCV, hepatitis C virus; MRCP, magnetic resonance cholangiopancreatography; P-ANCA, peripheral antineutrophil cytoplasmic antibody; SMA, smooth-muscle antibody.

antibody), sclerosing cholangitis (peripheral antineutrophil cytoplasmic antibody), and autoimmune hepatitis (antinuclear, smooth-muscle, and liver-kidney microsomal antibody). A simple delineation of laboratory abnormalities and common liver diseases is given in Table 347-3.

The use and interpretation of liver function tests are summarized in Chap. 348.

Diagnostic Imaging Great advances have been made in hepatobiliary imaging, although no method is adequately accurate in demonstrating underlying cirrhosis in its early stages. Of the many modalities available for imaging the liver, US, computed tomography (CT), and magnetic resonance imaging (MRI) are the most commonly employed and are complementary to one another. In general, US and CT are highly sensitive for detecting biliary duct dilation and are the first-line options for investigating cases of suspected obstructive jaundice. All three modalities can detect a fatty liver, which appears bright on imaging studies. Modifications of CT and MRI can be used to quantify liver fat, and this information may ultimately be valuable in monitoring response to therapy in patients with fatty liver disease. Advantages, disadvantages, and clinical utility of each modality are presented in Table 347-4. Magnetic resonance cholangiopancreatography (MRCP) and endoscopic retrograde cholangiopancreatography (ERCP) are the procedures of choice for visualization of the biliary tree. MRCP offers several advantages over ERCP: there is no need for contrast media or ionizing radiation, images can be acquired faster, the procedure is less operator dependent, and it carries no risk of pancreatitis. MRCP is superior to US and CT for detecting choledocholithiasis but is less specific. MRCP is useful in the diagnosis of bile duct obstruction and congenital biliary abnormalities, but ERCP is considered more valuable in evaluating ampullary lesions and primary sclerosing cholangitis. ERCP permits biopsy, direct visualization of the ampulla and common bile duct, and intraductal ultrasonography and brushings for cytologic evaluation of malignancy. It also provides several therapeutic options in patients with obstructive jaundice, such as sphincterotomy, stone extraction, and placement of nasobiliary catheters and biliary stents.

Doppler US and MRI are used to assess hepatic vasculature and hemodynamics and to monitor surgically or radiologically placed vascular shunts, including

TABLE 347-4 Diagnostic Tests to Assess Liver Fat

IMAGING MODALITY	ADVANTAGES	DISADVANTAGES	CLINICAL UTILITY
Ultrasound	No radiation Widely available	Operator dependent Imprecise qualitative assessment of fat severity, particularly mild steatosis	Initial screening test for suspected liver fat
Transient elastography with controlled attenuation parameter	No radiation Point-of-care assessment of liver fat Provides semiquantitative assessment of fat severity	Requires special software No reliable cutoff for diagnosis of liver fat Imprecise qualitative assessment of fat severity	Alternate screening test for suspected liver fat if available
Computed tomography	Rapid assessment Non–operator dependent Quantitative assessment of fat severity	Requires radiation Quantification of fat requires specific protocols Imprecise quantitative assessment of fat severity, particularly mild steatosis	Not recommended for clinical assessment of liver fat due to need for radiation exposure and low sensitivity for mild fat
Magnetic resonance imaging–proton density fat fraction	Direct assessment of liver fat Highly sensitive and specific	Relatively limited accessibility	Test of choice for quantitative assessment of liver fat if available

transjugular intrahepatic portosystemic shunts. Multidetector or spiral CT and MRI with contrast enhancement are the procedures of choice for the identification and evaluation of hepatic masses, the staging of liver tumors, and preoperative assessment. With regard to mass lesions, the sensitivity of hepatic imaging continues to increase; unfortunately, specificity remains a problem, and often two and sometimes three studies are needed before a diagnosis can be reached. An emerging imaging modality for the investigation of hepatic lesions is contrast-enhanced US. This procedure permits enhancement of liver lesions in a similar fashion as contrast-enhanced, cross-sectional CT or MRI. Major advantages are real-time assessment of liver perfusion throughout the vascular phases without risk of nephrotoxicity and radiation exposure. Other advantages are its widespread availability and lower cost. Limitations include body habitus of the patient and skill of the operator.

US is the recommended modality for HCC screening. Contrast-enhanced US, CT, and MRI are appropriate for further investigation of lesions detected on screening US. The American College of Radiologists has developed a Liver Imaging Reporting and Data System (LI-RADS) to standardize the reporting and data collection of CT, MRI, and contrast-enhanced US imaging for HCC. This system allows for more consistent reporting and reduces imaging interpretation variability and errors.

Recently, several US-based elastographic techniques have been developed and approved for the measurement of hepatic stiffness, providing an indirect assessment of fibrosis and cirrhosis. The most commonly used approaches in clinical practice include transient elastography, acoustic radiation force impulse imaging, shear-wave elasticity imaging, and supersonic shear imaging. These techniques can eliminate the need for liver biopsy if the only indication for the test is the assessment of disease stage. Magnetic resonance elastography is more sensitive than US elastography but is also more expensive and requires advanced scheduling and special equipment. Finally, interventional radiologic techniques allow for the biopsy of solitary lesions, the radiofrequency ablation and chemoembolization of cancerous lesions, the insertion of drains into hepatic abscesses, the measurement of portal pressure, and the creation of vascular shunts in patients with portal hypertension. Which modality to use depends on factors such as availability, cost, and experience of the radiologist with each technique.

Liver Biopsy Liver biopsy remains the gold standard in the evaluation of patients with liver disease, particularly chronic liver disease. Liver biopsy is necessary for diagnosis in selected instances but is more often useful for assessment of the severity (grade) and stage of liver damage, prediction of prognosis, and monitoring of the response to treatment. The size of the liver biopsy sample is an important determinant of reliability; a length of 1.5–2 cm with 10 portal tracts is necessary for accurate assessment of fibrosis. Because liver biopsy is an invasive procedure and not without complications, it should be used only when it will contribute materially to decisions about management and therapy. In the future, noninvasive means of assessing disease activity (batteries of blood tests) and fibrosis (elastography and fibrosis markers) may replace liver biopsy for the staging and grading of disease.

GRADING AND STAGING OF LIVER DISEASE

Grading refers to an assessment of the severity or activity of liver disease, whether acute or chronic; active or inactive; and mild, moderate, or severe. Liver biopsy is the most accurate means of assessing severity, particularly in chronic liver disease. Serum aminotransferase levels serve as convenient and noninvasive markers for disease activity but do not always reliably reflect disease severity. Thus, normal serum aminotransferase levels in patients with hepatitis B surface antigen in serum may indicate the inactive carrier state or may reflect mild chronic hepatitis B or hepatitis B with fluctuating disease activity. Serum testing for hepatitis B e antigen and hepatitis B virus DNA can help sort out these different patterns, but these markers can also fluctuate and change over time. Similarly, in chronic hepatitis C, serum aminotransferase levels can be normal despite moderate disease activity. Finally, in both alcoholic and nonalcoholic steatohepatitis, aminotransferase levels are quite unreliable in reflecting severity. In these conditions, liver biopsy is helpful in guiding management and identifying appropriate therapy, particularly if treatment is difficult, prolonged, and expensive. Of the several well-verified numerical scales for histologic grading of chronic liver disease, the most commonly used are the METAVIR and the histology activity index.

Liver biopsy is also the most accurate means of assessing stage of disease as early or advanced and as precirrhotic or cirrhotic. Staging of disease pertains largely to chronic liver diseases in which progression to cirrhosis and end-stage disease can occur but may require years or decades. Clinical features, biochemical tests, and hepatic imaging studies are helpful in assessing stage but generally become abnormal only in the middle to late stages of cirrhosis. Noninvasive tests that suggest advanced fibrosis include mild elevations of bilirubin, prolongation of prothrombin time, slight decreases in serum albumin, and mild thrombocytopenia (which is often the first indication of worsening fibrosis). Combinations of blood test results that include clinical features, routine laboratory tests, and special laboratory tests such as serum proteins or small molecules that are affected by or involved with fibrogenesis have been used to create models for predicting advanced liver disease, but these models are not reliable enough to use on a regular basis or for repeated measures and only separate advanced from early disease **(Table 347-5)**. Recently, elastography and noninvasive breath tests using ^{13}C-labeled compounds have been proposed as a means of detecting early stages of fibrosis and liver dysfunction, but their reliability and reproducibility remain to be proven. A major limitation of noninvasive markers is that they can be affected by disease activity. Even elastography is limited in this regard, in that it measures liver stiffness, not fibrosis per se, and can be affected by inflammation, edema, hepatocyte necrosis, and intrasinusoidal cellularity (inflammatory, malignant, or sickled cells). Thus, at present, mild to moderate stages of hepatic fibrosis are detectable only by liver biopsy. In the assessment of stage, the degree of fibrosis is usually used as the quantitative measure. The amount of fibrosis is generally staged on a scale of 0 to 4+ (METAVIR scale) or 0 to 6+ (Ishak scale). The importance of staging relates primarily to prognosis, recommendation of therapy, and optimal management to prevent complications of chronic liver disease. Patients with cirrhosis are candidates for screening and surveillance for esophageal varices and HCC. Patients without advanced fibrosis need not undergo screening.

Once cirrhosis develops, other scoring systems are employed to assess compensated versus decompensated disease and prognosis. The first staging system used for this purpose was the modified Child-Pugh

TABLE 347-5 Selected Noninvasive Methods of Assessing Hepatic Fibrosis and Cirrhosis

METHOD	PARAMETERS	ADVANCED FIBROSIS	CIRRHOSIS
APRI	AST, platelet count	>1	>1.5 (1–2)
ELF	Age, hyaluronic acid, MMP-3, TIMP-1	>7.7	>9.3
FIB-4	Age, AST, ALT, platelet count	>1.45	>3.25
Fibro test[a]	Haptoglobin, α_2-macroglobulin, apolipoprotein A1, γGT, total bilirubin	>0.45	>0.63
TE	Measures speed of a shear wave generated by vibration through liver tissue	>7.3 kPa	>15 kPa (9–26.5 kPa)
ARFI	Measures speed of shear wave generated by acoustic radiation force through liver tissue	>1.3 m/s	>1.87 m/s

[a]Patented models.

Note: The cut points presented in the table were mostly derived from patients with chronic hepatitis C. The cut points for the noninvasive models and tests presented in the table vary among different liver diseases and among patients with the same disease among different populations.

Abbreviations: ALT, alanine aminotransferase; APRI, AST-to-platelet ratio; ARFI, acoustic radiation force imaging; AST, aspartate aminotransferase; ELF, enhanced liver fibrosis panel; γGT, γ-glutamyl transpeptidase; MMP-3, metalloproteinase-3; TIMP-1, tissue inhibitor of metalloproteinase-1; TE, transient elastography.

TABLE 347-6 Child-Pugh Classification of Cirrhosis

FACTOR	UNITS	POINTS TOWARD TOTAL SCORE 1	2	3
Serum bilirubin	μmol/L	<34	34–51	>51
	mg/dL	<2.0	2.0–3.0	>3.0
Serum albumin	g/L	>35	30–35	<30
	g/dL	>3.5	3.0–3.5	<3.0
Prothrombin time	Seconds prolonged	<4	4–6	>6
	INR[a]	<1.7	1.7–2.3	>2.3
Ascites		None	Easily controlled	Poorly controlled
Hepatic encephalopathy		None	Minimal	Advanced

[a]International normalized ratio.

Note: The Child-Pugh score is calculated by adding the scores for the five factors and can range from 5 to 15. The resulting Child-Pugh class can be A (a score of 5–6), B (7–9), or C (≥10). Decompensation indicates cirrhosis, with a Child-Pugh score of ≥7 (class B). This level has been the accepted criterion for listing a patient for liver transplantation.

classification, with a scoring system of 5–15: scores of 5 and 6 represent Child-Pugh class A (consistent with "compensated cirrhosis"), scores of 7–9 represent class B, and scores of 10–15 represent class C **(Table 347-6)**. This scoring system was initially devised to stratify patients with cirrhosis into risk groups before portal decompressive surgery. The Child-Pugh score is a reasonably reliable predictor of survival in many liver diseases and predicts the likelihood of major complications of cirrhosis, such as bleeding from varices and spontaneous bacterial peritonitis. This classification scheme was used to assess prognosis in cirrhosis and to provide standard criteria for listing a patient as a candidate for liver transplantation (Child-Pugh class B). The Child-Pugh system has been replaced by the Model for End-Stage Liver Disease (MELD) system for the latter purpose. The MELD score is a prospectively derived system designed to predict the short-term mortality of patients awaiting orthotopic liver transplant and following a transjugular intrahepatic portosystemic shunt (TIPS). This score is calculated using three readily available objective variables: the prothrombin time expressed as the international normalized ratio (INR), the serum bilirubin level, and the serum creatinine concentration. The ability of the MELD score to predict outcome after liver transplantation is regularly monitored and was modified to increase its accuracy and improve allocation of donated livers. These modifications include serum sodium concentration as a factor in the model and a reweighting of the MELD components. A separate scoring system, the Pediatric End-Stage Liver Disease (PELD) score, is used for children (<12 years old). Transient elastography has also been used to stage cirrhosis and has been shown to be useful in predicting complications such as variceal hemorrhage, ascites development, and liver-related death.

The MELD system provides a more objective means of assessing disease severity and has less center-to-center variation than the Child-Pugh score as well as a wider range of values. The MELD and PELD systems are currently used to establish priority listing for liver transplantation in the United States. Convenient MELD and PELD calculators are available via the Internet (*https://optn.transplant.hrsa.gov*).

NONSPECIFIC ISSUES IN THE MANAGEMENT OF PATIENTS WITH LIVER DISEASE

Specifics on the management of different forms of acute or chronic liver disease are supplied in subsequent chapters, but certain issues are applicable to any patient with liver disease. These issues include advice regarding alcohol use, medication use, vaccination, and surveillance for certain liver diseases and complications of liver disease. Alcohol should be used sparingly, if at all, by patients with liver disease. Abstinence from alcohol should be encouraged for all patients with alcohol-related liver disease, patients with cirrhosis, and patients receiving interferon-based therapy for hepatitis B or D and during antiviral therapy of hepatitis C. With regard to vaccinations, all patients with liver disease should receive hepatitis A and hepatitis B vaccine, if not previously vaccinated, and screened for hepatitis C if not already done. Adherence to the recommendations of the Centers for Disease Control and Prevention (CDC) on other adult vaccinations should also be encouraged. Patients with liver disease should exercise caution in using any medications other than those that are most necessary. Drug-induced hepatotoxicity can mimic many forms of liver disease and can cause exacerbations of chronic hepatitis and cirrhosis; drugs should be suspected in any situation in which the cause of exacerbation is unknown. Finally, consideration should be given to surveillance for complications of chronic liver disease such as variceal hemorrhage and HCC. Cirrhosis warrants upper endoscopy to assess the presence of varices, and the patient should receive chronic therapy with beta blockers or should be offered endoscopic obliteration if large varices are found. Moreover, cirrhosis warrants screening and long-term surveillance for development of HCC. While the optimal regimen for such surveillance has not been established, an appropriate approach is US of the liver at 6- to 12-month intervals.

348 Evaluation of Liver Function

Emily D. Bethea, Daniel S. Pratt

There are a number of tests that can be used to evaluate liver function. These tests include biochemical tests, radiologic tests, and pathologic tests.

Serum biochemical tests, also commonly referred to as "liver function tests," can be used to (1) detect the presence of liver disease, (2) distinguish among different types of liver disorders, (3) gauge the extent of liver damage, and (4) follow the response to treatment. However, serum biochemical tests have shortcomings. They lack sensitivity and specificity; they can be normal in patients with serious liver disease and abnormal in patients with diseases that do not affect the liver. Liver tests rarely suggest a specific diagnosis; rather, they suggest a general category of liver disease, such as hepatocellular or cholestatic, which then further directs the evaluation. The liver carries out thousands of biochemical functions, most of which cannot be easily measured by blood tests. Laboratory tests measure only a limited number of these functions. In fact, many tests, such as the aminotransferases and alkaline phosphatase, do not measure liver function at all. Rather, they detect liver cell damage or interference with bile flow. Thus, no one biochemical test enables the clinician to accurately assess the liver's total functional capacity.

To increase the sensitivity and the specificity of biochemical tests in the detection of liver disease, it is best to use them as a battery. Tests usually employed in clinical practice include the bilirubin, aminotransferases, alkaline phosphatase, albumin, and prothrombin time tests. When more than one of these tests provide abnormal findings or the findings are persistently abnormal on serial determinations, the probability of liver disease is high. When all test results are normal, the probability of missing occult liver disease is low.

Serum Bilirubin (See also Chap. 52) Bilirubin, a breakdown product of the porphyrin ring of heme-containing proteins, is found in the blood in two fractions—conjugated and unconjugated. The unconjugated fraction, also termed the *indirect fraction*, is insoluble in water and is bound to albumin in the blood. The conjugated (direct) bilirubin fraction is water-soluble and can therefore be excreted by the kidney. Normal values of total serum bilirubin are reported between 1 and 1.5 mg/dL with 95% of a normal population falling between 0.2 and 0.9 mg/dL. If the direct-acting fraction is <15% of the total, the bilirubin can be considered to all be indirect. The most frequently reported upper limit of normal for conjugated bilirubin is 0.3 mg/dL.

Elevation of the unconjugated fraction of bilirubin is rarely due to liver disease. An isolated elevation of unconjugated bilirubin is seen primarily in hemolytic disorders and in a number of genetic conditions such as Crigler-Najjar and Gilbert's syndromes (Chap. 52). Isolated unconjugated hyperbilirubinemia (bilirubin elevated but <15% direct) should prompt a workup for hemolysis (Fig. 348-1). In the absence of hemolysis, an isolated, unconjugated hyperbilirubinemia in an otherwise healthy patient can be attributed to Gilbert's syndrome, and no further evaluation is required.

In contrast, conjugated hyperbilirubinemia almost always implies liver or biliary tract disease. The rate-limiting step in bilirubin metabolism is not conjugation of bilirubin, but rather the transport of conjugated bilirubin into the bile canaliculi. Thus, elevation of the conjugated fraction may be seen in any type of liver disease including fulminant liver failure. In most liver diseases, both conjugated and unconjugated fractions of the bilirubin tend to be elevated. Except in the presence of an isolated hyperbilirubinemia, fractionation of the bilirubin is rarely helpful in determining the cause of jaundice.

Although the degree of elevation of the serum bilirubin has not been critically assessed as a prognostic marker, it is important in a number of conditions. In viral hepatitis, the higher the serum bilirubin, the greater is the hepatocellular damage. Total serum bilirubin correlates with poor outcomes in alcoholic hepatitis. It is also a critical component of the Model for End-Stage Liver Disease (MELD) score, a tool used to estimate survival of patients with end-stage liver disease, prioritize patients awaiting liver transplantation, and assess operative risk of patients with cirrhosis. An elevated total serum bilirubin in patients with drug-induced liver disease indicates more severe injury. Total bilirubin has also been shown to be of prognostic value in primary biliary cholangitis.

Unconjugated bilirubin always binds to albumin in the serum and is not filtered by the kidney. Therefore, any bilirubin found in the urine is conjugated bilirubin; the presence of bilirubinuria implies the presence of liver disease or obstructive jaundice. A urine dipstick test can theoretically give the same information as fractionation of the serum bilirubin. This test is almost 100% accurate. Phenothiazines may give a false-positive reading with the Ictotest tablet. In patients recovering from jaundice, the urine bilirubin clears prior to the serum bilirubin.

Serum Enzymes The liver contains thousands of enzymes, some of which are also present in the serum in very low concentrations. These enzymes have no known function in the serum and behave like other

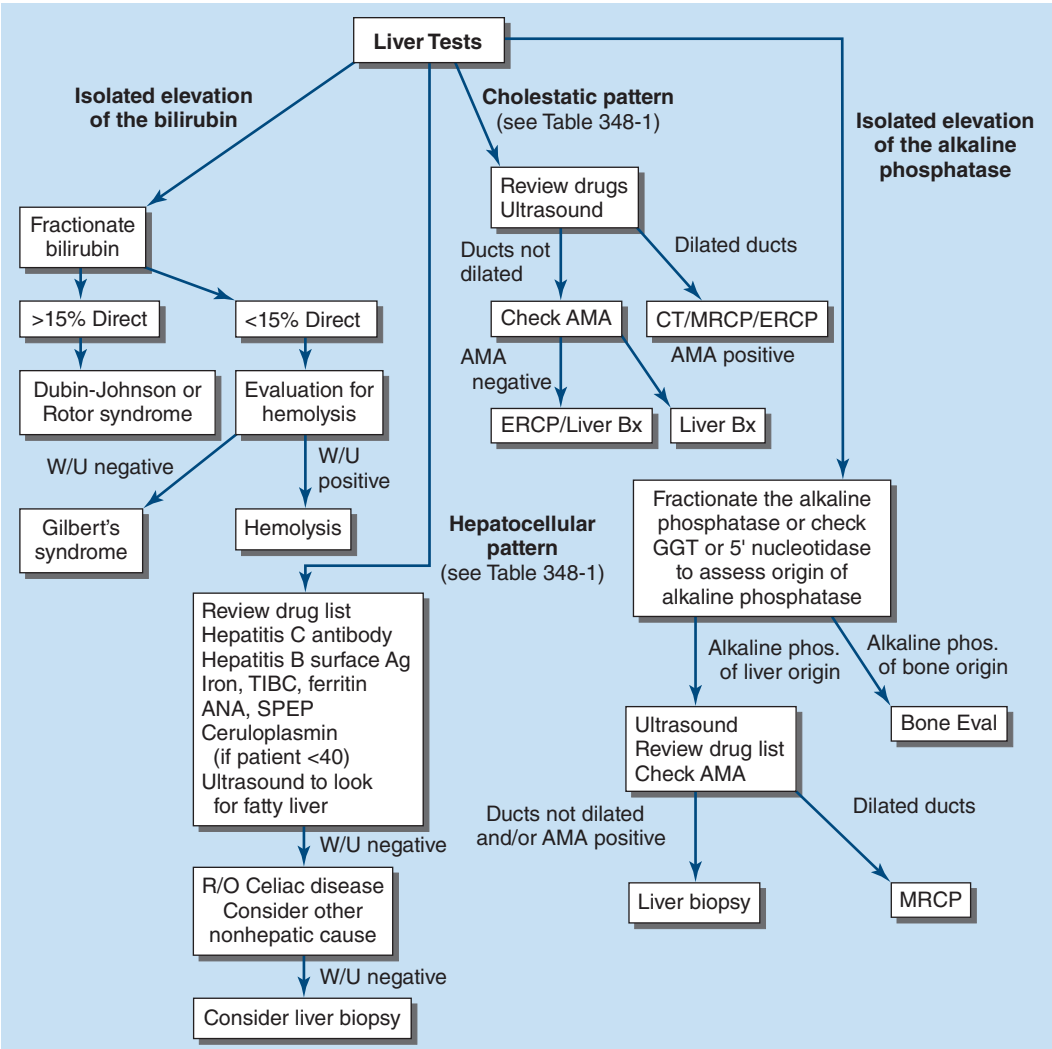

FIGURE 348-1 Algorithm for the evaluation of chronically abnormal liver tests. Ag, antigen; AMA, antimitochondrial antibody; ANA, antinuclear antibody; Bx, biopsy; CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; GGT, γ-glutamyl transpeptidase; MRCP, magnetic resonance cholangiopancreatography; R/O, rule out; SPEP, serum protein electrophoresis; TIBC, total iron-binding capacity; W/U, workup.

serum proteins. They are distributed in the plasma and in interstitial fluid and have characteristic half-lives, which are usually measured in days. Very little is known about the catabolism of serum enzymes, although they are probably cleared by cells in the reticuloendothelial system. The elevation of a given enzyme activity in the serum is thought to primarily reflect its increased rate of entrance into serum from damaged liver cells.

Serum enzyme tests can be grouped into two categories: (1) enzymes whose elevation in serum reflects damage to hepatocytes and (2) enzymes whose elevation in serum reflects cholestasis.

ENZYMES THAT REFLECT DAMAGE TO HEPATOCYTES The aminotransferases (transaminases) are sensitive indicators of liver cell injury and are most helpful in recognizing acute hepatocellular diseases such as hepatitis. They include aspartate aminotransferase (AST) and alanine aminotransferase (ALT). AST is found in the liver, cardiac muscle, skeletal muscle, kidneys, brain, pancreas, lungs, leukocytes, and erythrocytes in decreasing order of concentration. ALT is found primarily in the liver and is therefore a more specific indicator of liver injury. The aminotransferases are normally present in the serum in low concentrations. These enzymes are released into the blood in greater amounts when there is damage to the liver cell membrane, resulting in increased permeability. Liver cell necrosis is not required for the release of the aminotransferases, and there is a poor correlation between the degree of liver cell damage and the level of the aminotransferases. Thus, the absolute elevation of the aminotransferases is of no prognostic significance in acute hepatocellular disorders.

The normal range for aminotransferases varies widely among laboratories, but generally ranges from 10 to 40 IU/L. The interlaboratory variation in normal range is due to technical reasons; no reference standards exist to establish upper limits of normal for ALT and AST. Some have recommended revisions of normal limits of the aminotransferases to adjust for sex and body mass index, but others have noted the potential costs and unclear benefits of implementing this change.

Any type of liver cell injury can cause modest elevations in the serum aminotransferases. Levels of up to 300 IU/L are nonspecific and may be found in any type of liver disorder. Minimal ALT elevations in asymptomatic blood donors rarely indicate severe liver disease; studies have shown that fatty liver disease is the most likely explanation. Striking elevations—that is, aminotransferases >1000 IU/L—occur almost exclusively in disorders associated with extensive hepatocellular injury such as (1) viral hepatitis, (2) ischemic liver injury (prolonged hypotension or acute heart failure), or (3) toxin- or drug-induced liver injury.

The pattern of the aminotransferase elevation can be helpful diagnostically. In most acute hepatocellular disorders, the ALT is higher than or equal to the AST. Whereas the AST:ALT ratio is typically <1 in patients with chronic viral hepatitis and nonalcoholic fatty liver disease, a number of groups have noted that as cirrhosis develops, this ratio rises to >1. An AST:ALT ratio >2:1 is suggestive, whereas a ratio >3:1 is highly suggestive, of alcohol-related liver disease. The AST in alcohol-related liver disease is rarely >300 IU/L, and the ALT is often normal. A low level of ALT in the serum is due to an alcohol-induced deficiency of pyridoxal phosphate.

The aminotransferases are usually not greatly elevated in obstructive jaundice. One notable exception occurs during the acute phase of biliary obstruction caused by the passage of a gallstone into the common bile duct. In this setting, the aminotransferases can briefly be in the 1000–2000 IU/L range. However, aminotransferase levels decrease quickly, and the biochemical tests rapidly evolve into those typical of cholestasis.

ENZYMES THAT REFLECT CHOLESTASIS The activities of three enzymes—alkaline phosphatase, 5′-nucleotidase, and γ-glutamyl transpeptidase (GGT)—are usually elevated in cholestasis. Alkaline phosphatase and 5′-nucleotidase are found in or near the bile canalicular membrane of hepatocytes, whereas GGT is located in the endoplasmic reticulum and in bile duct epithelial cells. Reflecting its more diffuse localization in the liver, GGT elevation in serum is less specific for cholestasis than are elevations of alkaline phosphatase or 5′-nucleotidase. Some have advocated the use of GGT to identify patients with occult alcohol use. Its lack of specificity makes its use in this setting questionable.

The normal serum alkaline phosphatase consists of many distinct isoenzymes found in the liver, bone, placenta, and, less commonly, the small intestine. Patients over age 60 can have a mildly elevated alkaline phosphatase (1–1.5 times normal), whereas individuals with blood types O and B can have an elevation of the serum alkaline phosphatase after eating a fatty meal due to the influx of intestinal alkaline phosphatase into the blood. It is also elevated in children and adolescents undergoing rapid bone growth because of bone alkaline phosphatase and late in normal pregnancies due to the influx of placental alkaline phosphatase.

Elevation of liver-derived alkaline phosphatase is not totally specific for cholestasis, and a less than threefold elevation can be seen in almost any type of liver disease. Alkaline phosphatase elevations greater than four times normal occur primarily in patients with cholestatic liver disorders, infiltrative liver diseases such as cancer and amyloidosis, and bone conditions characterized by rapid bone turnover (e.g., Paget's disease). In bone diseases, the elevation is due to increased amounts of the bone isoenzymes. In liver diseases, the elevation is almost always due to increased amounts of the liver isoenzyme.

If an elevated serum alkaline phosphatase is the only abnormal finding in an apparently healthy person or if the degree of elevation is higher than expected in the clinical setting, identification of the source of elevated isoenzymes is helpful (Fig. 348-1). This problem can be approached in two ways. First, and most precise, is the fractionation of the alkaline phosphatase by electrophoresis. The second, best substantiated, and most available approach involves the measurement of serum 5′-nucleotidase or GGT.

In the absence of jaundice or elevated aminotransferases, an elevated alkaline phosphatase of liver origin often, but not always, suggests early cholestasis and, less often, hepatic infiltration by tumor or granulomata. Other conditions that cause isolated elevations of the alkaline phosphatase include primary biliary cholangitis, primary or secondary sclerosing cholangitis, Hodgkin's disease, diabetes, hyperthyroidism, congestive heart failure, and amyloidosis.

The level of serum alkaline phosphatase elevation is not helpful in distinguishing between intrahepatic and extrahepatic cholestasis. There is essentially no difference among the values found in obstructive jaundice due to cancer, common duct stone, sclerosing cholangitis, or bile duct stricture. Values are similarly increased in patients with intrahepatic cholestasis due to drug-induced hepatitis, primary biliary cholangitis, sepsis, rejection of transplanted livers, and, rarely, alcohol-induced steatohepatitis. Values are also greatly elevated in hepatobiliary disorders seen in patients with AIDS (e.g., AIDS cholangiopathy due to cytomegalovirus or cryptosporidial infection and tuberculosis with hepatic involvement).

TESTS THAT MEASURE BIOSYNTHETIC FUNCTION OF THE LIVER

Serum Albumin Serum albumin is synthesized exclusively by hepatocytes. Serum albumin has a long half-life: 18–20 days, with ~4% degraded per day. Because of this slow turnover, the serum albumin is not a good indicator of acute or mild hepatic dysfunction; only minimal changes in the serum albumin are seen in acute liver conditions such as viral hepatitis, drug-related hepatotoxicity, and obstructive jaundice. In hepatitis, albumin levels <3 g/dL should raise the possibility of chronic liver disease. Hypoalbuminemia is more common in chronic liver disorders such as cirrhosis and usually reflects severe liver damage and decreased albumin synthesis. However, hypoalbuminemia is not specific for liver disease and may occur in protein malnutrition of any cause, as well as protein-losing enteropathies, nephrotic syndrome, and chronic infections that are associated with prolonged increases in levels of cytokines that inhibit albumin synthesis, such as serum interleukin 1 and/or tumor necrosis factor. Serum albumin should not be measured to screen patients in whom there is no suspicion of liver disease. A general medical clinic study of consecutive patients in whom no indications were present for albumin measurement showed that although

12% of patients had abnormal test results, the finding was of clinical importance in only 0.4%.

Serum Globulins Serum globulins are a group of proteins made up of γ globulins (immunoglobulins) produced by B lymphocytes and α and β globulins produced primarily in hepatocytes. γ Globulins are increased in chronic liver disease, such as chronic hepatitis and cirrhosis. In cirrhosis, the increased serum γ globulin concentration is due to the increased synthesis of antibodies, some of which are directed against intestinal bacteria. This occurs because the cirrhotic liver fails to clear bacterial antigens that normally reach the liver through the hepatic circulation.

Increases in the concentration of specific isotypes of γ globulins are often helpful in the recognition of certain chronic liver diseases. Diffuse polyclonal increases in IgG levels are common in autoimmune hepatitis; increases >100% should alert the clinician to this possibility. Increases in the IgM levels are common in primary biliary cholangitis, whereas increases in the IgA levels occur in alcoholic liver disease.

COAGULATION FACTORS

With the exception of factor VIII, which is produced by vascular endothelial cells, the blood clotting factors are made exclusively in hepatocytes. Their serum half-lives are much shorter than albumin, ranging from 6 h for factor VII to 5 days for fibrinogen. Because of their rapid turnover, measurement of the clotting factors is the single best acute measure of hepatic synthetic function and helpful in both diagnosis and assessing the prognosis of acute parenchymal liver disease. Useful for this purpose is the *serum prothrombin time*, which collectively measures factors II, V, VII, and X. Biosynthesis of factors II, VII, IX, and X depends on vitamin K. The international normalized ratio (INR) is used to express the degree of anticoagulation on warfarin therapy. The INR standardizes prothrombin time measurement according to the characteristics of the thromboplastin reagent used in a particular lab, which is expressed as an International Sensitivity Index (ISI); the ISI is then used in calculating the INR.

The prothrombin time may be elevated in hepatitis and cirrhosis as well as in disorders that lead to vitamin K deficiency such as obstructive jaundice or fat malabsorption of any kind. Marked prolongation of the prothrombin time, >5 s above control and not corrected by parenteral vitamin K administration, is a poor prognostic sign in acute viral hepatitis and other acute and chronic liver diseases. The INR, along with the total serum bilirubin, creatinine, albumin, and sodium, are components of the MELD 3.0 score, which is used as a measure of hepatic decompensation and to allocate organs for liver transplantation.

OTHER DIAGNOSTIC TESTS

Although tests may direct the physician to a category of liver disease, additional biochemical testing, radiologic testing, and procedures are often necessary to make the proper diagnosis, as shown in Fig. 348-1. The most commonly used ancillary tests are reviewed here, as are the noninvasive tests available for assessing hepatic fibrosis.

Ammonia Ammonia is produced in the body during normal protein metabolism and by intestinal bacteria, primarily those in the colon. The liver plays a role in the detoxification of ammonia by converting it to urea, which is excreted by the kidneys. Striated muscle also plays a role in detoxification of ammonia, where it is combined with glutamic acid to form glutamine. Patients with advanced liver disease typically have significant muscle wasting, which likely contributes to hyperammonemia. Some physicians use the blood ammonia for detecting encephalopathy or for monitoring hepatic synthetic function, although its use for either of these indications has problems. There is very poor correlation between either the presence or the severity of acute encephalopathy and elevation of blood ammonia; it can be occasionally useful for identifying occult liver disease in patients with mental status changes. There is also a poor correlation of the blood serum ammonia and hepatic function. The ammonia can be elevated in patients with severe portal hypertension and portal blood shunting around the liver even in the presence of normal or near-normal hepatic function. Elevated arterial ammonia levels have been shown to correlate with outcome in fulminant hepatic failure.

Liver Biopsy Percutaneous biopsy of the liver is a safe procedure that is easily performed with local anesthesia and ultrasound guidance. Liver biopsy is of proven value in the following situations: (1) hepatocellular disease of uncertain cause, (2) prolonged hepatitis with the possibility of autoimmune hepatitis, (3) unexplained hepatomegaly, (4) unexplained splenomegaly, (5) hepatic lesions uncharacterized by radiologic imaging, (6) fever of unknown origin, and (7) staging of malignant lymphoma. Liver biopsy is most accurate in disorders causing diffuse changes throughout the liver and is subject to sampling error in focal disorders. Liver biopsy should not be the initial procedure in the diagnosis of cholestasis. The biliary tree should first be assessed for signs of obstruction. Contraindications to performing a percutaneous liver biopsy include significant ascites and prolonged INR. Under these circumstances, the biopsy can be performed via the transjugular approach.

Noninvasive Tests to Detect Hepatic Fibrosis Although liver biopsy is the standard for the assessment of hepatic fibrosis, noninvasive measures of hepatic fibrosis have gained favor. These measures include multiparameter tests aimed at detecting and staging the degree of hepatic fibrosis and imaging techniques. FibroTest (marketed as FibroSure in the United States) is the best evaluated of the multiparameter blood tests. The test incorporates haptoglobin, bilirubin, GGT, apolipoprotein A-I, and α_2-macroglobulin and has been found to have high positive and negative predictive values for diagnosing advanced fibrosis in patients with chronic hepatitis C, chronic hepatitis B, alcoholic liver disease, or metabolic dysfunction–associated steatotic liver disease (MASLD) and patients taking methotrexate for psoriasis. The Enhanced Liver Fibrosis (ELF) test is a multiparameter blood test that uses markers of fibrogenesis and cytolysis to estimate hepatic fibrosis: type III procollagen peptide, hyaluronic acid, and tissue inhibitor of metalloproteinase-1. It has been validated in patients with MASLD and is gaining favor in cholestatic liver disease. The FIB4 index is a liver fibrosis biomarker that is easily calculated using age and three routine laboratory parameters: ALT, AST, and platelet count. While originally proposed to help assess hepatic fibrosis in patients with human immunodeficiency virus and hepatitis C virus coinfection, it has been validated for hepatitis C virus, hepatitis B virus, and MASLD. Transient elastography (TE), marketed as FibroScan, and magnetic resonance elastography (MRE) both have gained U.S. Food and Drug Administration approval for use in the management of patients with liver disease. TE uses ultrasound waves to measure hepatic stiffness noninvasively. TE has been shown to be accurate for identifying advanced fibrosis in patients with chronic hepatitis C, primary biliary cholangitis, hemochromatosis, nonalcoholic fatty liver disease, and recurrent chronic hepatitis after liver transplantation. MRE has been found to be superior to TE for staging liver fibrosis in patients with a variety of chronic liver diseases but requires access to a magnetic resonance imaging scanner and is more expensive.

Ultrasonography Ultrasonography is the first diagnostic test to use in patients whose liver tests suggest cholestasis, to look for the presence of a dilated intrahepatic or extrahepatic biliary tree or to identify gallstones. In addition, it shows space-occupying lesions within the liver, enables the clinician to distinguish between cystic and solid masses, and helps direct percutaneous biopsies. Ultrasound with Doppler imaging can detect the patency of the portal vein, hepatic artery, and hepatic veins and determine the direction of blood flow. This is the first test ordered in patients suspected of having Budd-Chiari syndrome.

USE OF LIVER TESTS

As previously noted, the best way to increase the sensitivity and specificity of laboratory tests in the detection of liver disease is to employ a battery of tests that includes the aminotransferases, alkaline phosphatase, bilirubin, albumin, and prothrombin time along with the

TABLE 348-1 Liver Test Patterns in Hepatobiliary Disorders

TYPE OF DISORDER	BILIRUBIN	AMINOTRANSFERASES	ALKALINE PHOSPHATASE	ALBUMIN	PROTHROMBIN TIME
Hemolysis/Gilbert's syndrome	Normal to 86 μmol/L (5 mg/dL) 85% due to indirect fractions No bilirubinuria	Normal	Normal	Normal	Normal
Acute hepatocellular necrosis (viral, ischemic, and drug- or toxin-induced hepatitis)	Both fractions may be elevated Peak usually follows aminotransferases Bilirubinuria	Elevated, often >500 IU, ALT > AST	Normal to <3× normal elevation	Normal	Usually normal. If >5× above control and not corrected by parenteral vitamin K, suggests poor prognosis
Chronic hepatocellular disorders	Both fractions may be elevated Bilirubinuria	Elevated, but usually <300 IU	Normal to <3× normal elevation	Often decreased	Often prolonged Fails to correct with parenteral vitamin K
Alcoholic hepatitis, cirrhosis	Both fractions may be elevated Bilirubinuria	AST:ALT >2 suggests alcoholic hepatitis or cirrhosis	Normal to <3× normal elevation	Often decreased	Often prolonged Fails to correct with parenteral vitamin K
Intra- and extrahepatic cholestasis (obstructive jaundice)	Both fractions may be elevated Bilirubinuria	Normal to moderate elevation Rarely >500 IU	Elevated, often >4× normal elevation	Normal, unless chronic	Normal If prolonged, will correct with parenteral vitamin K
Infiltrative diseases (tumor, granulomata)	Usually normal	Normal to slight elevation	Elevated, often >4× normal elevation Fractionate, or confirm liver origin with 5′-nucleotidase or γ-glutamyl transpeptidase	Normal	Normal

Abbreviations: ALT, alanine aminotransferase; AST, aspartate aminotransferase.

judicious use of the other tests described in this chapter. Table 348-1 shows how patterns of liver tests can lead the clinician to a category of disease that will direct further evaluation. However, it is important to remember that no single set of liver tests will necessarily provide a diagnosis. It is often necessary to repeat these tests on several occasions over days to weeks for a diagnostic pattern to emerge. Figure 348-1 is an algorithm for the evaluation of chronically abnormal liver tests.

GLOBAL CONSIDERATIONS

The tests and principles presented in this chapter are applicable worldwide. The causes of liver test abnormalities vary according to region. In developing nations, infectious diseases are more commonly the etiology of abnormal serum liver tests than in developed nations.

349 The Hyperbilirubinemias

Allan W. Wolkoff

BILIRUBIN METABOLISM

The details of bilirubin metabolism are presented in Chap. 52. However, the hyperbilirubinemias are best understood in terms of perturbations of specific aspects of bilirubin metabolism and transport, and these will be briefly reviewed here as depicted in Fig. 349-1.

Bilirubin is the end product of heme degradation. Some 70–90% of bilirubin is derived from degradation of the hemoglobin of senescent red blood cells. Bilirubin produced in the periphery is transported to the liver within the plasma, where, due to its insolubility in aqueous solutions, it is tightly bound to albumin. Under normal circumstances, bilirubin is removed from the circulation rapidly and efficiently by hepatocytes. Transfer of bilirubin from blood to bile involves four distinct but interrelated steps (Fig. 349-1).

1. *Hepatocellular uptake:* Uptake of bilirubin by the hepatocyte has carrier-mediated kinetics. Although a number of candidate bilirubin transporters have been proposed, the identity of the actual transporter remains elusive.
2. *Intracellular binding:* Within the hepatocyte, bilirubin is kept in solution by binding as a nonsubstrate ligand to several of the glutathione-*S*-transferases, formerly called ligandins.
3. *Conjugation:* Bilirubin is conjugated with one or two glucuronic acid moieties by a specific UDP-glucuronosyltransferase to form

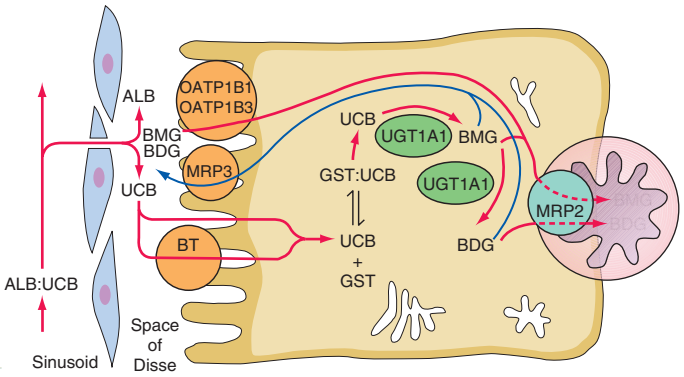

FIGURE 349-1 Hepatocellular bilirubin transport. Albumin-bound bilirubin in sinusoidal blood passes through endothelial cell fenestrae to reach the hepatocyte surface, entering the cell by both facilitated and simple diffusional processes. Within the cell, it is bound to glutathione-*S*-transferases and conjugated by bilirubin-UDP-glucuronosyltransferase (UGT1A1) to mono- and diglucuronides, which are actively transported across the canalicular membrane into the bile. In addition to this direct excretion of bilirubin glucuronides, a portion are transported into the portal circulation by MRP3 and subjected to reuptake into the hepatocyte by OATP1B1 and OATP1B3. ALB, albumin; BDG, bilirubin diglucuronide; BMG, bilirubin monoglucuronide; BT, proposed bilirubin transporter; GST, glutathione-*S*-transferase; MRP2 and MRP3, multidrug resistance–associated proteins 2 and 3; OATP1B1 and OATP1B3, organic anion transport proteins 1B1 and 1B3; UCB, unconjugated bilirubin; UGT1A1, bilirubin-UDP-glucuronosyltransferase.

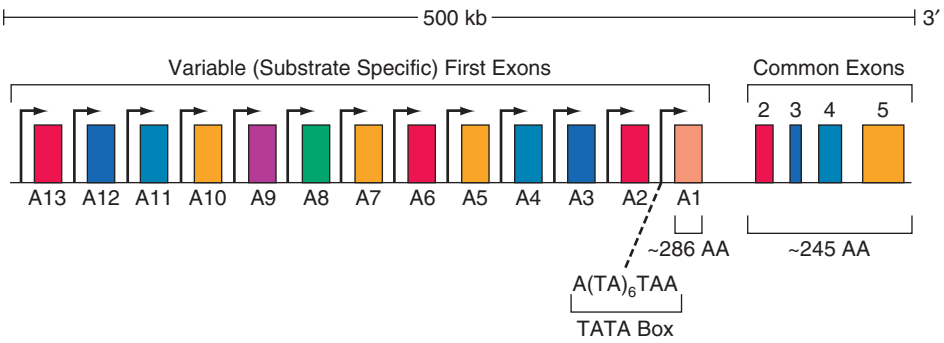

FIGURE 349-2 Structural organization of the human *UGT1* gene complex. This large complex on chromosome 2 contains at least 13 substrate-specific first exons (A1, A2, etc.). Since four of these are pseudogenes, nine UGT1 isoforms with differing substrate specificities are expressed. Each exon 1 has its own promoter and encodes the amino-terminal substrate-specific ~286 amino acids of the various *UGT1*-encoded isoforms, and common exons 2–5 encode the 245 carboxyl-terminal amino acids common to all of the isoforms. mRNAs for specific isoforms are assembled by splicing a particular first exon such as the bilirubin-specific exon A1 to exons 2 to 5. The resulting message encodes a complete enzyme, in this particular case, bilirubin-UDP-glucuronosyltransferase (UGT1A1). Mutations in a first exon affect only a single isoform. Those in exons 2–5 affect all enzymes encoded by the UGT1 complex.

bilirubin mono- and diglucuronide, respectively. Conjugation disrupts the internal hydrogen bonding that limits aqueous solubility of bilirubin, and the resulting glucuronide conjugates are highly soluble in water. Conjugation is obligatory for excretion of bilirubin across the bile canalicular membrane into bile. The UDP-glucuronosyltransferases have been classified into gene families based on the degree of homology among the mRNAs for the various isoforms. Those that conjugate bilirubin and certain other substrates have been designated the *UGT1* family. These are expressed from a single gene complex by alternative promoter usage. This gene complex contains multiple substrate-specific first exons, designated A1, A2, etc. **(Fig. 349-2)**, each with its own promoter and each encoding the amino-terminal half of a specific isoform. In addition, there are four common exons (exons 2–5) that encode the shared carboxyl-terminal half of all of the *UGT1* isoforms. The various first exons encode the specific aglycone substrate binding sites for each isoform, while the shared exons encode the binding site for the sugar donor, UDP-glucuronic acid, and the transmembrane domain. Exon A1 and the four common exons, collectively designated as the *UGT1A1* gene (Fig. 349-2), encode the physiologically critical enzyme bilirubin-UDP-glucuronosyltransferase (UGT1A1). A functional corollary of the organization of the *UGT1* gene is that a mutation in one of the first exons will affect only a single enzyme isoform. By contrast, a mutation in exons 2–5 will alter all isoforms encoded by the *UGT1* gene complex.

4. *Biliary excretion:* It has been thought until recently that bilirubin mono- and diglucuronides are excreted directly across the canalicular plasma membrane into the bile canaliculus by an ATP-dependent transport process mediated by a canalicular membrane protein called *multidrug resistance–associated protein 2* (MRP2, ABCC2). Mutations of MRP2 result in the Dubin-Johnson syndrome (see below). However, studies in patients with Rotor syndrome (see below) indicate that after formation, a portion of the glucuronides is transported into the portal circulation by a sinusoidal membrane protein called *multidrug resistance–associated protein 3* (MRP3, ABCC3) and is subjected to reuptake into the hepatocyte by the sinusoidal membrane uptake transporters *organic anion transport protein 1B1* (OATP1B1, SLCO1B1) and OATP1B3 (SLCO1B3).

EXTRAHEPATIC ASPECTS OF BILIRUBIN DISPOSITION

Bilirubin in the Gut Following secretion into bile, conjugated bilirubin reaches the duodenum and passes down the gastrointestinal tract without reabsorption by the intestinal mucosa. An appreciable fraction is converted by bacterial metabolism in the gut to the water-soluble colorless compound urobilinogen. Urobilinogen undergoes enterohepatic cycling. Urobilinogen not taken up by the liver reaches the systemic circulation, from which some is cleared by the kidneys. Unconjugated bilirubin ordinarily does not reach the gut except in neonates or, by ill-defined alternative pathways, in the presence of severe unconjugated hyperbilirubinemia (e.g., Crigler-Najjar syndrome, type I [CN-I]). Unconjugated bilirubin that reaches the gut is partly reabsorbed, amplifying any underlying hyperbilirubinemia.

Renal Excretion of Bilirubin Conjugates Unconjugated bilirubin is not excreted in urine, as it is too tightly bound to albumin for effective glomerular filtration and there is no tubular mechanism for its renal secretion. In contrast, the bilirubin conjugates are readily filtered at the glomerulus and can appear in urine in disorders characterized by increased bilirubin conjugates in the circulation. It should be kept in mind that the kidney can serve as an "overflow valve" for conjugated bilirubin. Consequently, the level of jaundice in individuals with conjugated hyperbilirubinemia can be amplified in the presence of renal failure.

DISORDERS OF BILIRUBIN METABOLISM LEADING TO UNCONJUGATED HYPERBILIRUBINEMIA

INCREASED BILIRUBIN PRODUCTION

Hemolysis Increased destruction of erythrocytes leads to increased bilirubin turnover and unconjugated hyperbilirubinemia; the hyperbilirubinemia is usually modest in the presence of normal liver function. In particular, the bone marrow is only capable of a sustained eightfold increase in erythrocyte production in response to a hemolytic stress. Therefore, hemolysis alone cannot result in a sustained hyperbilirubinemia of more than ~68 μmol/L (4 mg/dL). Higher values imply concomitant hepatic dysfunction. When hemolysis is the only abnormality in an otherwise healthy individual, the result is a purely unconjugated hyperbilirubinemia, with the direct-reacting fraction as measured in a typical clinical laboratory being ≤15% of the total serum bilirubin. In the presence of systemic disease, which may include a degree of hepatic dysfunction, hemolysis may produce a component of conjugated hyperbilirubinemia in addition to an elevated unconjugated bilirubin concentration. Prolonged hemolysis may lead to the precipitation of bilirubin salts within the gallbladder or biliary tree, resulting in the formation of gallstones in which bilirubin, rather than cholesterol, is the major component. Such pigment stones may lead to acute or chronic cholecystitis, biliary obstruction, or any other biliary tract consequence of calculous disease.

Ineffective Erythropoiesis During erythroid maturation, small amounts of hemoglobin may be lost at the time of nuclear extrusion, and a fraction of developing erythroid cells is destroyed within the marrow. These processes normally account for a small proportion of bilirubin that is produced. In various disorders, including thalassemia major, megaloblastic anemias due to folate or vitamin B_{12} deficiency, congenital erythropoietic porphyria, lead poisoning, and various congenital and acquired dyserythropoietic anemias, the fraction of total bilirubin production derived from ineffective erythropoiesis is increased, reaching as much as 70% of the total. This may be sufficient to produce modest degrees of unconjugated hyperbilirubinemia.

Miscellaneous Degradation of the hemoglobin of extravascular collections of erythrocytes, such as those seen in massive tissue infarctions or large hematomas, may lead transiently to unconjugated hyperbilirubinemia.

DECREASED HEPATIC BILIRUBIN CLEARANCE

Decreased Hepatic Uptake Decreased hepatic bilirubin uptake is believed to contribute to the unconjugated hyperbilirubinemia of Gilbert syndrome (GS), although the molecular basis for this finding remains unclear (see below). Several drugs, including flavaspidic acid, novobiocin, and rifampin, as well as various cholecystographic contrast agents, have been reported to inhibit bilirubin uptake. The resulting unconjugated hyperbilirubinemia resolves with cessation of the medication.

Impaired Conjugation • PHYSIOLOGIC NEONATAL JAUNDICE Bilirubin produced by the fetus is cleared by the placenta and eliminated by the maternal liver. Immediately after birth, the neonatal liver must assume responsibility for bilirubin clearance and excretion. However, many hepatic physiologic processes are incompletely developed at birth. Levels of UGT1A1 are low, and alternative excretory pathways allow passage of unconjugated bilirubin into the gut. Since the intestinal flora that convert bilirubin to urobilinogen are also undeveloped, an enterohepatic circulation of unconjugated bilirubin ensues. As a consequence, most neonates develop mild unconjugated hyperbilirubinemia between days 2 and 5 after birth. Peak levels are typically <85–170 μmol/L (5–10 mg/dL) and decline to normal adult concentrations within 2 weeks, as mechanisms required for bilirubin disposition mature. Prematurity, often associated with more profound immaturity of hepatic function and hemolysis, can result in higher levels of unconjugated hyperbilirubinemia. A rapidly rising unconjugated bilirubin concentration, or absolute levels >340 μmol/L (20 mg/dL), puts the infant at risk for bilirubin encephalopathy, or kernicterus. Under these circumstances, bilirubin crosses an immature blood-brain barrier and precipitates in the basal ganglia and other areas of the brain. The consequences range from appreciable neurologic deficits to death. Treatment options include phototherapy, which converts bilirubin into water-soluble photoisomers that are excreted directly into bile, and exchange transfusion. The canalicular mechanisms responsible for bilirubin excretion are also immature at birth, and their maturation may lag behind that of UGT1A1; this can lead to transient conjugated neonatal hyperbilirubinemia, especially in infants with hemolysis.

ACQUIRED CONJUGATION DEFECTS A modest reduction in bilirubin conjugating capacity may be observed in advanced hepatitis or cirrhosis. However, in this setting, conjugation is better preserved than other aspects of bilirubin disposition, such as canalicular excretion. Various drugs, including pregnanediol, novobiocin, chloramphenicol, gentamicin, and atazanavir, may produce unconjugated hyperbilirubinemia by inhibiting UGT1A1 activity. Bilirubin conjugation may be inhibited by certain fatty acids that are present in breast milk, but not serum, of mothers whose infants have excessive neonatal hyperbilirubinemia (*breast milk jaundice*). Alternatively, there may be increased enterohepatic circulation of bilirubin in these infants. The pathogenesis of breast milk jaundice appears to differ from that of transient familial neonatal hyperbilirubinemia (Lucey-Driscoll syndrome), in which there may be a UGT1A1 inhibitor in maternal serum.

HEREDITARY DEFECTS IN BILIRUBIN CONJUGATION

Three familial disorders characterized by differing degrees of unconjugated hyperbilirubinemia have long been recognized. The defining clinical features of each are described below **(Table 349-1)**. While these disorders have been recognized for decades to reflect differing degrees of deficiency in the ability to conjugate bilirubin, recent advances in the molecular biology of the *UGT1* gene complex have elucidated their interrelationships and clarified previously puzzling features.

Crigler-Najjar Syndrome, Type I CN-I is characterized by striking unconjugated hyperbilirubinemia of ~340–765 μmol/L (20–45 mg/dL) that appears in the neonatal period and persists for life. Other conventional hepatic biochemical tests such as serum aminotransferases and alkaline phosphatase are normal, and there is no evidence of hemolysis. Hepatic histology is also essentially normal except for the occasional presence of bile plugs within canaliculi. Bilirubin glucuronides are virtually absent from the bile, and there is no detectable constitutive expression of UGT1A1 activity in hepatic tissue. Neither UGT1A1 activity nor the serum bilirubin concentration responds to administration of phenobarbital or other enzyme inducers. Unconjugated bilirubin accumulates in plasma, from which it is eliminated very slowly by alternative pathways that include direct passage into the bile and small intestine, possibly via bilirubin photoisomers. This accounts for the small amount of urobilinogen found in feces. No bilirubin is found in the urine. First described in 1952, the disorder is rare (estimated prevalence, 0.6–1.0 per million). Many patients are from geographically or socially isolated communities in which consanguinity is common, and pedigree analyses show an autosomal recessive pattern of inheritance. The majority of patients (type IA) exhibit defects in the glucuronide conjugation of a spectrum of substrates in addition to bilirubin, including various drugs and other xenobiotics. These individuals have mutations in one of the common exons (2–5) of the *UGT1* gene (Fig. 349-2). In a smaller subset (type IB), the defect is limited largely to bilirubin conjugation, and the causative mutation is in the bilirubin-specific exon A1. Estrogen glucuronidation is mediated by UGT1A1 and is defective in all CN-I patients. More than 30 different genetic lesions of *UGT1A1* responsible for CN-I have been identified, including deletions, insertions, alterations in intron splice donor and acceptor sites, exon skipping,

TABLE 349-1 Principal Differential Characteristics of Gilbert and Crigler-Najjar Syndromes

FEATURE	CRIGLER-NAJJAR SYNDROME		GILBERT SYNDROME
	TYPE I	TYPE II	
Total serum bilirubin, μmol/L (mg/dL)	310–755 (usually >345) (18–45 [usually >20])	100–430 (usually ≤345) (6–25 [usually ≤20])	Typically ≤70 μmol/L (≤4 mg/dL) in absence of fasting or hemolysis
Routine liver tests	Normal	Normal	Normal
Response to phenobarbital	None	Decreases bilirubin by >25%	Decreases bilirubin to normal
Kernicterus	Usual	Rare	No
Hepatic histology	Normal	Normal	Usually normal; increased lipofuscin pigment in some
Bile characteristics			
Color	Pale or colorless	Pigmented	Normal dark color
Bilirubin fractions	>90% unconjugated	Largest fraction (mean: 57%) monoconjugates	Mainly diconjugates but monoconjugates increased (mean: 23%)
Bilirubin UDP-glucuronosyltransferase activity	Typically absent; traces in some patients	Markedly reduced: 0–10% of normal	Reduced: typically 10–33% of normal
Inheritance (all autosomal)	Recessive	Predominantly recessive	Promoter mutation: recessive Missense mutations: 7 of 8 dominant; 1 reportedly recessive

and point mutations that introduce premature stop codons or alter critical amino acids. Their common feature is that they all encode proteins with absent or, at most, traces of bilirubin-UDP-glucuronosyltransferase enzymatic activity.

Prior to the use of phototherapy, most patients with CN-I died of bilirubin encephalopathy (*kernicterus*) in infancy or early childhood. A few lived as long as early adult life without overt neurologic damage, although more subtle testing usually indicated mild but progressive brain damage, now termed bilirubin-induced neurologic dysfunction (BIND). In the absence of liver transplantation, death eventually supervened from late-onset bilirubin encephalopathy, which often followed a nonspecific febrile illness. Although isolated hepatocyte transplantation has been used in a small number of cases of CN-I, early liver transplantation **(Chap. 356)** remains the best hope to prevent brain injury and death at present. It is anticipated that gene replacement therapy may be an option in the future.

Crigler-Najjar Syndrome, Type II (CN-II) This condition was recognized as a distinct entity in 1962 and is characterized by marked unconjugated hyperbilirubinemia in the absence of abnormalities of other conventional hepatic biochemical tests, hepatic histology, or hemolysis. It differs from CN-I in several specific ways (Table 349-1): (1) although there is considerable overlap, average bilirubin concentrations are lower in CN-II; (2) accordingly, CN-II is only infrequently associated with kernicterus; (3) bile is deeply colored, and bilirubin glucuronides are present, with a striking, characteristic increase in the proportion of monoglucuronides; (4) UGT1A1 in liver is usually present at reduced levels (typically ≤10% of normal); and (5) while typically detected in infancy, hyperbilirubinemia was not recognized in some cases until later in life and, in one instance, at age 34. As with CN-I, most CN-II cases exhibit abnormalities in the conjugation of other compounds, such as salicylamide and menthol, but in some instances, the defect appears limited to bilirubin. Reduction of serum bilirubin concentrations by >25% in response to enzyme inducers such as phenobarbital distinguishes CN-II from CN-I, although this response may not be elicited in early infancy and often is not accompanied by measurable UGT1A1 induction. Bilirubin concentrations during phenobarbital administration do not return to normal but are typically in the range of 51–86 μmol/L (3–5 mg/dL). Although the incidence of kernicterus in CN-II is low, instances have occurred, not only in infants but also in adolescents and adults, often in the setting of an intercurrent illness, fasting, or another factor that temporarily raises the serum bilirubin concentration above baseline and reduces serum albumin levels. For this reason, phenobarbital therapy is widely recommended, a single bedtime dose often sufficing to maintain clinically safe serum bilirubin concentrations.

Over 100 different mutations in the *UGT1* gene have been identified as causing CN-I or CN-II. It was found that missense mutations are more common in CN-II patients, as would be expected in this less severe phenotype. Their common feature is that they encode for a bilirubin-UDP-glucuronosyltransferase with markedly reduced, but detectable, enzymatic activity. The spectrum of residual enzyme activity explains the spectrum of phenotypic severity of the resulting hyperbilirubinemia. Molecular analysis has established that a large majority of CN-II patients are either homozygotes or compound heterozygotes for CN-II mutations and that individuals carrying one mutated and one entirely normal allele have normal bilirubin concentrations.

Gilbert Syndrome This syndrome is characterized by mild unconjugated hyperbilirubinemia, normal values for standard hepatic biochemical tests, and normal hepatic histology other than a modest increase of lipofuscin pigment in some patients. Serum bilirubin concentrations are most often <51 μmol/L (<3 mg/dL), although both higher and lower values are frequent. The clinical spectrum of hyperbilirubinemia fades into that of CN-II at serum bilirubin concentrations of 86–136 μmol/L (5–8 mg/dL). At the other end of the scale, the distinction between mild cases of GS and a normal state is often blurred. Bilirubin concentrations may fluctuate substantially in any given individual, and at least 25% of patients will exhibit temporarily normal values during prolonged follow-up. More elevated values are associated with stress, fatigue, alcohol use, reduced caloric intake, and intercurrent illness, while increased caloric intake or administration of enzyme-inducing agents produces lower bilirubin levels. GS is most often diagnosed at or shortly after puberty or in adult life during routine examinations that include multichannel biochemical analyses. UGT1A1 activity is typically reduced to 10–35% of normal, and bile pigments exhibit a characteristic increase in bilirubin monoglucuronides. Studies of radiobilirubin kinetics indicate that hepatic bilirubin clearance is reduced to an average of one-third of normal. Administration of phenobarbital normalizes both the serum bilirubin concentration and hepatic bilirubin clearance; however, failure of UGT1A1 activity to improve in many such instances suggests the possible coexistence of an additional defect. Compartmental analysis of bilirubin kinetic data suggests that GS patients may have a defect in bilirubin uptake as well as in conjugation, although this has not been shown directly. Defects in the hepatic uptake of other organic anions that at least partially share an uptake mechanism with bilirubin, such as sulfobromophthalein and indocyanine green (ICG), are observed in a minority of patients. The metabolism and transport of bile acids that do not utilize the bilirubin uptake mechanism are normal. The magnitude of changes in the serum bilirubin concentration induced by provocation tests such as 48 h of fasting or the IV administration of nicotinic acid has been reported to be of help in separating GS patients from normal individuals. Other studies dispute this assertion. Moreover, on theoretical grounds, the results of such studies should provide no more information than simple measurements of the baseline serum bilirubin concentration. Family studies indicate that GS and hereditary hemolytic anemias such as hereditary spherocytosis, glucose-6-phosphate dehydrogenase deficiency, and β-thalassemia trait sort independently. Reports of hemolysis in up to 50% of GS patients are believed to reflect better case finding, since patients with both GS and hemolysis have higher bilirubin concentrations and are more likely to be jaundiced than patients with either defect alone.

GS is common, with many series placing its prevalence as high as 8%. Males predominate over females by reported ratios ranging from 1.5:1 to >7:1. However, these ratios may have a large artifactual component since normal males have higher mean bilirubin levels than normal females, but the diagnosis of GS is often based on comparison to normal ranges established in men. The high prevalence of GS in the general population may explain the reported frequency of mild unconjugated hyperbilirubinemia in liver transplant recipients. The disposition of most xenobiotics metabolized by glucuronidation appears to be normal in GS, as is oxidative drug metabolism in the majority of reported studies. The principal exception is the metabolism of the antitumor agent irinotecan (CPT-11), whose active metabolite (SN-38) is glucuronidated specifically by bilirubin-UDP-glucuronosyltransferase. Administration of CPT-11 to patients with GS has resulted in several toxicities, including intractable diarrhea and myelosuppression. Some reports also suggest abnormal disposition of menthol, estradiol benzoate, acetaminophen, tolbutamide, and rifamycin SV. Although some of these studies have been disputed, and there have been no reports of clinical complications from use of these agents in GS, prudence should be exercised in prescribing them or any agents metabolized primarily by glucuronidation in this condition. It should also be noted that the HIV protease inhibitors indinavir and atazanavir **(Chap. 208)** can inhibit UGT1A1, resulting in hyperbilirubinemia that is most pronounced in patients with preexisting GS.

Most older pedigree studies of GS were consistent with autosomal dominant inheritance with variable expressivity. However, studies of the *UGT1* gene in GS have indicated a variety of molecular genetic bases for the phenotypic picture and several different patterns of inheritance. Studies in Europe and the United States found that nearly all patients had normal coding regions for UGT1A1 but were homozygous for the insertion of an extra TA (i.e., $A[TA]_7TAA$ rather than $A[TA]_6TAA$) in the promoter region of the first exon. This appeared to be necessary, but not sufficient, for clinically expressed GS, since 15% of normal controls were also homozygous for this variant. While normal by standard criteria, these individuals had somewhat higher

bilirubin concentrations than the rest of the controls studied. Heterozygotes for this abnormality had bilirubin concentrations identical to those homozygous for the normal A[TA]$_6$TAA allele. The prevalence of the A[TA]$_7$TAA allele in a general Western population is 30%, in which case 9% would be homozygotes. This is slightly higher than the prevalence of GS based on purely phenotypic parameters. It was suggested that additional variables, such as mild hemolysis or a defect in bilirubin uptake, might be among the factors enhancing phenotypic expression of the defect.

Phenotypic expression of GS due solely to the A[TA]$_7$TAA promoter abnormality is inherited as an autosomal recessive trait. A number of CN-II kindreds have been identified in whom there is also an allele containing a normal coding region but the A[TA]$_7$TAA promoter abnormality. CN-II heterozygotes, who have the A[TA]$_6$TAA promoter, are phenotypically normal, whereas those with the A[TA]$_7$TAA promoter express the phenotypic picture of GS. GS in such kindreds may also result from homozygosity for the A[TA]$_7$TAA promoter abnormality. Seven different missense mutations in the *UGT1* gene that reportedly cause GS with dominant inheritance have been found in Japanese individuals. Another Japanese patient with mild unconjugated hyperbilirubinemia was homozygous for a missense mutation in exon 5. GS in her family appeared to be recessive.

DISORDERS OF BILIRUBIN METABOLISM LEADING TO MIXED OR PREDOMINANTLY CONJUGATED HYPERBILIRUBINEMIA

In hyperbilirubinemia due to acquired liver disease (e.g., acute hepatitis, common bile duct stone), there are usually elevations in the serum concentrations of both conjugated and unconjugated bilirubin. Although biliary tract obstruction or hepatocellular cholestatic injury may present on occasion with a predominantly conjugated hyperbilirubinemia, it is generally not possible to differentiate intrahepatic from extrahepatic causes of jaundice based on the serum levels or relative proportions of unconjugated and conjugated bilirubin. The major reason for determining the amounts of conjugated and unconjugated bilirubin in the serum is for the initial differentiation of hepatic parenchymal and obstructive disorders (mixed conjugated and unconjugated hyperbilirubinemia) from the inheritable and hemolytic disorders discussed above that are associated with unconjugated hyperbilirubinemia.

FAMILIAL DEFECTS IN HEPATIC EXCRETORY FUNCTION

Dubin-Johnson Syndrome (DJS) This benign, relatively rare disorder is characterized by low-grade, predominantly conjugated hyperbilirubinemia (Table 349-2). Total bilirubin concentrations are typically between 34 and 85 μmol/L (2 and 5 mg/dL) but on occasion can be in the normal range or as high as 340–430 μmol/L (20–25 mg/dL) and can fluctuate widely in any given patient. The degree of hyperbilirubinemia may be increased by intercurrent illness, oral contraceptive use, and pregnancy. Because the hyperbilirubinemia is due to a predominant rise in conjugated bilirubin, bilirubinuria is characteristically present. Aside from elevated serum bilirubin levels, other routine laboratory tests are normal. Physical examination is usually normal except for jaundice, although an occasional patient may have hepatosplenomegaly.

Patients with DJS are usually asymptomatic, although some may have vague constitutional symptoms. These latter patients have usually undergone extensive diagnostic examinations for unexplained jaundice and have high levels of anxiety. In women, the condition may be subclinical until the patient becomes pregnant or receives oral contraceptives, at which time chemical hyperbilirubinemia becomes frank jaundice. Even in these situations, other routine liver function tests, including serum alkaline phosphatase and transaminase activities, are normal.

A cardinal feature of DJS is the accumulation of dark, coarsely granular pigment in the lysosomes of centrilobular hepatocytes. As a result, the liver may be grossly black in appearance. This pigment is thought to be derived from epinephrine metabolites that are not excreted normally. The pigment may disappear during bouts of viral hepatitis, only to reaccumulate slowly after recovery.

Biliary excretion of a number of anionic compounds is compromised in DJS. These include various cholecystographic agents, as well as sulfobromophthalein (Bromsulphalein [BSP]), a synthetic dye formerly used in a test of liver function. In this test, the rate of disappearance of BSP from plasma was determined following bolus IV administration. BSP is conjugated with glutathione in the hepatocyte; the resulting conjugate is normally excreted rapidly into the bile canaliculus. Patients with DJS exhibit characteristic rises in plasma concentrations at 90 min after injection, due to reflux of conjugated BSP into the circulation from the hepatocyte. Dyes such as ICG that are taken up by hepatocytes but are not further metabolized prior to biliary excretion do not show this reflux phenomenon. Continuous BSP infusion studies suggest a reduction in the time to maximum plasma concentration (t_{max}) for biliary excretion. Bile acid disposition, including hepatocellular uptake and biliary excretion, is normal in DJS. These patients have normal serum and biliary bile acid concentrations and do not have pruritus.

By analogy with findings in several mutant rat strains, the selective defect in biliary excretion of bilirubin conjugates and certain other classes of organic compounds, but not of bile acids, that characterizes DJS in humans was found to reflect defective expression of MRP2 (ABCC2), an ATP-dependent canalicular membrane transporter. Several different mutations in the *ABCC2* gene produce the Dubin-Johnson phenotype, which has an autosomal recessive pattern of inheritance. Although MRP2 is undoubtedly important in the biliary excretion of

TABLE 349-2 Principal Differential Characteristics of Inheritable Disorders of Bile Canalicular Function

	DJS	ROTOR	PFIC1	BRIC1	PFIC2	BRIC2	PFIC3

Serum bile acids	Normal	Normal	↑↑	↑↑ during episodes	↑↑	↑↑ during episodes	↑↑
Clinical features	Mild conjugated hyperbilirubinemia; otherwise, normal liver function; dark pigment in liver; characteristic pattern of urinary coproporphyrins	Mild conjugated hyperbilirubinemia; otherwise, normal liver function; liver without abnormal pigmentation	Severe cholestasis beginning in childhood	Recurrent episodes of cholestasis beginning at any age	Severe cholestasis beginning in childhood	Recurrent episodes of cholestasis beginning at any age	Severe cholestasis beginning in childhood; decreased phospholipids in bile

Abbreviations: BRIC, benign recurrent intrahepatic cholestasis; BSEP, bile salt excretory protein; DJS, Dubin-Johnson syndrome; GGT, γ-glutamyl transferase; MRP2, multidrug resistance–associated protein 2; OATP1A/1B, organic anion transport proteins 1B1 and 1B3; PFIC, progressive familial intrahepatic cholestasis; ↑↑, increased.

conjugated bilirubin, the fact that this pigment is still excreted in the absence of MRP2 suggests that other, as yet uncharacterized, transport proteins may serve in a secondary role in this process.

Patients with DJS also have a diagnostic abnormality in urinary coproporphyrin excretion. There are two naturally occurring coproporphyrin isomers, I and III. Normally, ~75% of the coproporphyrin in urine is isomer III. In urine from DJS patients, total coproporphyrin content is normal, but ≥80% is isomer I. Heterozygotes for the syndrome show an intermediate pattern. The molecular basis for this phenomenon remains unclear.

Rotor Syndrome (RS) This benign, autosomal recessive disorder is clinically similar to DJS (Table 349-2), although it is seen even less frequently. A major phenotypic difference is that the liver in patients with RS has no increased pigmentation and appears totally normal. The only abnormality in routine laboratory tests is an elevation of total serum bilirubin, due to a predominant rise in conjugated bilirubin. This is accompanied by bilirubinuria. Several additional features differentiate RS from DJS. In RS, the gallbladder is usually visualized on oral cholecystography, in contrast to the nonvisualization that is typical of DJS. The pattern of urinary coproporphyrin excretion also differs. The pattern in RS resembles that of many acquired disorders of hepatobiliary function, in which coproporphyrin I, the major coproporphyrin isomer in bile, refluxes from the hepatocyte back into the circulation and is excreted in urine. Thus, total urinary coproporphyrin excretion is substantially increased in RS, in contrast to the normal levels seen in DJS. Although the fraction of coproporphyrin I in urine is elevated, it is usually <70% of the total, compared with ≥80% in DJS. The disorders also can be distinguished by their patterns of BSP excretion. Although clearance of BSP from plasma is delayed in RS, there is no reflux of conjugated BSP back into the circulation as seen in DJS. Kinetic analysis of plasma BSP infusion studies suggests the presence of a defect in intrahepatocellular storage of this compound. This has never been demonstrated directly. Recent studies indicate that the molecular basis of RS results from simultaneous deficiency of the hepatocyte plasma membrane transporters OATP1B1 (SLCO1B1) and OATP1B3 (SLCO1B3). This results in reduced reuptake by these transporters of conjugated bilirubin that has been pumped out of the hepatocyte into the portal circulation by MRP3 (ABCC3) (Fig. 349-1). It should be noted that these transporters normally mediate uptake into the liver of a variety of drugs such as statins, and the possibility of drug toxicity resulting from their deficiency in RS must be considered.

Benign Recurrent Intrahepatic Cholestasis (BRIC) This rare disorder is characterized by recurrent attacks of pruritus and jaundice. The typical episode begins with mild malaise and elevations in serum aminotransferase levels, followed rapidly by rises in alkaline phosphatase and conjugated bilirubin and onset of jaundice and itching. The first one or two episodes may be misdiagnosed as acute viral hepatitis. The cholestatic episodes, which may begin in childhood or adulthood, can vary in duration from several weeks to months, followed by a complete clinical and biochemical resolution. Intervals between attacks may vary from several months to years. Between episodes, physical examination is normal, as are serum levels of bile acids, bilirubin, transaminases, and alkaline phosphatase. The disorder is familial and has an autosomal recessive pattern of inheritance. BRIC is considered a benign disorder in that it does not lead to cirrhosis or end-stage liver disease. However, the episodes of jaundice and pruritus can be prolonged and debilitating, and some patients have undergone liver transplantation to relieve the intractable and disabling symptoms. Treatment during the cholestatic episodes is symptomatic; there is no specific treatment to prevent or shorten the occurrence of episodes.

A gene termed *FIC1* was recently identified and found to be mutated in patients with BRIC. Curiously, this gene is expressed strongly in the small intestine but only weakly in the liver. The protein encoded by *FIC1* shows little similarity to those that have been shown to play a role in bile canalicular excretion of various compounds. Rather, it appears to be a member of a P-type ATPase family that transports aminophospholipids from the outer to the inner leaflet of a variety of cell membranes. Its relationship to the pathobiology of this disorder remains unclear. A second phenotypically identical form of BRIC, termed BRIC type 2, has been described resulting from mutations in the bile salt excretory protein (BSEP), the protein that is defective in progressive familial intrahepatic cholestasis (PFIC) type 2 (Table 349-2). How some mutations in this protein result in the episodic BRIC phenotype is unknown.

Progressive Familial Intrahepatic Cholestasis This name is applied to three phenotypically related syndromes (Table 349-2). PFIC type 1 (Byler's disease) presents in early infancy as cholestasis that may be initially episodic. However, in contrast to BRIC, Byler's disease progresses to malnutrition, growth retardation, and end-stage liver disease during childhood. This disorder is also a consequence of an *FIC1* mutation. The functional relationship of the FIC1 protein to the pathogenesis of cholestasis in these disorders is unknown. Two other types of PFIC (types 2 and 3) have been described. PFIC type 2 is associated with a mutation in the protein originally named *sister of P-glycoprotein*, now known as *bile salt excretory protein* (BSEP, ABCB11), which is the major bile canalicular exporter of bile acids. As noted above, some mutations of this protein are associated with BRIC type 2, rather than the PFIC type 2 phenotype. PFIC type 3 has been associated with a mutation of MDR3 (ABCB4), a protein that is essential for normal hepatocellular excretion of phospholipids across the bile canaliculus. Although all three types of PFIC have similar clinical phenotypes, only type 3 is associated with high serum levels of γ-glutamyl transferase (GGT) activity. In contrast, activity of this enzyme is normal or only mildly elevated in symptomatic BRIC and PFIC types 1 and 2. Interestingly, mutations in FIC1 or BSEP are not found in approximately one-third of patients with clinical PFIC and normal GGT. Recent studies have shown that patients with mutations in *NR1H4*, the gene encoding the farnesoid X receptor (FXR), a nuclear hormone receptor activated by bile acids, have a syndrome identical to PFIC2 with absent expression of BSEP. Mutations in tight junction protein 2 (TJP2) as well as ubiquitin-specific protease 53 (USP53), a protein that interacts with TJP2, have also been associated with severe cholestasis with normal GGT levels, likely due to disruption of tight junctions at the bile canaliculus.

350 Acute Viral Hepatitis

Esperance A. K. Schaefer, Raymond T. Chung, Jules L. Dienstag

Acute viral hepatitis is a systemic infection affecting the liver predominantly. Almost all cases of acute viral hepatitis are caused by one of five viral agents: hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), the HBV-associated delta agent or hepatitis D virus (HDV), and hepatitis E virus (HEV). All these human hepatitis viruses are RNA viruses, except for hepatitis B, which is a DNA virus but replicates like a retrovirus. Although these agents can be distinguished by their molecular and antigenic properties, all types of viral hepatitis produce clinically similar acute illnesses. These range from asymptomatic and inapparent to fulminant and fatal acute infections, which can be observed in all types. On the other hand, the bloodborne types (HBV, HCV, HDV) may also manifest a spectrum of chronic disease, from subclinical, persistent infections to rapidly progressive chronic liver disease with cirrhosis and even hepatocellular carcinoma. Rarely, infections with other viruses (e.g., cytomegalovirus, Epstein-Barr virus, other herpes viruses, SARS-CoV-2) can be associated with mild or severe, even fulminant, hepatitis, more often in immunocompromised hosts but also in otherwise healthy persons. In 2021 and 2022, after the peak years of the COVID-19 pandemic, multiple reports appeared globally of severe acute, often fulminant, hepatitis in previously healthy children. While these instances of severe acute hepatitis remain unexplained, links have been reported of infection with adenovirus type 41 and adeno-associated virus 2, ordinarily not causes of liver injury. A reduction in circulating respiratory virus infections during the isolation of the COVID-19 pandemic has been postulated to have accounted for the increased susceptibility to and severity of the acute hepatitis associated with these nonhepatotropic viruses.

VIROLOGY AND ETIOLOGY

Hepatitis A HAV is a nonenveloped 27-nm, heat-, acid-, and ether-resistant, single-stranded, positive-sense RNA virus in the *Hepatovirus* genus of the picornavirus family **(Fig. 350-1)**. Quasi-enveloped virus particles encased in host plasma membrane–derived membranous vesicles circulate in the bloodstream. The virion contains four structural capsid polypeptides, designated VP1–VP4, as well as six nonstructural proteins, which are cleaved posttranslationally from the polyprotein product of a 7500-nucleotide genome. Inactivation of viral activity can be achieved by boiling for 1 min, by contact with formaldehyde and chlorine, or by ultraviolet irradiation. Despite nucleotide sequence variation of up to 20% among isolates of HAV and despite the recognition of six genotypes (three of which affect humans), all strains of this virus are immunologically indistinguishable and belong to one serotype. Human HAV can infect and cause hepatitis in chimpanzees, tamarins (marmosets), and several monkey species. HAV-like hepatoviruses have also been identified in small mammals, including bats and rodents.

Hepatitis A has an incubation period of ~3–4 weeks. Its replication is limited to the liver, but the virus is present in the liver, bile, stools, and blood during the late incubation period and acute preicteric/presymptomatic phase of illness. Despite slightly longer persistence of virus in the liver, fecal shedding, viremia, and infectivity diminish rapidly once jaundice becomes apparent. Detection of HAV RNA by sensitive reverse transcription polymerase chain reaction assays has been reported to persist at low levels in stool, the liver, and serum for up to several months after acute illness; however, this does not correlate with persistent infectivity, probably because of the presence of neutralizing antibody. HAV can be cultivated reproducibly in vitro and in primate models.

Antibodies to HAV (anti-HAV) can be detected during acute illness when serum aminotransferase activity is elevated and fecal HAV shedding is still occurring. This early antibody response is predominantly of the IgM class and persists for several (~3) months, rarely for 6–12 months. During convalescence, however, anti-HAV of the IgG class becomes the predominant antibody **(Fig. 350-2)**. Therefore, the diagnosis of hepatitis A is made during acute illness by demonstrating anti-HAV of the IgM class. After acute illness, anti-HAV of the IgG class remains detectable indefinitely, and patients with serum anti-HAV are immune to reinfection. Neutralizing antibody activity parallels the appearance of anti-HAV, and the IgG anti-HAV present in immune globulin accounts for the protection it affords against HAV infection.

Hepatitis B HBV is a DNA virus with a remarkably compact genomic structure; despite its small, circular, 3200-bp size, HBV DNA codes for four sets of viral products with a complex, multiparticle structure. HBV achieves its genomic economy by relying on an efficient strategy of encoding proteins from four overlapping genes: S, C, P, and X **(Fig. 350-3)**, as detailed below. Once thought to be unique among viruses, HBV is now recognized as one of a family of animal viruses, hepadnaviruses (hepatotropic DNA viruses), and is classified as hepadnavirus type 1. Similar viruses infect certain species of woodchucks, ground and tree squirrels, and Pekin ducks, to mention the most carefully characterized; genetic evidence of ancient HBV-like virus forbears has been found in fossils of ancient birds, and an HBV-like virus has been identified in contemporary fish. Studies of ancient HBV genomes date an association between HBV and human beings back as long as 21,000 years ago; primate HBV-like viruses date back millions of years, suggesting that HBV predated the emergence of modern humans. Like HBV, all have the same distinctive three morphologic forms, have counterparts to the envelope and nucleocapsid virus antigens of HBV, replicate in the liver but exist in extrahepatic sites, contain their own endogenous DNA polymerase, have partially double-strand and partially single-strand genomes, are associated with acute and chronic hepatitis and hepatocellular carcinoma, and rely on a replicative strategy unique among DNA viruses but typical of retroviruses. Entry of HBV into hepatocytes is mediated by binding to the sodium taurocholate cotransporting polypeptide (NTCP) receptor. Instead of DNA replication directly from a DNA template, hepadnaviruses rely on reverse transcription (effected by the DNA polymerase) of minus-strand DNA from a "pregenomic" RNA intermediate. Then, plus-strand DNA is transcribed from the minus-strand DNA template by the DNA-dependent DNA polymerase and converted in the hepatocyte nucleus to a covalently closed circular DNA, which serves as a template for messenger RNA and pregenomic RNA. Viral proteins

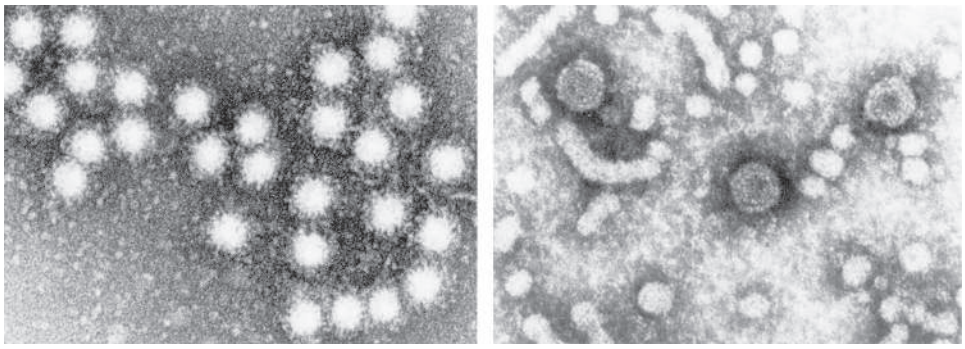

FIGURE 350-1 Electron micrographs of hepatitis A virus particles and serum from a patient with hepatitis B. ***Left:*** 27-nm hepatitis A virus particles purified from stool of a patient with acute hepatitis A and aggregated by antibody to hepatitis A virus. ***Right:*** Concentrated serum from a patient with hepatitis B, demonstrating the 42-nm virions, tubular forms, and spherical 22-nm particles of hepatitis B surface antigen. 132,000×. (Hepatitis D resembles 42-nm virions of hepatitis B but is smaller, 35–37 nm; hepatitis E resembles hepatitis A virus but is slightly larger, 32–34 nm; hepatitis C has been visualized as a 55-nm particle.)

are translated by the messenger RNA, and the proteins and genome are packaged into virions and secreted from the hepatocyte. Hepatitis B virus has been difficult to cultivate in vitro from clinical materials; therefore, a model that recapitulates the entire HBV life cycle has been particularly elusive. In recent decades, however, advances in molecular virology have permitted the comprehensive study of HBV replication and its viral genes and proteins.

VIRAL PROTEINS AND PARTICLES Three particulate forms of HBV appear in the circulation **(Table 350-1)**, the complete virion and two incomplete or subviral particles. Of these, the most numerous are the 22-nm particles, which appear as spherical or long filamentous forms; these are antigenically indistinguishable from the outer surface or envelope protein of HBV and are thought to represent excess viral envelope protein. Outnumbered in serum by a factor of 100 or 1000 to 1 compared with the spheres and tubules are large, 42-nm, double-shelled spherical particles, which represent the intact hepatitis B virion (Fig. 350-1). The envelope protein expressed on the outer surface of the virion and on the smaller spherical and tubular structures is referred to as *hepatitis B surface antigen* (HBsAg). The concentration of HBsAg and virus particles in the blood may reach 500 μg/mL and 10 trillion particles per milliliter, respectively; HBsAg assays in common clinical use detect all forms of HBsAg (virion and subviral particles). The envelope protein, HBsAg, is the product of the S gene of HBV.

HBV isolates fall into 10 different genotypes (A–J) and multiple subtypes, which are determined by unique gene sequences of the envelope

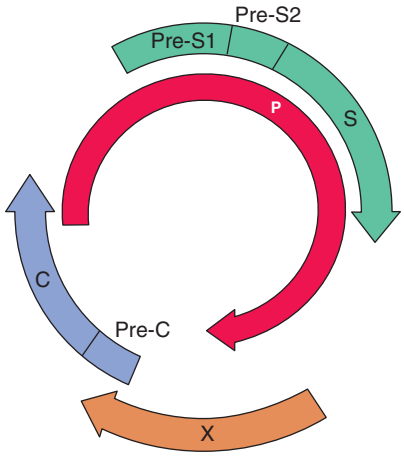

FIGURE 350-3 Compact genomic structure of hepatitis B virus (HBV). This structure, with overlapping genes, permits HBV to code for multiple proteins. The S gene codes for the "major" envelope protein, HBsAg. Pre-S1 and pre-S2, upstream of S, combine with S to code for two larger proteins, "middle" protein, the product of pre-S2 + S, and "large" protein, the product of pre-S1 + pre-S2 + S. The largest gene, P, codes for DNA polymerase. The C gene codes for two nucleocapsid proteins, HBeAg, a soluble, secreted protein (initiation from the pre-C region of the gene), and HBcAg, the intracellular core protein (initiation after pre-C). The X gene codes for HBxAg, which can transactivate the transcription of cellular and viral genes; its clinical relevance is not known, but it may contribute to carcinogenesis by binding to p53.

HBsAg protein. Envelope HBsAg subdeterminants include a common group-reactive antigen, *a*, shared by all HBsAg isolates and one of several subtype-specific antigens—*d* or *y*, *w* or *r*. Geographic distribution of genotypes and subtypes varies; genotypes A (corresponding to subtype *adw*) and D (*ayw*) predominate in the United States and Europe, whereas genotypes B (*adw*) and C (*adr*) predominate in Asia; however, these geographic distinctions have been blunted by recent-decade migration across continents. Clinical course and outcome are independent of subtype, but genotype B appears to be associated with less rapidly progressive liver disease and cirrhosis and a lower likelihood, or delayed appearance, of hepatocellular carcinoma than genotype C, D, or F. In a large Japanese cohort, after acute infection, patients with genotype A were more likely to have persistent infection (23.4% with genotype A vs 8.6% with non-A genotypes). Also, genotype may influence response to treatment with interferon and other antiviral agents; for example, higher rates of HBeAg and HBsAg loss have been observed in patients with genotype A. An additional important consequence of genotype is the propensity for "precore" mutations to emerge (see below).

Upstream of the S gene are the pre-S genes (Fig. 350-3), which code for pre-S gene products, including receptors on the HBV surface for polymerized human serum albumin and for hepatocyte membrane proteins. The pre-S region actually consists of both pre-S1 and pre-S2. Depending on where translation is initiated, three potential HBsAg gene products are synthesized. The protein product of the S gene is HBsAg (*major protein*), the product of the S region plus the adjacent pre-S2 region is the *middle protein*, and the product of the pre-S1 plus pre-S2 plus S regions is the *large protein*. Compared with the smaller spherical and tubular particles of HBV, complete 42-nm virions are enriched in the large protein. Both pre-S proteins and their respective antibodies can be detected during HBV infection, and the period of pre-S antigenemia appears to coincide with other markers of virus replication, as detailed below; however, pre-S proteins have little clinical relevance and are not included in routine serologic testing repertoires.

The intact 42-nm virion contains a 27-nm nucleocapsid core particle. Nucleocapsid proteins are coded for by the C gene. The antigen expressed on the surface of the nucleocapsid core is *hepatitis B core antigen* (HBcAg), and its corresponding antibody is anti-HBc. A third HBV antigen is HBeAg, a soluble, nonparticulate, nucleocapsid protein that is immunologically distinct from intact HBcAg but is a product of the same C gene. The C gene has two initiation codons: a precore and a core region (Fig. 350-3). If translation is initiated at the precore region, the protein product is HBeAg, which has a signal peptide that binds it to the smooth endoplasmic reticulum, the secretory apparatus of the cell, leading to its secretion into the circulation. If translation begins at the core region, HBcAg is the protein product; it has no signal peptide and is not secreted, but it assembles into nucleocapsid particles, which bind to and incorporate RNA and which, ultimately, contain HBV DNA. Also packaged within the nucleocapsid core is a DNA polymerase, which directs replication and repair of HBV DNA. When packaging within viral proteins is complete, synthesis of the incomplete plus strand stops; this accounts for the single-strand gap and for differences in the size of the gap. HBcAg particles remain in the hepatocyte, where they are readily detectable by immunohistochemical staining and are exported after encapsidation by an envelope of HBsAg. Therefore, naked core particles do not circulate in the serum. The secreted nucleocapsid protein, HBeAg, provides a convenient, readily detectable, qualitative marker of HBV replication and relative infectivity.

HBsAg-positive serum containing HBeAg is more likely to be highly infectious and to be associated with the presence of hepatitis B virions (and detectable HBV DNA, see below) than HBeAg-negative or anti-HBe-positive serum. For example, HBsAg-positive mothers who are HBeAg positive almost invariably (>90%) transmit hepatitis B infection to their offspring, whereas HBsAg-positive mothers with anti-HBe rarely (10–15%) infect their offspring.

Early during the course of acute hepatitis B, HBeAg appears transiently; its disappearance may be a harbinger of clinical improvement and resolution of infection. Persistence of HBeAg in serum beyond the first 3 months of acute infection may be predictive of the development

TABLE 350-1 Nomenclature and Features of Hepatitis Viruses

HEPATITIS TYPE	VIRUS PARTICLE, nm	MORPHOLOGY	GENOME[a]	CLASSIFICATION	ANTIGEN(S)	ANTIBODIES	REMARKS
HAV	27	Icosahedral nonenveloped	7.5-kb RNA, linear, ss, +	*Hepatovirus*	HAV	Anti-HAV	Early fecal shedding Diagnosis: IgM anti-HAV Previous infection: IgG anti-HAV
HBV	42	Double-shelled virion (surface and core) spherical	3.2-kb DNA, circular, ss/ds	Hepadnavirus	HBsAg HBcAg HBeAg	Anti-HBs Anti-HBc Anti-HBe	Bloodborne virus; carrier state Acute diagnosis: HBsAg, IgM anti-HBc Chronic diagnosis: IgG anti-HBc, HBsAg Markers of replication: HBeAg, HBV DNA
	27	Nucleocapsid core			HBcAg HBeAg	Anti-HBc Anti-HBe	Liver, lymphocytes, other organs Nucleocapsid contains DNA and DNA polymerase; present in hepatocyte nucleus; HBcAg does not circulate; HBeAg (soluble, nonparticulate) and HBV DNA circulate—correlate with infectivity and complete virions
	22	Spherical and filamentous; represents excess virus coat material			HBsAg	Anti-HBs	HBsAg detectable in >95% of patients with acute hepatitis B; found in serum, body fluids, hepatocyte cytoplasm; anti-HBs appears following infection—protective antibody
HCV	55	Enveloped	9.4-kb RNA, linear, ss, +	*Hepacivirus*	HCV core antigen	Anti-HCV	Bloodborne agent, formerly labeled non-A, non-B hepatitis Acute diagnosis: anti-HCV, HCV RNA Chronic diagnosis: anti-HCV, HCV RNA; cytoplasmic location in hepatocytes
HDV	35–37	Enveloped hybrid particle with HBsAg coat and HDV core	1.7-kb RNA, circular, ss, –	Resembles viroids and plant satellite viruses (genus *Deltavirus*)	HBsAg HDAg	Anti-HBs Anti-HDV	Defective RNA virus, requires helper function of HBV (hepadnaviruses); HDV antigen (HDAg) present in hepatocyte nucleus Diagnosis: anti-HDV, HDV RNA; HBV/HDV co-infection—IgM anti-HBc and anti-HDV; HDV superinfection—IgG anti-HBc and anti-HDV
HEV	32–34	Nonenveloped icosahedral	7.6-kb RNA, linear, ss, +	*Orthohepevirus*	HEV antigen	Anti-HEV	Agent of enterically transmitted hepatitis; rare in the United States; occurs in Asia, Mediterranean countries, Central America Diagnosis: IgM/IgG anti-HEV (assays not routinely available); virus in stool, bile, hepatocyte cytoplasm

[a]ss, single-strand; ss/ds, partially single-strand, partially double-strand; –, minus-strand; +, plus-strand.

Note: See text for abbreviations.

of chronic infection, and the presence of HBeAg during chronic hepatitis B tends to be associated with ongoing viral replication, infectivity, and inflammatory liver injury (except during the early decades after perinatally acquired HBV infection; see below).

The third and largest of the HBV genes, the P gene (Fig. 350-3), codes for HBV DNA polymerase; as noted above, this enzyme has both DNA-dependent DNA polymerase and RNA-dependent reverse transcriptase activities. The fourth gene, X, codes for a small, nonparticulate protein, *hepatitis B x antigen* (HBxAg), which is capable of transactivating the transcription of both viral and cellular genes (Fig. 350-3). This function underpins its role in promoting both viral replication and HBV-related hepatocellular carcinoma. In the cytoplasm, HBxAg effects calcium release (possibly from mitochondria), which activates signal-transduction pathways that lead to stimulation of HBV reverse transcription and HBV DNA replication. Such transactivation may enhance the replication of HBV; the transactivating activity can enhance the transcription and replication of other viruses besides HBV, such as HIV. The clinical relevance of HBxAg is limited, however, and testing for it is not part of routine clinical practice.

SEROLOGIC AND VIROLOGIC MARKERS After a person is infected with HBV, the first virologic marker detectable in serum within 1–12 weeks, usually between 8 and 12 weeks, is HBsAg **(Fig. 350-4)**. Circulating HBsAg precedes elevations of serum aminotransferase activity and clinical symptoms by 2–6 weeks and remains detectable during the entire icteric or symptomatic phase of acute hepatitis B and beyond. In typical self-limited cases, HBsAg becomes undetectable 1–2 months after the onset of jaundice and rarely persists beyond 6 months. After HBsAg disappears, antibody to HBsAg (anti-HBs) becomes detectable in serum and remains detectable indefinitely thereafter. Because HBcAg is intracellular and, when in the serum, sequestered within an HBsAg coat, naked core particles do not circulate in serum, and therefore, assays for HBcAg are not included in routine clinical testing. By contrast, anti-HBc is readily demonstrable in serum, beginning within the first 1–2 weeks after the appearance of HBsAg and preceding detectable levels of anti-HBs by weeks to months. Because variability exists in the time of appearance of anti-HBs after HBV

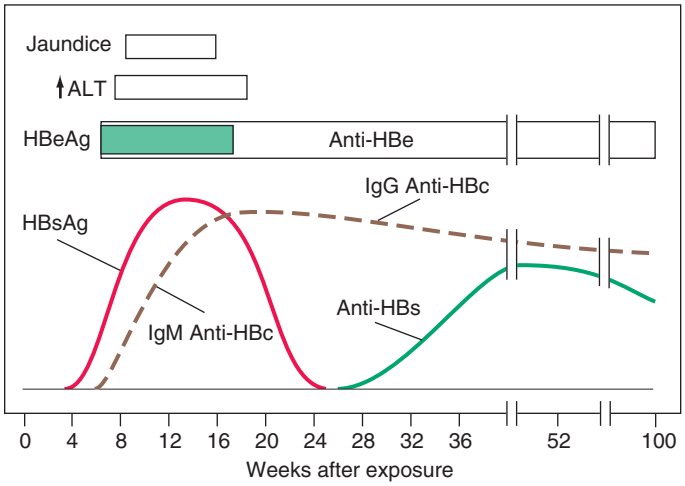

FIGURE 350-4 Scheme of typical clinical and laboratory features of acute hepatitis B. ALT, alanine aminotransferase.

infection, occasionally a gap of several weeks or longer may separate the disappearance of HBsAg and the appearance of anti-HBs. During this "gap" or "window" period, IgM anti-HBc may represent the only serologic evidence of current or recent HBV infection, and blood containing anti-HBc in the absence of HBsAg and anti-HBs had been implicated in the past in transfusion-associated hepatitis B. In part because the sensitivity of immunoassays for HBsAg and anti-HBs has increased, however, this window period is rarely encountered. In some persons, years after HBV infection, anti-HBc may persist in the circulation longer than anti-HBs. Therefore, isolated anti-HBc does not necessarily indicate active virus replication; most instances of isolated anti-HBc represent hepatitis B infection in the remote past. Rarely, however, isolated anti-HBc represents low-level hepatitis B viremia, with HBsAg below the detection threshold, and occasionally, isolated anti-HBc represents a cross-reacting or false-positive immunologic specificity.

Recent and remote HBV infections can be distinguished by determination of the immunoglobulin class of anti-HBc. Anti-HBc of the IgM class (IgM anti-HBc) predominates during the first 6 months after acute infection, whereas IgG anti-HBc is the predominant class of anti-HBc beyond 6 months. Therefore, patients with current or recent acute hepatitis B, including those in the anti-HBc window, have IgM anti-HBc in their serum. In patients who have recovered from hepatitis B in the remote past as well as those with chronic HBV infection, anti-HBc is predominantly of the IgG class. Infrequently, in ≤1–5% of patients with acute HBV infection, levels of HBsAg are too low to be detected; in such cases, the presence of IgM anti-HBc establishes the diagnosis of acute hepatitis B. When isolated anti-HBc occurs in the rare patient with chronic hepatitis B whose HBsAg level is below the sensitivity threshold of contemporary immunoassays (a low-level carrier), anti-HBc is of the IgG class. Generally, in persons who have recovered from hepatitis B, anti-HBs and anti-HBc persist indefinitely.

The temporal association between the appearance of anti-HBs and resolution of HBV infection as well as the observation that persons with anti-HBs in serum are protected against reinfection with HBV suggests that *anti-HBs is the protective antibody*. Therefore, strategies for prevention of HBV infection are based on providing susceptible persons with circulating anti-HBs (see below). Occasionally, in ~5–10% of patients with chronic hepatitis B, low-level, low-affinity anti-HBs can be detected. Although an unusual serologic pattern in chronic hepatitis B, coexisting HBsAg and anti-HBs positivity does not signal imminent clearance of hepatitis B. Recently, the presence of coexisting HBsAg and anti-HBs in 4.2% of 6534 Chinese patients with chronic hepatitis B was reported (in HBeAg-negative but not HBeAg-reactive patients) to be associated with a higher risk of advanced fibrosis and cirrhosis. The fact that the coexistent HBsAg–anti-HBs subset was significantly older suggests that the link with advanced disease was predominantly the result of longer-duration disease. These patients with HBsAg and such nonneutralizing anti-HBs should be categorized as having chronic HBV infection and, because of the reported association with advanced fibrosis, evaluated for a higher risk of advanced disease.

The other readily detectable serologic marker of HBV infection, HBeAg, appears concurrently with or shortly after HBsAg. Its appearance coincides temporally with high levels of virus replication and reflects the presence of circulating intact virions and detectable HBV DNA (with the notable exception of patients with precore mutations who cannot synthesize HBeAg—see "Molecular Variants"). Pre-S1 and pre-S2 proteins are also expressed during periods of peak replication, but assays for these gene products are not routinely available. In self-limited HBV infections, HBeAg becomes undetectable shortly after peak elevations in aminotransferase activity, before the disappearance of HBsAg, and anti-HBe then becomes detectable, coinciding with a period of relatively lower infectivity (Fig. 350-4). Because HBeAg appears transiently (and HBV DNA, see below, is always present) during typical cases of acute infection, testing for HBeAg and HBV DNA is of limited clinical utility; in contrast, testing for the presence of these markers is of substantial importance in patients with chronic infection.

Departing from the pattern typical of acute HBV infections, in chronic HBV infection, HBsAg remains detectable beyond 6 months,

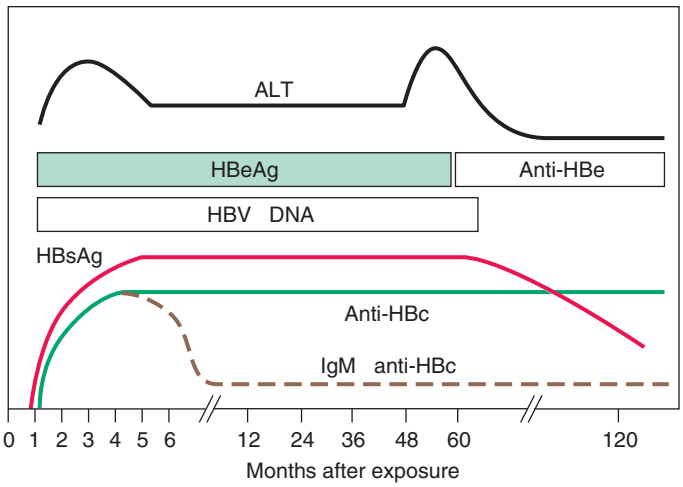

FIGURE 350-5 Scheme of typical laboratory features of wild-type chronic hepatitis B. HBeAg and hepatitis B virus (HBV) DNA can be detected in serum during the relatively *replicative phase* of chronic infection, which is associated with infectivity and liver injury. Seroconversion from the replicative phase to the relatively *nonreplicative phase* occurs at a rate of ~10% per year and is heralded by an acute hepatitis–like elevation of alanine aminotransferase (ALT) activity; during the nonreplicative phase, infectivity and liver injury are limited. In HBeAg-negative chronic hepatitis B associated with mutations in the precore region of the HBV genome, replicative chronic hepatitis B occurs in the absence of HBeAg.

anti-HBc is primarily of the IgG class, and anti-HBs is either undetectable or detectable at low levels (see "Laboratory Features") **(Fig. 350-5)**. During early chronic HBV infection, HBV DNA can be detected both in serum and in hepatocyte nuclei, where it is present in free or episomal form. This relatively highly *replicative stage* of HBV infection is the time of maximal infectivity and liver injury; HBeAg is a qualitative marker and HBV DNA a quantitative marker of this replicative phase, during which all three forms of HBV circulate, including intact virions. Over time, the relatively replicative phase of chronic HBV infection gives way to a relatively *nonreplicative phase*. This occurs at a rate of ~10% per year and is accompanied by seroconversion from HBeAg to anti-HBe. In many cases, this seroconversion coincides with a transient, usually mild, acute hepatitis-like elevation in aminotransferase activity, believed to reflect cell-mediated immune clearance of virus-infected hepatocytes. In this relatively nonreplicative or low-replicative phase of chronic infection, when HBV DNA is demonstrable in hepatocyte nuclei, it tends to be integrated into the host genome. In this phase, only spherical and tubular forms of HBV, *not intact virions*, circulate, and liver injury tends to subside. In this phase, clinical measures of liver injury (specifically alanine aminotransferase [ALT]) are normal. Most such patients would be characterized as *inactive HBV carriers*. In reality, the designations *replicative* and *nonreplicative* are only relative; even in the so-called nonreplicative phase, circulating HBV DNA can be detected at levels of approximately $\leq 10^3$ virions/mL with highly sensitive amplification probes such as the polymerase chain reaction (PCR); below this replication threshold, liver injury and infectivity of HBV are limited to negligible. Still, the distinctions are pathophysiologically and clinically meaningful. While true inactive carriers rarely progress to an immune active state, in 5% of cases, relatively nonreplicative HBeAg-negative chronic HBV infection converts back to replicative infection with re-expression of HBeAg. Such spontaneous reactivations may also be accompanied by expression of IgM anti-HBc, as well as by exacerbations of liver injury. Because high-titer IgM anti-HBc can reappear during acute exacerbations of chronic hepatitis B, relying on IgM anti-HBc versus IgG anti-HBc to distinguish between acute and chronic hepatitis B infection, respectively, may not always be reliable; in such cases, patient history and additional follow-up monitoring over time are invaluable in helping to distinguish de novo acute hepatitis B infection from acute exacerbation of chronic hepatitis B infection.

MOLECULAR VARIANTS Variation occurs throughout the HBV genome, and clinical isolates of HBV that do not express typical viral

proteins have been attributed to mutations in individual or even multiple gene locations. For example, variants have been described that lack nucleocapsid proteins (commonly), envelope proteins (very rarely), or both. Two categories of naturally occurring HBV variants have attracted the most attention: precore mutations and escape mutations.

One precore mutation was identified initially in Mediterranean countries among patients with severe chronic HBV infection and detectable HBV DNA, but with anti-HBe instead of HBeAg. These patients were found to be infected with an HBV mutant that contained an alteration in the precore region, rendering the virus incapable of encoding HBeAg. Although several potential mutation sites exist in the pre-C region, the region of the C gene necessary for the expression of HBeAg (see "Virology and Etiology"), the most commonly encountered in such patients is a single base substitution, from G to A in the second to last codon of the pre-C gene at nucleotide 1896. This substitution results in the replacement of the TGG tryptophan codon by a stop codon (TAG), which prevents the translation of HBeAg. Another mutation, in the core-promoter region, prevents transcription of the coding region for HBeAg and yields an HBeAg-negative phenotype. Patients with such mutations in the precore region and who are unable to secrete HBeAg may have severe liver disease that progresses more rapidly to cirrhosis, or alternatively, they are identified clinically later in the course of the natural history of chronic hepatitis B, when the disease is more advanced. Both "wild-type" HBV and precore-mutant HBV can coexist in the same patient, or mutant HBV may arise late during wild-type HBV infection. Clusters of fulminant hepatitis B have been observed in Japan and Israel among patients with precore mutant mutations, although, typically, in Europe and North America, most cases of fulminant hepatitis B occur in patients with wild-type virus. HBeAg-negative chronic hepatitis with mutations in the precore region is now the most frequently encountered form of hepatitis B in Mediterranean countries and in Europe. In the United States, where HBV genotype A (less prone to G1896A mutation) is prevalent, precore-mutant HBV had been much less common; however, as a result of immigration from Asia and Europe, the proportion of HBeAg-negative hepatitis B–infected persons has increased in the United States, now accounting for ~30–40% of patients with chronic hepatitis B. Characteristic of such HBeAg-negative chronic hepatitis B are lower levels of HBV DNA (usually $\leq 10^5$ IU/mL) and one of several patterns of aminotransferase activity—persistent elevations, periodic fluctuations above the normal range, and periodic fluctuations between the normal and elevated range.

The second important category of HBV mutants consists of *escape mutants*, in which a single amino acid substitution, from glycine to arginine, occurs at position 145 of the immunodominant *a* determinant common to all HBsAg subtypes. This HBsAg alteration leads to a critical conformational change that results in a loss of neutralizing activity by anti-HBs. This specific HBV/*a* mutant has been observed in two situations, active and passive immunization, in which humoral immunologic pressure may favor evolutionary change ("escape") in the virus—in a small number of hepatitis B vaccine recipients who acquired HBV infection despite the prior appearance of neutralizing anti-HBs and in HBV-infected liver transplant recipients treated with a high-potency human monoclonal anti-HBs preparation. Although such mutants have not been recognized frequently, their existence raises a concern that may complicate vaccination strategies and serologic diagnosis.

Different types of mutations emerge during antiviral therapy of chronic hepatitis B with nucleoside analogues; such YMDD and similar mutations in the polymerase motif of HBV are described in Chap. 352.

EXTRAHEPATIC SITES Hepatitis B antigens and HBV DNA have been identified in extrahepatic sites, including the lymph nodes, bone marrow, circulating lymphocytes, spleen, and pancreas. Although the virus does not appear to be associated with tissue injury in any of these extrahepatic sites, its presence in these "remote" reservoirs has been invoked (but is not necessary) to explain the recurrence of HBV infection after orthotopic liver transplantation. The clinical relevance of such extrahepatic HBV is limited.

Hepatitis D The delta hepatitis agent, or HDV, the only member of the genus *Deltavirus*, is a defective RNA virus that co-infects with and requires the helper function of HBV (or other hepadnaviruses) for its replication and expression. Slightly smaller than HBV, HDV is a formalin-sensitive, 35- to 37-nm virus with a hybrid structure. Its nucleocapsid expresses HDV antigen (HDAg), which bears no antigenic homology with any of the HBV antigens, and contains the virus genome. The HDV core is "encapsidated" by an outer envelope of HBsAg, indistinguishable from that of HBV except in its relative compositions of major, middle, and large HBsAg component proteins. The genome is a small, 1700-nucleotide, circular, single-strand RNA of negative polarity that is nonhomologous with HBV DNA (except for a small area of the polymerase gene) but that has features and the rolling circle model of replication common to genomes of plant satellite viruses or viroids. HDV RNA contains many areas of internal complementarity; therefore, it can fold on itself by internal base pairing to form an unusual, very stable, rod-like structure that contains a very stable, self-cleaving and self-ligating ribozyme. HDV RNA requires host RNA polymerase II for its replication in the hepatocyte nucleus via RNA-directed RNA synthesis by transcription of genomic RNA to a complementary antigenomic (plus strand) RNA; the antigenomic RNA, in turn, serves as a template for subsequent genomic RNA synthesis effected by host RNA polymerase I. HDV RNA has only one open reading frame, and HDAg, a product of the antigenomic strand, is the only known HDV protein; HDAg exists in two forms: a small, 195-amino-acid species, which plays a role in facilitating HDV RNA replication, and a large, 214-amino-acid species, which appears to suppress replication but is required for assembly of the antigen into virions. HDV antigens have been shown to bind directly to RNA polymerase II, resulting in stimulation of transcription. Viral assembly requires farnesylation of the large HDAg for ribonucleoprotein anchoring to HBsAg. Both HBV and HDV enter hepatocytes via the NTCP receptor. Although complete hepatitis D virions and liver injury require the cooperative helper function of HBV, intracellular replication of HDV RNA can occur without HBV. Genomic heterogeneity among HDV isolates has been described. Although pathophysiologic and clinical consequences of this genetic diversity have not been established definitively, preliminarily, genotype 2 has been linked to milder disease and genotype 3 to severe acute disease. The clinical spectrum of hepatitis D is common to all eight genotypes identified, the predominant of which is genotype 1.

HDV can either infect a person simultaneously with HBV (*co-infection*) or superinfect a person already infected with HBV (*superinfection*). In instances of superinfection, when HDV infection is transmitted from a donor with one HBsAg subtype to an HBsAg-positive recipient with a different subtype, HDV assumes the HBsAg subtype of the recipient, rather than the donor. Because HDV relies absolutely on HBV for its replication, the duration of HDV infection is determined by the duration of (and cannot outlast) HBV infection. HDV replication tends to suppress HBV replication; therefore, patients with hepatitis D tend to have lower levels of HBV replication. HDV antigen is expressed primarily in hepatocyte nuclei and is occasionally detectable in serum. During acute HDV infection, anti-HDV of the IgM class predominates, and 30–40 days may elapse after symptoms appear before anti-HDV can be detected. In self-limited infection, anti-HDV is low-titer and transient, rarely remaining detectable beyond the clearance of HBsAg and HDV antigen. In chronic HDV infection, anti-HDV circulates in high titer, and both IgM and IgG anti-HDV can be detected. HDV antigen in the liver and HDV RNA in serum and liver can be detected during HDV replication.

Hepatitis C Hepatitis C virus, which, before its identification, was labeled "non-A, non-B hepatitis," is a linear, single-strand, positive-sense, 9600-nucleotide RNA virus, the genome of which is similar in organization to that of flaviviruses and pestiviruses; HCV is the only member of the genus *Hepacivirus* in the family Flaviviridae. The HCV genome contains a single, large open reading frame (ORF) (gene) that codes for a virus polyprotein of ~3000 amino acids, which is cleaved after translation to yield 10 viral proteins. The 5′ end of

the genome consists of an untranslated region (containing an internal ribosomal entry site [IRES]) adjacent to the genes for three structural proteins, the nucleocapsid core protein, C, and two envelope glycoproteins, E1 and E2. The 5′ untranslated region and core gene are highly conserved among genotypes, but the envelope proteins are coded for by the hypervariable region, which varies from isolate to isolate and may allow the virus to evade host immunologic containment directed at accessible virus-envelope proteins. The 3′ end of the genome also includes an untranslated region and contains the genes for seven nonstructural (NS) proteins: p7, NS2, NS3, NS4A, NS4B, NS5A, and NS5B. p7 is a membrane ion channel protein necessary for efficient assembly and release of HCV. The NS2 cysteine protease cleaves NS3 from NS2, and the NS3-4A serine protease cleaves all the downstream proteins from the polyprotein. Important NS proteins involved in virus replication include the NS3 helicase; NS3-4A serine protease; the multifunctional membrane-associated phosphoprotein NS5A, an essential component of the viral replication membranous web (along with NS4B); and the NS5B RNA-dependent RNA polymerase **(Fig. 350-6)**. Because HCV does not replicate via a DNA intermediate, it does not integrate into the host genome. Because HCV tends to circulate in relatively low titer, 10^3–10^7 virions/mL, visualization of the 50- to 80-nm virus particles remains difficult. Still, the replication rate of HCV is very high, 10^{12} virions per day; its half-life is 2.7 h. Historically, the study of HCV had been hampered by few adequate in vitro and animal models. In 2005, however, complete replication of HCV and intact 55-nm virions was described in cell culture systems. These and other subsequent models were fundamental toward the development of targeted, effective antiviral therapies for HCV infection. Still, the continued absence of robust animal models poses a barrier to much-needed vaccine development. Albeit a helpful animal model, the chimpanzee is cumbersome to study, and access to chimpanzees for medical research has been curtailed substantially. In addition, while HCV replication has been documented in a xenograft immunodeficient mouse model containing explants of human liver and in transgenic mouse and rat models, a tractable immunocompetent murine model has remained elusive.

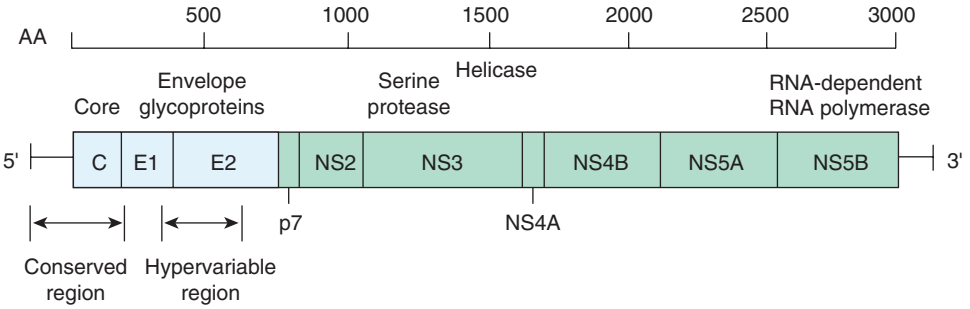

FIGURE 350-6 Organization of the hepatitis C virus genome and its associated, 3000-amino-acid (AA) proteins. The three structural genes at the 5′ end are the core region, C, which codes for the nucleocapsid, and the envelope regions, E1 and E2, which code for envelope glycoproteins. The 5′ untranslated region and the C region are highly conserved among isolates, whereas the envelope domain E2 contains the hypervariable region. At the 3′ end are seven nonstructural (NS) regions—p7, a membrane protein adjacent to the structural proteins that appears to function as an ion channel; NS2, which codes for a cysteine protease; NS3, which codes for a serine protease and an RNA helicase; NS4 and NS4B; NS5A, a multifunctional membrane-associated phosphoprotein, an essential component of the viral replication membranous web; and NS5B, which codes for an RNA-dependent RNA polymerase. After translation of the entire polyprotein, individual proteins are cleaved by both host and viral proteases.

In vitro study has also elucidated important cofactors for the hepatitis C viral life cycle. For example, HCV entry into the hepatocyte occurs via the non-liver-specific CD81 receptor and the liver-specific tight junction protein claudin-1. A growing list of additional host receptors to which HCV binds upon cell entry includes occludin, low-density lipoprotein receptors, glycosaminoglycans, scavenger receptor B1, and epidermal growth factor receptor, among others. After viral entry and uncoating, translation is initiated by the IRES on the endoplasmic reticulum membrane, and the HCV polyprotein is cleaved during translation and posttranslationally by host cellular proteases as well as HCV NS2-3 and NS3-4A proteases. Host cofactors involved in HCV replication include cyclophilin A, which binds to NS5A and yields conformational changes required for viral replication, and the liver-specific host microRNA miR-122. Relying on the same assembly and secretion pathway as low-density and very-low-density lipoproteins, HCV is a lipoviroparticle and masquerades as a lipoprotein, which may limit its visibility to the adaptive immune system, explain its ability to evade immune containment and clearance, and account for the lower circulating LDL levels observed in patients with chronic hepatitis C.

At least six distinct major genotypes (and a minor genotype 7), as well as >50 subtypes within genotypes, of HCV have been identified by nucleotide sequencing. Some HCV genotypes are distributed worldwide, whereas others are more confined geographically (see "Epidemiology and Global Features"). Genotype differences can affect choice of direct-acting antiviral treatment and can affect clinical course (e.g., hepatic steatosis and clinical progression are more likely in genotype 3). Genotypes differ from one another in sequence homology by ≥30%, and subtypes differ by ~20%. Because divergence of HCV isolates within a genotype or subtype and within the same host may vary insufficiently to define a distinct genotype, these intragenotypic differences are referred to as *quasispecies* and differ in sequence homology by only a few percent. The genotypic and quasispecies diversity of HCV, resulting from its high mutation rate, interferes with effective humoral immunity. Neutralizing antibodies to HCV have been demonstrated, but they tend to be short-lived, and HCV infection does not induce lasting immunity against reinfection with different virus isolates or even the same virus isolate. Indeed, the presence of detectable anti-HCV does not indicate protection against re-infection. Thus, neither *heterologous* nor *homologous* immunity appears to develop commonly after acute HCV infection

Currently available, third-generation immunoassays, which incorporate proteins from the core, NS3, and NS5 regions, detect anti-HCV antibodies during acute infection. The most sensitive indicator of HCV infection is the presence of HCV RNA, which requires molecular amplification, for example, by PCR **(Fig. 350-7)**. To allow standardization of the quantification of HCV RNA among laboratories and commercial assays, HCV RNA is reported as international units (IUs) per milliliter; quantitative assays with a broad dynamic range are available that allow detection of HCV RNA with a sensitivity as low as 5 IU/mL. HCV RNA can be detected within a few days of exposure to HCV—well before the appearance of anti-HCV—and tends to persist for the duration of HCV infection. Application of sensitive molecular probes for HCV RNA has revealed the presence of replicative HCV in peripheral blood lymphocytes of infected persons; however, as is the case for HBV in lymphocytes, the clinical relevance of HCV lymphocyte infection is not known.

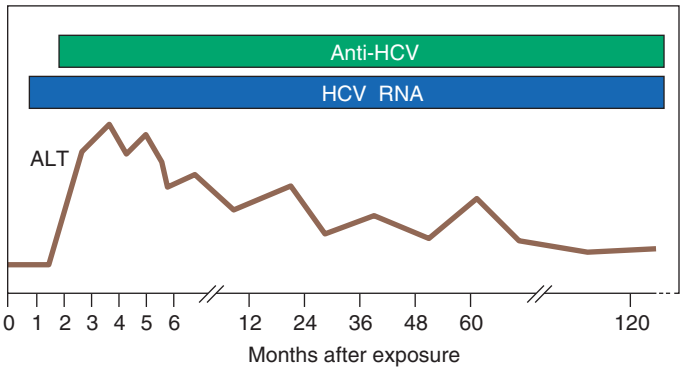

FIGURE 350-7 Scheme of typical laboratory features during acute hepatitis C progressing to chronicity. Hepatitis C virus (HCV) RNA is the first detectable event, preceding alanine aminotransferase (ALT) elevation and the appearance of anti-HCV.

Hepatitis E Previously labeled *epidemic* or *enterically transmitted non-A, non-B hepatitis*, HEV is an enterically transmitted virus that causes clinically apparent hepatitis primarily in India, Asia, Africa, and Central America. In those geographic areas, HEV is the most common cause of acute hepatitis; one-third of the global population appears to have been infected. This agent, with epidemiologic features resembling those of hepatitis A, is a 27- to 34-nm, nonenveloped, heat-stable, HAV-like virus with a 7200-nucleotide, single-strand, positive-sense RNA genome. Like HAV, HEV also exists in a quasi-enveloped form enclosed within host-cell-derived membranes. HEV has three overlapping ORFs (genes), the largest of which, *ORF1*, encodes nonstructural proteins involved in virus replication (the viral replicase, which includes a protease, polymerase, and helicase). A middle-sized gene, *ORF2*, encodes the nucleocapsid protein, the major structural protein, and the smallest, *ORF3*, encodes a small structural phosphoprotein involved in virus particle secretion. All HEV isolates appear to belong to a single serotype, despite genomic heterogeneity of up to 25% and the existence of four species (A–D) and eight genotypes, only four of which, all within species A, have been detected in humans. Genotype associations are important in HEV infection. Genotypes 1 and 2 (common in developing countries) appear to be more virulent anthrotropic variants. In contrast, genotypes 3 (the most common in the United States and Europe) and 4 (seen in China), are endemic in animal species (enzootic variants), represent a zoonotic reservoir for human infections, and are associated with more attenuated or subclinical infection in healthy hosts but with chronic infection in immunocompromised hosts. Contributing to the perpetuation of this virus are the animal reservoirs described above, most notably in swine but also in camels, deer, rats, and rabbits, among others. No genomic or antigenic homology, however, exists between HEV and HAV or other picornaviruses; and HEV, although resembling caliciviruses, is sufficiently distinct from any known agent to merit its own classification as a unique genus, *Orthohepevirus*, within the family Hepeviridae (which includes similar viruses infecting mammals, birds, and fish). The virus has been detected in stool, bile, and liver and is excreted in the stool during the late incubation period. Both IgM anti-HEV during early acute infection and IgG anti-HEV predominating after the first 3 months can be detected (a serologic pattern similar to that of hepatitis A, see above). The presence of HEV RNA in serum and stool accompanies acute infection; viremia resolves as clinical-biochemical recovery ensues, while HEV RNA in stool may outlast viremia by several weeks. Currently, serologic/virologic testing for HEV infection—not approved or licensed by the U.S. Food and Drug Administration (FDA)—can be done in specialized laboratories (e.g., the Centers for Disease Control and Prevention [CDC]) and some commercial laboratories.

PATHOGENESIS

Under ordinary circumstances, none of the hepatitis viruses are known to be directly cytopathic to hepatocytes. Evidence suggests that the clinical manifestations and outcomes after acute liver injury associated with viral hepatitis are determined by the immunologic responses of the host. Among the viral hepatitides, the immunopathogenesis of hepatitis B and C has been studied most extensively.

Hepatitis B For HBV, the existence of inactive hepatitis B carriers or "immune tolerant" (see below) patients with normal liver histology and function suggests that the virus is not directly cytopathic. The fact that patients with defects in cellular immune competence are more likely to remain chronically infected rather than to clear HBV supports the role of cellular immune responses in the pathogenesis of hepatitis B–related liver injury. The model that has the most experimental support involves cytolytic T cells sensitized specifically to recognize host and hepatitis B viral antigens on the liver cell surface. Nucleocapsid proteins (HBcAg and possibly HBeAg), present on the cell membrane in minute quantities, are the viral target antigens that, with host antigens, invite cytolytic T cells to destroy HBV-infected hepatocytes. Differences in the robustness and broad polyclonality of CD8+ cytolytic T-cell responsiveness; in the level of HBV-specific helper CD4+ T cells; in attenuation, depletion, and exhaustion of virus-specific T cells; in viral T-cell epitope escape mutations that allow the virus to evade T-cell containment; and in the elaboration of antiviral cytokines by T cells have been invoked to explain differences in outcomes between those who recover after acute hepatitis and those who progress to chronic hepatitis or between those with mild and those with severe (fulminant) acute HBV infection. Ultimately, a robust CD8+ T-cell response is central both to viral clearance and to liver injury.

Although a robust cytolytic T-cell response occurs and eliminates virus-infected liver cells during acute hepatitis B, >90% of HBV DNA has been found in experimentally infected chimpanzees to disappear from the liver and blood before maximal T-cell infiltration of the liver and before most of the biochemical and histologic evidence of liver injury. This observation suggests that components of the innate immune system and inflammatory cytokines, independent of cytopathic antiviral mechanisms, participate in the early immune response to HBV infection; this effect has been shown to represent elimination of HBV replicative intermediates from the cytoplasm and covalently closed circular viral DNA from the nucleus of infected hepatocytes. In turn, the innate immune response to HBV infection is mediated largely by natural killer (NK) cell cytotoxicity, activated by immunosuppressive cytokines (e.g., interleukin [IL] 10 and transforming growth factor [TGF] β), reduced signals from inhibitory receptor expression (e.g., major histocompatibility complex), or increased signals from activating receptor expression on infected hepatocytes. In addition, NK cells reduce helper CD4+ cells, which results in reduced CD8+ cells and exhaustion of the virus-specific T-cell response to HBV infection. Adding to the evidence supporting the role of these immunologic perturbations in the pathogenesis of HBV-associated liver injury are the observations that many of these departures from normal immune function are restored after successful antiviral therapy. Ultimately, HBV-HLA–specific cytolytic T-cell responses of the adaptive immune system are felt to be responsible for recovery from HBV infection.

Debate continues over the relative importance of viral and host factors in the pathogenesis of HBV-associated liver injury and its outcome. As noted above, precore genetic mutants of HBV have been associated with the more severe outcomes of HBV infection (severe chronic and fulminant hepatitis), suggesting that, under certain circumstances, relative pathogenicity is a property of the virus, not the host. The facts that concomitant HDV and HBV infections are associated with more severe liver injury than HBV infection alone and that cells transfected in vitro with the gene for HDV antigen express HDV antigen and then become necrotic in the absence of any immunologic influences are also consistent with a viral effect on pathogenicity. Similarly, in patients who undergo liver transplantation for end-stage chronic hepatitis B, occasionally, rapidly progressive liver injury appears in the new liver. This clinical presentation is associated with an unusual histologic pattern in the new liver, *fibrosing cholestatic hepatitis*, which, ultrastructurally, appears to represent a choking of the cell with overwhelming quantities of HBsAg. This observation suggests that, under the influence of the potent immunosuppressive agents required to prevent allograft rejection, HBV may have a direct cytopathic effect on liver cells, independent of the immune system.

Although the precise mechanism of liver injury in HBV infection remains elusive, studies of nucleocapsid proteins have shed light on the profound immunologic tolerance to HBV of babies born to mothers with highly replicative (HBeAg-positive), chronic HBV infection. In HBeAg-expressing transgenic mice, in utero exposure to HBeAg, which is sufficiently small to traverse the placenta, induces T-cell tolerance to both nucleocapsid proteins. This, in turn, may explain why, when infection occurs so early in life, immunologic clearance does not occur, and protracted, lifelong infection ensues. An alternative explanation proposed to explain why robust liver injury does not accompany neonatal HBV infection but predisposes to chronic infection is defective priming of HBV-specific T cells during in utero exposure to HBV.

"IMMUNE TOLERANT" VERSUS "IMMUNE ACTIVE" CHRONIC HEPATITIS B An important distinction should be drawn between HBV infection acquired at birth, common in endemic areas, such as East Asia, and infection acquired in adulthood, common in the West.

Infection in the neonatal period is associated with the acquisition of what appears to be a high level of immunologic tolerance to HBV and absence of an acute hepatitis illness but the almost invariable establishment of chronic, often lifelong infection. Neonatally acquired HBV infection can culminate decades later in cirrhosis and hepatocellular carcinoma (see "Complications and Sequelae"). In contrast, when HBV infection is acquired during adolescence or early adulthood, the host immune response to HBV-infected hepatocytes tends to be robust, an acute hepatitis-like illness is the rule, and failure to recover is the exception. After adulthood-acquired infection, chronicity is uncommon, and the risk of hepatocellular carcinoma is very low. Based on these observations, some authorities categorize chronic HBV infection into an "immune tolerant" phase, an "immune active" phase, and an "inactive" phase. This somewhat simplistic formulation, however, does not apply at all to typical adult infection with self-limited acute hepatitis B. Moreover, even in early-life-acquired chronic infection, this duality is limited by nuance and imprecision in its distinctions. For example, even among those with neonatally acquired HBV infection, in whom immunologic tolerance appears to be established, immunologic responses to HBV infection have been demonstrated (albeit typically at reduced levels), and intermittent bursts of hepatic necroinflammatory activity punctuate the early decades of life during which liver injury appears to be quiescent. Thus, while labeled by some as the "immune tolerant" phase, it more accurately is a period of dissociation between high-level HBV replication and a paucity of inflammatory liver injury. In addition, even when clinically apparent liver injury and progressive fibrosis emerge and predominate during later decades (the so-called immune active phase), the level of immunologic tolerance to HBV and the corresponding failure of immunologic containment and clearance of HBV infection remain substantial. More accurately, in patients with neonatally acquired HBV infection, a dynamic equilibrium exists between tolerance and intolerance, the outcome of which determines the clinical expression of chronic infection. Persons infected as neonates tend to have a relatively higher level of immunologic tolerance (high replication, low necroinflammatory activity) during the early decades of life and a relatively lower level (but only rarely a loss) of tolerance (and necroinflammatory activity reflecting the level of virus replication) in the later decades of life. Adding to the confusion is an indeterminate category of patients in a gray zone that borders both relative immune activity and relative immune tolerance.

Hepatitis C Cell-mediated immune responses and elaboration by T cells of antiviral cytokines contribute to the multicellular innate and adaptive immune responses involved in the containment of infection and pathogenesis of liver injury associated with hepatitis C. The fact that HCV is so efficient in evading these immune mechanisms is a testament to its highly evolved ability to disrupt host immune responses at multiple levels. After exposure to HCV, the host cell identifies viral product motifs (pattern recognition receptors) that distinguish the virus from "self," resulting in the elaboration of interferons and other cytokines that result in activation of innate and adaptive immune responses. Intrahepatic human leukocyte antigen (HLA) class 1–restricted cytolytic T cells directed at nucleocapsid, envelope, and nonstructural viral protein antigens have been demonstrated in patients with chronic hepatitis C; however, such virus-specific cytolytic T-cell responses do not correlate adequately with the degree of liver injury or with recovery. Yet a consensus has emerged supporting a role in the pathogenesis of HCV-associated liver injury of virus-activated CD4+ helper T cells that stimulate, via the cytokines they elaborate, HCV-specific CD8+ cytotoxic T cells. These responses appear to be more robust (higher in number, more diverse in viral antigen specificity, more functionally effective, and longer lasting) in those who recover from HCV infection than in those who have chronic infection. Contributing to chronic infection are a CD4+ proliferative defect that results in rapid contraction of CD4+ responses, mutations in CD8+ T cell–targeted viral epitopes that allow HCV to escape immune-mediated clearance, and upregulation of inhibitory receptors on functionally impaired, exhausted T cells. Although attention has focused on adaptive immunity, HCV proteins have been shown to interfere with innate immunity by resulting in blocking of type 1 interferon responses and inhibition of interferon signaling and effector molecules in the interferon signaling cascade.

Several single nucleotide polymorphisms have been linked with self-limited hepatitis C, the most convincing of which is the CC haplotype of the *IL28B* gene, which codes for interferon λ3, a component of innate immune antiviral defense. The link between non-CC *IL28B* polymorphisms and failure to clear HCV infection has been explained by a chromosome 19q13.13 frameshift variant upstream of *IL28B*, the ΔG polymorphism of which creates an ORF in a novel interferon gene (*IFN-λ4*) associated with impaired HCV clearance. Also shown to contribute to limiting HCV infection are NK cells of the innate immune system; in spontaneous clearance, NK cells show enhanced IFN-γ elaboration and expression of activating receptors. Conversely, in persistent infection, both peripheral cytotoxicity and intrahepatic NK cell cytotoxicity are dysfunctional. In addition, an important intersection between *IL28B* genotype and NK function can be inferred from the fact that patients with hepatitis C and unfavorable (non-CC, associated with reduced HCV clearance) *IL28B* alleles have been shown to have depressed NK cell/innate immune function. Adding to the complexity of the immune response, HCV core, NS4B, and NS5B have been shown to suppress the immunoregulatory nuclear factor (NF)-κB pathway, resulting in reduced antiapoptotic proteins and a resultant increased vulnerability to tumor necrosis factor (TNF) α-mediated cell death. Finally, the rapid mutation rate of the virus impairs the host immune response; the emergence of substantial viral quasispecies diversity and HCV sequence variation allows the virus to evade attempts by the host to contain HCV infection by both humoral and cellular immune mechanisms.

Hepatitis A and E Viral shedding in these acute hepatitides predates clinical evidence of liver injury, consistent with the absence of a relationship between viral replication and target-organ injury. Instead, as shown for hepatitis B and C, in hepatitis A and E, experimental evidence supports a cytolytic CD8+ T-cell response as the instrument of liver cell injury, in concert with or dwarfed by CD4+ helper T cells or CD4+ interferon γ–secreting cells. Furthermore, in acute HAV infection, expansion of CD8+ T cells active against other, non-HAV, viruses has been demonstrated, and this nonspecific CD8+ T-cell activation correlated with liver injury. HEV, similar to the other hepatitides, has also been shown to interfere with host antiviral defenses, such as interferon signaling and effector function, and to downregulate interferon-stimulated genes. The demonstration of an activated innate immune response in patients with these hepatitides argues for a multitude of immunologic mechanisms in the pathogenesis of the acute liver injury resulting from HAV and HEV infection.

EXTRAHEPATIC MANIFESTATIONS

Immune complex–mediated tissue damage appears to play a pathogenetic role in the extrahepatic manifestations of acute hepatitis B. The occasional prodromal serum sickness–like syndrome observed in acute hepatitis B appears to be related to the deposition in tissue blood vessel walls of HBsAg–anti-HBs circulating immune complexes, leading to activation of the complement system and depressed serum complement levels. Other extrahepatic manifestations of HBV infection may include immune complex–mediated diseases, such as polyarteritis nodosa (generalized vasculitis affecting small- and medium-sized arterioles), glomerulonephritis with nephrotic syndrome, and cryoglobulinemia, which are very rare in acute hepatitis B but far more common in chronic disease **(Chaps. 326 and 375)**.

Immune complex disorders have been linked, albeit rarely, with both hepatitis A and E. In hepatitis E, rare neurologic (including Guillain-Barré syndrome), renal, pancreatic, and hematologic complications have been postulated to result from both immunologic mechanisms and/or direct extrahepatic-site infection with the virus.

PATHOLOGY

Liver biopsy is rarely needed for the diagnosis or management of acute viral hepatitis, for which clinical features and serologic testing remain

the cornerstone of diagnosis. The typical morphologic lesions of all types of viral hepatitis are similar and consist of panlobular infiltration with mononuclear cells, hepatic cell necrosis, hyperplasia of Kupffer cells, and variable degrees of cholestasis. Hepatic cell regeneration is present, as evidenced by numerous mitotic figures, multinucleated cells, and "rosette" or "pseudoacinar" formation. The mononuclear infiltration consists primarily of small lymphocytes, although plasma cells and eosinophils occasionally are present. Liver cell damage consists of hepatic cell degeneration and necrosis, cell dropout, ballooning of cells, and acidophilic degeneration of hepatocytes (forming so-called Councilman or apoptotic bodies). Large hepatocytes with a ground-glass appearance of the cytoplasm may be seen in chronic but not in acute HBV infection; these cells contain HBsAg and can be identified histochemically with orcein or aldehyde fuchsin. In uncomplicated viral hepatitis, the reticulin framework is preserved.

In hepatitis C, the histologic lesion is often remarkable for a relative paucity of inflammation, a marked increase in activation of sinusoidal lining cells, lymphoid aggregates, the presence of fat (more frequent in genotype 3 and linked to increased fibrosis), and, occasionally, bile duct lesions in which biliary epithelial cells appear to be piled up without interruption of the basement membrane. Occasionally, microvesicular steatosis occurs in hepatitis D. In hepatitis E, a common histologic feature is marked cholestasis. A cholestatic variant of slowly resolving acute hepatitis A has been described as well.

In the setting of severe acute liver injury, less-specific histologic findings, including portal and lobular inflammation and confluent necrosis, may be present. A more severe histologic lesion, *bridging hepatic necrosis*, also termed *subacute* or *confluent necrosis* or *interface hepatitis*, is observed occasionally in acute hepatitis. "Bridging" between lobules results from large areas of hepatic cell dropout, with collapse of the reticulin framework. Characteristically, the bridge consists of condensed reticulum, inflammatory debris, and degenerating liver cells that span adjacent portal areas, portal to central veins, or central vein to central vein. This lesion had been thought to have prognostic significance; in many of the originally described patients with this lesion, a subacute course terminated in death within several weeks to months, or severe chronic hepatitis and cirrhosis developed; however, the association between bridging necrosis and a poor prognosis in patients with acute hepatitis has not been upheld. Therefore, although demonstration of this lesion in patients with chronic hepatitis has prognostic significance **(Chap. 352)**, its demonstration during acute hepatitis is less meaningful, and liver biopsies to identify this lesion are no longer undertaken routinely in patients with acute hepatitis. In *massive hepatic necrosis* (fulminant hepatitis, "acute yellow atrophy"), the striking feature at postmortem examination is the finding of a small, shrunken, soft liver. Histologic examination reveals massive necrosis and dropout of liver cells of most lobules with extensive collapse and condensation of the reticulin framework. When histologic documentation is required in the management of fulminant or very severe hepatitis, a biopsy can be done by the angiographically guided transjugular route, which permits the performance of this invasive procedure in the presence of severe coagulopathy.

Immunohistochemical and electron-microscopic studies have localized HBsAg to the cytoplasm and plasma membrane of infected liver cells. In contrast, HBcAg predominates in the nucleus, but, occasionally, scant amounts are also seen in the cytoplasm and on the cell membrane. HDV antigen is localized to the hepatocyte nucleus, whereas HAV and HCV antigens are localized to the cytoplasm. Hepatitis E ORF-2 protein staining is distributed in both a cytoplasmic and nuclear pattern.

EPIDEMIOLOGY AND GLOBAL FEATURES

Before the availability of serologic tests for hepatitis viruses, all viral hepatitis cases were labeled either as "infectious" or "serum" hepatitis. Modes of transmission overlap, however, and *a clear distinction among the different types of viral hepatitis cannot be made solely based on clinical or epidemiologic features* **(Table 350-2)**. The most accurate means to distinguish the various types of viral hepatitis involves specific serologic testing.

Hepatitis A *This agent is transmitted almost exclusively by the fecal-oral route*. Person-to-person spread of HAV is enhanced by poor personal hygiene and overcrowding; large outbreaks as well as sporadic cases have been traced to contaminated food, water, milk, frozen raspberries and strawberries, green onions imported from Mexico, and shellfish (e.g., scallops imported from the Philippines used to make sushi, the culprit identified in a 2016 Hawaiian outbreak). Intrafamily and intrainstitutional spreads are also common. Early epidemiologic observations supported a predilection for hepatitis A to occur in late fall and early winter. In temperate zones, epidemic waves have been recorded every 5–20 years as new segments of nonimmune population appeared; however, in developed countries, the incidence of hepatitis A has been declining, presumably as a function of improved sanitation and environmental hygiene, and these cyclic patterns are no longer observed; still, episodic outbreaks among certain high-risk populations continue to be reported (see below). No HAV carrier state has been identified after acute hepatitis A; perpetuation of the virus in nature depends presumably on nonepidemic, inapparent subclinical infection, ingestion of contaminated food or water in, or imported from, endemic areas, and/or contamination linked to environmental reservoirs.

In the general population, anti-HAV, a marker for previous HAV infection, increases in prevalence as a function of increasing age and of decreasing socioeconomic status. In the 1970s, serologic evidence of prior hepatitis A infection occurred in ~40% of urban populations in the United States, most of whose members never recalled having had a symptomatic case of hepatitis. In subsequent decades, however, the prevalence of anti-HAV declined in the United States. In developing countries, exposure, infection, and subsequent immunity are almost universal in childhood. As the frequency of subclinical childhood infections declines in developed countries, a susceptible cohort of adults emerges. Hepatitis A tends to be more symptomatic in adults; therefore, paradoxically, as the frequency of HAV infection declines, the likelihood of clinically apparent, even severe, HAV illnesses increases in the susceptible adult population. Travel to endemic areas is a common source of infection for adults from nonendemic areas. Important recognized epidemiologic foci of HAV infection include childcare centers, neonatal intensive care units, promiscuous men who have sex with men, injection drug users, and unvaccinated close contacts of newly arrived international adopted children, most of whom emanate from countries with intermediate-to-high hepatitis A endemicity. Although hepatitis A is rarely bloodborne, several outbreaks have been recognized in recipients of clotting-factor concentrates. In the United States, the introduction of hepatitis A vaccination programs among children from high-incidence states has resulted in a >70% reduction in the annual incidence of new HAV infections and has shifted the burden of new infections from children to adults. In the 2007–2012 U.S. Public Health Service National Health and Nutrition Examination Survey (NHANES), the prevalence of anti-HAV in the U.S. population aged ≥20 years had declined to 24.2% from the 29.5% measured in NHANES 1999–2006. From 2007 to 2016, the overall anti-HAV prevalence rose, from 30% in 2007–2010 to 40% in 2011–2016 in U.S.-born persons over the age of 2; the largest increases were observed in children (2–11 years) and teenagers (12–19 years), with a slight increase among young adults (age 20–29). In all other age cohorts among U.S.-born adults, however, the prevalence of anti-HAV remained unchanged between 2007 and 2017; no more than 25% of any age group had protective antibodies. The lowest age-specific prevalence of anti-HAV (16.1–17.6%) occurred in adults in the fourth and fifth decades (aged 30–49 years). This is a subgroup of the population who remain susceptible to acute hepatitis A acquired during travel to endemic areas and from contaminated foods, especially those imported from endemic countries. Recognized initially in San Diego, California, in 2016, widespread person-to-person outbreaks, attributed to fecally contaminated environments, of acute hepatitis A occurred primarily among homeless persons and persons who were using injection drugs. Ultimately, this outbreak extended to at least 32 states (highest number of cases in Kentucky), and by March 2020, 31,950 cases were reported, resulting in 19,548 hospitalizations (61% of cases) and 322 deaths (1% of reported cases, 1.6% of hospitalized cases). By 2022, 315 hepatitis A

TABLE 350-2 Clinical and Epidemiologic Features of Viral Hepatitis

FEATURE	HAV	HBV	HCV	HDV	HEV
Incubation (days)	15–45, mean 30	30–180, mean 60–90	15–160, mean 50	30–180, mean 60–90	14–60, mean 40
Onset	Acute	Insidious or acute	Insidious or acute	Insidious or acute	Acute
Age preference	Children, young adults	Young adults (sexual and percutaneous), babies, toddlers	Any age, but more common in adults	Any age (similar to HBV)	Epidemic cases: young adults (20–40 years); sporadic cases: older adults (>60)
Transmission					
Fecal-oral	+++	–	–	–	+++
Percutaneous	Unusual	+++	+++	+++	–
Perinatal	–	+++	±[a]	+	–
Sexual	±	++	±[a]	++	–
Clinical					
Severity	Mild	Occasionally severe	Moderate	Occasionally severe	Mild
Fulminant	0.1%	0.1–1%	0.1%	5–20%[b]	1–2%[c]
Progression to chronicity	None	Occasional (1–10%)	Common (85%)	Common[d]	None[e]
Carrier	None	(90% of neonates)	1.5–3.2%	Variable[g]	None
Cancer	None	0.1–30%[f] + (neonatal infection)	+	±	None
Prognosis	Excellent	Worse with age, debility	Moderate	Acute, good; chronic, poor	Good
Prophylaxis	Ig, inactivated vaccine	HBIG, recombinant vaccine	None	HBV vaccine (none for HBV carriers)	Vaccine
Therapy	None	Interferon[h] Lamivudine[h] Adefovir[h] Pegylated interferon[i] Entecavir[i] Telbivudine[i] Tenofovir disoproxil fumarate[i] Tenofovir alafenamide[i]	Pegylated interferon ribavirin,[h] telaprevir,[h] boceprevir,[h] simeprevir,[h] sofosbuvir, ledipasvir, paritaprevir/ritonavir,[h] ombitasvir,[h] dasabuvir,[h] daclatasvir,[h] velpatasvir, grazoprevir, elbasvir, glecaprevir, pibrentasvir, voxilaprevir	Pegylated interferon ±	None[j]

[a]Primarily with HIV co-infection and high-level viremia in index case; more likely in persons with multiple sex partners or sexually transmitted diseases; risk ~5%. [b]Up to 5% in acute HBV/HDV co-infection; up to 20% in HDV superinfection of chronic HBV infection. [c]10–20% in pregnant women. [d]In acute HBV/HDV co-infection, the frequency of chronicity is the same as that for HBV; in HDV superinfection, chronicity is invariable. [e]Except as observed in immunosuppressed liver allograft recipients or other immunosuppressed hosts. [f]Varies considerably throughout the world and in subpopulations within countries; see text. [g]Common in Mediterranean countries; rare in North America and western Europe. [h]No longer recommended or not included in first-line therapy. [i]First-line agents. [j]Anecdotal reports and retrospective studies suggest that pegylated interferon and/or ribavirin are effective in treating chronic hepatitis E, observed in immunocompromised persons; ribavirin monotherapy has been used successfully in acute, severe hepatitis E.

Abbreviation: HBIG, hepatitis B immunoglobulin. See text for other abbreviations.

outbreak–related deaths were reported across 37 states. The increased clinical severity, rate of hospitalization, and death in these outbreaks can be attributed to their involving an older population (mean age ranging from 36 to 42 years; median age of death was 55), born before the introduction of universal childhood hepatitis A vaccination and in whom clinical severity, as noted above, is higher than in children. Moreover, the affected homeless and drug-using populations suffer from multiple comorbidities (including HBV or HCV co-infection) and disparities in access to health care. Addressing this multistate outbreak has required a vigorous hepatitis A vaccination effort (still falling short of adequate coverage) as well as environmental sanitation/hygiene and education among these susceptible populations.

Hepatitis B Percutaneous inoculation has long been recognized as a major route of hepatitis B transmission, but the outmoded designation "serum hepatitis" is an inaccurate label for the epidemiologic spectrum of HBV infection. As detailed below, most of the hepatitis transmitted by blood transfusion is not caused by HBV; moreover, in approximately two-thirds of patients with acute type B hepatitis, no history of an identifiable percutaneous exposure can be elicited. We now recognize that many cases of hepatitis B result from less obvious modes of nonpercutaneous or covert percutaneous transmission. HBsAg has been identified in almost every body fluid from infected persons, and at least some of these body fluids—most notably semen and saliva—are infectious, albeit less so than serum, when administered percutaneously or nonpercutaneously to experimental animals. Among the nonpercutaneous modes of HBV transmission, oral ingestion has been documented as a potential but inefficient route of exposure. By contrast, the two nonpercutaneous routes considered to have the greatest impact are intimate (especially sexual) contact and perinatal transmission.

In sub-Saharan Africa, intimate contact among toddlers is considered instrumental in contributing to the maintenance of the high frequency of hepatitis B in the population. Perinatal transmission occurs primarily in infants born to mothers with chronic hepatitis B or (rarely) mothers with acute hepatitis B during the third trimester of pregnancy or during the early postpartum period. Perinatal transmission is uncommon in North America and western Europe but occurs with great frequency and is the most important mode of HBV perpetuation in East Asia and developing countries. Although the precise mode of perinatal transmission is unknown, and although ~10% of infections may be acquired in utero, epidemiologic evidence suggests that most infections occur approximately at the time of delivery and are not related to breast-feeding (which is not contraindicated in women with hepatitis B). The likelihood of perinatal transmission of HBV correlates with the presence of HBeAg and high-level viral replication; 90% of HBeAg-positive mothers but only 10–15% of anti-HBe-positive mothers transmit HBV infection to their offspring. In most cases, acute infection in the neonate is clinically asymptomatic, but the child is very likely to remain chronically infected.

The over 290 million persons with chronic HBV infection in the world constitute the main reservoir of hepatitis B in human beings. Whereas serum HBsAg is infrequent (0.1–0.5%) in normal populations in the United States and western Europe, the global prevalence is

estimated at 3.5%, and a prevalence of up to 5–10% has been found in East Asia, sub-Saharan Africa, and tropical countries. The prevalence can be even higher in certain high-risk groups, including persons with Down syndrome, lepromatous leprosy, leukemia, Hodgkin disease, polyarteritis nodosa, and chronic renal disease on hemodialysis, as well as in injection drug users.

Other groups with high rates of HBV infection include spouses of acutely infected persons; sexually promiscuous persons (especially promiscuous men who have sex with men); health care workers and first responders exposed to blood; persons who require repeated transfusions especially with pooled blood-product concentrates (e.g., hemophiliacs); residents and staff of custodial institutions for the developmentally handicapped; prisoners; and, to a lesser extent, family members of chronically infected patients. Because of highly sensitive virologic screening (antigen, antibody, and nucleic acid testing) of donor blood, the risk of acquiring HBV infection from a blood transfusion is estimated to be 1 in 360,000.

Prevalence of infection, modes of transmission, and human behavior conspire to mold geographically different epidemiologic patterns of HBV infection. In East Asia and Africa, hepatitis B, a disease of the newborn and young children, is perpetuated by a cycle of maternal-neonatal spread. In North America and western Europe, hepatitis B is primarily a disease of adolescence and early adulthood, the time of life when intimate sexual contact and recreational and occupational percutaneous exposures tend to occur. To some degree, however, this dichotomy between high-prevalence and low-prevalence geographic regions has been minimized by immigration from high-prevalence to low-prevalence areas. For example, in the United States, NHANES data from 2007 to 2012 revealed an overall prevalence of current HBV infection (detectable HBsAg) of 0.3%; however, the prevalence in Asian persons, 93% of whom were foreign-born, was tenfold higher, 3.1%, representing 50% of the U.S. national disease burden. As a result of adoption of safe behaviors in high-risk groups as well as screening and vaccination programs, the incidence of newly reported HBV infections fell by >80% in the United States during the 1990s and has remained low in the 21st century (with a low of 0.6 cases per 100,000 population in 2021). Paralleling that trend, the imbalance between cases in U.S.-born and foreign-born persons widened; currently, imported cases in non-U.S.-born persons outnumber domestic cases by manyfold; in NHANES 2017–2020, the prevalence of HBV infection was 1.0% in foreign-born versus 0.2% in the entire cohort; non-U.S.-born persons accounted for 73.6% of all infections. The introduction of hepatitis B vaccine in the early 1980s and adoption of universal childhood vaccination policies in many countries resulted in a dramatic, ~90% decline in the incidence of new HBV infections in those countries as well as in the dire consequences of chronic infection, including hepatocellular carcinoma. In the United States, as demonstrated in NHANES 2007–2012, following the 1991 implementation of universal childhood vaccination, HBsAg seropositivity had declined in children aged 6–19 years to as low as 0.03%, an ~85% reduction.

TABLE 350-3 Populations with a High Risk for HBV Infection[a]

Persons born in countries/regions with a high (≥8%) and intermediate (≥2%) prevalence of HBV infection including immigrants and adopted children and including persons born in the United States who were not vaccinated as infants and whose parents emigrated from areas of high HBV endemicity
Household and sexual contacts of, or needle sharing with, persons who have hepatitis B
Babies born to HBsAg-positive mothers
Persons who have used injection drugs
Persons with multiple sexual contacts or a history of sexually transmitted disease
Men who have sex with men
Persons incarcerated in a correctional facility or other detention settings
Persons with elevated alanine or aspartate aminotransferase levels
Persons with HCV or HIV infection
Hemodialysis patients
Health care and laboratory workers and first responders exposed to blood

[a]Screening for hepatitis B had been recommended in the past for persons in these high-risk groups; however, in 2023, the Centers for Disease Control and Prevention recommended universal screening of all adults (>18 years of age) for hepatitis B. Other groups who should be tested for hepatitis B include pregnant women; persons who are the source of blood or body fluids that would be an indication for postexposure prophylaxis (e.g., needlestick, mucosal exposure sexual assault); and persons who require immunosuppressive or cytotoxic therapy (including anti–tumor necrosis factor α therapy for rheumatologic or inflammatory bowel disorders).

UNIVERSAL SCREENING FOR HEPATITIS B Populations and groups at high risk for hepatitis B are listed in **Table 350-3**. Screening for HBV infection used to be recommended in these high-risk populations; however, because risk-group screening had not been shown to be effective in reducing the prevalence of HBV infection in the population and the majority of acute hepatitis B cases were found to occur in persons who were not in these high-risk groups, *universal screening of all adults* (≥18 years) for hepatitis B was recommended in 2023 by the CDC. Because current antiviral therapy has been highly effective in reducing the clinical progression and consequences of HBV infection, such universal screening was found to be cost-effective in reducing the morbidity and mortality associated with chronic hepatitis B.

Hepatitis D Infection with HDV has a worldwide distribution, but two epidemiologic patterns exist. In Mediterranean countries (northern Africa, southern Europe, the Middle East), HDV infection is endemic among those with hepatitis B, and the disease is transmitted predominantly by nonpercutaneous means, especially close personal contact. In nonendemic areas, such as the United States (where hepatitis D is rare among persons with chronic hepatitis B) and northern Europe, HDV infection is confined to persons exposed frequently to blood and blood products, primarily injection drug users (especially in HIV-infected injection drug users) and hemophiliacs. In the United States, the prevalence of HDV infection in the national population was 0.02% in NHANES 1999–2012 and 0.11% in NHANES 2011–2016; however, among HBsAg-positive persons, the prevalence of HDV infection is highest in injection drug users (11–36%) and hemophiliacs (19%). In one study of persons who inject drugs (PWID) in San Francisco, the overall prevalence of HDV infection was 1.1% but as high as 34.6% in PWID who had chronic HBV infection. HDV infection can be introduced into a population through drug users or by migration of persons from endemic to nonendemic areas. Thus, patterns of population migration and human behavior facilitating percutaneous contact play important roles in the introduction and amplification of HDV infection. Occasionally, the migrating epidemiology of hepatitis D is expressed in explosive outbreaks of severe hepatitis, such as those that have occurred in remote South American villages (e.g., "Lábrea fever" in the Amazon basin) as well as in urban centers in the United States. Ultimately, such outbreaks of hepatitis D—either of co-infections with acute hepatitis B or of superinfections in those already infected with HBV—may blur the distinctions between endemic and nonendemic areas. On a global scale, HDV infection declined at the end of the 1990s. Even in Italy, an HDV-endemic area, public health measures introduced to control HBV infection (e.g., mass hepatitis B vaccination) resulted during the 1990s in a 1.5%/year reduction in the prevalence of HDV infection. Still, the frequency of HDV infection during the first decade of the twenty-first century has not fallen below levels reached during the 1990s; the reservoir has been sustained by survivors infected during 1970–1980 and recent immigrants from still-endemic (e.g., eastern Europe and Central Asia) to less-endemic countries. The current global prevalence of HDV infection has been estimated at 12 million people, albeit with significant regional variation. Of the eight HDV genotypes, genotype 1 is distributed worldwide, while the others are more geographically confined (e.g., genotypes 2 and 4 in the Far East, 3 in South America, and 5–8 in Africa).

Hepatitis C Routine screening of blood donors for HBsAg and the elimination of commercial blood sources in the early 1970s reduced the frequency of, but did not eliminate, transfusion-associated hepatitis. During the 1970s, the likelihood of acquiring hepatitis after transfusion of voluntarily donated, HBsAg-screened blood was

~10% per patient (up to 0.9% per unit transfused); 90–95% of these cases were classified, based on serologic exclusion of hepatitis A and B, as "non-A, non-B" hepatitis. For patients requiring transfusion of pooled products, such as clotting factor concentrates, the risk was even higher, up to 20–30%.

During the 1980s, voluntary self-exclusion of blood donors with risk factors for AIDS and then the introduction of donor screening for anti-HIV reduced further the likelihood of transfusion-associated hepatitis to <5%. During the late 1980s and early 1990s, the introduction first of "surrogate" screening tests for non-A, non-B hepatitis (ALT and anti-HBc, both shown to identify blood donors with a higher likelihood of transmitting non-A, non-B hepatitis to recipients) and, subsequently, after the discovery of HCV, progressively more sensitive immunoassays for anti-HCV and then the application of automated PCR testing of donated blood for HCV RNA reduced the risk of transfusion-associated hepatitis C even further, to almost imperceptible levels ranging between 1 in 2.3 million transfusions to 1 in 4.7 million transfusions.

In addition to being transmitted by transfusion, hepatitis C can be transmitted by other percutaneous routes, such as injection drug use. This virus can be transmitted by occupational exposure to blood, and the likelihood of infection is increased in hemodialysis units. Although the frequency of transfusion-associated hepatitis C fell as a result of blood-donor screening, the *overall* frequency of reported hepatitis C cases did not change until the 1990s, when the overall frequency of reported cases fell by 80%, in parallel with a reduction in the number of new cases in injection drug users, the source of most of the HCV reservoir. After the exclusion of anti-HCV-positive plasma units from the donor pool, rare, sporadic instances occurred of hepatitis C among recipients of immunoglobulin preparations for intravenous (but not intramuscular) use.

Serologic evidence for HCV infection occurs in 90% of patients with a history of transfusion-associated hepatitis (almost all occurring before 1992, when second-generation HCV screening tests were introduced); hemophiliacs and others treated with clotting factors; injection drug users; 60–70% of patients with sporadic "non-A, non-B" hepatitis who lack identifiable risk factors; 0.5% of volunteer blood donors; and, in the NHANES survey conducted in the United States between 1999 and 2002, 1.6% of the general population in the United States, which translated into 4.1 million persons (3.2 million with viremia), the majority of whom were unaware of their infections. Moreover, such population surveys do not include higher-risk groups such as incarcerated persons, homeless persons, and active injection drug users, indicating that the actual prevalence is even higher (estimated to add an additional 1 million with anti-HCV antibody and 0.8 million with HCV RNA in a later cohort assessed in 2003–2010). Comparable frequencies of HCV infection occur in most countries around the world, with 71 million persons infected worldwide, but extraordinarily high prevalences of HCV infection occur in certain countries such as Egypt, where >20% of the population (as high as 50% in persons born prior to 1960) in some cities is infected. The high frequency in Egypt is attributable to contaminated equipment used for medical procedures and unsafe injection practices in the 1950s to 1980s (during a campaign to eradicate schistosomiasis with intravenous tartar emetic). Thanks to a 2018–2019 Egyptian government program to screen its entire adult population (79% participation among >60 million people) for hepatitis C and treat infected persons (2.2 million, 4.6% of those screened; of the 83% with a documented outcome, 99% were cured; the cost to identify and cure a person was $130) with generic versions of direct-acting antiviral (DAA) therapy **(Chap. 352)**, hepatitis C has been nearly eliminated there.

In the United States, African Americans and Mexican Americans have higher frequencies of HCV infection than whites. Data from NHANES showed that between 1988 and 1994, 30- to 40-year-old men had the highest prevalence of HCV infection; however, in the NHANES survey conducted between 1999 and 2002, the peak age decile had shifted to those aged 40–49 years; an increase in hepatitis C–related mortality has paralleled this secular trend, increasing since 1995 predominantly in the 45- to 65-year age group. Thus, despite an 80% reduction in new reported HCV infections during the 1990s, the prevalence of HCV infection in the population was sustained by an aging cohort that had acquired their infections three to four decades earlier, during the 1960s and 1970s, as a result predominantly of self-inoculation with recreational drugs. Retrospective phylogenetic mapping of >45,000 HCV genotype 1a isolates revealed that the hepatitis C epidemic emerged in the United States between 1940 and 1965, peaking in 1950 and aligning temporally with the post–World War II expansion of medical procedures (including reuse of glass syringes). Thus, HCV was amplified iatrogenically not only in Egypt but also in the United States; in the United States, the seeds sewn by medical procedures in the 1950s were reaped in the 1960s and 1970s among transfusion recipients and injection drug users, even those whose drug use was confined to brief adolescent experimentation.

In NHANES 2003–2010, the prevalence of HCV infection (HCV RNA reactivity) in the United States had actually fallen to 1% (2.7 million persons) from 1.3% (3.2 million) the decade before (NHANES 1999–2002), attributable to deaths among the HCV-infected population. In NHANES data from 2013–2016, the prevalence of current HCV infection (HCV RNA reactivity) had fallen lower, to 0.9%. Worth emphasizing, however, is that NHANES datasets account for only the domiciled and noninstitutionalized U.S. civilian population. In the same time frame, the prevalence among incarcerated and homeless persons was estimated to be 10.7%.

As deaths resulting from HIV infection fell after 1999, age-adjusted mortality associated with HCV infection surpassed that of HIV infection in 2007; >70% of HCV-associated deaths occurred in the "baby boomer" cohort born between 1945 and 1965. By 2012, HCV mortality had surpassed deaths from HIV, tuberculosis, hepatitis B, and 57 other notifiable infectious diseases (i.e., *all* infectious diseases) reported to the CDC. In NHANES 1999–2002, compared to the 1.6% prevalence of HCV infection in the population at large, the prevalence in the 1945–1965 birth cohort was 3.2%, representing three-quarters of all infected persons. Therefore, in 2012, the CDC and, in 2013, the U.S. Preventive Services Task Force (USPSTF) recommended that all persons born between 1945 and 1965 be screened for hepatitis C, without ascertainment of risk, a recommendation shown to be cost-effective and predicted to identify 800,000 infected persons. Because of the availability of highly effective antiviral therapy, such screening would have the potential to avert 200,000 cases of cirrhosis and 47,000 cases of hepatocellular carcinoma and to prevent 120,000 hepatitis-related deaths; with the availability of the new generation of DAAs (efficacy >95%, **see Chap. 352)**, screening baby boomers and treating those with hepatitis C have been predicted to reduce the HCV-associated disease burden by 50–70% through 2050.

Still, persons with chronic hepatitis C identified by 1945–1965 birth-cohort screening are older than 50, and by the time they are identified, >20% already have advanced liver disease. In 2020, based on (1) the 95–99% efficacy of all-oral, well-tolerated, highly effective DAAs; (2) the demonstration that the endpoint of DAA therapy (sustained virologic response) was associated with a marked decrease in liver and all-cause mortality, cirrhosis, and hepatocellular carcinoma **(Chap. 352)**; (3) a reduction in the initially high cost of DAA therapy; (4) the demonstration of higher cost-effectiveness of screening all adults rather than birth-cohort screening; and (5) the shifting demographics of HCV infection (see below), especially since 2010, toward a younger population exposed through injection drug use, the American Association for the Study of Liver Diseases and the Infectious Diseases Society of America as well as the USPSTF and CDC expanded recommended *hepatitis C screening to all adolescents and adults* aged 18–79 (and because of the substantial increase in HCV infections among women of child-bearing age [age 20–39], expanded such screening to pregnant women).

Hepatitis C accounts for 40% of chronic liver disease and, before the introduction of high-efficacy DAA therapy, was the most frequent indication for liver transplantation; hepatitis C is estimated to account for 8000–10,000 deaths per year in the United States. The distribution of HCV genotypes varies in different parts of the world. Worldwide, genotype 1 is the most common. In the United States, genotype 1 accounts for 70% of HCV infections, whereas genotypes 2

and 3 account for the remaining 30%; among African Americans, the frequency of genotype 1 is even higher (i.e., 90%). Genotype 4 predominates in Egypt; genotype 5 is localized to South Africa, genotype 6 to Hong Kong, and genotype 7 to Central Africa.

As a bloodborne infection, HCV potentially can be transmitted sexually and perinatally; however, both modes of transmission are inefficient for hepatitis C. Although 10–15% of patients with acute hepatitis C report having potential sexual sources of infection, most studies have failed to identify sexual transmission of this agent. The chances of sexual and perinatal transmission have been estimated to be ~5% but have shown in a prospective study to be only 1% between monogamous sexual partners, well below comparable rates for HIV and HBV infections. An important exception to the low rate of perinatal transmission is the high risk—typically in excess of 10%—in babies born to HIV-HCV coinfected mothers. Moreover, sexual transmission appears to be confined to such subgroups as persons with multiple sexual partners and sexually transmitted diseases; for example, isolated clusters of sexually transmitted HCV infection have been reported in HIV-infected men who have sex with men. Breast-feeding does not increase the risk of HCV infection between an infected mother and her infant. Infection of health workers is not dramatically higher than among the general population; however, health workers are more likely to acquire HCV infection through accidental needle punctures, the efficiency of which is ~3%. Infection of household contacts is rare as well. Most asymptomatic blood donors found to have anti-HCV and ~20–30% of persons with reported cases of acute hepatitis C do not fall into a recognized risk group; however, many such blood donors do recall long forgotten, risk-associated behaviors when questioned carefully.

Besides persons born between 1945 and 1965, other groups with an increased frequency of HCV infection are listed in **Table 350-4**. In immunosuppressed individuals, levels of anti-HCV may be undetectable, and a diagnosis may require testing for HCV RNA. Although new acute cases of hepatitis C are rare outside of the injection drug–using community, newly diagnosed cases are common among otherwise healthy persons who experimented briefly with injection drugs, as noted above, four or five decades earlier. Such instances usually remain unrecognized for years, until unearthed by laboratory screening for routine medical examinations, insurance applications, and attempted blood donation. Although, overall, the annual incidence of new HCV infections has continued to fall, the rate of new infections has been increasing since 2002, has accelerated since 2010 (tripling from 0.3/100,000 to 1.2/100,000 between 2009 and 2018), and has been amplified by the recent epidemic of opioid use in a new cohort of young injection drug users aged 20–39 years (accounting for a 3.8-fold increase in cases between 2010 and 2017 and for more than two-thirds of all acute cases), who, unlike older cohorts, had not learned to take precautions to prevent bloodborne infections. Reflecting this emerging development, the prevalence of current HCV infection (HCV RNA reactivity) in the United States rose from 0.65% (1.7 million persons) in a 2010–2014 NHANES analysis to 0.9% (2.04 million persons) in a 2013–2016 NHANES analysis. Moreover, based on an estimate of populations excluded from this NHANES analysis, the prevalence would be even higher, 0.93% (2.27 million persons). This late temporal trend was attributed to the increase of acute cases in injections drug users, driven by increases in states most affected by the opioid/injection drug use epidemic. Also, in parallel with this trend, the prevalence of HCV infection in women aged 15–44 years (of child-bearing age) doubled between 2016 and 2014; accordingly, screening of pregnant women for HCV infection is now recommended as well.

TABLE 350-4 Populations with a High Risk for HCV Infection[a]

All adults aged 18–79 should be screened, a recommendation that supplants the earlier focus on persons born between 1945 and 1965[a]
Persons who have ever used injection drugs
Persons with HIV infection
Hemophiliacs treated with clotting factor concentrates prior to 1987
Persons who have ever undergone long-term hemodialysis
Persons with unexplained elevations of aminotransferase levels
Transfusion or transplantation recipients prior to July 1992
Recipients of blood or organs from a donor found to be positive for hepatitis C
Children born to women with hepatitis C
Health care, public safety, and emergency medical personnel following needle injury or mucosal exposure to HCV-contaminated blood
Sexual partners of persons with hepatitis C infection
Pregnant women

[a]Screening for hepatitis C had been recommended in the past for persons in these high-risk groups; however, in 2020, the Centers for Disease Control and Prevention recommended universal screening of all adults (>18 years of age) for hepatitis C.

Hepatitis E This type of hepatitis, identified in India, Asia, Africa, the Middle East, and Central America (endemic areas), resembles hepatitis A in its primarily enteric mode of spread. The commonly recognized cases occur after contamination of water supplies such as after monsoon flooding, but sporadic, isolated cases occur. An epidemiologic feature that distinguishes HEV from other enteric agents is the rarity of secondary person-to-person spread from infected persons to their close contacts. Large waterborne outbreaks in endemic areas are linked to genotypes 1 and 2, arise in populations that are immune to HAV, favor young adults, and account for antibody prevalences of 30–80%. The worldwide annual incidence of acute HEV infections has been estimated conservatively to be at least 20 million (of which 3.3 million are symptomatic), rendering HEV infection as the most common cause of acute viral hepatitis. In nonendemic areas of the world, such as the United States, clinically apparent acute hepatitis E is extremely rare; however, during the 1988–1994 NHANES III survey conducted by the U.S. Public Health Service, the prevalence of anti-HEV was 21%, reflecting subclinical infections, infection with genotypes 3 and 4, predominantly in older males (>60 years). A repeat NHANES study in 2009–2010, however, showed a substantial 70% two-decade reduction in anti-HEV to only 6%, more consistent with the rarity of acute hepatitis E in the United States than the previous NHANES result would suggest and perhaps a reflection of a more specific anti-HEV assay used in the second time period. A subsequent examination of the 2009–2016 NHANES dataset demonstrated a seroprevalence of HEV infection of 6.1%. Moreover, supporting the concern for influence of assay differences on population estimates, a re-interrogation of the NHANES III cohort based on assays of the highest sensitivity identified varying prevalence estimates ranging from 16–21%. Again, in the 2009–2016 cohort, older age was associated with anti-HEV seropositivity, as were non-Hispanic Asian ethnicity and birth outside the United States.

In nonendemic areas, HEV accounts for only a small proportion of cases of sporadic (labeled "autochthonous" or indigenous) hepatitis; however, cases imported from endemic areas have been found in the United States. Evidence supports a zoonotic reservoir for HEV primarily in swine (but also in deer, camels, and rabbits), which may account for the mostly subclinical infections primarily of genotypes 3 and 4 in nonendemic areas. Globally, ~60% of swine have evidence of prior HEV infection, and 13% have active HEV infection. A previously unrecognized high distribution of HEV infection, linked to uncooked or undercooked pork-product ingestion, has been discovered in western Europe (e.g., in Germany, an estimated annual incidence of 300,000 cases and a 17% prevalence of anti-HEV among adults; in France, a 22% prevalence of anti-HEV in healthy blood donors).

CLINICAL AND LABORATORY FEATURES

Symptoms and Signs Acute viral hepatitis occurs after an incubation period that varies according to the responsible agent. Generally, incubation periods for hepatitis A range from 15 to 45 days (mean, 4 weeks), for hepatitis B and D from 30 to 180 days (mean, 8–12 weeks), for hepatitis C from 15 to 160 days (mean, 7 weeks), and for hepatitis E from 14 to 60 days (mean, 5–6 weeks). The *prodromal symptoms* of

acute viral hepatitis are systemic and quite variable. Constitutional symptoms—which may include anorexia, nausea and vomiting, diarrhea, fatigue, malaise, arthralgias, myalgias, headache, and photophobia—tend to precede the onset of jaundice (if jaundice occurs). The nausea, vomiting, and anorexia are frequently associated with alterations in olfaction and taste. A low-grade fever between 38° and 39°C (100°–102°F) is more often present in hepatitis A and E than in hepatitis B or C, except when hepatitis B is heralded by a serum sickness–like syndrome; rarely, a fever of 39.5°–40°C (103°–104°F) may accompany the constitutional symptoms. Dark urine and clay-colored stools may be noticed by the patient from 1–5 days before the onset of clinical jaundice.

Many patients will not become jaundiced (anicteric hepatitis), and the likelihood of jaundice varies by virus (e.g., substantially more common in acute hepatitis B than in acute hepatitis C). With the onset of *clinical jaundice*, the constitutional prodromal symptoms usually diminish, but in some patients, mild weight loss (2.5–5 kg) is common and may continue during the entire icteric phase. The liver becomes enlarged and tender and may be associated with right upper quadrant pain and discomfort. Infrequently, patients present with a cholestatic picture, suggesting extrahepatic biliary obstruction. Splenomegaly and cervical adenopathy are present in 10–20% of patients with acute hepatitis. Rarely, a few spider angiomas appear during the icteric phase and disappear during convalescence. During the *recovery phase*, constitutional symptoms disappear, but usually some liver enlargement and abnormalities in liver biochemical tests are still evident. The duration of the posticteric phase is variable, ranging from 2 to 12 weeks, and is usually more prolonged in acute hepatitis B and C. Complete clinical and biochemical recovery is to be expected 1–2 months after all cases of hepatitis A and E and 3–4 months after the onset of jaundice in three-quarters of uncomplicated, self-limited cases of hepatitis B and C (among healthy adults, acute hepatitis B is self-limited in 95–99%, whereas hepatitis C is self-limited in only ~15–20%). In the remainder, biochemical recovery may be delayed.

Infection with HDV can occur in the presence of acute (coinfection) or chronic (superinfection) HBV infection; the duration of HBV infection determines the duration of HDV infection. When acute HDV and HBV infections occur simultaneously (coinfection), clinical and biochemical features may be indistinguishable from those of HBV infection alone, and the clinical severity can range from mild to fulminant disease. When acute HDV infection occurs in a patient with preexisting *chronic* HBV infection (superinfection), the clinical presentation is more commonly severe, and the HDV superinfection mirrors the chronic HBV infection in becoming persistent. In such cases, the HDV superinfection appears as a clinical exacerbation or an episode resembling acute viral hepatitis in someone already chronically infected with HBV. Superinfection with HDV in a patient with chronic hepatitis B often leads to clinical deterioration (see below).

In addition to superinfections with other hepatitis agents, acute hepatitis-like clinical events in persons with chronic hepatitis B may accompany spontaneous HBeAg to anti-HBe seroconversion or spontaneous reactivation (i.e., reversion from relatively nonreplicative to replicative infection). Occasionally, acute clinical exacerbations of chronic hepatitis B may represent the emergence of a precore mutant (see "Virology and Etiology"), and the subsequent course in such patients may be characterized by periodic exacerbations. Reactivations can occur as well in therapeutically immunosuppressed patients with chronic HBV infection when cytotoxic/immunosuppressive drugs are withdrawn; in these cases, restoration of immune competence is thought to allow resumption of previously checked cell-mediated immune cytolysis of HBV-infected hepatocytes. Cancer-directed therapies can also result in HBV or HCV reactivation, with the greatest risk from the B-cell (CD20)-depleting antibody rituximab in HBV. Immune checkpoint inhibitors (ICIs) have been an important new class of antitumor therapies, and the impact of ICI therapy on hepatitis caused by chronic HBV or HCV infection is not yet well characterized, but acute exacerbations of chronic viral hepatitis have been reported and may be related to restoring function of "exhausted" T-cell populations. Of interest, however, in pilot studies of ICIs given for chronic hepatitis B, restoration of T-cell function has also been associated with functional cure in a limited subset.

Laboratory Features The serum aminotransferases aspartate aminotransferase (AST) and ALT (previously designated SGOT and SGPT) increase to a variable degree during the prodromal phase of acute viral hepatitis and precede the rise in bilirubin level (Figs. 350-2 and 350-4). The level of these enzymes, however, does not correlate well with the degree of liver cell damage. Peak levels vary from ~400 to ~4000 IU or more; these levels are usually reached at the time the patient is clinically icteric and diminish progressively during the recovery phase of acute hepatitis. The diagnosis of anicteric hepatitis is based on clinical features and on aminotransferase elevations.

Jaundice is usually visible in the sclera or skin when the serum bilirubin value is >43 μmol/L (2.5 mg/dL). When jaundice appears, the serum bilirubin typically rises to levels ranging from 85 to 340 μmol/L (5–20 mg/dL). The serum bilirubin may continue to rise despite falling serum aminotransferase levels. In most instances, the total bilirubin is equally divided between the conjugated and unconjugated fractions. Bilirubin levels >340 μmol/L (20 mg/dL) extending and persisting late into the course of viral hepatitis are more likely to be associated with severe disease. In certain patients with underlying hemolytic anemia, however, such as glucose-6-phosphate dehydrogenase deficiency and sickle cell anemia, a high serum bilirubin level is common, resulting from superimposed hemolysis. In such patients, bilirubin levels >513 μmol/L (30 mg/dL) have been observed and are not necessarily associated with a poor prognosis.

Neutropenia and lymphopenia are transient and are followed by a relative lymphocytosis. Atypical lymphocytes (varying between 2 and 20%) are common during the acute phase. Measurement of the prothrombin time (PT) is important in patients with acute viral hepatitis, because a prolonged value may reflect a severe hepatic synthetic defect, signify extensive hepatocellular necrosis, and indicate a worse prognosis. Occasionally, a prolonged PT may occur with only mild increases in the serum bilirubin and aminotransferase levels. Prolonged nausea and vomiting, inadequate carbohydrate intake, and poor hepatic glycogen reserves may contribute to hypoglycemia noted occasionally in patients with severe viral hepatitis. Serum alkaline phosphatase may be normal or only mildly elevated, whereas a fall in serum albumin is uncommon in uncomplicated acute viral hepatitis. In some patients, mild and transient steatorrhea has been noted, as well as slight microscopic hematuria and minimal proteinuria.

A diffuse but mild elevation of the γ globulin fraction is common during acute viral hepatitis. Serum IgG and IgM levels are elevated in about one-third of patients during the acute phase of viral hepatitis, but the serum IgM level is elevated more characteristically during acute hepatitis A. During the acute phase of viral hepatitis, antibodies to smooth muscle and other cell constituents may be present, and low titers of rheumatoid factor, nuclear antibody, and heterophile antibody can also be found occasionally. In hepatitis C and D, antibodies to LKM may occur; however, the species of LKM antibodies in the two types of hepatitis are different from each other as well as from the LKM antibody species characteristic of autoimmune hepatitis type 2 **(Chap. 352)**. The autoantibodies in viral hepatitis are nonspecific and can also be associated with other viral and systemic diseases. In contrast, virus-specific antibodies, which appear during and after hepatitis virus infection, are serologic markers of diagnostic importance.

As described above, serologic tests are available routinely with which to establish a diagnosis of hepatitis A, B, D, and C. Tests for fecal or serum HAV are not routinely available. Therefore, a diagnosis of hepatitis A is based on detection of IgM anti-HAV during acute illness (Fig. 350-2). Worth considering, false-positive IgM anti-HAV results have been observed in rheumatologic diseases (especially those with rheumatoid factor, which can mediate nonspecific binding in solid-phase immunoassays) and, very rarely, in other acute viral infections, such as with Epstein-Barr virus (EBV).

A diagnosis of HBV infection can usually be made by detection of HBsAg in serum. Infrequently, levels of HBsAg are too low to be detected during acute HBV infection, even with contemporary, highly

sensitive immunoassays. In such cases, the diagnosis can be established by the presence of IgM anti-HBc.

The titer of HBsAg bears little relation to the severity of clinical disease. Indeed, an inverse correlation exists between the serum concentration of HBsAg and the degree of liver cell damage. For example, titers are highest in immunosuppressed patients, lower in patients with chronic liver disease (but higher in mild chronic than in severe chronic hepatitis), and very low in patients with acute fulminant hepatitis. These observations suggest that in hepatitis B the degree of liver cell damage and the clinical course are related to variations in the patient's immune response to HBV rather than to the amount of circulating HBsAg. In immunocompetent persons, however, a correlation exists between markers of HBV *replication* and liver injury (see below).

Another important serologic marker in patients with hepatitis B is HBeAg. Its principal clinical usefulness is as an indicator of relative infectivity. Because HBeAg is invariably present during early acute hepatitis B, HBeAg testing is indicated primarily in chronic infection.

In patients with hepatitis B surface antigenemia of unknown duration (e.g., blood donors found to be HBsAg positive), testing for IgM anti-HBc may be useful to distinguish between acute or recent infection (IgM anti-HBc positive) and chronic HBV infection (IgM anti-HBc negative, IgG anti-HBc positive). A false-positive test for IgM anti-HBc may be encountered in patients with high-titer rheumatoid factor. Also, IgM anti-HBc may be reexpressed during acute reactivation of chronic hepatitis B.

Anti-HBs is rarely detectable in the presence of HBsAg in patients with *acute* hepatitis B, but up to 10% of persons with *chronic* HBV infection may harbor anti-HBs. Variability of the *a* determinant of the S protein is thought to be central to this anti-HBs. The antibody is directed not against the common group determinant, *a*, but against the relatively closely related heterotypic subtype determinant (e.g., HBsAg of subtype *ad* with anti-HBs of subtype *y*). Clinically, patients with both HBsAg and anti-HBs tend to have higher aminotransferase levels, are older, and are more likely to have advanced fibrosis or cirrhosis (primarily in HBeAg-negative patients). This serologic pattern in patients with chronic hepatitis B is not a harbinger of imminent HBsAg clearance; however, in patients clearing HBsAg as acute hepatitis B resolves, infrequently, transiently, both HBsAg and anti-HBs may be detected simultaneously.

After immunization with hepatitis B vaccine, which consists of HBsAg alone, anti-HBs is the only serologic marker to appear. The commonly encountered serologic patterns of hepatitis B and their interpretations are summarized in **Table 350-5**. Tests for the detection of HBV DNA in liver and serum are now available. Like HBeAg, serum HBV DNA is an indicator of HBV replication, but tests for HBV DNA are more sensitive and quantitative. First-generation hybridization assays for HBV DNA had a sensitivity of 10^5–10^6 virions/mL, a relative threshold below which infectivity and liver injury are limited and HBeAg is usually undetectable. Currently, testing for HBV DNA has shifted from insensitive hybridization assays to amplification assays (e.g., the PCR-based assay, which can detect as few as 10 or 100 virions/mL); among the commercially available PCR assays, the most useful are those with the highest sensitivity (5–10 IU/mL) and the largest dynamic range (100–10^9 IU/mL). With increased sensitivity, amplification assays remain reactive well below the current 10^3–10^4 IU/mL threshold for infectivity and liver injury. These markers are useful in following the course of HBV replication in patients with chronic hepatitis B receiving antiviral chemotherapy **(Chap. 352)**. Except for the early decades of life after perinatally acquired HBV infection (see above), in immunocompetent adults with chronic hepatitis B, a general correlation exists between the level of HBV replication, as reflected by the level of serum HBV DNA, and the degree of liver injury. High-serum HBV DNA levels, increased expression of viral antigens, and necroinflammatory activity in the liver go hand in hand unless immunosuppression interferes with cytolytic T-cell responses to virus-infected cells; reduction of HBV replication with antiviral drugs tends to be accompanied by an improvement in liver histology. Among patients with chronic hepatitis B, high levels of HBV DNA increase the risk of cirrhosis, hepatic decompensation, and hepatocellular carcinoma (see "Complications and Sequelae").

A diagnosis of acute hepatitis C hinges upon the presence of anti-HCV and/or HCV RNA with or without the presence of anti-HCV. Compared with the other viral hepatitides, assays specific for IgM anti-HCV, never found to be of clinical value, are lacking; available highly sensitive assays detect IgG anti-HCV. While, in the past, with early-generation immunoassays, up to 12 weeks could elapse before anti-HCV became detectable during acute hepatitis C, with contemporary, late-generation assays, anti-HCV is readily detectable during early acute hepatitis C. Thus, when contemporary immunoassays are used, anti-HCV can be detected in acute hepatitis C during the initial phase of elevated aminotransferase activity and remains detectable both after recovery from acute infection as well as during chronic infection. As alluded to above, nonspecificity can confound immunoassays for anti-HCV, especially in persons with a low prior probability of infection, such as volunteer blood donors, or in persons with circulating rheumatoid factor, which can bind nonspecifically to assay reagents; testing for HCV RNA can be used in such settings to distinguish between true-positive and false-positive anti-HCV determinations. While spontaneous recovery from acute HCV infection occurs no more often than 15–20% of the time, persons who do recover will have

TABLE 350-5 Commonly Encountered Serologic Patterns of Hepatitis B Infection

HBsAg	ANTI-HBs	ANTI-HBc	HBeAg	ANTI-HBe	INTERPRETATION
+	–	IgM	+	–	Acute hepatitis B, high infectivity[a]
+	–	IgG	+	–	Chronic hepatitis B, high infectivity
+	–	IgG	–	+	1. Late acute or chronic hepatitis B, low infectivity 2. HBeAg-negative ("precore-mutant") hepatitis B (chronic or, rarely, acute)
+	+	+	+/–	+/–	1. HBsAg of one subtype and heterotypic anti-HBs (common) 2. Process of seroconversion from HBsAg to anti-HBs (rare)
–	–	IgM	+/–	+/–	1. Acute hepatitis B[a] 2. Anti-HBc "window"
–	–	IgG	–	+/–	1. Low-level hepatitis B carrier 2. Hepatitis B in remote past
–	+	IgG	–	+/–	Recovery from hepatitis B
–	+	–	–	–	1. Immunization with HBsAg (after vaccination) 2. Hepatitis B in the remote past (?) 3. False-positive

[a]IgM anti-HBc may reappear during acute reactivation of chronic hepatitis B.

Note: See text for abbreviations.

a persistent anti-HCV but are not protected against reinfection. In high-risk groups, notably PWID, a pattern of *positive* anti-HCV and HCV RNA may reflect acute reinfection rather than chronic infection. In this setting, prior laboratory tests and clinical history are critical in differentiating between chronic and repeat acute infections.

Assays for HCV RNA are the most sensitive tests for HCV infection and represent the "gold standard" in establishing a diagnosis of hepatitis C. HCV RNA can be detected even before acute elevation of aminotransferase activity and before the appearance of anti-HCV in patients with acute hepatitis C. In addition, HCV RNA remains detectable indefinitely, although at varying levels, in patients with chronic hepatitis C. In the very small minority of patients with hepatitis C who lack anti-HCV, a diagnosis can be supported by detection of HCV RNA. In the rare instance when all these tests are negative and the patient has a well-characterized case of hepatitis after percutaneous exposure to blood or blood products, a diagnosis of hepatitis caused by an unidentified agent can be entertained.

Amplification techniques are required to detect HCV RNA. Currently, such target amplification (i.e., synthesis of multiple copies of the viral genome) is achieved by PCR, in which the viral RNA is reverse transcribed to complementary DNA and then amplified by repeated cycles of DNA synthesis. Quantitative PCR assays provide a measurement of relative "viral load"; current PCR assays have a sensitivity of 10 (lower limit of detection) to 25 (lower limit of quantitation) IU/mL and a wide dynamic range (10–10^7 IU/mL). Determination of HCV RNA level is not a reliable marker of disease severity or prognosis but is helpful in predicting relative responsiveness to antiviral therapy. The same is true for determinations of HCV genotype **(Chap. 352)**. Of course, HCV RNA monitoring during and after antiviral therapy is the *sine qua non* for determining on-treatment and durable responsiveness.

A proportion of patients with hepatitis C have isolated anti-HBc in their blood, a reflection of a common risk in certain populations of exposure to multiple bloodborne hepatitis agents. The anti-HBc in such cases is almost invariably of the IgG class and usually represents HBV infection in the remote past (HBV DNA undetectable); it rarely represents current HBV infection with low-level virus carriage. Detectable anti-HCV in the absence of HCV RNA signifies spontaneous or therapeutically induced recovery from ("cured") hepatitis C.

The presence of HDV infection can be identified by demonstrating intrahepatic HDV antigen or, more practically, an anti-HDV (IgM or IgG) seroconversion (a rise in titer of anti-HDV or de novo appearance of anti-HDV). Serum HDV RNA or antigen can be detected early during acute coinfection but is often transient and detectable only briefly, if at all. Because anti-HDV is often undetectable once HBsAg disappears, retrospective serodiagnosis of acute self-limited, simultaneous HBV and HDV infection is difficult. Early diagnosis of acute infection may be hampered by a delay of up to 30–40 days in the appearance of IgG anti-HDV.

When a patient presents with acute hepatitis and has HBsAg and anti-HDV in serum, determination of the class of anti-HBc is helpful in establishing the relationship between infection with HBV and HDV. Although IgM anti-HBc does not distinguish *absolutely* between acute and chronic HBV infection, its presence is a reliable indicator of recent infection and its absence a reliable indicator of infection in the remote past. In simultaneous acute HBV and HDV infections, IgM anti-HBc will be detectable, whereas in acute HDV infection superimposed on chronic HBV infection, anti-HBc will be of the IgG class. Assays for HDV RNA, available in specialized laboratories and yet to be standardized, can be used to confirm HDV infection and to monitor treatment during chronic infection.

The serologic/virologic course of events during acute hepatitis E is entirely analogous to that of acute hepatitis A, with brief fecal shedding of virus and viremia and an early IgM anti-HEV response that predominates during approximately the first 3 months but is eclipsed thereafter by long-lasting IgG anti-HEV. Diagnostic tests of varying reliability for hepatitis E are commercially available outside the United States; in the United States, although tests for HEV infection are not approved by the FDA, reliable diagnostic serologic/virologic assays can be performed at the CDC or other commercial or academic laboratories.

Liver biopsy is rarely necessary or indicated in acute viral hepatitis, except when the diagnosis is questionable or when clinical evidence suggests an alternate diagnosis of chronic hepatitis (e.g., autoimmune hepatitis).

A diagnostic algorithm can be applied in the evaluation of cases of acute viral hepatitis. A patient with acute hepatitis should undergo five serologic tests: HBsAg, IgM anti-HAV, IgM anti-HBc, anti-HCV, and HCV RNA **(Table 350-6)**. The presence of HBsAg, with or without IgM anti-HBc, represents HBV infection. If IgM anti-HBc is present, the HBV infection is considered acute (or, less commonly, an acute reactivation); if IgM anti-HBc is absent, the HBV infection is considered chronic. A diagnosis of acute hepatitis B can be made in the absence of HBsAg when IgM anti-HBc is detectable. A diagnosis of acute hepatitis A is based on the presence of IgM anti-HAV. If IgM anti-HAV coexists with HBsAg, a diagnosis of simultaneous HAV and HBV infections can be made; if IgM anti-HBc (with or without HBsAg) is detectable, the patient has simultaneous acute hepatitis A and B, and if IgM anti-HBc is undetectable, the patient has acute hepatitis A superimposed on chronic HBV infection. In a patient with an acute hepatitis illness, the presence of anti-HCV supports a diagnosis of acute hepatitis C. In the past, sensitivity of anti-HCV assays was limited during acute hepatitis, leading to a delay in the appearance anti-HCV; however, contemporary assays detect anti-HCV reliably during acute hepatitis. If acute hepatitis C is suspected but anti-HCV is undetectable, testing for HCV RNA helps to establish the diagnosis. The serologic diagnosis of acute hepatitis C or B may be challenging, for example, when an acute hepatitis-like illness occurs in someone already infected chronically with HBV or HCV. Still, when encountering a person with acute hepatitis, a series of standard serologic assays for hepatitis A, B, and C is a reliable first step. If these assays are all negative, testing for hepatitis E, especially in the presence of risk factors, is available from specialty laboratories or the CDC. Acute hepatitis D belongs in the differential diagnosis of acute hepatitis, but negative serologic testing for hepatitis B excludes hepatitis D infection. In the setting of serologically documented acute

hepatitis B, patients who are at high risk for hepatitis D are candidates to be tested for anti-HDV and/or HDV RNA. Absence of all serologic markers is consistent with a diagnosis of "non-A-E," hepatitis (no other proven human hepatitis viruses have been identified). As noted above, an outbreak of severe acute liver injury and liver failure in children was found to be associated with adenovirus infection, and elevations in aminotransferase levels are observed as well in a variety of other acute viral illnesses.

In patients with chronic hepatitis, initial testing should consist of HBsAg and anti-HCV. Anti-HCV supports and HCV RNA testing establishes the diagnosis of chronic hepatitis C. If a serologic diagnosis of chronic hepatitis B is made, testing for HBeAg and anti-HBe is indicated to evaluate relative infectivity. Testing for HBV DNA in such patients provides a more quantitative and sensitive measure of the level of virus replication and therefore is very helpful during antiviral therapy **(Chap. 352)**. In patients with established chronic hepatitis B and normal aminotransferase activity in the absence of HBeAg, serial testing over time is often required to distinguish between the inactive carrier state and HBeAg-negative chronic hepatitis B with fluctuating virologic and necroinflammatory activity. In persons with hepatitis B, testing for anti-HDV is useful in those with severe and fulminant disease, with severe chronic disease, with chronic hepatitis B and acute hepatitis-like exacerbations, with frequent percutaneous exposures (or known HBV acquisition from percutaneous exposure), and from areas where HDV infection is endemic.

PROGNOSIS

Virtually all previously healthy patients with hepatitis A recover completely with no clinical sequelae. Similarly, in acute hepatitis B, 95–99% of previously healthy adults have a favorable course and recover completely. Certain clinical and laboratory features, however, suggest a more complicated and protracted course. Patients of advanced age and with serious underlying medical disorders may have a prolonged course and are more likely to experience severe hepatitis. Initial presenting features such as ascites, peripheral edema, and symptoms of hepatic encephalopathy suggest a poorer prognosis. In addition, a prolonged PT, low serum albumin level, hypoglycemia, and very high serum bilirubin values suggest severe hepatocellular disease. Patients with these clinical and laboratory features deserve prompt hospital admission. The case-fatality rate in hepatitis A and B is very low (~0.1%) but is increased by advanced age and underlying debilitating disorders. Among patients ill enough to be hospitalized for acute hepatitis B, the fatality rate is 1%. Hepatitis C is less severe during the acute phase than hepatitis B and is more likely to be anicteric; fatalities are rare, but the precise case-fatality rate is not known. Interestingly, while spontaneous resolution of HCV is the exception rather than the rule, symptomatic infection (and icteric hepatitis in particular) is associated with a higher likelihood of viral containment. In outbreaks of waterborne hepatitis E (genotypes 1 and 2) in India and Asia, the case-fatality rate is 1–2% and up to 10–20% in pregnant women. Contributing to fulminant hepatitis E in endemic countries (but only very rarely or not at all in nonendemic countries) are instances of acute hepatitis E superimposed on underlying chronic liver disease ("acute-on-chronic" liver disease). Patients with simultaneous acute hepatitis B and D coinfection do not necessarily experience a higher mortality rate than do patients with acute hepatitis B alone; however, in several outbreaks of acute simultaneous HBV and HDV infection among injection drug users, the case-fatality rate was ~5%. When HDV superinfection occurs in a person with chronic hepatitis B, the likelihood of fulminant hepatitis and death is increased substantially. Although the case-fatality rate for hepatitis D is not known definitively, in outbreaks of severe HDV superinfection in isolated populations with a high hepatitis B carrier rate ("Lábrea fever"), a mortality rate >20% has been recorded.

COMPLICATIONS AND SEQUELAE

A small proportion of patients with hepatitis A experience *relapsing hepatitis* weeks to months after apparent recovery from acute hepatitis. Relapses are characterized by recurrence of symptoms, aminotransferase elevations, occasional jaundice, and fecal excretion of HAV. Another unusual variant of acute hepatitis A is *cholestatic hepatitis*, characterized by protracted cholestatic jaundice and pruritus. Rarely, liver test abnormalities persist for many months, even up to 1 year. Even when these complications occur, hepatitis A remains self-limited and does not progress to chronic liver disease.

During the prodromal phase of acute hepatitis B, a serum sickness–like syndrome characterized by arthralgia or arthritis, rash, angioedema, and, rarely, hematuria and proteinuria may develop in 5–10% of patients. This syndrome occurs before the onset of clinical jaundice, and these patients are often diagnosed erroneously as having rheumatologic diseases. The diagnosis can be established by measuring serum aminotransferase levels, which are almost invariably elevated, and serum HBsAg. In patients with chronic hepatitis B or C, immune complex and other extrahepatic manifestations may occur, including metabolic disorders (including insulin resistance and other manifestations of the metabolic syndrome), dermatologic disorders (e.g., porphyria cutanea tarda and lichen planus in chronic hepatitis C), lymphoproliferative and rheumatologic disorders, and, in addition to hepatocellular carcinoma, nonliver malignancies **(Chap. 352)**. In addition, population studies of patients with chronic hepatitis C have shown a convincing increase in cardiovascular and cerebrovascular disease, renal disease, and mental health and cognitive disorders.

The most feared complication of acute viral hepatitis is *fulminant hepatitis* (massive hepatic necrosis); fortunately, this is a rare event. Fulminant hepatitis is seen primarily in hepatitis B, D, and E, but rare fulminant cases of hepatitis A occur primarily in older adults and in persons with underlying chronic liver disease, including, according to some reports, chronic hepatitis B and C. Hepatitis B accounts for >50% of fulminant cases of viral hepatitis, a sizable proportion of which are associated with HDV infection and another proportion with underlying chronic hepatitis C. Fulminant hepatitis is hardly ever seen in hepatitis C, but hepatitis E, as noted above, can be complicated by fatal fulminant hepatitis in 1–2% of all cases and in up to 20% of cases in pregnant women. Patients usually present with signs and symptoms of encephalopathy that may evolve to deep coma. The liver is usually small and the PT excessively prolonged. The combination of rapidly shrinking liver size, rapidly rising bilirubin level, and marked prolongation of the PT, even as aminotransferase levels fall, together with clinical signs of confusion, disorientation, somnolence, ascites, and edema, indicates that the patient has hepatic failure with encephalopathy. Cerebral edema is common; brainstem compression, gastrointestinal bleeding, sepsis, respiratory failure, cardiovascular collapse, and renal failure are terminal events. The mortality rate can be exceedingly high (>80% in patients with deep coma) without liver transplantation, but patients who survive may have a complete biochemical and histologic recovery **(Chap. 356)**. Documenting the disappearance of HBsAg after apparent clinical recovery from acute hepatitis B is particularly important. Before laboratory methods were available to distinguish between acute hepatitis and acute hepatitis–like exacerbations (*spontaneous reactivations*) of chronic hepatitis B, observations suggested that ~10% of previously healthy patients remained HBsAg positive for >6 months after the onset of clinically apparent acute hepatitis B. One-half of these persons cleared the antigen from their circulations during the next several years, but the other 5% remained chronically HBsAg positive. More recent observations suggest that the true rate of chronic infection after clinically apparent acute hepatitis B is as low as 1% in normal, immunocompetent, young adults. Earlier, higher estimates may have been confounded by inadvertent inclusion of acute exacerbations in chronically infected patients; these patients, chronically HBsAg positive before exacerbation, were unlikely to seroconvert to HBsAg negative thereafter. Whether the rate of chronicity is 10% or 1%, such patients have IgG anti-HBc in serum; anti-HBs is either undetected or detected at low titer against the opposite subtype specificity of the antigen (see "Laboratory Features"). These patients may (1) be inactive carriers; (2) have low-grade, mild chronic hepatitis; or (3) have moderate to severe chronic hepatitis with or without cirrhosis. The likelihood of remaining chronically infected after acute HBV infection is especially high among neonates, persons with Down syndrome, chronically

hemodialyzed patients, and immunosuppressed patients, including persons with HIV infection.

Chronic hepatitis is an important late complication of acute hepatitis B occurring in a small proportion of patients with acute disease but more common in those who present with chronic infection without having experienced an acute illness, as occurs typically after neonatal infection or after infection in an immunosuppressed host **(Chap. 352)**. The following clinical and laboratory features suggest progression of acute hepatitis to chronic hepatitis: (1) lack of complete resolution of clinical symptoms of anorexia, weight loss, fatigue, and the persistence of hepatomegaly; (2) the presence of bridging/interface or multilobular hepatic necrosis on liver biopsy during protracted, severe acute viral hepatitis; (3) failure of the serum aminotransferase, bilirubin, and globulin levels to return to normal within 6–12 months after the acute illness; and (4) the persistence of HBeAg for >3 months or HBsAg for >6 months after acute hepatitis.

Although acute hepatitis D infection does not increase the likelihood of chronicity of simultaneous acute hepatitis B, hepatitis D has the potential for contributing to the severity of chronic hepatitis B. Hepatitis D superinfection can transform inactive or mild chronic hepatitis B into severe, progressive chronic hepatitis and cirrhosis; it also can accelerate the course of chronic hepatitis B and accelerate the risk of hepatocellular carcinoma. Some HDV superinfections in patients with chronic hepatitis B lead to fulminant hepatitis. As defined in longitudinal studies over three decades, the annual rate of cirrhosis in patients with chronic hepatitis D is 4%. Although HDV and HBV infections are associated with severe liver disease, mild hepatitis and even inactive carriage have been identified in some patients, and the disease may become indolent beyond the early years of infection.

After acute HCV infection, the likelihood of remaining chronically *infected* approaches 85–90%. Although many patients with chronic hepatitis C have no symptoms, cirrhosis may develop in as many as 20% within 10–20 years of acute illness; in prior series of cases reported by referral centers, cirrhosis has been reported in as many as 50% of patients with chronic hepatitis C. Among cirrhotic patients with chronic hepatitis C, the annual risk of hepatic decompensation is ~4%; the annual risk of hepatocellular carcinoma in cirrhotic patients with chronic hepatitis C has been reported in a range between 1 and 4% and, in a recent definitive report, was 3.36%. With the advent of highly effective DAA therapy during the second decade of the 21st century, a decline in HCV-related cirrhosis and hepatocellular carcinoma has been observed. Progression of chronic hepatitis C may be influenced by advanced age of acquisition, long duration of infection, immunosuppression, coexisting excessive alcohol use, concomitant hepatic steatosis, other hepatitis virus infection, or HIV co-infection. In fact, instances of severe and rapidly progressive chronic hepatitis B and C are recognized with increasing frequency in patients with HIV infection **(Chap. 208)**. In contrast, neither HAV nor HEV causes chronic liver disease in immunocompetent hosts; however, cases of chronic hepatitis E (including cirrhosis and end-stage liver disease and even hepatocellular carcinoma) have been observed in immunosuppressed organ-transplant recipients, persons receiving cytotoxic chemotherapy, and persons with HIV infection. Among patients with chronic hepatitis (e.g., caused by hepatitis B or C, alcohol, etc.) in endemic countries, hepatitis E has been reported as the cause of acute-on-chronic liver failure; however, in most experiences among patients from nonendemic countries, HEV has not been found to contribute commonly to hepatic decompensation in patients with chronic hepatitis.

Persons with chronic hepatitis B, particularly those infected in infancy or early childhood and especially those with HBeAg and/or high-level HBV DNA, have an enhanced risk of hepatocellular carcinoma. The risks of cirrhosis and hepatocellular carcinoma increase with the level of HBV replication. The annual rate of hepatocellular carcinoma in patients with chronic hepatitis D and cirrhosis is ~3%.

Rare complications of acute viral hepatitis include pancreatitis, myocarditis, atypical pneumonia, aplastic anemia, transverse myelitis, peripheral neuropathy, and Guillain-Barré syndrome. In children, hepatitis B may present rarely with anicteric hepatitis, a nonpruritic papular rash of the face, buttocks, and limbs, and lymphadenopathy (papular acrodermatitis of childhood or Gianotti-Crosti syndrome).

Rarely, autoimmune hepatitis **(Chap. 352)** can be triggered by a bout of otherwise self-limited acute hepatitis, as reported after acute hepatitis A, B, and C.

DIFFERENTIAL DIAGNOSIS

Viral diseases such as infectious mononucleosis (EBV); those due to cytomegalovirus, herpes simplex virus, adenovirus, and coxsackieviruses; and toxoplasmosis may share certain clinical features with viral hepatitis and cause elevations in serum aminotransferase and, less commonly, in serum bilirubin levels. Tests such as the differential heterophile and serologic tests for these agents may be helpful in the differential diagnosis if HBsAg, anti-HBc, IgM anti-HAV, and anti-HCV (and anti-HEV) determinations are negative. Aminotransferase elevations can accompany almost any systemic viral infection, including the coronavirus SARS-CoV-2 (~10% of all cases and up to half of severe cases); other rare causes of liver injury confused with viral hepatitis are infections with *Leptospira*, *Candida*, *Brucella*, *Mycobacteria*, and *Pneumocystis*. A complete drug history is particularly important, because many drugs and certain anesthetic agents can produce a picture of either acute hepatitis or cholestasis **(Chap. 351)**. Equally important is a history of unexplained "repeated episodes" of acute hepatitis. This history should alert the physician to the possibility that the underlying disorder is chronic hepatitis, for example, autoimmune hepatitis **(Chap. 352)**. Alcohol-associated hepatitis (AH), which can cause an acute icteric hepatitis, must also be considered, but usually the serum aminotransferase levels are not as markedly elevated (generally not much above 200 IU/mL, almost always below 400 IU/mL) in AH, and a heavy drinking history must be present (at least 40 g/d in women and 60 g/d in men for at least 6 months). The finding on liver biopsy of fatty infiltration, a neutrophilic inflammatory reaction, and "alcoholic hyaline" would be consistent with alcohol-induced rather than viral liver injury. Because acute hepatitis may present with right upper quadrant abdominal pain, nausea and vomiting, fever, and icterus, it is often confused with acute cholecystitis, common duct stone, or ascending cholangitis. Patients with acute viral hepatitis may tolerate surgery poorly, and surgical risk is particularly high in the elderly and those with underlying chronic liver disease; therefore, excluding biliary disease clinically and with imaging is important. In confusing cases, a percutaneous liver biopsy may be helpful. Viral hepatitis in the elderly is often misdiagnosed as obstructive jaundice resulting from a common duct stone or carcinoma of the pancreas. Another clinical constellation that may mimic acute hepatitis is right ventricular failure with passive hepatic congestion or hypoperfusion syndromes, such as those associated with shock, severe hypotension, and severe left ventricular failure. Also included in this general category is any disorder that interferes with venous return to the heart, such as right atrial myxoma, constrictive pericarditis, hepatic vein occlusion (Budd-Chiari syndrome), or venoocclusive disease. Clinical features are usually sufficient to distinguish among these vascular disorders and viral hepatitis. Acute fatty liver of pregnancy, cholestasis of pregnancy, eclampsia, and the HELLP (*h*emolysis, *e*levated *l*iver tests, and *l*ow *p*latelets) syndrome can be confused with viral hepatitis during pregnancy. Very rarely, malignancies metastatic to the liver can mimic acute or even fulminant viral hepatitis. Occasionally, genetic or metabolic liver disorders (e.g., Wilson's disease, α_1 antitrypsin deficiency) and nonalcoholic fatty liver disease (NAFLD; now labeled metabolic dysfunction–associated steatotic liver disease [MASLD]; what used to be called nonalcoholic steatohepatitis [NASH] is now labeled metabolic dysfunction–associated steatohepatitis [MASH]) are confused with acute viral hepatitis **(Chap. 354)**. Among patients with biochemical evidence for severe liver injury, i.e., aminotransferase levels of ≥1000 IU/L, the most common causes are ischemic liver injury, drug-induced liver injury (especially caused by acetaminophen), acute viral hepatitis, and pancreaticobiliary disorders.

TREATMENT

Acute Viral Hepatitis

Most persons with acute hepatitis (especially hepatitis A, B, and E) recover spontaneously and do not require specific antiviral therapy. In hepatitis B, among previously healthy adults who present with clinically apparent acute hepatitis, recovery occurs in ~99%; therefore, antiviral therapy is not likely to improve the rate of recovery and is not required. In rare instances of severe acute hepatitis B, treatment with a nucleoside analogue at oral doses used to treat chronic hepatitis B **(Chap. 352)** is included in treatment guidelines by the American Association for the Study of Liver Diseases (AASLD) and the European Association for the Study of the Liver (EASL). Indications include fulminant liver failure (along with such therapy, referral to a liver transplantation center is advised) and a prolonged course (>4 weeks) of acute hepatitis B. Although clinical trials have not been done to establish the efficacy or duration of this approach, most authorities would recommend institution of antiviral therapy with a nucleoside analogue (entecavir or tenofovir, the most potent and least resistance-prone agents) for severe, but not mild-moderate, acute hepatitis B. Treatment should continue until 3 months after HBsAg seroconversion or 6 months after HBeAg seroconversion.

In typical cases of acute hepatitis C, recovery is rare (~15–20% in most experiences), and progression to chronic hepatitis is the rule. Patients with jaundice, those with HCV genotype 1, women, and those with earlier age of infection, lower level of HCV RNA, and HBV co-infection, are more likely to recover from acute hepatitis C, as are persons who have genetic markers associated with spontaneous recovery (favorable *IL28B* CC haplotype).

Because spontaneous recovery can occur and because most cases of acute hepatitis C are not clinically severe or rapidly progressive, during the era of interferon-based therapy, delaying antiviral therapy of acute hepatitis C for 3–6 months was recommended; however, in the current era of highly effective (95–100%) oral DAA therapy, waiting for potential spontaneous recovery is no longer advised. Instead, early treatment with a standard, full 8- to 12-week course of one of the first-line drug combinations approved for treatment of chronic hepatitis C **(Chap. 352)** is recommended for treatment of patients with acute hepatitis C.

Because of the vast reservoir of acute HCV infections acquired four to five decades ago in the 1945–1965 birth cohort, most newly recognized HCV infections are chronic. Opportunities to identify and treat patients with acute hepatitis C occur in two population subsets: (1) in health care workers who sustain hepatitis C–contaminated needle sticks (occupational accidents), monitoring for ALT elevations and the presence of HCV RNA identify acute hepatitis C in ~3%, and this group should be treated; (2) in persons who use injection drugs, the risk of acute hepatitis C has been on the rise during the previous two decades, and the epidemic of opioid use has contributed to an amplification of HCV infection among drug users. Such persons are candidates for antiviral therapy, and efforts to combine antiviral therapy with drug rehabilitation therapy have been very successful.

Notwithstanding these specific therapeutic considerations, in most cases of typical acute viral hepatitis, specific treatment generally is not necessary. Although hospitalization may be required for clinically severe illness, most patients do not require hospital care. Forced and prolonged bed rest is not essential for full recovery, but many patients will feel better with restricted physical activity. A high-calorie diet is desirable, and because many patients may experience nausea late in the day, the major caloric intake is best tolerated in the morning. Intravenous feeding is necessary in the acute stage if the patient has persistent vomiting and cannot maintain oral intake. Drugs capable of producing adverse reactions such as cholestasis and drugs metabolized by the liver should be avoided. If severe pruritus is present, the use of the bile salt–sequestering resin cholestyramine is helpful. Glucocorticoid therapy has no value in acute viral hepatitis, even in severe cases, and may be deleterious, even increasing the risk of chronicity (e.g., of acute hepatitis B).

Physical isolation of patients with hepatitis to a single room and bathroom is rarely necessary except in the case of fecal incontinence for hepatitis A and E or uncontrolled, voluminous bleeding for hepatitis B (with or without concomitant hepatitis D) and C. Because most patients hospitalized with hepatitis A excrete little, if any, HAV, the likelihood of HAV transmission from these patients during their hospitalization is low. Therefore, burdensome *enteric precautions are no longer recommended*. Although gloves should be worn when the bed pans or fecal material of patients with hepatitis A are handled, these precautions do not represent a departure from sensible procedure and contemporary universal precautions for all hospitalized patients. For patients with hepatitis B and C, emphasis should be placed on blood precautions (i.e., avoiding direct, ungloved hand contact with blood and other body fluids). Enteric precautions are unnecessary. The importance of simple hygienic precautions such as hand washing cannot be overemphasized. Universal precautions that have been adopted for all patients apply to patients with viral hepatitis. Hospitalized patients may be discharged following substantial symptomatic improvement, a significant downward trend in the serum aminotransferase and bilirubin values, and a return to normal of the PT. Mild aminotransferase elevations should not be considered contraindications to the gradual resumption of normal activity.

In *fulminant hepatitis*, the goal of therapy is to support the patient by maintenance of fluid balance, nutrition, support of circulation and respiration, control of bleeding, correction of hypoglycemia, early identification and treatment of infection, and treatment of other complications of the comatose state in anticipation of liver regeneration and repair. Glucocorticoid therapy has been shown in controlled trials to be ineffective. Likewise, exchange transfusion, plasmapheresis, human cross-circulation, porcine liver cross-perfusion, hemoperfusion, and extracorporeal liver-assist devices have not been proven to enhance survival. The cornerstone of management is meticulous intensive care with vigilant monitoring for infection (and low threshold for initiation of antibiotics and antifungals), careful mental status/cerebral edema monitoring, and management of bleeding complications. Liver transplantation is resorted to with increasing frequency, with excellent results, in patients with fulminant hepatitis **(Chap. 356)**. Fulminant hepatitis C is very rare; however, in fulminant hepatitis B, oral antiviral therapy has been used successfully, although the benefit may be limited once late-stage acute liver failure is present. In clinically severe acute hepatitis E or acute-on-chronic liver failure, successful therapy with ribavirin (600 mg twice daily, 15 mg/kg) has been reported; however, the precise dose and duration of therapy have not been established, and conflicting reports have appeared documenting the futility of ribavirin in this setting. Unfortunately, when fulminant hepatitis E occurs in pregnant women (as it does in up to 20% of pregnant women with acute hepatitis E), ribavirin, which is teratogenic, is contraindicated. In cases of hepatitis E in organ-transplant recipients, reduction in overall immunosuppressive drug doses and switching from tacrolimus to cyclosporine A have been shown to be effective, often without antiviral therapy, in achieving eradication of HEV. If a change in immunosuppression is inadequate, ribavirin treatment for 3 months has been observed to achieve a sustained virologic response in 78% of treated patients; again however, the optimal dose, duration, and efficacy of ribavirin therapy remain to be determined.

PROPHYLAXIS

Because application of therapy for acute viral hepatitis is limited and because chronic viral hepatitis requires prolonged and costly courses of antiviral therapy **(Chap. 352)**, emphasis is placed on prevention through immunization. The prophylactic approach differs for each of the types of viral hepatitis. In the past, immunoprophylaxis

relied exclusively on passive immunization with antibody-containing globulin preparations purified by cold ethanol fractionation from the plasma of hundreds of normal donors. Currently, for hepatitis A, B, and E, active immunization with vaccines is the preferable approach to prevention.

Hepatitis A Both passive immunization with immunoglobulin (IG) and active immunization with killed vaccines are available. Passive immunization, which can be considered in the setting of recent exposure, is 80–90% effective at preventing infection and provides 12–20 weeks of protection; however, its utility is limited by availability and cost (and the competing appeal of active immunization with vaccine). For postexposure prophylaxis of intimate contacts (household, sexual, institutional) of persons with hepatitis A, the administration of 0.1 mL/kg is recommended as early after exposure as possible but must be within 14 days. Prophylaxis is not necessary for those who have already received hepatitis A vaccine, for casual contacts (office, factory, school, or hospital), for most elderly persons, who are very likely to be immune, or for those known to have anti-HAV in their serum. By the time most common-source outbreaks of hepatitis A are recognized, it is usually too late in the incubation period for IG to be effective; however, prophylaxis may have limited the frequency of secondary cases. For travelers to tropical countries, developing countries, and other areas outside standard tourist routes, IG prophylaxis had been recommended before a vaccine became available.

Recommendations for postexposure prophylaxis and for preexposure prophylaxis for international travel were updated in 2020. Currently, hepatitis A vaccine, not IG, is recommended for all persons aged ≥12 months for postexposure prophylaxis and for preexposure prophylaxis prior to international travel to HAV-endemic areas. Even though hepatitis A vaccine is indicated for children ≥12 months of age, when infants aged 6–11 months travel internationally to areas with a risk of HAV infection, they should receive the vaccine for preexposure prophylaxis; however, this travel-related dose should not be counted toward the universal childhood two-dose hepatitis A vaccine recommendation, which begins at age 12 months. For postexposure prophylaxis of persons with contraindications to hepatitis A vaccination and infants aged <12 months, the use of IG (0.1 mL/kg) should be retained. In addition, for postexposure prophylaxis in immunocompromised adults and persons with chronic liver disease, *both* hepatitis A vaccination and IG administration (0.1 mL/kg), at different IM sites, are recommended. Finally, for infants aged <6 months and for persons with contraindications to hepatitis A vaccination, preexposure prophylaxis for travel consists of IG at doses of 0.1 mg/kg for travel durations up to 1 month, 0.2 mg/kg for travel up to 2 months, and repeat 0.2 mg/kg every 2 months thereafter for the remainder of travel. Thus, except for these limited considerations, hepatitis A vaccine has supplanted IG in almost all cases for both postexposure prophylaxis and preexposure prophylaxis for travel. In general, practical use of IG at this point tends to be confined to outbreaks, in which early containment is critical. Unlike IG prophylaxis, the protection afforded by active immunization with vaccine is durable and simpler to administer.

Formalin-inactivated vaccines made from strains of HAV attenuated in tissue culture have been shown to be safe, immunogenic, and effective in preventing hepatitis A. Hepatitis A vaccines are approved for use in persons who are at least 1 year old and appear to provide adequate protection beginning 4 weeks after a primary inoculation. As noted above, for travel to an endemic area, hepatitis A vaccine is the preferred approach to *preexposure* immunoprophylaxis and provides long-lasting protection (protective levels of anti-HAV should last at least 20 years after vaccination). Shortly after its introduction, hepatitis A vaccine was recommended for children living in communities with a high incidence of HAV infection; in 1999, this recommendation was extended to include all children living in states, counties, and communities with high rates of HAV infection. As of 2006, the Advisory Committee on Immunization Practices of the U.S. Public Health Service recommended *routine hepatitis A vaccination of all children*. Other groups considered being at increased risk for HAV infection and who are candidates for hepatitis A vaccination include military personnel, populations with cyclic outbreaks of hepatitis A (e.g., Alaskan natives), employees of day-care centers and persons working in facilities for the developmentally delayed, primate handlers, laboratory workers exposed to hepatitis A or fecal specimens, and patients with chronic liver disease (including persons with aminotransferase elevations ≥2 times the upper limit of normal). Because of an increased risk of fulminant hepatitis A—observed in some experiences but not confirmed in others—among patients with chronic hepatitis C, patients with chronic hepatitis C are candidates for hepatitis A vaccination, as are persons with chronic hepatitis B, persons with HIV infection, and the expanding population of persons with nonalcoholic liver disease (MASLD). Other populations whose recognized risk of hepatitis A is increased should be vaccinated, including men who have sex with men, persons who use injection or noninjection drugs, persons experiencing homelessness, persons traveling from the United States to countries with high or intermediate hepatitis A endemicity, postexposure prophylaxis for contacts of persons with hepatitis A, and household members and other close contacts of (or anyone who anticipates close personal contact with) adopted children arriving from countries with high and moderate hepatitis A endemicity. Hepatitis A vaccine is now recommended as well for pregnant women at risk of infection or severe outcomes from infection during pregnancy. Recommendations for dose and frequency differ for the two approved vaccine preparations in the United States and the combination vaccines that include hepatitis A **(Table 350-7)**; all injections are IM. Hepatitis A vaccine has been reported to be effective in preventing secondary household and day-care center–associated cases of acute hepatitis A. In the United States, reported mortality resulting from hepatitis A declined in parallel with hepatitis A vaccine–associated reductions in the annual incidence of new infections.

Hepatitis B Until 1982, prevention of hepatitis B was based on *passive* immunoprophylaxis either with standard IG, containing modest levels of anti-HBs, or hepatitis B immunoglobulin (HBIG), containing high-titer anti-HBs. The efficacy of standard IG has never been established and remains questionable; even the efficacy of HBIG, demonstrated in several clinical trials, has been challenged, and its contribution appears to be in reducing the frequency of clinical *illness*, not in preventing *infection*. The first vaccine for *active* immunization, introduced in 1982, was prepared from purified, noninfectious, 22-nm spherical HBsAg particles derived from the plasma of healthy HBsAg carriers. In 1987, the plasma-derived vaccine was supplanted by a genetically engineered vaccine derived from recombinant yeast. The latter vaccine consists of HBsAg particles that are nonglycosylated but are otherwise indistinguishable from natural HBsAg; two recombinant vaccines were licensed for use in the United States in the 1980s (Recombivax-HB 1986; Engerix-B 1989), a third (Heplisav-B) was licensed in 2017, and a fourth recombinant vaccine (PreHevbrio, VBI Vaccines) was licensed in 2022. In the United States,

TABLE 350-7 Hepatitis A Vaccination Schedules

AGE, YEARS	NO. OF DOSES	DOSE	SCHEDULE, MONTHS
HAVRIX (GlaxoSmithKline)[a]			
1–18	2	720 ELU[b] (0.5 mL)	0, 6–12
≥19	2	1440 ELU (1 mL)	0, 6–12
VAQTA (Merck)			
1–18	2	25 units (0.5 mL)	0, 6–18
≥19	2	50 units (1 mL)	0, 6–18

[a]A combination of this hepatitis A vaccine and hepatitis B vaccine, TWINRIX, is licensed for simultaneous protection against both of these viruses among adults (age ≥18 years). Each 1-mL dose contains 720 ELU of hepatitis A vaccine and 20 µg of hepatitis B vaccine. These doses are recommended at months 0, 1, and 6. [b]Enzyme-linked immunoassay units. [c]Combination hepatitis A and typhoid vaccines, Hepatyrix (GlaxoSmithKline) and Viatim (Sanofi Pasteur), are available, targeted primarily for travelers to endemic areas. Please consult product insert for doses and schedules

TABLE 350-8 Preexposure Hepatitis B Vaccinations

NAME	VACCINE TYPE	AGE GROUP	NO. OF DOSES	SCHEDULE, MONTH	NOTES
Engerix-B (GlaxoSmithKline)	Single antigen recombinant	From birth, not on dialysis	3	0, 1, 6	0.5-mL dose for 0–19 years 1-mL dose for ≥20 years Contraindicated with severe yeast allergy
		Adults on dialysis	4	0, 1, 2, 6	2-mL dose for adults
Recombivax HB (Merck)	Single antigen recombinant	From birth, not on dialysis	3	0, 1, 6	0.5-mL dose for 0–19 years 1-mL dose for ≥20 years Contraindicated with severe yeast allergy
Recombivax HBV dialysis formulation (Merck)	Single antigen recombinant	Adults on dialysis	3	0, 1, 6	1-mL dose for adults
Heplisav-B (Dynavax)	Single antigen adjuvanted recombinant	≥18 years	2	0, 1	0.5-mL dose Higher levels of protective antibodies, particularly in adults ≥40 years Not for use in severe yeast allergy
PreHevbrio (VBI)*	Three antigen recombinant	≥18 years	3	0, 1, 6	1-mL dose Higher rates of seroprotection in adults ≥45 years Not for use in pregnant women
Twinrix (GlaxoSmithKline)	Combined single antigen recombinant hepatitis A and hepatitis B	≥18 years	3	0, 1, 6 *Note: accelerated 4-dose regimen, days 0, 7, and 21–30, 12 months*	1-mL dose Severe allergy to yeast or any hepatitis A vaccine

*In November 2024, distribution of this vaccine in the United States was discontinued by the manufacturer, because of bankruptcy and termination of operations.

universal birth vaccination against HBV infection has been the standard of care since 2002, with more recent recommendations suggesting further that the birth dose be administered within 12 hours of delivery. For unvaccinated persons, current recommendations can be divided into those for preexposure and postexposure prophylaxis.

For *preexposure* prophylaxis against hepatitis B in persons with a high risk of exposure, three IM (deltoid, not gluteal) injections of hepatitis B vaccine are recommended at 0, 1, and 6 months (other, optional schedules are summarized in **Table 350-8**). In 2022, the Advisory Committee on Immunization Practices (ACIP) recommended universal vaccination for *all unvaccinated persons aged 19–59 years*. Among persons 60 years and older, vaccination is recommended for those at high risk as well as any interested person. Groups considered at high risk include (1) those with sexual exposure (sex workers, those with HBsAg partners, patients at sexually transmitted disease clinics), (2) those with frequent blood exposure (health care workers, first responders, persons who use injection drugs, hemophiliacs, dialysis patients, persons with end-stage renal disease), (3) those who frequently travel to, or first-generation immigrants from, moderate- to high-endemicity areas (>2% prevalence of HBV infection), (4) those with chronic liver disease (HCV infection, steatotic liver disease, autoimmune hepatitis, alcohol-associated liver disease, or aminotransferases >2 times the upper limit of normal), and (5) several other groups (e.g., incarcerated persons and those with HIV infection and diabetes mellitus). Pregnancy is *not* a contraindication to vaccination details of the use of Heplisav-B, a two-injection course a month apart, appear in Table 350-8. In areas of low HBV endemicity such as the United States, despite the availability of safe and effective hepatitis B vaccines, a strategy of vaccinating persons in high-risk groups was not effective. The incidence of new hepatitis B cases continued to increase in the United States after the introduction of vaccines; <10% of all targeted persons in high-risk groups were actually vaccinated, and ~30% of persons with sporadic acute hepatitis B did not fall into any high-risk group category. Therefore, to have an impact on the frequency of HBV infection in an area of low endemicity such as the United States, universal hepatitis B vaccination is now recommended. In HBV-hyperendemic areas (e.g., Asia), universal vaccination of children has resulted in a marked (~70–90%) 40-year decline in complications of hepatitis B, including liver-related mortality and hepatocellular carcinoma.

The original two available aluminum-adjuvanted recombinant hepatitis B vaccines are comparable, one containing 10 μg of HBsAg (Recombivax-HB) and the other containing 20 μg of HBsAg (Engerix-B), and recommended doses for each injection vary for the two preparations (Table 350-8). Combinations of hepatitis B vaccine with other childhood vaccines are available as well (Table 350-8).

More recently, two new recombinant hepatitis B vaccines have been approved for use. One is a recombinant vaccine with a novel adjuvant that activates toll-like 9 receptors (Heplisav-B) and is approved for adults aged 18 or older (although it should be avoided in pregnancy). In a series of prospective trials, compared to three Engerix-B injections, two IM doses a month apart yielded higher proportions with protective levels of anti-HBs (≥10 mIU/mL): 95% of adults aged 18–55 or 18–70 (vs 81% for Engerix-B), 90% of older adults aged 40–70 (vs 71% for Engerix-B), and 90% of adults aged 18–70 with type 2 diabetes (vs 65% for Engerix-B). This two-injection regimen may be useful for revaccination of persons who failed to respond to the original vaccines. The second novel recombinant vaccine (PreHevbrio, VBI Vaccines), which contains all three hepatitis B surface antigen proteins, S, pre-S1, and pre-S2, has been shown in clinical trials (three IM doses at 0, 1, and 6 months) to achieve higher proportions with protective anti-HBs and higher antibody levels than Engerix-B (which contains S antigen only). In addition, PreHevbrio was shown in clinical trials to be associated with higher rates of seroprotection, e.g., in persons ≥45 years (89% compared to 73.1% with an old standard vaccine). This vaccine was approved by the FDA on December 1, 2021, for adults age ≥18 years and recommended for use by the ACIP of the CDC in March 2022. It is the only vaccine not contraindicated in the presence of a yeast allergy.*

For unvaccinated persons sustaining an exposure to HBV, *postexposure* prophylaxis with a combination of HBIG (for rapid achievement of high-titer circulating anti-HBs) and hepatitis B vaccine (for achievement of long-lasting immunity as well as its apparent efficacy in attenuating clinical illness after exposure) is recommended. For *perinatal* exposure of infants born to HBsAg-positive

*In November 2024, distribution of this vaccine in the United States was discontinued by the manufacturer, because of bankruptcy and termination of operations.

mothers, a single dose of HBIG, 0.5 mL, should be administered IM in the thigh *immediately after birth*, followed by a complete course of three injections of recombinant hepatitis B vaccines approved for children (see doses above) to be started within the first 12 h of life. For those experiencing a direct percutaneous inoculation or transmucosal exposure to HBsAg-positive blood or body fluids (e.g., accidental needle stick, other mucosal penetration, or ingestion), a single IM dose of HBIG, 0.06 mL/kg, administered as soon after exposure as possible, is followed by a complete course of hepatitis B vaccine to begin within the first week. For pregnant mothers with high-level HBV DNA (>2 × 10^5 IU/mL), adding antiviral nucleoside analogues (e.g., pregnancy class B tenofovir, **see Chap. 352**) during the third trimester of pregnancy reduces perinatal transmission even further. For persons exposed by *sexual* contact to a patient with acute hepatitis B, a single IM dose of HBIG, 0.06 mL/kg, should be given within 14 days of exposure, to be followed by a complete course of hepatitis B vaccine. When both HBIG and hepatitis B vaccine are recommended, they may be given at the same time but at separate sites. Testing adults for anti-HBs after a course of vaccine is advisable to document the acquisition of immunity (and can guide management in nonresponders, e.g., whether HBIG and/or repeat vaccination with a more immunogenic vaccine preparation is warranted), but because hepatitis B vaccine immunogenicity is nearly universal in infants, postvaccination anti-HBs testing of children is not recommended. Similarly, testing for the presence of anti-HBs in exposed adults can help guide management (e.g., HBIG, repeat vaccination).

The precise duration of protection afforded by hepatitis B vaccine is unknown; however, ~80–90% of immunocompetent adult vaccinees retain protective levels of anti-HBs for at least 5 years, and 60–80% for 10 years, and protective antibody has been documented to last for at least two decades after vaccination in infancy. Thereafter and even after anti-HBs becomes undetectable, long-term protection (via an anamnestic immune response) persists against clinical hepatitis B, hepatitis B surface antigenemia, and chronic HBV infection. Currently, *booster* immunizations are not recommended routinely, except in immunosuppressed persons who have lost detectable anti-HBs or immunocompetent persons who sustain percutaneous HBsAg-positive inoculations after losing detectable antibody. Specifically, for hemodialysis patients, annual anti-HBs testing is recommended after vaccination; booster doses are recommended when anti-HBs levels fall to <10 mIU/mL. As noted above, for persons at risk of both hepatitis A and B, a combined vaccine is available containing 720 enzyme-linked immunoassay units (ELUs) of inactivated HAV and 20 μg of recombinant HBsAg (at 0, 1, and 6 months).

Hepatitis D Infection with hepatitis D can be prevented by vaccinating susceptible persons with hepatitis B vaccine. No product is available for immunoprophylaxis to prevent HDV superinfection in persons with chronic HBV infection; for these patients, avoidance of percutaneous exposures and limitation of intimate contact with persons who have HDV infection are recommended.

Hepatitis E For prevention of hepatitis E, IG derived from HEV-endemic populations does not appear to be effective. Two safe and effective three-dose (0, 1, and 6 months), recombinant genotype 1 capsid protein vaccines have been shown in randomized, placebo-controlled trials to be highly protective (including against other genotypes) against symptomatic acute hepatitis E. A Chinese vaccine, Hecolin, achieved 100% 12-month efficacy and was licensed in China in 2011; its long-lasting protection (87% efficacy) was documented for up to 4.5 years. A second vaccine developed by GlaxoSmithKline and the U.S. Army achieved a 12-month 96% efficacy. The second vaccine was never developed commercially. The Chinese vaccine is available in China but is not FDA approved or available in the United States.

Hepatitis C IG is ineffective in preventing hepatitis C and is no longer recommended for postexposure prophylaxis in cases of perinatal, needle stick, or sexual exposure. Although prototype vaccines that induce antibodies to HCV envelope proteins have been developed, currently, hepatitis C vaccination is not feasible practically. Genotype and quasispecies viral heterogeneity, as well as rapid evasion of neutralizing antibodies by this rapidly mutating virus, conspire to render HCV a difficult target for immunoprophylaxis with a vaccine. Prevention of transfusion-associated hepatitis C has been accomplished successfully by implementation of highly sensitive virologic screening tests, and the current estimated risk is less than 1 in 10 million.

In the absence of active or passive immunization, prevention of hepatitis C includes behavior changes and precautions to limit exposures to infected persons. Recommendations designed to identify patients with clinically inapparent hepatitis as candidates for medical management have as a secondary benefit the identification of persons whose contacts could be at risk of becoming infected. A so-called look-back program has been recommended to identify persons who were transfused before 1992 with blood from a donor found subsequently to have hepatitis C. In addition, anti-HCV testing, once recommended for persons born between 1945 and 1965, has now been expanded to include all persons 18 years or older, independent of risk factors. For stable, monogamous sexual partners, sexual transmission of hepatitis C is unlikely, and sexual barrier precautions are not recommended. For persons with multiple sexual partners or with sexually transmitted diseases, the risk of sexual transmission of hepatitis C is increased, and barrier precautions (latex condoms) are recommended. A person with hepatitis C should avoid sharing such items as razors, toothbrushes, and nail clippers with sexual partners and family members. No special precautions are recommended for babies born to mothers with hepatitis C, and breast-feeding does not have to be restricted.

A more recent, ambitious goal toward HCV prevention steers focus toward its global eradication by 2030, which would require higher rates of and investment in global surveillance, immediate reflex treatment in persons who test positive for HCV infection, and undelayed, streamlined initiation of treatment (including, and perhaps most importantly, in people who inject drugs to prevent secondary spread) (Table 350-4).

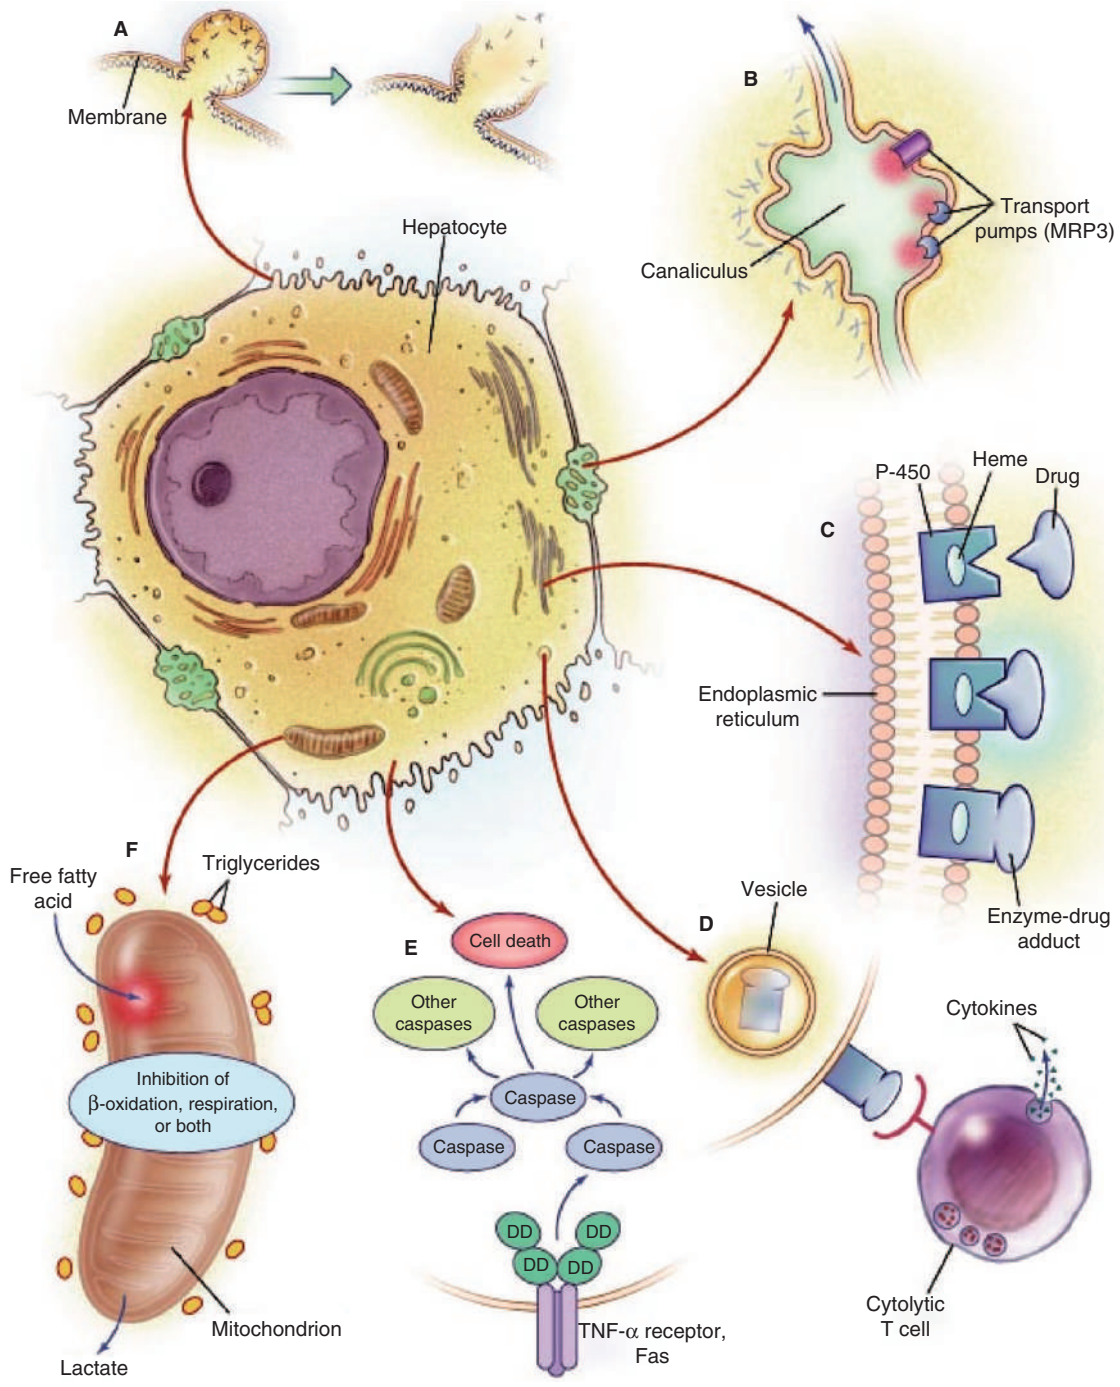
351 Toxic and Drug-Induced Hepatitis

William M. Lee, Jules L. Dienstag

Liver injury is a possible consequence of ingestion of any xenobiotic, including industrial toxins, pharmacologic agents, and complementary and alternative medications (CAMs). Among patients with acute liver failure, drug-induced liver injury (DILI) is the most common cause, and evidence for hepatotoxicity detected during clinical trials for drug development is the most common reason for failure of compounds to reach approval status. DILI requires careful history-taking to identify unrecognized exposure to chemicals used in work or at home, drugs taken by prescription or bought over the counter, and herbal or dietary supplement medicines. Hepatotoxic drugs can injure the hepatocyte directly, for example, via a free-radical or metabolic intermediate that causes peroxidation of membrane lipids and that results in liver cell injury. Alternatively, a drug or its metabolite may activate components of the innate or adaptive immune system, stimulate apoptotic pathways, or initiate damage to bile excretory pathways **(Fig. 351-1)**. Interference with bile canalicular pumps can allow endogenous bile acids, which can injure the liver, to accumulate. Such secondary injury, in turn, may lead to necrosis of hepatocytes; injure bile ducts, producing cholestasis; or block pathways of lipid movement, inhibit protein synthesis, or impair mitochondrial oxidation of fatty acids, resulting in lactic acidosis and intracellular triglyceride accumulation (expressed histologically as microvesicular steatosis). In other instances, drug metabolites sensitize hepatocytes to toxic cytokines. The differences observed between susceptible and nonsusceptible drug recipients may be attributable to human leukocyte antigen (HLA) haplotypes that determine binding of drug-related haptens on the cell surface as well as to polymorphisms in elaboration of competing, protective cytokines, as has been suggested for acetaminophen hepatotoxicity (see below). Immune mechanisms may include cytotoxic lymphocytes or antibody-mediated cellular cytotoxicity. In addition, a role has been shown for activation of nuclear transporters, such as the constitutive androstane receptor (CAR) or, more recently, the pregnane X receptor (PXR), in the induction of drug hepatotoxicity.



DRUG METABOLISM

Most drugs, which are water-insoluble, undergo a series of metabolic steps, culminating in a water-soluble form appropriate for renal or biliary excretion. This process begins with oxidation or methylation mediated initially by the microsomal mixed function oxygenases, cytochrome P450 (phase I reaction), followed by glucuronidation or sulfation (phase II reaction) or inactivation by glutathione. Most drug hepatotoxicity is the result of formation of a phase I toxic metabolite, but glutathione depletion, precluding inactivation of harmful compounds by glutathione *S*-transferase, can contribute as well by ensuring that the toxic compound is not abrogated.

LIVER INJURY CAUSED BY DRUGS

In general, two major types of chemical hepatotoxicity have been recognized: (1) direct toxic and (2) idiosyncratic. As shown in **Table 351-1**, direct toxic hepatitis occurs with predictable regularity in individuals exposed to the offending agent and is dose-dependent. The latent period between exposure and liver injury is usually short (often several hours), although clinical manifestations may be delayed for 24–48 h. Agents producing toxic hepatitis are generally systemic poisons or are converted in the liver to toxic metabolites. The direct hepatotoxins result in morphologic abnormalities that are reasonably characteristic and reproducible for each toxin. Examples of rare toxins currently include carbon tetrachloride and trichloroethylene that characteristically produce a centrilobular zonal necrosis. The hepatotoxic octapeptides of *Amanita phalloides* usually produce massive hepatic necrosis; the lethal dose of the toxin is ~10 mg, the amount found in a single deathcap mushroom. Acetaminophen, the prime example of a direct toxin, is discussed below.

In idiosyncratic drug reactions, the occurrence of liver injury is infrequent (1 in 10^3–10^5 patients) and unpredictable; the response is not as clearly dose-dependent as is injury associated with direct hepatotoxins, and liver injury may occur at any time after exposure to the drug but typically between 5 and 90 days following its initiation. Although regarded as not dose-related in the fashion of direct toxins, most agents causing idiosyncratic toxicity are given at relatively high daily doses, typically exceeding 100 mg, suggesting a role for dose—drugs with low potency must be given in higher doses that engender greater chances for "off-target" effects. Likewise, drugs given in milligram amounts are of high potency and rarely cause liver or other off-target effects. Adding to the difficulty of predicting or identifying idiosyncratic drug hepatotoxicity is the occurrence of mild, transient, nonprogressive serum aminotransferase elevations that resolve with continued drug use. Such "adaptation," the mechanism of which is unknown, is well recognized for drugs such as isoniazid (INH), valproate, phenytoin, and HMG-CoA reductase inhibitors (statins). Extrahepatic manifestations of hypersensitivity, such as rash, arthralgias, fever, leukocytosis, and eosinophilia, occur in a small fraction of patients with idiosyncratic hepatotoxic drug reactions but are characteristic for certain drugs (phenytoin, trimethoprim-sulfamethoxazole) and not others. Both primary immunologic injury and direct hepatotoxicity related to idiosyncratic differences in generation of toxic metabolites have been invoked to explain idiosyncratic drug reactions. The most current data implicate the adaptive immune system responding to the formation of immune stimulatory compounds resulting from phase I metabolic activation of the offending drug. Differences in host susceptibility may result from varying kinetics of toxic metabolite generation and genetic polymorphisms in downstream drug-metabolizing

A. Rupture of cell membrane.
B. Injury of bile canaliculus (disruption of transport pumps).
C. P-450-drug covalent binding (drug adducts).
D. Drug adducts targeted by CTLs/cytokines.
E. Activation of apoptotic pathway by TNFα/Fas.
F. Inhibition of mitochondrial function.

FIGURE 351-1 Potential mechanisms of drug-induced liver injury. The normal hepatocyte may be affected adversely by drugs through (***A***) disruption of intracellular calcium homeostasis that leads to the disassembly of actin fibrils at the surface of the hepatocyte, resulting in blebbing of the cell membrane, rupture, and cell lysis; (***B***) disruption of actin filaments next to the canaliculus (the specialized portion of the cell responsible for bile excretion), leading to loss of villous processes and interruption of transport pumps such as multidrug resistance–associated protein 3 (MRP3), which, in turn, prevents the excretion of bilirubin and other organic compounds; (***C***) covalent binding of the heme-containing cytochrome P450 enzyme to the drug, thus creating nonfunctioning adducts; (***D***) migration of these enzyme-drug adducts to the cell surface in vesicles to serve as target immunogens for cytolytic attack by T cells, stimulating an immune response involving cytolytic T cells and cytokines; (***E***) activation of apoptotic pathways by tumor necrosis factor α (TNF-α) receptor or Fas (DD denotes death domain), triggering the cascade of intercellular caspases, resulting in programmed cell death; or (***F***) inhibition of mitochondrial function by a dual effect on both β-oxidation and the respiratory-chain enzymes, leading to failure of free fatty acid metabolism, a lack of aerobic respiration, and accumulation of lactate and reactive oxygen species (which may disrupt mitochondrial DNA). Toxic metabolites excreted in bile may damage bile-duct epithelium (not shown). CTLs, cytolytic T lymphocytes. *(From WM Lee: Drug-induced hepatotoxicity. N Engl J Med 349:474, 2003. TABLE 351-1 Some Features of Toxic and Drug-Induced Hepatic Injury

	DIRECT TOXIC EFFECT[a]		IDIOSYNCRATIC[a]			OTHER[a]
FEATURES	CARBON TETRACHLORIDE	ACETAMINOPHEN	AMOXICILLIN-CLAVULANATE	ISONIAZID	CIPROFLOXACIN	ESTROGENS/ ANDROGENIC STEROIDS
Predictable and dose-related toxicity	+	+	0	0	0	+
Latent period	Short	Short	Delayed onset	Variable	May be short	Variable
Arthralgia, fever, rash, eosinophilia	0	0	0	0	0	0
Liver morphology	Necrosis, fatty infiltration	Centrilobular necrosis	Mixed hepatocellular/ cholestatic	Hepatocellular injury resembling viral hepatitis	Hepatocellular injury resembling viral hepatitis	Cholestasis *without* portal inflammation

[a]The drugs listed are typical examples.

pathways or cytokine activation; in addition, certain HLA haplotypes have been associated with hepatotoxicity of certain drugs such as amoxicillin-clavulanate and flucloxacillin. Occasionally, however, the clinical features of an allergic reaction (e.g., prominent tissue eosinophilia, autoantibodies) are difficult to ignore and suggest activation of IgE pathways. A few instances of drug hepatotoxicity are observed to be associated with autoantibodies, including a class of antibodies to liver-kidney microsomes, anti-LKM2, directed against a cytochrome P450 enzyme. Four agents that specifically have a phenotype of autoimmune hepatitis with a high likelihood of positive antinuclear antibodies (ANAs) include nitrofurantoin, minocycline, hydralazine, and α-methyldopa.

Idiosyncratic reactions lead to a morphologic pattern that is more variable than those produced by direct toxins; a single agent is often capable of causing a variety of lesions, although certain patterns tend to predominate. Depending on the agent involved, idiosyncratic hepatitis may result in a clinical and morphologic picture indistinguishable from that of viral hepatitis (e.g., INH or ciprofloxacin). So-called hepatocellular injury is the most common form, featuring spotty necrosis in the liver lobule with a predominantly lymphocytic infiltrate resembling that observed in acute hepatitis A, B, or C. Drug-induced cholestasis ranges from mild to increasingly severe: (1) bland cholestasis with limited hepatocellular injury (e.g., estrogens, 17,α-substituted androgens); (2) inflammatory cholestasis (e.g., amoxicillin-clavulanic acid [the most frequently implicated antibiotic among cases of DILI], oxacillin, erythromycin estolate); (3) sclerosing cholangitis (e.g., after intrahepatic infusion of the chemotherapeutic agent floxuridine for hepatic metastases from a primary colonic carcinoma); and (4) disappearance of bile ducts, "ductopenic" cholestasis or vanishing bile duct syndrome, similar to that observed in chronic rejection **(Chap. 357)** following liver transplantation (e.g., carbamazepine, levofloxacin). More recently, a picture resembling primary sclerosing cholangitis has been observed secondary to chemotherapy and after long-term ketamine use. Cholestasis may result from binding of drugs to canalicular membrane transporters, accumulation of toxic bile acids resulting from canalicular pump failure, or genetic defects in canalicular transporter proteins. Clinically, the distinction between a hepatocellular and a cholestatic reaction is indicated by the R value, the ratio of alanine aminotransferase (ALT) to alkaline phosphatase values, both expressed as multiples of the upper limit of normal. An R value of >5.0 is associated with hepatocellular injury, R <2.0 with cholestatic injury, and R between 2.0 and 5.0 with mixed hepatocellular-cholestatic injury.

Morphologic alterations may also include hepatic granulomas (e.g., sulfonamides) or macrovesicular or microvesicular steatosis or steatohepatitis. Severe hepatotoxicity associated with steatohepatitis, most likely a result of mitochondrial toxicity, was recognized with certain antiretroviral therapies, although most of these drugs have been withdrawn **(Chap. 208)**. Another potential target for idiosyncratic drug hepatotoxicity is sinusoidal lining cells; when these are injured, such as by high-dose chemotherapeutic agents (e.g., cyclophosphamide, melphalan, busulfan) administered prior to bone marrow transplantation, venoocclusive disease can result. Nodular regenerative hyperplasia, a subtle form of portal hypertension, may also result from vascular injury to portal or hepatic venous endothelium following systemic chemotherapy, such as with oxaliplatin, as part of adjuvant treatment for colon cancer.

Not all adverse hepatic drug reactions can be classified as either toxic or idiosyncratic. For example, oral contraceptives, which combine estrogenic and progestational compounds, may result in impairment of liver tests and, occasionally, jaundice; however, they do not produce necrosis or fatty change, manifestations of hypersensitivity are generally absent, and susceptibility to the development of oral contraceptive–induced cholestasis appears to be genetically determined. Such estrogen-induced cholestasis is more common in women with cholestasis of pregnancy, a disorder linked to genetic defects in multidrug resistance–associated canalicular transporter proteins.

Any idiosyncratic reaction that occurs in <1:10,000 recipients will go unrecognized in most clinical trials, which involve at most several thousand subjects. The U.S. Food and Drug Administration (FDA) and pharmaceutical companies have learned to look for even subtle indications of serious toxicity and monitor regularly the number of trial subjects in whom any aminotransferase elevations develop, as a possible surrogate for more serious toxicity. Even more valid as a predictor of severe hepatotoxicity is the occurrence of jaundice in patients enrolled in a clinical drug trial, so-called "Hy's Law," named after Dr. Hyman Zimmerman, one of the pioneers of the field of drug hepatotoxicity. He recognized that, if jaundice occurred during a phase 3 trial, more serious liver injury was likely, with a 10:1 ratio between cases of jaundice and liver failure (i.e., 10 patients with jaundice would result in 1 patient with acute liver failure). Thus, the finding of such Hy's Law (jaundiced) cases during drug development often portends failure of approval, particularly if any of the subjects sustains a bad outcome. Troglitazone, a peroxisome proliferator–activated receptor γ agonist, was the first in its class of thiazolidinedione insulin-sensitizing agents. Although in retrospect, Hy's Law cases of jaundice had occurred during phase 3 trials, no instances of liver failure were recognized until well after the drug was introduced, emphasizing the importance of postmarketing surveillance in identifying toxic drugs and in leading to their withdrawal from use. Fortunately, such hepatotoxicity is not characteristic of the second-generation thiazolidinediones rosiglitazone and pioglitazone; in clinical trials, the frequency of aminotransferase elevations in patients treated with these medications did not differ from that in placebo recipients, and isolated reports of liver injury among recipients are extremely rare. Since troglitazone was withdrawn from the market in 2001, no fully approved drugs have had to be withdrawn from the market by the FDA. Several agents have received black box warnings indicating that caution is needed; overall, the industry and FDA in concert have been able to avert severe toxicity in approved agents over the past 25 years.

Proving that an episode of liver injury is caused by a drug (causality) is difficult in many cases. DILI is nearly always a presumptive diagnosis, and many other disorders produce a similar clinicopathologic picture. Thus, causality may be difficult to establish and requires several separate supportive assessment variables to lead to a high level of certainty, including temporal association (time of onset, time to resolution), clinical-biochemical features, type of injury (hepatocellular vs cholestatic), extrahepatic features, likelihood that a given agent is to blame based on

its past record, and exclusion of other potential causes. Scoring systems such as the Roussel-Uclaf Causality Assessment Method (RUCAM) yield residual uncertainty and have not been adopted widely. Currently, the U.S. Drug-Induced Liver Injury Network (DILIN) relies on a structured expert opinion process requiring detailed data on each case and a comprehensive review by three experts who arrive at a consensus on a five-degree scale of likelihood (definite, highly likely, probable, possible, unlikely); however, this approach is not practical for routine clinical application. A new Revised Electronic Causality Assessment Method (RECAM) has now been developed to improve on the other two methods but, to date, is not yet in widespread use. The RECAM website can be accessed via the link *dilirecam.com*.

Generally, drug hepatotoxicity is not more frequent in persons with underlying chronic liver disease, although the severity of the outcome may be amplified. Reported exceptions include hepatotoxicity of aspirin, methotrexate, INH (only in certain experiences), antiretroviral therapy for HIV infection, and certain drugs such as conditioning regimens for bone marrow transplantation in the presence of hepatitis C.

TREATMENT

Toxic and Drug-Induced Hepatic Disease

Treatment is largely supportive, except in acetaminophen hepatotoxicity (for which *N*-acetylcysteine is effective, see below). Acute liver failure develops in 10% of patients with DILI; spontaneous recovery, once that threshold is reached, occurs in <30%, and liver transplantation is performed in >40% of those who reach the level of severity of acute liver failure (coagulopathy and hepatic encephalopathy) **(Chap. 356)**. Withdrawal of the suspected agent is indicated at the first sign of an adverse reaction or when aminotransferase levels reach five times the upper limit of normal. A number of studies have suggested that lethal outcomes follow continued use of an agent in the face of symptoms and signs of liver injury. In the case of the direct toxins, liver involvement should not divert attention from renal or other organ involvement, which may also threaten survival. Agents used occasionally but of questionable value include glucocorticoids for DILI with allergic features, silibinin for mushroom poisoning, and ursodeoxycholic acid for cholestatic drug hepatotoxicity. While these medications have been shown to be effective and to have reasonable safety profiles, they are of uncertain value. A double-blind, randomized controlled trial of the use of *N*-acetylcysteine for nonacetaminophen acute liver failure, including cases of DILI, demonstrated benefit, particularly for patients with early-stage hepatic encephalopathy; however, the drug has not been approved by the FDA for this indication, pending "further studies," which, however, are unlikely to be undertaken.

In **Table 351-2**, several classes of chemical agents are listed together with examples of the pattern of liver injury they produce. Certain drugs appear to be responsible for the development of chronic as well as acute hepatic injury. For example, nitrofurantoin, minocycline, hydralazine, and methyldopa have been associated with moderate to severe chronic hepatitis with autoimmune features; corticosteroids may be used and can virtually always be discontinued after 6 months of therapy. Methotrexate, tamoxifen, and amiodarone have been implicated in the development of cirrhosis. Portal hypertension in the absence of cirrhosis, termed *nodular regenerative hyperplasia*, may result from alterations in hepatic architecture produced by excessive intake of vitamin A or following chemotherapy with oxaliplatin. Oral contraceptives have been implicated in the development of focal nodular hyperplasia or hepatic adenoma (both benign lesions) and, rarely, hepatocellular carcinoma and hepatic vein occlusion (Budd-Chiari syndrome). Another unusual lesion, peliosis hepatis (blood cysts of the liver), has been observed in some patients treated with anabolic or contraceptive steroids. The existence of these hepatic disorders expands the spectrum of liver injury induced by chemical agents and emphasizes the need for a thorough drug history in all patients with liver dysfunction. The comprehensive, authoritative LiverTox website, which contains up-to-date information on DILI, is available as a valuable reference through the National Institutes of Health and the National Library of Medicine (*livertox.nih.gov*).

The following are patterns of adverse hepatic reactions for some prototypic agents.

ACETAMINOPHEN HEPATOTOXICITY (DIRECT TOXIN)

Acetaminophen represents the most prevalent cause of acute liver failure in the Western world; up to 72% of patients with acetaminophen hepatotoxicity in Scandinavia—somewhat lower frequencies in the United Kingdom and the United States—progress to encephalopathy and coagulopathy. Acetaminophen causes dose-related centrilobular hepatic necrosis after single-time-point ingestions, as intentional self-harm, or over extended periods, as unintentional overdoses, when multiple drug preparations or inappropriate drug amounts are used daily for several days, for example, for relief of pain or fever. In these instances, 8 g/d, twice the daily recommended maximum dose, over several days can readily lead to liver failure. Use of opioid-acetaminophen combinations appears to be particularly harmful, because habituation to the opioid may occur with a gradual increase in opioid-acetaminophen combination dosing over days or weeks. A single dose of 10–15 g, occasionally less, may produce clinical evidence of liver injury. Fatal fulminant disease is usually (although not invariably) associated with ingestion of ≥25 g. Blood levels of acetaminophen correlate with severity of hepatic injury (levels >300 μg/mL 4 h after ingestion are predictive of the development of severe damage; levels <150 μg/mL suggest that hepatic injury is highly unlikely). Nausea, vomiting, diarrhea, abdominal pain, and shock are early manifestations occurring 4–12 h after ingestion. Then 24–48 h later, when these features are abating, hepatic injury becomes apparent. Maximal abnormalities and hepatic failure are evident 3–5 days after ingestion, and aminotransferase levels exceeding 10,000 IU/L are not uncommon (i.e., levels far exceeding those in patients with viral hepatitis). Renal failure and myocardial injury may be present. Whether or not a clear history of overdose can be elicited, clinical suspicion of acetaminophen hepatotoxicity should be raised by the presence of the extremely high aminotransferase levels in association with low bilirubin levels that are characteristic of this hyperacute injury. This biochemical signature should trigger further questioning of the subject if possible; however, outright denial (or denial of high doses) or altered mentation may confound diagnostic efforts. In this setting, a presumptive diagnosis is reasonable, and the proven antidote, *N*-acetylcysteine, is both safe and will be effective if given early (within 12 h) but is also used even when injury has evolved.

Acetaminophen is metabolized predominantly by a phase II reaction to innocuous sulfate and glucuronide metabolites; however, a small proportion is metabolized by a phase I reaction to a hepatotoxic metabolite formed from the parent compound by cytochrome P450 CYP2E1. This metabolite, *N*-acetyl-p-benzoquinone-imine (NAPQI), is detoxified by binding to "hepatoprotective" glutathione to become harmless, water-soluble mercapturic acid, which undergoes renal excretion. When excessive amounts of NAPQI are formed, or when glutathione levels are low, glutathione levels are depleted and overwhelmed, permitting covalent binding to nucleophilic hepatocyte macromolecules forming acetaminophen-protein "adducts." These adducts, which can be measured in serum by high-performance liquid chromatography, hold promise as diagnostic markers of acetaminophen hepatotoxicity, and a point-of-care assay for acetaminophen-Cys adducts is under development. The binding of acetaminophen to hepatocyte macromolecules is believed to lead to hepatocyte necrosis; the precise sequence and mechanism are unknown. Hepatic injury may be potentiated by prior administration of alcohol, phenobarbital, INH, or other drugs; by conditions that stimulate the mixed-function oxidase system; or by conditions such as starvation (including inability to maintain oral intake during severe febrile illnesses) that reduce hepatic glutathione levels. Alcohol induces cytochrome P450 CYP2E1; consequently, increased levels of the toxic metabolite NAPQI may be produced in chronic alcoholics after acetaminophen ingestion, but the role of alcohol in potentiating acute acetaminophen injury is still debated. Alcohol

TABLE 351-2 Principal Alterations of Hepatic Morphology Produced by Some Commonly Used Drugs and Chemicals[a]

PRINCIPAL MORPHOLOGIC CHANGE	CLASS OF AGENT	EXAMPLE
Cholestasis	Anabolic steroid	Methyl testosterone, many other body-building supplements
	Antibiotic	Erythromycin estolate, nitrofurantoin, rifampin, amoxicillin-clavulanic acid, oxacillin
	Anticonvulsant	Carbamazepine
	Antidepressant	Duloxetine, mirtazapine, tricyclic antidepressants
	Anti-inflammatory	Sulindac
	Antiplatelet	Clopidogrel
	Antihypertensive	Irbesartan, fosinopril
	Antithyroid	Methimazole
	Calcium channel blocker	Nifedipine, verapamil
	Immunosuppressive	Cyclosporine
	Lipid-lowering	Ezetimibe
	Oncotherapeutic	Anabolic steroids, busulfan, tamoxifen, irinotecan, cytarabine, temozolomide
	Oral contraceptive	Norethynodrel with mestranol
	Oral hypoglycemic	Chlorpropamide
	Tranquilizer	Chlorpromazine[b]
Fatty liver	Antiarrhythmic	Amiodarone
	Antibiotic	Tetracycline (high-dose, IV)
	Anticonvulsant	Valproic acid
	Antiviral	Dideoxynucleosides (e.g., zidovudine), protease inhibitors (e.g., indinavir, ritonavir)
	Oncotherapeutic	Asparaginase, methotrexate, tamoxifen
Hepatitis	Anesthetic	Halothane, fluothane
	Antiandrogen	Flutamide
	Antibiotic	Isoniazid,[c] rifampicin, nitrofurantoin, telithromycin, minocycline,[d] pyrazinamide, trovafloxacin[e]
	Anticonvulsant	Phenytoin, carbamazepine, valproic acid, phenobarbital
	Antidepressant	Iproniazid, amitriptyline, trazodone, venlafaxine, fluoxetine, paroxetine, duloxetine, sertraline, nefazodone[e]
	Antifungal	Ketoconazole, fluconazole, itraconazole
	Antihypertensive	Methyldopa,[c] captopril, enalapril, lisinopril, losartan
	Anti-inflammatory	Ibuprofen, indomethacin, diclofenac, sulindac, bromfenac
	Antipsychotic	Risperidone
	Antiviral	Zidovudine, didanosine, stavudine, nevirapine, ritonavir, indinavir, tipranavir, zalcitabine
	Calcium channel blocker	Nifedipine, verapamil, diltiazem
	Cholinesterase inhibitor	Tacrine
	Diuretic	Chlorothiazide
	Laxative	Oxyphenisatin[c,e]
	Norepinephrine reuptake inhibitor	Atomoxetine
	Oral hypoglycemic	Troglitazone,[e] acarbose
	Immune checkpoint inhibitor	Ipilimumab, pembrolizumab, nivolumab
Mixed hepatitis/cholestatic	Antibiotic	Amoxicillin-clavulanic acid, trimethoprim-sulfamethoxazole
	Antibacterial	Clindamycin
	Antifungal	Terbinafine
	Antihistamine	Cyproheptadine
	Immunosuppressive	Azathioprine
	Lipid-lowering	Nicotinic acid, lovastatin, ezetimibe
Toxic (necrosis)	Analgesic	Acetaminophen
	Hydrocarbon	Carbon tetrachloride
	Metal	Yellow phosphorus
	Mushroom	*Amanita phalloides*
	Solvent	Dimethylformamide
Granulomas	Antiarrhythmic	Quinidine, diltiazem
	Antibiotic	Sulfonamides
	Anticonvulsant	Carbamazepine
	Anti-inflammatory	Phenylbutazone
	Xanthine oxidase inhibitor	Allopurinol
Vascular injury	Chemotherapeutic	Oxaliplatin, melphalan

[a]Several agents cause more than one type of liver lesion and appear under more than one category. [b]Rarely associated with primary biliary cholangitis-like lesion. [c]Occasionally associated with chronic hepatitis or bridging hepatic necrosis or cirrhosis. [d]Associated with an autoimmune hepatitis-like syndrome. [e]Withdrawn from use because of severe hepatotoxicity.

also suppresses hepatic glutathione production. Therefore, in chronic alcoholics, the toxic dose of acetaminophen may be as low as 2 g, and alcoholic patients should be warned specifically about the dangers of even standard doses of this commonly used drug. In a 2006 study, aminotransferase elevations were identified in 31–44% of normal subjects treated for 14 days with the maximal recommended dose of acetaminophen, 4 g daily (administered alone or as part of an acetaminophen-opioid combination); because these changes were transient and never associated with bilirubin elevation, the clinical relevance of these findings remains to be determined. Although underlying hepatitis C virus (HCV) infection was found to be associated with an increased risk of acute liver injury in patients hospitalized for acetaminophen overdose, generally, in patients with nonalcoholic liver disease, acetaminophen taken in recommended doses is well tolerated. Acetaminophen use in cirrhotic patients has not been associated with hepatic decompensation. On the other hand, because of the link between acetaminophen use and liver injury and because of the limited safety margin between safe and toxic doses, the FDA has recommended that the daily dose of acetaminophen be reduced from 4 g to 3 g (even lower for persons with chronic alcohol use), that all acetaminophen-containing products be labeled prominently as containing acetaminophen, and that the potential for liver injury be prominent in the packaging of acetaminophen and acetaminophen-containing products. Within opioid combination products, the limit for the acetaminophen component has been lowered to 325 mg per tablet. Adoption of this limit appears to have had a salutary effect in decreasing the number of hospital admissions and instances of liver failure associated with acetaminophen-opioid combinations.

TREATMENT

Acetaminophen Overdosage

Treatment includes gastric lavage, supportive measures, and oral administration of activated charcoal or cholestyramine to prevent absorption of residual drug. Neither charcoal nor cholestyramine appears to be effective if given >30 min after acetaminophen ingestion; if they are used, the stomach lavage should be done before other agents are administered orally. The chances of possible, probable, and high-risk hepatotoxicity can be derived from a nomogram plot, readily available in emergency departments, as a function of measuring acetaminophen plasma levels 4–8 h after ingestion. In patients with high acetaminophen blood levels (>200 μg/mL measured at 4 h or >100 μg/mL at 8 h after ingestion), the administration of *N*-acetylcysteine reduces markedly the severity of hepatic necrosis. This agent provides sulfhydryl donor groups to replete glutathione, which is required to render harmless toxic metabolites that would otherwise bind covalently via sulfhydryl linkages to cell proteins, resulting in the formation of drug metabolite-protein adducts. Therapy should be begun within 8 h of ingestion but may be at least partially effective when given as late as 24–36 h after overdose. Routine use of *N*-acetylcysteine has substantially reduced the occurrence of fatal acetaminophen hepatotoxicity. *N*-acetylcysteine may be given orally but is more commonly used as an IV solution, with a loading dose of 140 mg/kg over 1 h, followed by 70 mg/kg every 4 h for 15–20 doses. Whenever a patient with potential acetaminophen hepatotoxicity is encountered, a local poison control center should be contacted. Treatment can be stopped when plasma acetaminophen levels indicate that the risk of liver damage is low. If signs of hepatic failure (e.g., progressive jaundice, coagulopathy, confusion) occur despite *N*-acetylcysteine therapy for acetaminophen hepatotoxicity, liver transplantation may be the only option. Early arterial blood lactate levels among such patients with acute liver failure may distinguish patients highly likely to require liver transplantation (lactate levels >3.5 mmol/L) from those likely to survive without liver replacement. Acute renal injury occurs in nearly 75% of patients with severe acetaminophen injury but is virtually always self-limited.

Survivors of acute acetaminophen overdose rarely, if ever, have ongoing liver injury or sequela but may be subject to repeat overdosing.

ISONIAZID HEPATOTOXICITY (IDIOSYNCRATIC REACTION)

INH remains central to most antituberculous prophylactic and therapeutic regimens, despite its long-standing recognition as a hepatotoxin. In 10% of patients treated with INH, elevated serum aminotransferase levels develop during the first few weeks of therapy; however, these elevations in most cases are self-limited, are mild (values for ALT <200 IU/L), and resolve despite continued drug use. This adaptive response allows continuation of the agent if symptoms and progressive enzyme elevations do not follow the initial elevations. Acute hepatocellular DILI secondary to INH is evident with a variable latency period up to 6 months and is more frequent in alcoholics and patients taking certain other medications, such as barbiturates, rifampin, and pyrazinamide. If the clinical threshold of encephalopathy is reached, severe hepatic injury is likely to be fatal or to require liver transplantation. Liver biopsy reveals morphologic changes similar to those of viral hepatitis or bridging hepatic necrosis. Substantial liver injury appears to be age-related, increasing substantially after age 35; the highest frequency is in patients over age 50, and the lowest is in patients under the age of 20. Even for patients >50 years of age monitored carefully during therapy, hepatotoxicity occurs in only ~2%, well below the risk estimate derived from earlier experiences. Fever, rash, eosinophilia, and other manifestations of drug allergy are distinctly unusual. Antibodies to INH have been detected in INH recipients, but a link to causality of liver injury remains unclear. A clinical picture resembling chronic hepatitis has been observed in a few patients. Many public health programs that require INH prophylaxis for a positive tuberculin skin test or blood test (Quantiferon or T-Spot) include monthly monitoring of aminotransferase levels, although this practice has been called into question. Even more effective in limiting serious outcomes may be encouraging patients to be alert for symptoms such as nausea, fatigue, or jaundice, because most fatalities occur in the setting of continued INH use despite clinically apparent illness. The incidence of severe INH toxicity may be declining as a result of less frequent use and/or better management.

SODIUM VALPROATE HEPATOTOXICITY (TOXIC AND IDIOSYNCRATIC REACTION)

Sodium valproate, an anticonvulsant useful in the treatment of petit mal and other seizure disorders, has been associated with the development of severe hepatic toxicity and, rarely, fatalities, predominantly in children but also in adults. Among children listed as candidates for liver transplantation, valproate is the most common antiepileptic drug implicated. Asymptomatic elevations of serum aminotransferase levels have been recognized in as many as 45% of treated patients. These "adaptive" changes, however, appear to have no clinical importance, because major hepatotoxicity is not seen in the majority of patients despite continuation of drug therapy. In the rare patients in whom jaundice, encephalopathy, and evidence of hepatic failure are found, examination of liver tissue reveals microvesicular fat and bridging hepatic necrosis, predominantly in the centrilobular zone. Bile duct injury may also be apparent. Most likely, sodium valproate is not directly hepatotoxic, but its metabolite, 4-pentenoic acid, may be responsible for hepatic injury. Valproate hepatotoxicity is more common in persons with mitochondrial enzyme deficiencies and may be ameliorated by IV administration of carnitine, which valproate therapy can deplete. Valproate toxicity has been linked to HLA haplotypes (*DR4* and *B*1502*) and to mutations in mitochondrial DNA polymerase gamma 1.

NITROFURANTOIN HEPATOTOXICITY (IDIOSYNCRATIC REACTION)

This commonly used antibiotic for urinary tract infections may cause an acute hepatitis leading to fatal outcome or, more frequently, chronic hepatitis of varying severity but indistinguishable from autoimmune

hepatitis. These two scenarios may reflect the frequent use and reuse of the drug for treatment of recurrent cystitis in women. Although most toxic agents manifest injury within 6 months of first ingestion, nitrofurantoin may have a longer latency period, in part perhaps because of its intermittent, recurrent use. Autoantibodies to nuclear components, smooth muscle, and mitochondria are seen and may subside after resolution of injury; however, glucocorticoid or other immunosuppressive medication may be necessary to resolve the autoimmune injury, and cirrhosis may be seen in cases that are not recognized quickly. Interstitial pulmonary fibrosis presenting as chronic cough and dyspnea may be present and resolve slowly with medication withdrawal. Histologic findings are identical to those of autoimmune hepatitis. A similar disease pattern can be observed with minocycline, which is used repeatedly for the treatment of acne in teenagers, as well as with hydralazine and α-methyldopa.

AMOXICILLIN-CLAVULANATE HEPATOTOXICITY (IDIOSYNCRATIC MIXED REACTION)

Currently, the most common agent implicated as causing DILI in the United States and in Europe is amoxicillin-clavulanate (most frequent brand name: Augmentin). This medication causes a very specific syndrome of mixed or primarily cholestatic injury. Because hepatotoxicity may follow amoxicillin-clavulanate therapy after a relatively long latency period, the liver injury may begin to manifest after the drug has been withdrawn. The high prevalence of hepatotoxicity reflects in part the very frequent use of this drug for respiratory tract infections, including community-acquired pneumonia. The mechanism of hepatotoxicity is unclear, but the liver injury is thought to be caused by amoxicillin toxicity that is potentiated in some way by clavulanate, which itself appears not to be toxic. Symptoms include nausea, anorexia, fatigue, and jaundice—which may be prolonged—with pruritus. Rash is quite uncommon. On occasion, amoxicillin-clavulanate, like other cholestatic hepatotoxic drugs, causes permanent injury to small bile ducts, leading to the so-called "vanishing bile duct syndrome." In vanishing bile duct syndrome, initially, liver injury is minimal except for severe cholestasis; however, over time, histologic evidence of bile duct abnormalities is replaced by a paucity and eventual absence of discernible ducts on subsequent biopsies.

AMIODARONE HEPATOTOXICITY (TOXIC AND IDIOSYNCRATIC REACTION)

Therapy with this potent antiarrhythmic drug is accompanied in 15–50% of patients by modest elevations of serum aminotransferase levels that may remain stable or diminish despite continuation of the drug. Such abnormalities may appear days to many months after beginning therapy. A proportion of those with elevated aminotransferase levels have detectable hepatomegaly, and clinically important liver disease develops in <5% of patients. Features that represent a direct effect of the drug on the liver and that are common to the majority of long-term recipients are ultrastructural phospholipidosis, unaccompanied by clinical liver disease, and interference with hepatic mixed-function oxidase metabolism of other drugs. The cationic amphiphilic drug and its major metabolite desethylamiodarone accumulate in hepatocyte lysosomes and mitochondria and in bile duct epithelium. The relatively common elevations in aminotransferase levels are also considered a predictable, dose-dependent, direct hepatotoxic effect. On the other hand, in the rare patient with clinically apparent, symptomatic liver disease, liver injury resembling that seen in alcoholic liver disease is observed. The so-called pseudoalcoholic liver injury can range from steatosis, to alcoholic hepatitis–like neutrophilic infiltration and Mallory's hyaline, to cirrhosis. Electron-microscopic demonstration of phospholipid-laden lysosomal lamellar bodies can help to distinguish amiodarone hepatotoxicity from typical alcoholic hepatitis. This category of liver injury appears to be a metabolic idiosyncrasy that allows hepatotoxic metabolites to be generated. Rarely, an acute idiosyncratic hepatocellular injury resembling viral hepatitis or cholestatic hepatitis occurs. Hepatic granulomas have occasionally been observed. Because amiodarone has a long half-life, liver injury may persist for months after the drug is stopped.

ANABOLIC STEROIDS (CHOLESTATIC REACTION)

The most common form of liver injury caused by CAMs is the profound cholestasis associated with anabolic steroids used by body builders. Unregulated agents sold in gyms and health food stores as diet supplements, which are taken by athletes to improve their performance, may contain anabolic steroids. In a young male, jaundice that is accompanied by a cholestatic, rather than a hepatitic, laboratory profile almost invariably will turn out to be caused by the use of one of a variety of androgen congeners. Such agents have the potential to injure bile transport pumps and to cause intense cholestasis; the time to onset is variable, and resolution, which is the rule, may require many weeks to months. Initially, anorexia, nausea, and malaise may occur, followed by pruritus in some but not all patients. Serum aminotransferase levels are usually <100 IU/L, and serum alkaline phosphatase levels are generally moderately elevated with bilirubin levels frequently exceeding 342 μmol/L (20 mg/dL). Examination of liver tissue reveals cholestasis without substantial inflammation or necrosis. Anabolic steroids have also been used by prescription to treat bone marrow failure. In this setting, hepatic centrizonal sinusoidal dilatation and peliosis hepatis have been reported in rare patients, as have hepatic adenomas and hepatocellular carcinoma. Recently, a large series of cases with a uniform phenotype has been described. Unfortunately, no genomic signature has become evident despite the unique features of the injury. No permanent sequelae are evident besides prolonged jaundice, lasting frequently 10 weeks or more.

TRIMETHOPRIM-SULFAMETHOXAZOLE HEPATOTOXICITY (IDIOSYNCRATIC REACTION)

This antibiotic combination is used routinely for urinary tract infections in immunocompetent persons and for prophylaxis against and therapy of *Pneumocystis jirovecii* pneumonia in immunosuppressed persons (transplant recipients, patients with AIDS). With its increasing use, its occasional hepatotoxicity is being recognized with growing frequency. Its likelihood is unpredictable, but when it occurs, trimethoprim-sulfamethoxazole hepatotoxicity follows a relatively uniform latency period of several weeks and is often accompanied by eosinophilia, rash, and other features of a hypersensitivity reaction, including the drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome. Biochemically and histologically, acute hepatocellular necrosis predominates, but cholestatic features are quite frequent. Occasionally, cholestasis without necrosis occurs, and very rarely, a severe cholangiolytic pattern of liver injury is observed. In most cases, liver injury is self-limited, but rare fatalities have been recorded. The hepatotoxicity is attributable to the sulfamethoxazole component of the drug and is similar in features to that seen with other sulfonamides; tissue eosinophilia and granulomas may be seen. The risk of trimethoprim-sulfamethoxazole hepatotoxicity is increased in persons with HIV infection. In a recent study, unique HLA associations in European Americans and in African Americans have been identified.

HMG-COA REDUCTASE INHIBITORS (STATINS) (IDIOSYNCRATIC MIXED HEPATOCELLULAR AND CHOLESTATIC REACTION)

Between 1 and 2% of patients taking lovastatin, simvastatin, pravastatin, fluvastatin, or one of the newer statin drugs for the treatment of hypercholesterolemia experience asymptomatic, reversible elevations (greater than threefold) of aminotransferase activity. Acute hepatitis-like histologic changes, centrilobular necrosis, and centrilobular cholestasis have been described in a very small number of cases. In a larger proportion, minor aminotransferase elevations appear during the first several weeks of therapy. Careful laboratory monitoring can distinguish between patients with minor, transitory changes, who may continue therapy, and those with more profound and sustained abnormalities, who should discontinue therapy. Because clinically meaningful aminotransferase elevations are so rare after statin use and do not differ in meta-analyses from the frequency of such laboratory abnormalities in placebo recipients, a panel of liver experts recommended to the National Lipid Association's Safety Task Force that liver test monitoring was not necessary in patients treated with statins and that statin therapy need not be discontinued in patients found to have

asymptomatic isolated aminotransferase elevations during therapy. Statin hepatotoxicity is not increased in patients with chronic hepatitis C, hepatic steatosis, or other underlying liver diseases, and statins can be used safely in these patients.

ALTERNATIVE AND COMPLEMENTARY MEDICINES (IDIOSYNCRATIC HEPATITIS, STEATOSIS)

Herbal medications that are of scientifically unproven efficacy and that lack prospective safety oversight by regulatory agencies account currently for >20% of DILI in the United States. Besides anabolic steroids, the most common category of dietary or herbal products is weight loss agents. Included among the herbal remedies associated with toxic hepatitis are Jin Bu Huan, xiao-chai-hu-tang, germander, chaparral, senna, mistletoe, skullcap, gentian, comfrey (containing pyrrolizidine alkaloids), ma huang, bee pollen, valerian root, pennyroyal oil, kava, celandine, Impila (*Callilepis laureola*), LipoKinetix, Hydroxycut, Oxy-Elite Pro, Herbalife, herbal nutritional supplements, and herbal teas containing *Camellia sinensis* (green tea extract). Well characterized are the acute hepatitis-like histologic lesions following Jin Bu Huan use: focal hepatocellular necrosis, mixed mononuclear portal tract infiltration, coagulative necrosis, apoptotic hepatocyte degeneration, tissue eosinophilia, and microvesicular steatosis. Megadoses of vitamin A can injure the liver, as can pyrrolizidine alkaloids, which often contaminate Chinese herbal preparations and can cause a venoocclusive injury leading to sinusoidal hepatic vein obstruction. Because some alternative medicines induce toxicity via active metabolites, alcohol and drugs that stimulate cytochrome P450 enzymes may enhance the toxicity of some of these products. Conversely, some alternative medicines also stimulate cytochrome P450 and may result in or amplify the toxicity of recognized drug hepatotoxins. In many instances, herbal and dietary supplements actually contain chemicals rather than only leaves, roots, and bark. Antirheumatic "herbs" have been found to contain a nonsteroidal anti-inflammatory drug (NSAID) such as diclofenac, for example. Given the widespread use of such poorly defined herbal preparations, hepatotoxicity is likely to be encountered with increasing frequency; therefore, a drug history in patients with acute and chronic liver disease should include use of "alternative medicines" and other nonprescription preparations sold in so-called health food stores.

CHECKPOINT INHIBITOR AND OTHER IMMUNOTHERAPIES FOR CANCER

The introduction of a new class of immunotherapeutic agents for melanoma and other cancers has ushered in a new kind of hepatotoxicity, that associated with activation of the immune response. The three classes of immune-active molecules are cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4), programmed cell death receptor 1 (PD-1), and programmed cell death receptor ligand 1 (PD-L1). Within weeks of beginning treatment with any one of several agents, including ipilimumab (CTLA-4), pembrolizumab (PD-1), or nivolumab (PD-1), an active hepatitis evolves that is associated with positive ANAs and appears to respond to glucocorticoid therapy. Liver histology may share some of the features of, but does not resemble the chronic changes observed in, autoimmune hepatitis. Instead, histologic findings are compatible with a nonspecific acute hepatic injury, assumed to result from the release of host modulation of anti-self-immune responses and mediated predominantly by CD8+ lymphocytes. Immune-mediated injury to thyroid, muscle, and colon may be seen as well. Few deaths have been reported related to these immunotherapies; while these novel agents may need to be halted temporarily, in many cases, they can be restarted (and are tolerated better on retreatment) if patients are showing a favorable antitumor response.

HIGHLY ACTIVE ANTIRETROVIRAL THERAPY FOR HIV INFECTION (MITOCHONDRIAL TOXIC, IDIOSYNCRATIC, STEATOSIS; HEPATOCELLULAR, CHOLESTATIC, AND MIXED)

The recognition of drug hepatotoxicity in persons with HIV infection is complicated in this population by the many alternative causes of liver injury (chronic viral hepatitis, fatty infiltration, infiltrative disorders, mycobacterial infection, etc.), but drug hepatotoxicity associated with highly active antiretroviral therapy (HAART) was a common type of liver injury in HIV-infected persons in the early days of HIV therapy; however, it is less frequent now **(Chap. 208)**. Implicated most frequently are combinations including the nucleoside analogue reverse transcriptase inhibitors zidovudine, didanosine, and, to a lesser extent, stavudine; the protease inhibitors ritonavir and indinavir (and amprenavir when used together with ritonavir), as well as tipranavir; and the nonnucleoside reverse transcriptase inhibitors nevirapine and, to a lesser extent, efavirenz. Distinguishing the impact of HAART hepatotoxicity in patients with HIV and hepatitis virus co-infection is made challenging by the following: (1) both chronic hepatitis B and hepatitis C can affect the natural history of HIV infection and the response to HAART, and (2) HAART can have an impact on chronic viral hepatitis. For example, immunologic reconstitution with HAART can result in immunologically mediated liver-cell injury in patients with chronic hepatitis B co-infection if treatment with an antiviral agent for hepatitis B (e.g., nucleoside analogues such as tenofovir) is withdrawn. Infection with HIV, especially with low CD4+ T-cell counts, has been reported to increase the rate of hepatic fibrosis associated with chronic hepatitis C, and HAART therapy can increase levels of serum aminotransferases and HCV RNA in patients with hepatitis C co-infection. Didanosine or stavudine should not be used with ribavirin in patients with HIV/HCV co-infection because of an increased risk of severe mitochondrial toxicity and lactic acidosis.

352 Chronic Hepatitis

Esperance A. K. Schaefer, Raymond T. Chung, Jules L. Dienstag

Chronic hepatitis represents a series of liver disorders of varying causes and severity in which hepatic inflammation and necrosis continue for at least 6 months. Milder forms are nonprogressive or only slowly progressive, while more severe forms may be associated with scarring and architectural reorganization, which, when advanced, lead ultimately to cirrhosis. Several broad categories of chronic hepatitis have been recognized. These include chronic viral hepatitis, drug-or toxin-induced chronic hepatitis **(Chap. 351)**, alcohol-associated liver disease **(Chap. 353)**, metabolic dysfunction-related chronic hepatitis **(Chap 354)**, and autoimmune chronic hepatitis. In many cases, clinical and laboratory features are insufficient to allow assignment into one of these distinct categories; these "idiopathic" cases are also believed to represent autoimmune chronic hepatitis. Moreover, because of the high prevalence of steatotic liver diseases (metabolic dysfunction-associated steatotic liver disease and alcohol-associated liver disease), patients with more than one, overlapping type of hepatitis are encountered not infrequently (e.g., viral and steatotic liver injury, alcohol-related and nonalcohol-related steatotic liver injury). Finally, clinical and laboratory features of chronic hepatitis are observed occasionally in patients with other hereditary/metabolic disorders, such as Wilson disease (copper overload) and α_1 antitrypsin deficiency **(Chaps. 355 and 427)**. Although all types of chronic hepatitis share certain clinical, laboratory, and histopathologic features, chronic viral and chronic autoimmune hepatitis are sufficiently distinct to merit separate discussions. **For discussion of acute hepatitis, see Chap. 350.**

CLASSIFICATION OF CHRONIC HEPATITIS

Common to all forms of chronic hepatitis are histopathologic distinctions based on localization and extent of liver injury. These vary from the milder forms, previously labeled *chronic persistent hepatitis* and *chronic lobular hepatitis*, to the more severe form, formerly called *chronic active hepatitis*. When first defined, these designations were believed to have prognostic implications, which were not corroborated by subsequent observations. Categorization of chronic hepatitis based primarily on histopathologic features has been replaced by a more informative classification based on a combination of clinical, serologic, and histologic variables. Classification of chronic hepatitis is based on (1) its *cause*; (2) its histologic activity, or *grade*; and (3) its degree of progression based on level of fibrosis, or *stage*. Thus, neither clinical features alone nor histologic features—requiring liver biopsy or noninvasive markers of fibrosis—alone are sufficient to characterize and distinguish among the several categories of chronic hepatitis.

CLASSIFICATION BY CAUSE

Clinical and serologic features allow the establishment of a diagnosis of *chronic viral hepatitis*, caused by hepatitis B, hepatitis B plus D, or hepatitis C; *autoimmune hepatitis*, including several subcategories, I and II, based on serologic distinctions; *drug-associated chronic hepatitis*; and a category of unknown cause, or *cryptogenic chronic hepatitis* **(Table 352-1)**. These are addressed in more detail below.

CLASSIFICATION BY GRADE

Grade, a histologic assessment of necroinflammatory activity, is based on examination of the liver biopsy. An assessment of important histologic features includes the degree of *periportal necrosis* and the disruption of the limiting plate of periportal hepatocytes by inflammatory cells (so-called *piecemeal necrosis* or *interface hepatitis*); the degree of confluent necrosis that links or forms bridges between vascular structures—between portal tract and portal tract or even more important bridges between portal tract and central vein—referred to as *bridging necrosis*; the degree of hepatocyte degeneration and focal necrosis within the lobule; and the degree of *portal inflammation*. Several scoring systems for viral hepatitis that take these histologic features into account have been devised, and the most popular are the histologic activity index (HAI), used commonly in the United States, and the METAVIR score, used in Europe **(Table 352-2)**. Based on the presence and degree of these features of histologic activity, chronic hepatitis can be graded as mild, moderate, or severe.

TABLE 352-1 Clinical and Laboratory Features of Chronic Hepatitis

TYPE OF HEPATITIS	DIAGNOSTIC TEST(S)	THERAPY
Chronic hepatitis B	HBsAg, IgG anti-HBc, HBeAg, HBV DNA	IFN-α, PEG IFN-α Oral agents: First-line: entecavir, tenofovir
Chronic hepatitis C	Anti-HCV, HCV RNA	Sofosbuvir-ledipasvir, glecaprevir-pibrentasvir, sofosbuvir-velpatasvir, elbasvir-grazoprevir, sofosbuvir-velpatasvir-voxilaprevir[a]
Chronic hepatitis D	Anti-HDV, HDV RNA, HBsAg, IgG anti-HBc	IFN-α, PEG IFN-α[c,] bulevirtideb
Autoimmune hepatitis	ANA (homogeneous), anti-SMA, anti-SLA, anti-LKM1 (±) Hyperglobulinemia	First line: prednisone, azathioprine Second line: mycophenolate mofetil, tacrolimus, rituximab

See *www.hcvguidelines.org*.

[a]Detailed treatment recommendations can be found at *www.hcvguidelines.org*.
[b]Currently approved by European Medicines Agency, under review at the U.S. Food and Drug Administration.

Abbreviations: HBc, hepatitis B core; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; IFN-α, interferon α; IgG, immunoglobulin G; LKM, liver-kidney microsome; PEG IFN-α, pegylated interferon α; SLA, soluble liver antigen; SMA, smooth muscle antibody.

CLASSIFICATION BY STAGE

The stage of chronic hepatitis, which reflects the level of progression of the disease, is based on the degree of hepatic fibrosis. When fibrosis is so extensive that fibrous septa surround parenchymal nodules and alter the normal architecture of the liver lobule, the histologic lesion is defined as *cirrhosis*. Staging is based on the degree of fibrosis as categorized on a numerical scale 0–6 (HAI) or 0–4 (METAVIR) (Table 352-2). Several noninvasive approaches have been introduced to provide approximations of hepatic histologic stage, including serum biomarkers of fibrosis; fibrosis scores such as FIB-4, a validated algorithm based on such routine lab tests as aspartate and alanine aminotransferase (AST and ALT) levels and platelet counts (PLT) (age [years] × AST divided by PLT ×); the Enhanced Liver Fibrosis (ELF) score, a proprietary score (applied more frequently in steatotic liver disease than viral liver disease) based on a combination of three nonroutine blood tests (hyaluronic acid, procollagen III N-terminal peptide, and tissue inhibitor of metalloproteinase 1); and imaging determinations of liver elasticity/stiffness.

CHRONIC VIRAL HEPATITIS

Both of the enterically transmitted forms of viral hepatitis, hepatitis A and E, are self-limited and do not cause chronic hepatitis (rare reports notwithstanding in which acute hepatitis A serves as a trigger for the onset of autoimmune hepatitis in genetically susceptible patients or in which hepatitis E **[Chap. 350]** can cause chronic liver disease in immunosuppressed hosts, for example, after liver transplantation). In contrast, the entire clinicopathologic spectrum of chronic hepatitis occurs in patients with chronic viral hepatitis B and C as well as in patients with chronic hepatitis D superimposed on chronic hepatitis B.

CHRONIC HEPATITIS B

The likelihood of chronicity after acute hepatitis B varies as a function of age. Infection at birth is associated with clinically silent acute infection but a 90% chance of chronic infection, whereas infection in young adulthood in immunocompetent persons is typically associated with clinically apparent acute hepatitis but a risk of chronicity of only ~1%. Most cases of chronic hepatitis B among adults, however, are recognized

[a]Ishak K, Baptista A, Bianchi L, et al: Histologic grading and staging of chronic hepatitis. J Hepatol 22:696, 1995. [b]Bedossa P, Poynard T, French METAVIR Cooperative Study Group: An algorithm for grading activity in chronic hepatitis C. Hepatology 24:289, 1996. [c]Necroinflammatory grade: A0 = none; A1 = mild; A2 = moderate; A3 = severe.

in patients who never had a recognized episode of clinically apparent acute viral hepatitis. The degree of liver injury (grade) in patients with chronic hepatitis B is variable, ranging from none in inactive carriers to mild to moderate to severe. Among adults with chronic hepatitis B, histologic features are of prognostic importance. In one long-term study of 379 patients with untreated chronic hepatitis B in the United States, investigators found a 5-year survival rate of 97% for patients with mild chronic hepatitis, 86% for patients with moderate to severe chronic hepatitis, and only 55% for patients with chronic hepatitis and cirrhosis. The 15-year survival in these cohorts was 77%, 66%, and 40%, respectively. On the other hand, more recent observations do not allow us to be so sanguine about the prognosis in patients with mild chronic hepatitis; among such patients followed for 1–13 years, progression to more severe chronic hepatitis and cirrhosis has been observed in more than a quarter of cases. Co-infection with HIV has long been appreciated to accelerate the progression of hepatitis B; early studies documented a nearly 20-fold increase in liver-related mortality between persons with hepatitis B virus (HBV)-HIV co-infection compared to those with HBV infection alone. Similarly, coexisting steatohepatitis has also been found to accelerate disease progression; in one study, patients with HBV infection and steatohepatitis were found to have both higher-grade inflammation and more advanced-stage fibrosis.

More important to consider than histology alone in patients with chronic hepatitis B is the degree of HBV replication. As reviewed in **Chap. 350**, chronic HBV infection can occur in the presence or absence of serum hepatitis B e antigen (HBeAg), and generally, for both HBeAg-reactive and HBeAg-negative chronic hepatitis B, the level of HBV DNA correlates with the level of liver injury and risk of progression. In otherwise healthy adults with *HBeAg-positive chronic hepatitis B*, two phases have been recognized based on the relative level of HBV replication. The relatively *replicative phase* is characterized by the presence in the serum of HBeAg and HBV DNA levels well in excess of 10^3–10^4 IU/mL, sometimes exceeding 10^9 IU/mL; by the presence in the liver of detectable intrahepatocyte nucleocapsid antigens (primarily hepatitis B core antigen [HBcAg]); by high infectivity; and by accompanying liver injury (see below for an important exception during the early decades of life). In contrast, the relatively *nonreplicative phase* is characterized by the *absence* of the conventional serum marker of HBV replication (HBeAg), the appearance of anti-HBe, levels of HBV DNA below a threshold of ~10^3 IU/mL, the absence of intrahepatocytic HBcAg, limited infectivity, and minimal liver injury. Patients in the relatively replicative phase tend to have more severe chronic hepatitis and more rapid progression, whereas those in the relatively nonreplicative phase tend to have minimal or mild chronic hepatitis or to be inactive hepatitis B carriers. Thus, the transition between HBeAg-positive chronic hepatitis B to HBeAg-negative disease is of clinical importance, signaling a slowing of disease progression. In the past, the likelihood of spontaneous HBeAg loss was estimated to be ~10% per year; however, a 2020 systematic review of 26 studies involving 7550 persons with HBeAg-positive chronic hepatitis B revealed a spontaneous HBeAg clearance rate of 6.46 per 100 person-years. Such spontaneous HBeAg loss was found to occur more frequently with older age and in European populations but less frequently in patients with genotype C.

Distinctions in HBV replication and in histologic category, however, do not always coincide. In patients with *HBeAg-positive chronic HBV infection,* especially when acquired at birth or in early childhood, as recognized commonly in Asian countries, a dichotomy is common between very high levels of HBV replication during the early decades of life (when the level of apparent host immunologic tolerance of HBV is relatively high) and negligible levels of liver injury; during this phase of chronic hepatitis B (labeled by some as "HBeAg-positive chronic infection" or "immune tolerant," see **Chap. 350**, "Complications and Sequelae"), the level of viral replication does not correlate with liver injury or late complications. Yet despite the relatively immediate, apparently benign nature of liver disease for many decades in this population, in the middle decades, activation of liver injury emerges as what appears to be the relative tolerance of the host to HBV declines, and these patients with childhood-acquired HBV infection are ultimately at increased risk later in life for cirrhosis, hepatocellular carcinoma (HCC) **(Chap. 87)**, and liver-related death; the link between high-level HBV replication and these late liver complications has been demonstrated convincingly in, and confined mostly to, persons in their middle decades, especially age ≥40. **A discussion of the pathogenesis of liver injury in patients with chronic hepatitis B appears in Chap. 350.**

HBeAg-negative chronic hepatitis B (i.e., chronic HBV infection with active virus replication and readily detectable HBV DNA but without HBeAg [anti-HBe-reactive]) is more common than HBeAg-positive chronic hepatitis B in Mediterranean and European countries and in Asia. Compared to patients with HBeAg-reactive chronic hepatitis B, patients with HBeAg-negative chronic hepatitis B have HBV

DNA levels several orders of magnitude lower (usually no more than 10^5–10^6 IU/mL) than those observed in the HBeAg-reactive subset. Most such HBeAg-negative cases represent precore or core-promoter mutations acquired late in the natural history of mostly early-life-onset disease; these mutations prevent translation of HBeAg from the precore component of the HBV genome (precore mutants) or are characterized by downregulated transcription of precore mRNA (core-promoter mutants; **Chap. 350**). Although their levels of HBV DNA tend to be lower than among patients with HBeAg-reactive chronic hepatitis B, patients with HBeAg-negative chronic hepatitis B can have progressive liver injury (complicated by cirrhosis and HCC) and experience episodic reactivation of liver disease reflected in fluctuating levels of aminotransferase activity ("flares"). The biochemical and histologic activity of HBeAg-negative disease tends to correlate closely with levels of HBV replication. Worth reiterating, the level of HBV replication is the most important risk factor for the ultimate development of cirrhosis and HCC in both HBeAg-reactive and HBeAg-negative patients. Although levels of HBV DNA are lower and more readily suppressed by therapy to undetectable levels in HBeAg-negative (compared to HBeAg-reactive) chronic hepatitis B, achieving sustained responses that permit discontinuation of antiviral therapy is less likely in HBeAg-negative patients (see below). Inactive carriers are patients with circulating hepatitis B surface antigen (HBsAg), normal serum aminotransferase levels, minimal or no histologic evidence of liver injury, undetectable HBeAg, and levels of HBV DNA that are either undetectable or present at a threshold of $\leq 10^3$ IU/mL. This serologic profile occurs not only in inactive carriers but also in patients with HBeAg-negative chronic hepatitis B during periods of relative inactivity; distinguishing between the two requires sequential biochemical and virologic monitoring over many months.

The spectrum of *clinical features* of chronic hepatitis B is broad, ranging from asymptomatic infection to debilitating disease or even end-stage, fatal hepatic failure. As noted above, the onset of the disease tends to be insidious in most patients, apart from the very few in whom chronic disease follows failure of resolution of clinically apparent acute hepatitis B. **The clinical and laboratory features associated with progression from acute to chronic hepatitis B are discussed in Chap. 350.**

Fatigue is a common symptom, and persistent or intermittent *jaundice* is a common feature in severe or advanced cases. Intermittent deepening of jaundice and recurrence of malaise and anorexia, as well as worsening fatigue, are reminiscent of acute hepatitis; such exacerbations may occur spontaneously, often coinciding with evidence of virologic reactivation; may lead to progressive liver injury; and, when superimposed on well-established cirrhosis, may cause hepatic decompensation. Complications of cirrhosis occur in end-stage chronic hepatitis and include ascites, edema, bleeding gastroesophageal varices, hepatic encephalopathy, coagulopathy, and hypersplenism. Occasionally, these complications bring the patient to initial clinical attention. Extrahepatic complications of chronic hepatitis B, similar to those seen during the prodromal phase of acute hepatitis B, are associated with tissue deposition of circulating hepatitis B antigen–antibody immune complexes. These include arthralgias and arthritis, which are common, and the rarer purpuric cutaneous lesions (leukocytoclastic vasculitis), immune-complex glomerulonephritis, and generalized vasculitis (polyarteritis nodosa) **(Chap. 375)**.

Laboratory features of chronic hepatitis B do not always distinguish adequately between histologically mild and severe hepatitis. Aminotransferase elevations tend to be modest for chronic hepatitis B but may fluctuate in the range of 100 to 1000 units. As is true for acute viral hepatitis B, ALT tends to be more elevated than AST; however, once cirrhosis is established, AST tends to exceed ALT. Levels of alkaline phosphatase activity tend to be normal or only marginally elevated. In severe cases, moderate elevations in serum bilirubin (51.3–171 μmol/L [3–10 mg/dL]) occur. Hypoalbuminemia and prolongation of the prothrombin time occur in severe or end-stage cases. Hyperglobulinemia and detectable circulating autoantibodies are distinctly absent in chronic hepatitis B (in contrast to autoimmune hepatitis). **Viral markers of chronic HBV infection are discussed in Chap. 350.**

TREATMENT

Chronic Hepatitis B

Although progression to cirrhosis is more likely in severe than in mild or moderate chronic hepatitis B, all forms of chronic hepatitis B can be progressive, and progression occurs primarily in patients with active HBV replication. Moreover, in populations of patients with chronic hepatitis B who are at risk for HCC **(Chap. 87)**, the risk is highest for those with continued, high-level HBV replication and lower for persons in whom initially high-level HBV DNA falls spontaneously over time. Therefore, management of chronic hepatitis B is directed at suppressing the level of virus replication. Although clinical trials tend to focus on clinical endpoints achieved over 1–2 years (e.g., suppression of HBV DNA to undetectable levels, loss of HBeAg/HBsAg, improvement in histology, normalization of ALT), these short-term gains translate into reductions in the risk of clinical progression, hepatic decompensation, HCC, liver transplantation, and death; regression of cirrhosis and of esophageal varices has been documented to follow long-term pharmacologic suppression of HBV replication. In addition, restoration of impaired HBV-specific T-cell function has been shown following successful suppression of HBV replication with antiviral therapy. To date, eight drugs have been approved for treatment of chronic hepatitis B: injectable interferon (IFN) α and pegylated interferon (long-acting IFN bound to polyethylene glycol, PEG [PEG IFN]) and the oral agents lamivudine, adefovir dipivoxil, entecavir, telbivudine, tenofovir disoproxil fumarate (TDF), and tenofovir alafenamide (TAF).

Antiviral therapy for hepatitis B has evolved rapidly since the mid-1990s, as has the sensitivity of tests for HBV DNA. When IFN and the first oral antiviral lamivudine were evaluated in clinical trials, HBV DNA was measured by insensitive hybridization assays with detection thresholds of 10^5–10^6 virions/mL; when subsequent treatments were studied in clinical trials, HBV DNA was measured by sensitive amplification assays (polymerase chain reaction [PCR]) with detection thresholds of 10^1–10^3 viral copies/mL or IU/mL. Recognition of these distinctions is helpful when comparing results of clinical trials that established the efficacy of these therapies (reviewed below). Of the eight approved treatments, PEG IFN, entecavir, and the two tenofovir preparations (TDF and TAF) are recommended as first-line agents, and generally, the oral agents are favored over injectable PEG IFN.

HISTORICAL, EARLY-GENERATION ANTIVIRAL AGENTS

Interferon IFN-α was the first approved therapy (1992) for chronic hepatitis B. Although it is no longer used to treat hepatitis B, standard IFN is important historically, having provided important lessons about antiviral therapy in general. For immunocompetent adults with *HBeAg-reactive chronic hepatitis B* (who tend to have high-level HBV DNA [$>10^5$–10^6 virions/mL] and histologic evidence of chronic hepatitis on liver biopsy), a 16-week course of subcutaneous IFN, 5 million units daily or 10 million units thrice weekly, resulted in a loss of HBeAg and hybridization-detectable HBV DNA (i.e., a reduction to levels below 10^5–10^6 virions/mL) in ~30% of patients, with a concomitant improvement in liver histology. Seroconversion from HBeAg to anti-HBe occurred in ~20%, and, in early trials, ~8% lost HBsAg. Successful IFN therapy and seroconversion were often accompanied by an acute hepatitis-like elevation in aminotransferase activity, postulated to result from enhanced cytolytic T-cell clearance of HBV-infected hepatocytes. Relapse after successful therapy was rare (1 or 2%). Responsiveness to IFN was higher in patients with low-level HBV DNA and substantial ALT elevations. Therapy with IFN was not effective in immunosuppressed persons, persons with neonatal acquisition of infection and minimal-to-mild ALT elevations, or patients with decompensated chronic hepatitis B (in whom such therapy was actually detrimental, sometimes precipitating decompensation, often associated with severe adverse effects). After HBeAg loss

during IFN therapy, 80% experienced eventual loss of HBsAg and ALT normalization over the ensuing decade. In addition, improved long-term and complication-free survival as well as a reduction in the frequency of HCC were documented among IFN responders, supporting the conclusion that successful antiviral therapy improves the natural history of chronic hepatitis B.

Brief-duration IFN therapy in patients with *HBeAg-negative chronic hepatitis B* was disappointing, suppressing HBV replication transiently during therapy but resulting only rarely in sustained antiviral responses.

Complications of IFN therapy include systemic "flu-like" symptoms; marrow suppression; emotional lability (irritability, depression, anxiety); autoimmune reactions (especially autoimmune thyroiditis); and miscellaneous side effects such as alopecia, rashes, diarrhea, and numbness and tingling of the extremities. With the possible exception of autoimmune thyroiditis, all these side effects are reversible upon dose lowering or cessation of therapy.

Although no longer competitive with the newer generation of antivirals, IFN did represent the first successful antiviral approach, set a standard against which to measure efficacy of subsequent drugs, and demonstrated the benefit of antiviral therapy on the natural history of chronic hepatitis B. Standard IFN has been supplanted by long-acting PEG IFN (see below).

Lamivudine The first of the nucleoside analogues to be approved (in 1998) for hepatitis B, the dideoxynucleoside lamivudine inhibits reverse transcriptase activity of both HIV and HBV and is an effective agent for chronic hepatitis B; however, it is now superseded by newer, more potent, less resistance-prone agents. For a summary of its virologic, serologic, biochemical, and histologic efficacy, as well as its resistance profile, please refer to **Table 352-3**. In clinical

TABLE 352-3 Comparison of Pegylated Interferon (PEG IFN), Lamivudine, Adefovir, Entecavir, Telbivudine, and Tenofovir Therapy for Chronic Hepatitis B[a]

FEATURE	PEG IFN[b]	LAMIVUDINE	ADEFOVIR	ENTECAVIR	TELBIVUDINE	TENOFOVIR (TDF)	TENOFOVIR (TAF)
Route of administration	Subcutaneous injection (180 μg/week)	Oral (100 mg/d)	Oral (10 mg/d)	Oral (0.5 mg/d)	Oral (600 mg/d)	Oral (300 mg/d)	Oral 25 mg/d)

[a]Generally, these comparisons are based on data on each drug tested individually versus placebo in registration clinical trials; with rare exception, these comparisons are not based on head-to-head testing of these drugs. In addition, the sensitivity of HBV DNA assays increased in sensitivity over the two decades between the introduction of the earliest and latest of these approved drugs. Therefore, relative advantages and disadvantages should be interpreted cautiously. [b]Although standard interferon α administered daily or three times a week is approved as therapy for chronic hepatitis B, it has been supplanted by PEG IFN, which is administered once a week and is more effective. Standard interferon has no advantages over PEG IFN. [c]Duration of therapy in clinical efficacy trials; use in clinical practice may vary. [d]Because of a computer-generated randomization error that resulted in misallocation of drug versus placebo during the second year of clinical trial treatment, the frequency of HBeAg seroconversion beyond the first year is an estimate (Kaplan-Meier analysis) based on the small subset in whom adefovir was administered correctly. [e]7% during a year of therapy (43% at year 4) in lamivudine-resistant patients. [f]Despite its category C designation, lamivudine has an extensive pregnancy safety record in women with HIV/AIDS.

Abbreviations: ALT, alanine aminotransferase; HAI, histologic activity index; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; NA, not applicable; PEG IFN, pegylated interferon; PCR, polymerase chain reaction; Rx, therapy; yr, year; TAF, tenofovir alafenamide; TDF, tenofovir disoproxil fumarate.

trials, lamivudine therapy at daily doses of 100 mg for 48–52 weeks suppressed HBV DNA, as measured by sensitive PCR amplification assays, by a median of ~5.5 $\log_{10}$ copies/mL in HBeAg-positive chronic hepatitis B and ~4.5 $\log_{10}$ copies/mL in HBeAg-negative chronic hepatitis B (baseline HBV DNA levels are lower in HBeAg-negative than in HBeAg-positive chronic hepatitis B) and to undetectable levels in ~40% and ~70%, respectively. Lamivudine was shown to improve histology, retard hepatic fibrosis, prevent progression to cirrhosis, and, in patients with advanced fibrosis, reduce decompensation. Lamivudine was also effective in patients unlikely to respond to IFN (e.g., those with high-level HBV DNA) or in prior IFN nonresponders.

In HBeAg-positive chronic hepatitis B, lamivudine-associated HBeAg seroconversion occurred in ~20%, as was true for IFN therapy. Also similar to IFN therapy, patients with near-normal ALT activity tended not to experience HBeAg responses (despite suppression of HBV DNA), while patients with ALT levels ≥5× the upper limit of normal could expect 1-year HBeAg seroconversion rates of 50–60%. Generally, HBeAg seroconversions were confined to patients who achieved suppression of HBV DNA to $<10^4$ copies/mL (equivalent to ~10^3 IU/mL). Lamivudine-associated HBeAg responses were accompanied by a delayed posttreatment HBsAg seroconversion rate comparable to that seen after IFN. Among Western patients who experienced HBeAg responses during a year-long course of therapy and in whom the response was sustained for 4–6 months after cessation of therapy, the response was durable thereafter in the vast majority (>80%); therefore, *the achievement of an HBeAg response represented a viable stopping point in therapy for HBeAg-positive patients*. Reduced durability, however, was reported in Asian patients; therefore, to support the durability of HBeAg responses, a period of consolidation therapy of ≥6 months in Western patients and ≥1 year in Asian patients was recommended after HBeAg seroconversion (see treatment guidelines below; a full 12-month consolidation period is recommended currently for treatment extension after oral agent–induced HBeAg seroconversion). Close posttreatment monitoring was recommended to identify HBV reactivation promptly and to resume therapy. If HBeAg was unaffected by lamivudine therapy, lamivudine was continued until an HBeAg response occurred, but long-term therapy was required to suppress HBV replication and, in turn, limit liver injury; HBeAg seroconversions increased to a level of 50% after 5 years of therapy. After a cumulative course of 3 years of lamivudine therapy, necroinflammatory activity was reduced in the majority of patients, and even cirrhosis was shown to regress to precirrhotic stages in as many as three-quarters of patients.

Losses of HBsAg were few during the first year of lamivudine therapy, and this observation had been cited as an advantage of IFN-based therapy over lamivudine therapy; however, in head-to-head comparisons between standard IFN and lamivudine monotherapy, HBsAg losses were rare in both groups. Trials in which lamivudine and IFN were administered in combination failed to show a benefit of combination therapy over lamivudine monotherapy for either treatment-naïve patients or prior IFN nonresponders.

Patients with *HBeAg-negative chronic hepatitis B* (i.e., in those with precore or core-promoter HBV mutations and who lack HBeAg) cannot achieve an HBeAg response to nucleoside analogue therapy—a stopping point in HBeAg-reactive patients; almost invariably, when therapy was discontinued, reactivation was the rule. Therefore, these patients required long-term lamivudine therapy.

Clinical and laboratory side effects of lamivudine were negligible and indistinguishable from those observed in placebo recipients; however, lamivudine doses were reduced in patients with reduced creatinine clearance. During lamivudine therapy, transient ALT elevations, resembling those seen during IFN therapy and during spontaneous HBeAg-to-anti-HBe seroconversions, occurred in one-fourth of patients. These ALT elevations may result from restored cytolytic T-cell activation permitted by suppression of HBV replication. Similar ALT elevations, however, occurred at an identical frequency in placebo recipients; however, ALT elevations associated temporally with HBeAg seroconversion in clinical trials were confined to lamivudine-treated patients. When therapy was stopped after a year, two- to threefold ALT elevations occurred in 20–30% of lamivudine-treated patients, representing renewed liver-cell injury as HBV replication returned. Although these posttreatment flares were almost always transient and mild, rare severe exacerbations, especially in cirrhotic patients, were observed, mandating close and careful clinical and virologic monitoring after discontinuation of treatment. Many authorities cautioned against discontinuing therapy in patients with cirrhosis, in whom posttreatment flares could precipitate decompensation.

Long-term monotherapy with lamivudine was associated with methionine-to-valine (M204V) or methionine-to-isoleucine (M204I) mutations, primarily at amino acid 204 in the tyrosine-methionine-aspartate-aspartate (YMDD) motif of the C domain of HBV DNA polymerase, analogous to mutations that occur in HIV-infected patients treated with this drug. During a year of therapy, YMDD mutations occurred in 15–30% of patients; the frequency increased with each year of therapy, reaching 70% at year 5. Ultimately, patients with YMDD mutants experienced degradation of clinical, biochemical, and histologic responses; therefore, if treatment was begun with lamivudine monotherapy, the emergence of lamivudine resistance, reflected clinically by a breakthrough from suppressed levels of HBV DNA and ALT, was managed by adding another antiviral to which YMDD variants are sensitive (e.g., adefovir, tenofovir; see below).

Currently, lamivudine has been eclipsed by more potent antivirals that have superior resistance profiles (see below); it is no longer recommended as first-line therapy. Still, as the first successful oral antiviral agent for use in hepatitis B, lamivudine provided proof of principle that polymerase inhibitors can achieve virologic, serologic, biochemical, and histologic benefits, including retardation and reversal of fibrosis and even of cirrhosis.

Cirrhosis In addition, lamivudine was shown to be effective in the treatment of patients with decompensated hepatitis B (for whom IFN is contraindicated), in some of whom decompensation can be reversed. Moreover, among patients with cirrhosis or advanced fibrosis, lamivudine was shown to be effective in reducing the risk of progression to hepatic decompensation and, based on subsequent population studies, the risk of HCC. In the half decade following the introduction in the United States of lamivudine therapy for hepatitis B, referral of patients with HBV-associated end-stage liver disease for liver transplantation fell by ~30%, supporting further the beneficial impact of oral antiviral therapy on the natural history of chronic hepatitis B.

HIV Co-infection Because lamivudine monotherapy in persons with HIV infection can result universally in the rapid emergence of YMDD variants, testing for HIV infection was recommended for all patients with chronic hepatitis B prior to lamivudine therapy; if HIV infection was identified, lamivudine monotherapy at the HBV daily dose of 100 mg was contraindicated. These patients require treatment for both HIV and HBV with an HIV drug regimen that includes or is supplemented by at least two drugs active against HBV; antiretroviral therapy (ART) often contains two drugs with antiviral activity against HBV (e.g., tenofovir and emtricitabine), but if lamivudine was part of the regimen, the 300-mg daily dose was required (Chap. 208). The safety of lamivudine during pregnancy has not been established; however, the drug is not teratogenic in rodents and has been used safely in pregnant women with HIV infection and with HBV infection. As shown for subsequent nucleoside analogues, administration of lamivudine during the last months of pregnancy to mothers with high-level hepatitis B viremia reduced the likelihood of perinatal transmission of hepatitis B.

Adefovir Dipivoxil At an oral daily dose of 10 mg, the acyclic nucleotide analogue adefovir dipivoxil, the prodrug of adefovir (approved for hepatitis B in 2002), reduces HBV DNA by ~3.5–4 $\log_{10}$

copies/mL; i.e., it is less potent than lamivudine or any of the newer antiviral agents. For a summary of its virologic, serologic, biochemical, and histologic efficacy, as well as its resistance profile, please refer to Table 352-3. Like IFN and lamivudine, adefovir dipivoxil is more likely to achieve an HBeAg response in patients with high baseline ALT; HBeAg responses to it are highly durable and can be relied upon as a treatment stopping point, after a period of consolidation therapy; and biochemical, serologic, and virologic outcomes improve over time with continued therapy.

In HBeAg-negative chronic hepatitis B, as was true for lamivudine, because HBeAg responses—a potential stopping point—cannot be achieved, reactivation is the rule when adefovir therapy is discontinued, and indefinite, long-term therapy is required. Reported attempts to stop adefovir after 5 years were followed by a period of maintained suppression of HBV DNA and ALT; however, most such patients had persistent hepatitis B viremia, and most HBeAg-negative patients were treated indefinitely unless HBsAg loss, albeit very rare, was achieved.

Adefovir was less prone to resistance than lamivudine, and thus the primary contribution of adefovir, its effectiveness in lamivudine-resistant, YMDD-mutant HBV, led to its adoption for lamivudine-resistant hepatitis B. When lamivudine resistance occurred, adding adefovir (i.e., maintaining lamivudine to preempt the emergence of adefovir resistance) was superior to switching to adefovir.

An advantage of adefovir was its relatively favorable resistance profile; however, it was not as potent as the other approved oral agents, it did not suppress HBV DNA as rapidly or as uniformly as the others, it was the least likely of all agents to result in HBeAg seroconversion, and 20–50% of patients failed to suppress HBV DNA by 2 $\log_{10}$ ("primary nonresponders"). For these reasons, adefovir, which has been supplanted in both treatment-naïve and lamivudine-resistant patients by the more potent, less resistance-prone tenofovir (see below), is no longer recommended as first-line therapy.

Telbivudine Telbivudine, a cytosine analogue (approved in 2006), is similar in efficacy to entecavir (see below) but slightly less potent in suppressing HBV DNA (median 6.4 $\log_{10}$ reduction in HBeAg-reactive disease and a 5.2 $\log_{10}$ reduction in HBeAg-negative disease). In its registration trial, telbivudine at an oral daily dose of 600 mg suppressed HBV DNA to <300 copies/mL in 60% of HBeAg-positive and 88% of HBeAg-negative patients, reduced ALT to normal in 77% of HBeAg-positive and 74% of HBeAg-negative patients, and improved histology in 65% of HBeAg-positive and 67% of HBeAg-negative patients. Although resistance to telbivudine (M204I, not M204V, mutations) was less frequent than resistance to lamivudine at the end of 1 year, resistance mutations after 2 years of treatment occurred in up to 22%. Generally well tolerated, telbivudine was associated with a low frequency of asymptomatic creatine kinase elevations and with a very low frequency of myopathy and peripheral neuropathy; frequency of administration had to be reduced for patients with impaired creatinine clearance. Its excellent potency notwithstanding, the inferior resistance and safety profile of telbivudine limited its appeal; telbivudine is neither recommended as first-line therapy nor used widely.

CURRENT FIRST-LINE TREATMENT OPTIONS

PEGYLATED IFN After long-acting PEG IFN was shown to be effective in the treatment of hepatitis C (see below), this more convenient IFN preparation was evaluated in the treatment of chronic hepatitis B. Once-a-week PEG IFN is more effective than the more frequently administered, standard IFN, and several large-scale trials of PEG IFN versus oral lamivudine were conducted in patients with chronic hepatitis B.

In HBeAg-reactive chronic hepatitis B, two large-scale studies were done. In one study, PEG IFN-α2b (100 μg weekly for 32 weeks, then 50 μg weekly for another 20 weeks for a total of 52 weeks) was evaluated against a comparison arm of combination PEG IFN with oral lamivudine in 307 subjects. The other study involved PEG IFN-α2a (180 μg weekly for 48 weeks) in 814 primarily Asian patients, three-fourths of whom had ALT ≥2× the upper limit of normal, with comparison arms of lamivudine monotherapy and combination PEG IFN plus lamivudine. At the end of therapy (48–52 weeks) in the PEG IFN monotherapy arms, HBeAg loss occurred in ~30%, HBeAg seroconversion in 22–27%, undetectable HBV DNA (<400 copies/mL by PCR) in 10–25%, and normal ALT in 34–39%, and a mean reduction in HBV DNA of 2 $\log_{10}$ copies/mL (PEG IFN-α2b) to 4.5 $\log_{10}$ copies/mL (PEG IFN-α2a) was seen. Six months after completing PEG IFN monotherapy in these trials, HBeAg losses were present in ~35%, HBeAg seroconversion in ~30%, undetectable HBV DNA in 7–14%, and normal ALT in 32–41%, and the mean reduction in HBV DNA was 2–2.4 $\log_{10}$ copies/mL. Although the combination of PEG IFN and lamivudine was superior at the end of therapy in one or more serologic, virologic, or biochemical outcomes, neither the combination arm (in both studies) nor the lamivudine monotherapy arm (in the PEG IFN-α2a trial) demonstrated any benefit compared to the PEG IFN monotherapy arms 6 months after therapy. Moreover, HBsAg seroconversion occurred in 3–7% of PEG IFN recipients (with or without lamivudine); some of these seroconversions were identified by the end of therapy, but many were identified during the posttreatment follow-up period. The likelihood of HBeAg loss in PEG IFN–treated HBeAg-reactive patients was associated with HBV genotype A > B > C > D (shown for PEG IFN-α2b but not for PEG IFN-α2a). PEG IFN-α2a was approved in the United States for hepatitis B in 2005; PEG IFN-α2b, which is not approved for hepatitis B in the United States, is used in other countries.

Based on these results, some authorities concluded that PEG IFN monotherapy should be the first-line therapy of choice in *HBeAg-reactive chronic hepatitis B*; however, this conclusion has been challenged. Although a finite, 1-year course of PEG IFN results in a higher rate of sustained response (6 months after treatment) than is achieved with oral nucleoside/nucleotide analogue therapy, the comparison is confounded by the fact that oral agents are not discontinued at the end of 1 year. Instead, taken orally and free of side effects, therapy with oral agents is extended indefinitely or until after the occurrence of an HBeAg response. The rate of HBeAg responses after 2 years of oral-agent nucleoside analogue therapy is at least as high as, if not higher than, that achieved with PEG IFN after 1 year; favoring oral agents is the absence of injections, difficult-to-tolerate side effects, and laboratory monitoring as well as lower direct and indirect medical care costs and inconvenience. HBsAg loss with PEG IFN therapy occurs in such a small proportion of patients that subjecting everyone to PEG IFN for the marginal gain of HBsAg responses during or immediately after therapy in such a very small minority is questionable. Moreover, with the newer, more potent nucleoside analogues, the frequency of HBsAg loss during the first year of therapy nearly equals that of PEG IFN. Of course, resistance is not an issue during PEG IFN therapy, but the risk of resistance is much lower with new agents (≤1% up to 3–8 years in previously treatment-naïve, entecavir-treated patients and 0% in tenofovir-treated patients; see below). Finally, the level of HBV DNA inhibition that can be achieved with the newer agents, and even with lamivudine, exceeds that achieved with PEG IFN, in some cases by several orders of magnitude.

In *HBeAg-negative chronic hepatitis B*, the role of PEG IFN is uncertain. One trial of PEG IFN-α2a (180 μg weekly for 48 weeks vs comparison arms of lamivudine monotherapy and of combination therapy) in 564 patients showed that PEG IFN monotherapy resulted at the end of therapy in suppression of HBV DNA by a mean of 4.1 $\log_{10}$ copies/mL, undetectable HBV DNA (<400 copies/mL by PCR) in 63%, normal ALT in 38%, and loss of HBsAg in 4%. Although lamivudine monotherapy and combination lamivudine–PEG IFN therapy were both superior to PEG IFN at the end of therapy, no advantage of lamivudine monotherapy or combination therapy was apparent over PEG IFN monotherapy 6 months after therapy—suppression of HBV DNA by a mean of 2.3 $\log_{10}$ copies/mL, undetectable HBV DNA in 19%, and normal ALT in 59%. In patients

involved in this trial followed for up to 5 years, among the two-thirds followed who had been treated initially with PEG IFN, 17% maintained HBV DNA suppression to <400 copies/mL, but ALT remained normal in only 22%; HBsAg loss increased gradually to 12%. As was the case for standard IFN therapy in HBeAg-negative patients, only a small proportion maintained responsiveness after completion of PEG IFN therapy, raising questions about the relative value of a finite period of PEG IFN versus a longer course with a potent, low-resistance oral nucleoside analogue in these patients. Moreover, the value of PEG IFN for HBeAg-negative chronic hepatitis B has not been confirmed. In the only other controlled clinical trial of PEG IFN for HBeAg-negative chronic hepatitis B, the hepatitis C regimen of PEG IFN plus ribavirin was compared to PEG IFN monotherapy. In this trial, HBV DNA suppression (<400 copies/mL) occurred in only 7.5% of the two groups combined, and no study subject lost HBsAg.

Reductions in quantitative HBsAg levels have been shown to correlate with and to be predictive of responsiveness to PEG IFN in chronic hepatitis B. If HBsAg levels fail to fall within the first 12–24 weeks or to reach <20,000 IU/mL by week 24, PEG IFN therapy is unlikely to be effective and should be discontinued. (Similar observations of HBsAg levels in oral agent–treated patients are of interest but of limited clinical relevance, given the very high likelihood of virologic responses during such therapy.) While PEG IFN remains one of the recommended first-line agents for hepatitis B, subsequent-generation, injection-free, very-well-tolerated, high-barrier-to-resistance, oral agents are used much more widely.

Entecavir Entecavir, an oral cyclopentyl guanosine analogue polymerase inhibitor (approved in 2005), is a highly potent HBV antiviral and is just as well tolerated as lamivudine. In *HBeAg-positive patients*, one 709-subject clinical trial compared oral entecavir, 0.5 mg daily, with lamivudine, 100 mg daily. At 48 weeks, entecavir was superior to lamivudine in suppression of HBV DNA (mean 6.9 vs 5.5 $\log_{10}$ copies/mL), percentage with undetectable HBV DNA (<300 copies/mL by PCR; 67 vs 36%), histologic improvement (≥2-point improvement in necroinflammatory HAI score; 72 vs 62%), and normal ALT (68 vs 60%). The two treatments were indistinguishable in percentage with HBeAg loss (22 vs 20%) and seroconversion (21 vs 18%). Among patients treated with entecavir for 96 weeks, HBV DNA was undetectable cumulatively in 80% (vs 39% for lamivudine), and HBeAg seroconversions had occurred in 31% (vs 26% for lamivudine). After 3–6 years of entecavir, HBeAg seroconversions were observed in 39–44% and HBsAg loss in 5–6%. Similarly, in a 638-subject clinical trial among *HBeAg-negative patients*, at week 48, oral entecavir, 0.5 mg daily, was superior to lamivudine, 100 mg daily, in suppression of HBV DNA (mean 5.0 vs 4.5 $\log_{10}$ copies/mL) and in percentage with undetectable HBV DNA (90 vs 72%), histologic improvement (70 vs 61%), and normal ALT (78 vs 71%). No resistance mutations were encountered in previously treatment-naïve, entecavir-treated patients during 96 weeks of therapy, and in a cohort of subjects treated for up to 6 years, resistance emerged in only 1.2%. Entecavir-induced HBeAg seroconversions are as durable as those achieved with other antivirals. Its high barrier to resistance coupled with its high potency renders entecavir a first-line drug for patients with chronic hepatitis B.

Entecavir is also effective against lamivudine-resistant HBV infection. In a trial of 286 lamivudine-resistant patients, entecavir, at a higher daily dose of 1 mg, was superior to lamivudine, as measured at week 48, in achieving suppression of HBV DNA (mean 5.1 vs 0.48 $\log_{10}$ copies/mL), undetectable HBV DNA (72 vs 19%), normal ALT (61 vs 15%), HBeAg loss (10 vs 3%), and HBeAg seroconversion (8 vs 3%). In this population of lamivudine-experienced patients, however, entecavir resistance emerged in 7% at 48 weeks. Although entecavir resistance requires both a YMDD mutation and a second mutation at one of several other sites (e.g., T184A, S202G/I, or M250V), resistance to entecavir in lamivudine-resistant chronic hepatitis B was reported to increase progressively to 43% at 4 years and 57% at 6 years; therefore, entecavir is not as attractive a choice (and is not recommended, despite its approval for this indication) as adefovir was or as tenofovir is for patients with lamivudine-resistant hepatitis B.

In clinical trials, entecavir had an excellent safety profile. In addition, on-treatment and posttreatment ALT flares are relatively uncommon and relatively mild in entecavir-treated patients. Doses should be reduced for patients with reduced creatinine clearance. Entecavir does have low-level antiviral activity against HIV and, therefore, cannot be used as monotherapy to treat HBV infection in HIV/HBV co-infected persons.

Tenofovir Tenofovir disoproxil fumarate (TDF), an acyclic nucleotide analogue and potent antiretroviral agent used to treat HIV infection (approved for hepatitis B in 2008), is similar to adefovir but more potent in suppressing HBV DNA and inducing HBeAg responses; it is highly active against both wild-type and lamivudine-resistant HBV and active in patients whose response to adefovir is slow and/or limited. At an oral once-daily dose of 300 mg for 48 weeks, tenofovir suppressed HBV DNA by 6.2 $\log_{10}$ (to undetectable levels [<400 copies/mL] in 76%) in HBeAg-positive patients and by 4.6 $\log_{10}$ (to undetectable levels in 93%) in HBeAg-negative patients; reduced ALT to normal in 68% of HBeAg-positive and 76% of HBeAg-negative patients; and improved histology in 74% of HBeAg-positive and 72% of HBeAg-negative patients. In HBeAg-positive patients, HBeAg seroconversions occurred in 21% by the end of year 1, 27% by year 2, 34% by year 3, and 40% by year 5 of tenofovir treatment; HBsAg loss occurred in 3% by the end of year 1, 6% at year 2, and 10% by year 5. After 5 years of tenofovir therapy, 87% of patients experienced histologic improvement, including reduction in fibrosis score (51%) and regression of cirrhosis (74%). The 5-year safety (negligible renal toxicity, in 1%, and mild reduction in bone density, in ~0.5%) and resistance profiles (none recorded through 8 years) of tenofovir are very favorable as well; therefore, tenofovir has supplanted adefovir both as first-line therapy for chronic hepatitis B and as rescue therapy for lamivudine-resistant chronic hepatitis B. Studies of tenofovir and entecavir reviewed in 2015 showed no difference in long-term risks of renal and bone toxicity; however, among patients treated with tenofovir, instances of acute renal failure and of low blood phosphate levels have been reported. Thus, in patients receiving tenofovir, monitoring bone density is not recommended, but periodic (at least annual) monitoring for renal injury is recommended (serum creatinine and phosphate, urine glucose and protein). Frequency of tenofovir administration should be reduced for patients with impaired creatinine clearance.

Tenofovir alafenamide (TAF), a second-generation tenofovir (approved for hepatitis B in 2016), is a prodrug of tenofovir that requires activation to tenofovir in hepatocytes. This targeted delivery to hepatocytes allows a lower dose to suffice and reduces systemic exposure by 90%, thereby minimizing TDF-associated proximal tubular renal injury, its associated phosphate wasting, and the potential consequent loss of bone mineral density. The dose of TAF is 25 mg, which is equivalent in antiviral potency to 300 mg of TDF; both formulations have the same high barrier to resistance, and clinical resistance has not been encountered. Randomized, controlled, double-blind, phase 3 noninferiority trials, one in HBeAg-positive patients and the other in HBeAg-negative patients, provided the safety and efficacy data to support TAF approval.

In 873 *HBeAg-positive* patients treated for 48 weeks, TAF versus TDF achieved (1) HBV DNA reductions to <29 IU/mL in 64% versus 67%; (2) ALT normalization in 72% versus 67% (an unexplained TAF biochemical advantage confirmed in other trials); (3) HBeAg loss in 14% versus 12%; (4) HBeAg seroconversion in 10% versus 8%; and (5) a negligible loss of HBsAg in 1% versus 0.3%. Compared to TDF, TAF was associated with reduced impairment of renal function (median reduction in estimated glomerular filtration rate of –0.6 mL/min for TAF vs –5.4 mL/min for TDF) and of bone density (in hip measurements, mean reduction of –0.10% for TAF vs –1.72% for TDF; adjusted difference, 1.62%).

In the parallel trial among 426 *HBeAg-negative* patients treated for 48 weeks, reductions in HBV DNA to <29 IU/mL occurred in 94% versus 93% of individuals treated with TAF versus TDF, respectively; normalization of ALT occurred in 83% versus 75%, but no HBsAg loss occurred in either group. Similar TAF advantages in maintaining renal function and bone density were reported: reduction in median estimated glomerular filtration rate (−1.8 mL/min for TAF vs −4.8 mL/min for TDF) and in median bone density (in hip measurements, mean reduction of −0.29% for TAF vs −2.16% for TDF; adjusted percentage difference, 1.87%).

At week 96, TAF and TDF HBV DNA and ALT reductions (including the TAF advantage observed at 48 weeks) were maintained. In the original TDF group, when TDF was switched to TAF after week 96, all differences observed during the first 96 weeks (in normalization of ALT and reductions in renal function and bone density) had resolved at week 120. Resistance did not emerge to either TAF or TDF throughout the trial.

Based on these trial outcomes, TAF joined the list of recommended first-line antiviral agents for chronic hepatitis B. This drug is recommended over TDF by the American Association for the Study of Liver Diseases (AASLD) and the European Association for the Study of the Liver (EASL) for patients with reduced renal function (creatinine clearance <50 mL/min), reduced bone density, and risk factors for renal injury (including, according to EASL guidelines, decompensated cirrhosis, creatinine clearance <60 mL/min, poorly controlled hypertension or diabetes, proteinuria, active glomerulonephritis, concomitant nephrotoxic medications, or solid-organ transplantation); the EASL recommendation extends to persons >60 years, who are at increased risk of TDF nephrotoxicity. In patients with creatinine clearances <15 mL/min, neither TDF nor TAF is recommended.

A comparison of antiviral therapies for chronic hepatitis B appears in Table 352-3; their relative potencies in suppressing HBV DNA are shown in Fig. 352-1.

Combination Therapies Adding a nucleos(t)ide inhibitor to PEG IFN does not appear to improve the frequency of HBeAg response or other treatment endpoints. Although the combination of lamivudine and PEG IFN suppresses HBV DNA more profoundly during therapy than does monotherapy with either drug alone (and is much less likely to be associated with lamivudine resistance), this combination used for a year is no better than a year of PEG IFN in achieving sustained responses. To date, combinations of oral nucleoside/nucleotide agents have not achieved an enhancement in virologic, serologic, or biochemical efficacy over that achieved by the more potent of the combined drugs given individually. In a 2-year trial of combination entecavir and tenofovir versus entecavir monotherapy, for a small subgroup of patients with very high HBV DNA levels ($\geq 10^8$ IU/mL), a reduction in HBV DNA to <50 IU/mL was higher in the combination group (79 vs 62%); however, no differences in HBeAg responses or any other endpoint were observed between the combination-therapy and monotherapy groups, even in the high-HBV DNA subgroup.

In the setting of resistant virus, combinations of nucleos(t)ide inhibitors can be effective. For resistance to lamivudine or adefovir, adding a second, non-cross-resistant agent was previously the chosen approach. Whereas, initially, in clinical studies of adefovir as rescue therapy for lamivudine resistance, *adding* adefovir to lamivudine (combination therapy) was considered a better strategy than replacing lamivudine with adefovir monotherapy (to minimize ALT flares and to avoid adefovir resistance), newer antiviral therapies have altered the paradigm. According to current treatment recommendations of the AASLD and the EASL, *switching* from the resistant drug to the new drug is preferred. Because the current generation of antivirals is so potent and has such a high barrier to resistance, monotherapy with the rescue drug (e.g., tenofovir for lamivudine resistance) is as effective (as demonstrated in observational reports for up to 5 years) in maintaining viral suppression without the emergence of resistance as combination therapy with the resistant drug and the rescue drug. Generally, in patients treated initially with entecavir and tenofovir preparations, antiviral drug resistance is no longer encountered. For currently rare patients who already have acquired multidrug resistance (to both nucleoside analogues [lamivudine, entecavir, telbivudine] and nucleotide analogues [adefovir, tenofovir]), treatment with a combination of entecavir and tenofovir has been shown to be highly effective in suppressing HBV DNA and overcoming drug resistance.

In addition to the eight approved antiviral drugs for hepatitis B, emtricitabine, a fluorinated cytosine analogue very similar to lamivudine in structure, efficacy, and resistance profile, offers no advantage over lamivudine. A combination of emtricitabine and tenofovir is approved for the treatment of HIV infection and is an appealing combination therapy for hepatitis B, especially for lamivudine-resistant disease; however, neither emtricitabine nor the combination is approved for hepatitis B. Worth considering, however, in patients with chronic hepatitis B who are at high risk of human immunodeficiency virus (HIV) exposure, the combination of TDF and emtricitabine (FTC) may have a unique but complicated role. Although clinical trial data are limited, combined TDF/FTC is used often as preexposure prophylaxis (PrEP) to prevent HIV infection, with a 94% reduction in new HIV infection. Thus, in patients with chronic hepatitis B who require treatment for their hepatitis B but who also desire PrEP, TDF/FTC may be an appealing treatment option. Adherence is essential, however, because virologic and clinical reactivation of hepatitis B is common if TDF/FTC is discontinued.

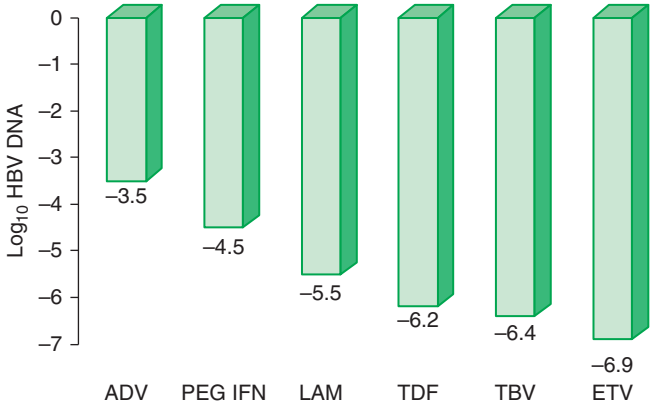

FIGURE 352-1 Relative potency of antiviral drugs for hepatitis B, as reflected by median $\log_{10}$ hepatitis B virus (HBV) DNA reduction in HBeAg-positive chronic hepatitis B. These data are from individual reports of large, randomized controlled registration trials that were the basis for approval of the drugs. In most instances, these data do not represent direct comparisons among the drugs, because study populations were different, baseline patient variables were not always uniform, and the sensitivity and dynamic range of the HBV DNA assays used in the trials varied. ADV, adefovir dipivoxil; ETV, entecavir; LAM, lamivudine; PEG IFN, pegylated interferon α2a; TBV, telbivudine; TDF, tenofovir disoproxil fumarate. Because of potency and a high barrier to resistance, ETV and tenofovir (either TDF or the second-generation tenofovir alafenamide) are recommended as first-line therapy. While PEG IFN remains a first-line agent, the oral agents developed earlier, LAM, ADV, and TBV, are no longer preferred agents.

Novel Antivirals and Strategies The current generation of well-tolerated oral antivirals has been very successful in the management of chronic hepatitis B and in altering its natural history favorably; however, most patients require long-duration, usually indefinite, therapy. Therefore, the quest continues for novel antiviral approaches that can achieve "cure" but are finite in duration. The cure of HBV infection is defined as either "functional cure," with loss of HBsAg and undetectable DNA (that are durable for at least 6 months after treatment), with or without the emergence of anti-HBs, or as "complete (sterilizing) cure," in which covalently closed circular DNA (cccDNA) is eradicated as well. Even an approach to achieving "functional cure" with finite-duration therapy, which is elusive in patients treated with nucleoside analogues, would be welcome. Currently, innovative approaches being investigated focus on

viral-targeting strategies or immunomodulatory strategies. Current virologic approaches in clinical testing include HBV entry blockers, therapies to block viral RNA translation, and HBV capsid assembly modulators. Bulevirtide, an entry inhibitor blocking the receptor for HBV on cell membranes, sodium taurocholate co-transporting polypeptide (NTCP), that decreases new cccDNA production, has been approved in the European Union for treatment of HBV/HDV co-infection (see HDV, below) but has not met with success in treating HBV mono-infection. Several therapies targeting viral RNA are under investigation. These include RNA interference (RNAi) therapies and antisense oligonucleotides (ASO). Experimental RNAi therapies tend to reduce HBsAg by ~2 $\log_{10}$ IU/mL during therapy, but ultimately, HBsAg reappears over time after therapy. An early signal of efficacy was reported for the ASO bepirovirsen, which achieved functional cure in ~10% of patients treated with six monthly injections (as monotherapy or in combination with nucleoside analogues); however, the durability of this response was degraded over ensuing follow-up, yielding a very small residual rate of functional cure. Drugs to inhibit capsid assembly have the potential to modulate cccDNA synthesis and contribute to functional cure; however, while this class of drugs reduces HBV DNA by ~2–3 $\log_{10}$ IU/mL, HBsAg levels remain unaffected. Moreover, at least one experimental drug in each of these categories of virologic inhibitors had to be abandoned for toxicity. Immunomodulators being studied have included toll-like receptor agonists (TLR7, TLR8), immune checkpoint inhibitors (programmed cell death 1 [PD-1] and programmed cell death ligand 1 [PD-L1] blockade), T-cell vaccines, and broadly neutralizing antibody approaches. While some immunomodulatory strategies have shown promise, such as one small phase 2 clinical trial in which treatment with the TLR8 agonist selgantolimod resulted in HBsAg loss in a small number, most immunomodulatory approaches have been abandoned for lack of efficacy or for toxicity (e.g., upregulation of RNA sensor retinoic acid-inducible gene I [RIG-I]). Even after more than a decade of early clinical trials, none of these treatments has yet been shown to "cure" hepatitis B, and none is likely to be competitive, unless it can be shown to go beyond current antivirals in achieving recovery (sustained HBsAg loss) from HBV infection. Whether combinations of immune modulators and direct antiviral agents will improve prospects for curative therapies remains to be seen.

TREATMENT RECOMMENDATIONS

Several learned societies and groups of expert physicians have issued treatment recommendations for patients with chronic hepatitis B; the most authoritative and updated are those of the AASLD and the EASL. Although the recommendations differ slightly, a consensus has emerged on most of the important points **(Table 352-4)**. No treatment is recommended or available for inactive "nonreplicative" hepatitis B carriers (*undetectable HBeAg* with normal ALT and HBV DNA ≤10^3 IU/mL documented serially over time). Nor is treatment recommended currently for *HBeAg-positive* chronic hepatitis B with normal ALT (labeled by some as reflecting a relatively "immune-tolerant" phase but more accurately a period of dissociation between high-level HBV replication and a paradoxical paucity of inflammatory liver injury; see **Chap. 350**, "Complications and Sequelae"); however, such patients merit careful monitoring with HBV DNA and ALT at least every 6 months. Conversely, treatment is universally recommended for any patient with compensated cirrhosis and detectable HBV DNA; in decompensated cirrhosis, treatment should be carefully considered. Treatment considerations otherwise are based on the presence or absence of HBeAg, HBV DNA levels and presence or absence of active necroinflammatory activity (as based on ALT or liver biopsy).

HBeAg Positive In patients with detectable HBeAg and HBV DNA levels >2 × 10^4 IU/mL, treatment is recommended by the AASLD for those with ALT levels >2× the upper limit of normal. (The EASL recommends treatment in HBeAg-positive patients for HBV DNA levels >2 × 10^3 IU/mL and ALT above the upper limit of normal.) For HBeAg-positive patients with ALT ≤2× the upper limit of normal, in whom sustained responses are not likely

TABLE 352-4 Recommendations for Treatment of Chronic Hepatitis B[a]

HBeAg STATUS	CLINICAL	HBV DNA (IU/mL)	ALT	RECOMMENDATION
HBeAg-reactive	[b]	>2 × 10^4	≤2 × ULN[c]	No treatment; monitor, *except* in patients >40, with family history of cirrhosis or hepatocellular carcinoma, with extrahepatic manifestations, with a history of previous treatment, and/or with liver biopsy (or noninvasive fibrosis determination) evidence for moderate to severe inflammation or fibrosis
	Chronic hepatitis	>2 × 10^4[d]	>2 × ULN[d]	Treat[d]
	Cirrhosis:			
	Cirrhosis compensated	>2 × 10^3	< or > ULN	Treat[d] with oral agents, not PEG IFN
		<2 × 10^3	>ULN	Treat[d] with oral agents, not PEG IFN; refer for liver transplantation
	Cirrhosis decompensated	Detectable	< or > ULN	Observe; refer for liver transplantation
		Undetectable	< or > ULN	
HBeAg-negative	[b]	≤2 × 10^3	≤ULN	Inactive carrier; treatment not necessary
	Chronic hepatitis	>2 × 10^3	1 to >2 × ULN[d]	No treatment; monitor, except in patients >40, with family history of cirrhosis or hepatocellular carcinoma, with extrahepatic manifestations, with a history of previous treatment, and/or with liver biopsy (or noninvasive fibrosis determination) evidence for moderate to severe inflammation or fibrosis
	Chronic hepatitis	>2 × 10^3	>2 × ULN[d]	Treat[e,f]
	Cirrhosis:			
	Cirrhosis compensated	>2 × 10^3	< or > ULN	Treat[d] with oral agents, not PEG IFN
		<2 × 10^3	>ULN	Treatment suggested[f]
	Cirrhosis decompensated	Detectable	< or > ULN	Treat[d] with oral agents[g], not PEG IFN; refer for liver transplantation
		Undetectable	< or > ULN	Observe; refer for liver transplantation

[a]Based on practice guidelines of the American Association for the Study of Liver Diseases (AASLD). Except as indicated in footnotes, these guidelines are similar to those issued by the European Association for the Study of the Liver (EASL). [b]Liver disease tends to be mild or inactive clinically; most such patients do not undergo liver biopsy. [c]According to the EASL guidelines, treat if HBV DNA is >2 × 10^3 IU/mL and ALT >ULN. [d]One of the potent oral drugs with a high barrier to resistance (entecavir or tenofovir) or PEG IFN can be used as first-line therapy (see text for further detail). [e]Because HBeAg seroconversion is not an option, the goal of therapy is to suppress HBV DNA and maintain a normal ALT. PEG IFN is administered by subcutaneous injection weekly for a year; caution is warranted in relying on a 6-month posttreatment interval to define a sustained response, because the majority of such responses are lost thereafter. Oral agents, entecavir or tenofovir, are administered daily, usually indefinitely or until, as very rarely occurs, virologic and biochemical responses are accompanied by HBsAg seroconversion. [f]For older patients and those with advanced fibrosis, consider lowering the HBV DNA threshold to >2 × 10^3 IU/mL.

Abbreviations: ALT, alanine aminotransferase; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; PEG IFN, pegylated interferon; ULN, upper limit of normal.

and who would require multiyear therapy, antiviral therapy is not recommended currently. As noted above, these untreated patients (as well as patients with HBV DNA between 2×10^3 and 2×10^4 IU/mL) merit continued monitoring with HBV DNA and ALT every 3–6 months. Even in these groups (in the "gray zone"), however, therapy would be considered for patients >40 years of age, with extrahepatic manifestations of HBV infection, or with a family history of cirrhosis or HCC; patients whose liver biopsy or noninvasive testing shows moderate to severe necroinflammatory activity or fibrosis; or patients with a history of previous treatment. In HBeAg-positive patients, treatment may be discontinued after HBeAg loss. In a 2016 systematic review of 1716 patients involved in 25 clinical trials, responses after oral-agent therapy were found to be durable. Among patients with HBeAg-reactive chronic hepatitis B, the pooled rates of durable HBeAg seroconversions maintained after cessation of nucleoside/nucleotide analogue therapy (including all the oral agents) were 92 and 88% at posttreatment months 12 and 24, respectively, unaffected by the duration of post-HBeAg-response consolidation therapy (>6 months in all studies evaluated); the pooled rate of durable biochemical remission after therapy in this population was 76%. Thus, per current AASLD recommendations, antiviral treatment with oral agents can be stopped after HBeAg loss/seroconversion in noncirrhotics, and the suggested period of consolidation therapy is 12 months with close monitoring for recurrent viremia (monthly × 6, then every 3 months for the rest of a year) after cessation of therapy.

HBeAg Negative For patients with HBeAg-negative chronic hepatitis B, antiviral therapy is recommended if ALT is >2× the upper limit of normal (above the upper limit of normal according to EASL) and HBV DNA is $>2 \times 10^3$ IU/mL. If HBV DNA is $>2 \times 10^3$ IU/mL and ALT is 1 to >2× the upper limit of normal, the same considerations apply as for HBeAg-positive patients with borderline ALT levels (the "gray zone") for patients >40 years of age, with extrahepatic manifestations of HBV infection, or with a family history of cirrhosis or HCC; patients whose liver biopsy or noninvasive testing shows moderate to severe necroinflammatory activity or fibrosis; or patients with a history of previous treatment. This group also merits continued careful monitoring with HBV DNA and ALT every 3–6 months. For patients with HBeAg-negative chronic hepatitis, the current recommendation with oral agents is for indefinite therapy; stopping therapy in this group can be considered after HBsAg loss, which remains exceedingly rare.

The potential for stopping antiviral therapy in noncirrhotic HBeAg-negative patients after protracted (≥2–5 years) antiviral therapy has been the subject of several studies After such prolonged courses of entecavir or tenofovir, in one small, 57-patient study (DARING-B), 18-month virologic relapse rates (HBV DNA >2000 IU/mL) were high (in 72%); however, 25% of study subjects underwent HBsAg loss after 18 months of follow-up. In a similar study (FINITE), virologic relapse rates were high, but 62% did not meet criteria for retreatment, and 19% lost HBsAg. In contrast, in a study among Asian patients, only ~30% had sustained responses for which resumption of therapy was not introduced, and HBsAg responses were negligible. In the only randomized, controlled trial of stopping therapy versus continuing therapy in HBeAg-negative patients after prolonged antiviral therapy (Toronto STOP study), only 33% had sustained responses after cessation of therapy, and HBsAg loss occurred with equal, small frequencies in both the stop-treatment group (4%) and the continue-treatment group (5%). Most recently, in a large 1552-subject, international cohort study (RETRACT B), treatment cessation in HBeAg-negative patients without cirrhosis was followed by virologic relapse rates of 68.9% at 12 months and 83.4% at 48 months. Relapse requiring retreatment occurred in 29.8% of subjects at 12 months and 54.7% at 48 months. Similar to prior studies, HBsAg loss was observed in 3.2% of subjects at 12 months and increased to 13% at 48 months. Predictors of HBsAg loss were identified, which may offer guidance to determine which patients may benefit from stopping nucleos(t)ide analogue therapy. In this study, the most important predictor of HBsAg loss was quantitative HBsAg level at the time therapy was discontinued (at posttreatment year 4, in Caucasian patients with HBsAg <1000 IU/mL, 41% had lost HBsAg, and in Asian patients with HBsAg <100 IU/mL, 33% had lost HBsAg). At present, however, quantitative HBsAg determination is not routinely available in clinical care. Generally, then, although HBsAg loss can be achieved in a small fraction, and although a subgroup may not require reintroduction of therapy in the short run, enthusiasm for this approach is limited, and for most HBeAg-negative patients, recommendations support indefinite treatment, unless they experience HBsAg loss.

For patients with compensated cirrhosis, because antiviral therapy has been shown to retard clinical progression, treatment is recommended regardless of HBeAg status and ALT as long as HBV DNA is detectable. In addition, stopping therapy in patients with cirrhosis comes with the risk of decompensation. For patients with decompensated cirrhosis, treatment is recommended regardless of serologic and biochemical status, as long as HBV DNA is detectable. In addition, patients with decompensated cirrhosis should be evaluated as candidates for liver transplantation. Cirrhotics should be treated indefinitely (see considerations for stopping antiviral therapy in noncirrhotics, above).

Choice of Treatment Agent Among the eight available drugs for hepatitis B, PEG IFN has supplanted standard IFN, entecavir has supplanted lamivudine, and tenofovir has supplanted adefovir **(Table 352-5)**. PEG IFN, entecavir, or tenofovir (TDF or TAF) is recommended as first-line therapy (Table 352-3). PEG IFN requires finite-duration therapy, achieves the highest rate of HBeAg

TABLE 352-5 Pegylated Interferon Versus Oral Nucleoside Analogues for the Treatment of Chronic Hepatitis B

	PEG IFN	NUCLEOSIDE ANALOGUES
Administration	Weekly injection	Daily, orally
Tolerability	Poorly tolerated, intensive monitoring	Well tolerated, limited monitoring
Duration of therapy	Finite, 48 weeks	≥1 year, indefinite in most patients
Maximum mean HBV DNA suppression	4.5 $\log_{10}$	6.9 $\log_{10}$
Effective in high-level HBV DNA (≥10^9 IU/mL)	No	Yes
HBeAg seroconversion		
During 1 year of therapy	~30%	~20%
During >1 year of therapy	Not applicable	30% (year 2) to up to 50% (year 5)
HBeAg-negative posttreatment HBV DNA suppression	17% at 5 years	7% at 4 years (lamivudine)
HBsAg loss		
During 1 year of therapy	3–4%	0–3%
During >1 year of therapy	Not applicable	3–8% at 5 years of therapy
After 1 year of therapy–HBeAg-negative	12% at 5 years	3.5% at 5 years
Antiviral resistance	None	Lamivudine: ~30% year 1, ~70% year 5 Adefovir: 0% year 1, ~30% year 5 Telbivudine: up to 4% year 1, 22% year 2 Entecavir: ≤1.2% through year 6 Tenofovir: 0% through year 8
Use in cirrhosis, transplantation, immunosuppressed	No	Yes
Cost, 1 year of therapy	++++	+ to ++

Abbreviations: HBV, hepatitis B virus; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; PEG IFN, pegylated interferon.

responses after a year of therapy, and does not support viral mutations, but it requires subcutaneous injections and is associated with inconvenience, more intensive clinical and laboratory monitoring, and intolerability. Oral agents do not require injections or cumbersome laboratory monitoring, are very well tolerated, lead to improved histology in 50–90% of patients, suppress HBV DNA more profoundly than PEG IFN, and are effective even in patients who fail to respond to IFN-based therapy. Although oral agents are less likely to result in HBeAg responses during the first year of therapy, as compared to PEG IFN, treatment with oral agents is usually extended beyond the first year and, by the end of the second year (of the current-generation, potent, high-barrier-to-resistance agents entecavir and tenofovir), yields HBeAg responses (and even HBsAg responses) comparable in frequency to those achieved after 1 year of PEG IFN (and without the associated side effects). Choice of agent should be based on clinical features, any history of prior treatment, and patient and physician preference; availability, relative cost, and insurance coverage often also play a role. As noted above, some physicians prefer to begin with PEG IFN, while most physicians and patients prefer oral agents as first-line therapy. Between the two first-line oral agents, entecavir and tenofovir, data to support the choice of one compared to the other are limited. Several observational studies have suggested that TDF is superior to entecavir in reducing the risk of HCC. Such studies, however, sophisticated statistical analyses notwithstanding, are subject to confounding influences that could favor TDF (e.g., physician preference for TDF in milder disease and for entecavir in more severe disease, including in older patients and those with impaired renal function). In addition, while several studies confirm a differential effect of TDF on long-term HCC risk, many others do not, and, in most cases, adjusting for such factors as age, sex, country, albumin, platelets, AFP, cirrhosis, and diabetes, eliminated the benefit of TDF over entecavir. Therefore, currently, the preponderance of data are insufficient to support this benefit of TDF over entecavir. Between TDF and TAF, TAF is preferred in patients with creatinine clearance <50 mL/min, reduced bone density, and risk factors for renal injury (e.g., decompensated cirrhosis, creatinine clearance <60 mL/min, poorly controlled hypertension or diabetes, proteinuria, active glomerulonephritis, concomitant nephrotoxic medications, or solid-organ transplantation). As noted above, the EASL recommendation for TAF extends to persons >60 years, who are at increased risk of TDF nephrotoxicity.

POPULATIONS WITH UNIQUE TREATMENT CONSIDERATIONS

Pregnancy Substantial experience with lamivudine during pregnancy (see above) has identified no teratogenicity; although widely used during pregnancy, lamivudine remains classified as pregnancy category C. Although IFNs do not appear to cause congenital anomalies, these have antiproliferative properties and should be avoided during pregnancy. Adefovir during pregnancy has not been associated with birth defects; however, the risk of spontaneous abortion may be increased, and adefovir is categorized as pregnancy category C. Data on the safety of entecavir during pregnancy have not been published (pregnancy category C). Sufficient data in animals and limited data in humans suggest that telbivudine and tenofovir (both pregnancy category B) can be used safely during pregnancy; however, telbivudine is not an acceptable first-line drug. In general, then, except for lamivudine and tenofovir, and until additional data become available, the other antivirals for hepatitis B should be avoided or used with extreme caution during pregnancy. Tenofovir is the current drug of choice in pregnancy.

Children For children aged 2 to <18 years old with HBeAg-positive hepatitis B (most children will be HBeAg-positive; children with HBeAg-negative chronic hepatitis B have not been well represented in treatment studies), treatment is recommended if HBV DNA is detectable and ALT levels are elevated, but not if ALT levels are normal. Each of the available first-line drugs is approved for different childhood age groups (PEG IFN α2a age ≥5 years [approved for hepatitis C, not B, but can be used in hepatitis B]; entecavir and tenofovir age ≥2 years). Package inserts should be consulted for childhood doses.

HIV Co-infection Patients with HBV-HIV co-infection can have progressive HBV-associated liver disease and, occasionally, a severe exacerbation of hepatitis B resulting from immunologic reconstitution following antiretroviral therapy. Tenofovir and the combination of tenofovir and emtricitabine in one pill are approved therapies for HIV and represent excellent choices for treating HBV infection in HBV-HIV co-infected patients. Generally, even for HBV-HIV co-infected patients who do not yet meet treatment criteria for HIV infection, treating for both HBV and HIV is recommended. In HIV-HBV co-infection, TAF, because of its better safety profile, is preferable to TDF.

Cirrhosis For patients with compensated or decompensated cirrhosis, PEG IFN should not be used; the emergence of such life-threatening side effects as sepsis can result in further deterioration and loss of antiviral effectiveness. Therefore, in this patient subset, therapy with a very favorable resistance profile (e.g., entecavir or tenofovir) is the preferred treatment. For patients with end-stage chronic hepatitis B who undergo liver transplantation, reinfection of the new liver is almost universal in the absence of antiviral therapy. The majority of patients become high-level viremic carriers with minimal liver injury. Before the availability of antiviral therapy, an unpredictable proportion experienced severe hepatitis B-related liver injury, sometimes a fulminant-like hepatitis and sometimes a rapid recapitulation of the original severe chronic hepatitis B **(Chap. 350)**. Currently, however, prevention of recurrent hepatitis B after liver transplantation has been achieved definitively by *combining* short-term (5–7 days) intravenous hepatitis B immune globulin (HBIG) with lifelong low-resistance oral entecavir or TDF or TAF **(Chap. 356)**; in some patients, especially those with a low risk for recurrence, the newer, more potent, and less resistance-prone oral agents may be used instead of HBIG for posttransplantation therapy. For patients at high risk for recurrence and progressive disease (e.g., patients with HDV-HBV or HIV-HBV co-infections) as well as for nonadherent patients, lifelong combination HBIG-oral agent therapy should be considered. For patients receiving livers from anti-HBc-positive donors, lifelong oral-agent therapy is recommended (without HBIG).

Immunosuppression Patients with chronic hepatitis B who undergo cytotoxic chemotherapy for treatment of malignancies as well as patients treated with immunosuppressive, anticytokine, or anti–tumor necrosis factor (TNF) therapies experience enhanced HBV replication and viral expression on hepatocyte membranes during chemotherapy coupled with suppression of cellular immunity. When chemotherapy is withdrawn, such patients are at risk for reactivation of hepatitis B, often severe and occasionally fatal. Such rebound reactivation represents restoration of cytolytic T-cell function against a target organ enriched in HBV expression. Preemptive treatment with the first of the oral HBV antivirals, lamivudine, prior to the initiation of chemotherapy was shown to reduce the risk of such reactivation substantially; treating *after* reactivation has occurred is less effective. The newer, more potent oral antiviral agents, entecavir and tenofovir, which are even more effective in preventing hepatitis B reactivation and with a lower risk of antiviral drug resistance, are preferred.

The risk of HBV reactivation and liver injury varies from highest (e.g., B cell–depleting agents, anthracycline derivatives, moderate-/high-dose corticosteroids for ≥4 weeks) to moderate (e.g., TNF-α inhibitors, cytokine or integrin inhibitors, tyrosine kinase inhibitors, low-dose corticosteroids for ≥4 weeks) to lowest (e.g., immunosuppressive agents like methotrexate and azathioprine, intraarticular corticosteroids, any dose of corticosteroids for ≤1 week). Most authorities (e.g., Centers for Disease Control and Prevention, AASLD, American Gastroenterological Association, EASL) recommend HBsAg and anti-HBc (± anti-HBs) screening of all patients prior to initiation of chemotherapy or other

long-term immunosuppressive regimens. Preemptive antiviral prophylaxis is recommended for any patient with detectable HBsAg, given the high risk of reactivation (which can occur in ~25% of cases but potentially in up to 68%). While, generally, reactivation in HBsAg-negative but anti-HBc-reactive patients is rare, in this population, careful monitoring is recommended, except in the setting of B cell–depleting therapies, which are associated with a high risk for reactivation. Thus, antiviral prophylaxis is recommended in HBsAg-negative/anti-HBc-positive patients undergoing B-cell depletion therapy or stem cell transplantation.

The optimal duration of antiviral therapy after completion of chemotherapy is not known, but a suggested approach is 6 months (12 months for B cell–depleting agents) for inactive hepatitis B carriers and longer-duration therapy in patients with baseline HBV DNA levels >2 × 10^3 IU/mL, until standard clinical endpoints are met (Table 352-4).

CHRONIC HEPATITIS D (DELTA HEPATITIS)

Chronic hepatitis D virus (HDV) infection is most commonly observed in patients who were exposed to HDV while already harboring chronic HBV infection (so-called superinfection). Chronic HDV infection may also follow acute co-infection with HBV and HDV but at a rate no higher than the rate of chronicity of acute hepatitis B. That is, although HDV co-infection can increase the severity of acute hepatitis B, HDV does not increase the likelihood of progression to chronic hepatitis B. When, however, HDV superinfection occurs in a person who is already chronically infected with HBV, long-term HDV infection is the rule, and a worsening of the liver disease is the expected consequence. Except for severity, chronic hepatitis B plus D has similar clinical and laboratory features to those seen in chronic hepatitis B alone. Relatively severe and progressive chronic hepatitis, with or without cirrhosis, is the rule, and mild chronic hepatitis is the exception. Occasionally, however, mild hepatitis or even, rarely, inactive carriage occurs in patients with chronic hepatitis B plus D, and the disease may become indolent after several years of infection. **The clinical and laboratory features of chronic HDV infection are summarized in Chap. 350.**

TREATMENT

Chronic Hepatitis D

Management is not well defined, and the host cellular RNA polymerase upon which HDV replication depends cannot be targeted by conventional antiviral agents. Treatment with type I interferons is the only approved treatment for chronic HDV infection, although, per expert opinion, treating underlying HBV infection is suggested as well if the HBV DNA level is >2 × 10^3 IU/mL. Preliminary experimental trials of IFN-α suggested that conventional doses and durations of therapy lower levels of HDV RNA and aminotransferase activity only transiently during treatment but have no impact on the natural history of the disease. In contrast, *high-dose* IFN-α (9 million units three times a week) for 12 months was reported to be associated with a sustained loss of HDV replication and clinical improvement in up to 50% of patients. Furthermore, a substantial improvement in 12-year survival after liver transplantation was observed in patients with hepatitis D who received high-dose IFN-α (86 vs 31% with standard-dose IFN-α). A suggested approach to therapy has been high-dose, long-term IFN for at least a year and, in responders, extension of therapy until HDV RNA and HBsAg clearance; however, extension of therapy to a second year provided no advantage, and sustained responses after completion of therapy have been rare. Compared to standard IFN-α, PEG IFN has been shown to be more effective in chronic hepatitis D but still of limited therapeutic value; after 48 weeks of therapy, durable undetectable HDV RNA for 24 posttreatment weeks has been reported in a quarter to just over a half of patients. Disappointingly, loss of virologic responses (reappearance of HDV RNA) was observed during long-term (median 4.5 years) monitoring in a majority of 24-week-posttreatment responders, with durable HDV RNA suppression to undetectable in only 12%. None of the nucleoside analogue antiviral agents for hepatitis B are effective in hepatitis D, and adding ribavirin or oral nucleoside agents (lamivudine and, more recently, adefovir and tenofovir) to PEG IFN was not found to be more effective than PEG IFN monotherapy. While recommended, 12 months of PEG IFN therapy is far from satisfactory. The lackluster response to type I interferon treatment with or without nucleoside agents highlights the need for novel therapies to target HDV infection.

The approach farthest along in clinical testing is the entry inhibitor bulevirtide, a lipopeptide that blocks the NTCP receptor, preventing hepatocyte entry of both HBV and HDV. In phase 2 studies of subcutaneous bulevirtide alone or combined with PEG IFN for varying treatment durations, a significant reduction occurred in HDV RNA in >71% of subjects, with a more pronounced effect in combination therapy. Similarly, a phase 2 study of bulevirtide combined with tenofovir (vs tenofovir monotherapy) for 24 weeks demonstrated significant reductions in HDV RNA at the end of treatment (50–77% vs 4% with tenofovir alone), but rebound of viremia was universal at follow-up week 48. Most recently, in an ongoing phase 3 clinical trial, ALT normalized in 51–56% of patients receiving bulevirtide after 48 weeks of treatment, and 45–48% of patients had a ≥2 $\log_{10}$ reduction in or undetectable HDV RNA; this treatment effect was maintained though 96 weeks of treatment. In 2020, bulevirtide was authorized conditionally by the European Medicines Agency for the treatment of HDV with or without PEG IFN or nucleoside analogues. Review by the U.S. Food and Drug Administration (FDA) is anticipated.

Preliminary trials have also been performed with lonafarnib, a prenylation inhibitor, which is combined with ritonavir to improve bioavailability. Prenylation, the posttranslational covalent addition of the prenyl lipid farnesyl to large HDV antigen, is required for this HDV protein to interact and form secreted viral particles with HBsAg. Phase 2 studies of lonafarnib/ritonavir have demonstrated significant, on-treatment reductions in HDV RNA, and in one study, the addition of IFNα increased the likelihood of achieving a viral response to 89%. Additional experimental approaches to the treatment of hepatitis D include nucleic acid polymer therapy, often combined with PEG IFNα. Nucleic acid polymer therapy is thought to inhibit HBsAg release and has been administered alone or with PEG IFN; to date, these studies have been done in one Eastern European site. While promising reductions in HDV RNA and HBsAg have been reported, these studies have been plagued by adverse effects, and confirmatory studies have not materialized.

In patients with end-stage liver disease secondary to chronic hepatitis D, liver transplantation has been effective. If hepatitis D recurs in the new liver without the expression of hepatitis B (an unusual serologic profile in immunocompetent persons but common in transplant patients), liver injury is limited. In fact, the outcome of transplantation for chronic hepatitis D is superior to that for chronic hepatitis B; in such patients, combination HBIG and nucleoside analogue therapy for hepatitis B is indicated **(Chap. 356)**.

CHRONIC HEPATITIS C

Regardless of the epidemiologic mode of acquisition of hepatitis C virus (HCV) infection, chronic hepatitis follows acute hepatitis C in 50–70% of cases; chronic infection is common even in those with a return to normal in aminotransferase levels after acute hepatitis C, adding up to an 85% likelihood of chronic HCV infection after acute hepatitis C. Few clues had emerged to explain host differences associated with chronic infection until recently, when variation in a single nucleotide polymorphism (SNP) on chromosome 19, *IL28B* (which codes for IFN-λ3, now renamed *IFNL3*), was identified that distinguished between responders and nonresponders to IFN-based antiviral therapy (see below). The same variants correlated with spontaneous resolution after acute infection: 53% in genotype C/C, 30% in genotype C/T, but only 23% in genotype T/T. The association with HCV clearance after acute infection is even stronger when *IL28B* (*IFNL3*)

haplotype is combined with haplotype G/G of an SNP near human leukocyte antigen (HLA) class II *DBQ1∗03:01*.

In patients with chronic hepatitis C followed for 20 years, progression to cirrhosis occurs in ~20–25%. Such is the case even for patients with relatively clinically mild chronic hepatitis, including those without symptoms, with only modest elevations of aminotransferase activity, and with mild chronic hepatitis on liver biopsy. Even in cohorts of well-compensated patients with chronic hepatitis C referred for clinical research trials (no complications of chronic liver disease and with normal hepatic synthetic function), the prevalence of cirrhosis may be as high as 50%. Most cases of hepatitis C are identified initially in asymptomatic patients who have no history of acute hepatitis C (e.g., those discovered while attempting to donate blood, while undergoing lab testing as part of an application for life insurance, or as a result of routine laboratory tests). The source of HCV infection in many of these cases is not defined, although a long-forgotten percutaneous exposure (e.g., injection drug use) in the remote past can be elicited in a substantial proportion and probably accounts for most infections; most of these infections were acquired in the 1960s and 1970s among persons in the 1945–1965 birth cohort **(Chap. 350)**, coming to clinical attention decades later.

Approximately one-third of patients with chronic hepatitis C have normal or near-normal aminotransferase activity; although one-third to one-half of these patients have chronic hepatitis on liver biopsy, the grade of liver injury and stage of fibrosis tend to be mild in the vast majority. In some cases, more severe liver injury has been reported—even, rarely, cirrhosis, most likely the result of previous histologic activity. Among patients with persistent normal aminotransferase activity sustained over ≥5–10 years, histologic progression has been shown to be rare; however, approximately one-fourth of patients with normal aminotransferase activity experience subsequent aminotransferase elevations, and histologic injury can be progressive once abnormal biochemical activity resumes. Therefore, continued clinical monitoring and antiviral therapy are indicated, even for patients with normal aminotransferase activity.

Despite this substantial rate of progression of chronic hepatitis C and even though liver failure can result from end-stage chronic hepatitis C, the long-term prognosis over 1–2 decades for chronic hepatitis C in most patients is relatively benign. Mortality over 10–20 years among patients with transfusion-associated chronic hepatitis C has been shown not to differ from mortality in a matched population of transfused patients in whom hepatitis C did not develop. Although death in the hepatitis group is more likely to result from liver failure and although hepatic decompensation may occur in ~15% of such patients over the course of a decade, the majority (almost 60%) of patients remain asymptomatic and well compensated, with no clinical sequelae of chronic liver disease. Overall, chronic hepatitis C tends to be very slowly and insidiously progressive, if at all, in most patients, whereas in approximately one-fourth of cases, chronic hepatitis C will progress eventually to end-stage cirrhosis. In fact, because HCV infection is so prevalent, and because a proportion of patients progress inexorably to end-stage liver disease, hepatitis C was the most frequent indication for liver transplantation **(Chap. 356)** in the era prior to the availability of direct-acting antiviral (DAA) therapy (see below). In the United States, hepatitis C accounts for up to 40% of all chronic liver disease; as of 2007, mortality caused by hepatitis C surpassed that associated with HIV/AIDS, and as of 2012, reported deaths caused by hepatitis C surpassed those associated with all other notifiable infectious diseases (HIV, tuberculosis, hepatitis B, and 57 other infectious diseases). Moreover, because the prevalence of HCV infection is so much higher in the "baby boomer" cohort born between 1945 and 1965, three-quarters of the mortality associated with hepatitis C occurs in this age cohort. In a 2010 modeling study based on the prevalence of HCV infection and its known natural history, liver disease mortality associated with hepatitis C was *projected* to peak in the year 2022; however, the *observed* HCV-related mortality in the United States peaked in 2013 and has fallen since, paralleling the introduction in 2013 of highly effective DAA agents (see below). The declining death rates related to HCV infection following the wide use of DAAs have been observed across most of the United States.

Progression of liver disease in patients with chronic hepatitis C has been reported to be more likely in patients with older age, longer duration of infection, advanced histologic stage and grade, more complex HCV quasispecies diversity, increased hepatic iron, concomitant other liver disorders (alcoholic liver disease, chronic hepatitis B, hemochromatosis, α_1 antitrypsin deficiency, and steatohepatitis), HIV infection, and obesity. Among these variables, however, duration of infection appears to be one of the most important, and some of the others probably reflect disease duration to some extent (e.g., quasispecies diversity, hepatic iron accumulation). No other epidemiologic or clinical features of chronic hepatitis C (e.g., severity of acute hepatitis, level of aminotransferase activity, level of HCV RNA, presence or absence of jaundice during acute hepatitis) are predictive of eventual outcome. Despite the relatively benign nature of chronic hepatitis C over time in many patients, cirrhosis following chronic hepatitis C has been associated with the late development, after several decades, of HCC **(Chap. 87)**; the annual rate of HCC in cirrhotic patients with hepatitis C is 1–4%, occurring primarily in patients who have had HCV infection for 30 years or more.

Referral bias may account for the more severe outcomes described in cohorts of patients reported from tertiary care centers (20-year progression of ≥20%) versus the more benign outcomes in cohorts of patients monitored from initial blood-product-associated acute hepatitis or identified in community settings (20-year progression of only 4–7%). Still unexplained, however, are the wide ranges in reported progression to cirrhosis, from 2% over 17 years (eventually 19% over 36 years) in a population of Irish women with hepatitis C infection acquired from contaminated anti-D immune globulin to 30% over ≤11 years in recipients of contaminated intravenous immune globulin.

Perhaps the best prognostic indicator in chronic hepatitis C is liver histology; the rate of hepatic fibrosis may be slow, moderate, or rapid. Patients with mild necrosis and inflammation as well as those with limited fibrosis have an excellent prognosis and limited progression to cirrhosis. In contrast, among patients with moderate to severe necroinflammatory activity or fibrosis, including septal or bridging fibrosis, progression to cirrhosis is highly likely over the course of 10–20 years. Among patients with compensated cirrhosis associated with hepatitis C, the 10-year survival rate is close to 80%; mortality occurs at a rate of 2–6% per year; decompensation at a rate of 4–5% per year; and, as noted above, HCC at a rate of 1–4% per year. Estimates of the natural history of chronic hepatitis C have been made, based on data available on the prevalence of HCV infection in the U.S. population and on the rate of disease progression. Weighted primarily by the concentration of chronic hepatitis C in the baby boomer generation, the peak prevalence was estimated to have occurred in 2015. The calculated frequency of cirrhosis in U.S. patients with hepatitis C was 5% in 1990 and 25% in 2010 and was projected to be 37% in 2020. **A discussion of the pathogenesis of liver injury in patients with chronic hepatitis C appears in Chap. 350.**

Clinical features of chronic hepatitis C are similar to those described above for chronic hepatitis B. Generally, fatigue is the most common symptom; jaundice is rare. Immune complex–mediated extrahepatic complications of chronic hepatitis C are less common than in chronic hepatitis B (despite the fact that assays for immune complexes are often positive in patients with chronic hepatitis C), with the exception of essential mixed cryoglobulinemia **(Chap. 350)**, which is linked to cutaneous vasculitis and membranoproliferative glomerulonephritis as well as lymphoproliferative disorders such as B-cell lymphoma and unexplained monoclonal gammopathy. In addition, chronic hepatitis C has been associated with extrahepatic complications unrelated to immune-complex injury. These include Sjögren's syndrome, lichen planus, porphyria cutanea tarda, renal injury, type 2 diabetes mellitus, and the metabolic syndrome (including insulin resistance and steatohepatitis). In addition, a link has been observed between HCV infection and cardiovascular/cerebrovascular disease, rheumatologic/immunologic disorders, mental health and cognitive disorders, and nonliver malignancies.

Laboratory features of chronic hepatitis C are similar to those in patients with chronic hepatitis B, but aminotransferase levels tend to

fluctuate more (the characteristic episodic pattern of aminotransferase activity) and to be lower, especially in patients with long-standing disease. An interesting and occasionally confusing finding in patients with chronic hepatitis C is the presence of autoantibodies. Rarely, patients with autoimmune hepatitis (see below) and hyperglobulinemia have false-positive immunoassays for anti-HCV. On the other hand, some patients with serologically confirmable chronic hepatitis C have circulating anti-LKM. These antibodies are anti-LKM1, as seen in patients with autoimmune hepatitis type 2 (see below), and are directed against a 33-amino-acid sequence of cytochrome P450 IID6.

Histopathologic features of chronic hepatitis C, especially those that distinguish hepatitis C from hepatitis B, are described in Chap. 350.

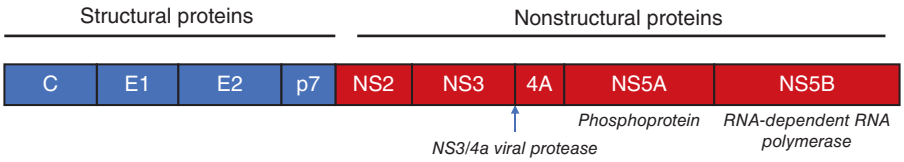
TREATMENT

Chronic Hepatitis C

Therapy for chronic hepatitis C has evolved substantially in the 30 years since IFN-α was introduced for this indication in 1991. The therapeutic armamentarium grew to include PEG IFN with ribavirin and, then, in 2011, the introduction of the first protease inhibitors, telaprevir and boceprevir, used in combination with PEG IFN and ribavirin in patients with HCV genotype 1. The field of antiviral therapy for hepatitis C was transformed beginning in 2013, with the approval of the first nucleoside analogue polymerase inhibitor sofosbuvir. Although several of these combination regimens have been supplanted by better, later-generation drugs, as of 2020, five all-oral, highly effective (>95%), low-resistance, pangenotypic, well-tolerated, short-duration (primarily 8–12 weeks) combination regimens of DAA drugs are recommended. The remarkable historical evolution of antiviral therapy for hepatitis C is instructive.

THE INTERFERON ERA (1991–2011)

IFN-based therapy has been supplanted by DAA agents introduced in the second decade of the twenty-first century; however, many important lessons about antiviral therapy for chronic hepatitis C were learned from the experience with IFN-based treatment, and many of the limitations of—and disparities in responsiveness to—IFN-based therapy have been overcome by current-generation DAA treatments. Mechanistically, HCV proteins inhibit several steps of the JAK-STAT signal transduction pathway, and by activation of JAK-STAT signaling, exogenous IFN culminates in and restores intracellular expression of IFN-stimulated genes and their protein products that have antiviral properties.



When first approved, subcutaneous IFN-α three times a week for 6 months achieved a sustained virologic response (SVR; defined then as a reduction of HCV RNA to PCR-undetectable levels ≥24 weeks after completion of therapy) in <10%. Doubling the duration of therapy increased the SVR rate to ~20%, and addition to the regimen of daily ribavirin (ineffective when used alone), an oral guanosine nucleoside, increased the SVR rate further to 40% by reducing the likelihood of virologic relapse after completion of treatment. Although its mechanism of action remains poorly understood, ribavirin retains a limited role in supporting DAA agents in several subgroups of otherwise refractory patients (see below).

Beginning in 2011, for the treatment of hepatitis C, standard IFNs were supplanted by PEG IFNs, which have substantially longer half-lives, permitting administration once (rather than three times) a week. Treatment with the combination of PEG IFN and ribavirin increased SVR rates to 55% overall—to >40% in genotypes 1 and 4, requiring 48 weeks of therapy, and to >80% in genotypes 2 and 3, requiring only 24 weeks of therapy—and resulted in histologic improvement in approximately three-fourths of patients. After initiation of IFN treatment, ALT levels fell precipitously, and up to 90% of virologic responses were achieved within the first 12 weeks of therapy. Failure to achieve an early virologic response (EVR), a ≥2 $\log_{10}$ reduction in HCV RNA by week 12, predicted failure to experience a subsequent SVR. Similarly, patients in whom HCV RNA became undetectable within 4 weeks (i.e., who achieve a rapid virologic response [RVR]) had a very high likelihood of achieving an SVR **(Fig. 352-2)**.

Most relapses occurred within the first 12 weeks after treatment, and absence of HCV RNA 12 weeks after completion of therapy has become the current standard for SVR (SVR_{12}); relapses are very rare 6 months to a year after SVR and almost unheard of after 2 years. Of documented durability decades after successful therapy, an SVR to antiviral therapy for chronic hepatitis C is tantamount to a cure and is followed by marked improvements in liver disease outcomes (see below).

Patient variables that correlated with IFN-based SVRs included favorable genotype (genotypes 2 and 3 as opposed to genotypes 1 and 4); low baseline HCV RNA level (<800,000 IU/mL); histologically mild hepatitis and minimal fibrosis, especially absence of cirrhosis; immunocompetence; age <40; female gender; and absence of comorbid metabolic disease. High levels of HCV RNA, more histologically advanced liver disease, and high HCV quasispecies diversity all went hand in hand with advanced duration of infection and reduced IFN responsiveness. Ironically, patients whose disease was least likely to progress were the ones *most* likely to respond to IFN and vice versa.

As described above in the discussion of spontaneous recovery from acute hepatitis C, IFN gene variants discovered in genome-wide association studies were shown to have a substantial impact on IFN responsiveness of patients with genotype 1 to antiviral therapy. In studies of patients treated with PEG IFN and ribavirin, variants

Target	NS3-4A protease inhibitors	NS5A inhibitors	NS5B inhibitors
Function	Block N3-4A cleavage	Inhibit NS5A protein, essential for replication	Block the RNA-dependent RNA polymerase
Suffix	-previr	-asvir	-buvir
Drugs	Glecaprevir, voxilaprevir	Velpatasvir, ledipasvir, pibrentasvir	Sofosbuvir

FIGURE 352-2 Hepatitis C virus (HCV) viral genome and drug targets. The HCV viral genome encodes three structural proteins (c-nucleocapsid and e1-2 envelope proteins) and seven nonstructural proteins. Current, first-line direct-acting antivirals have three viral targets: (1) the NS3/4A viral protease; (2) the NS5A protein, which is a critical component of the viral replication apparatus; and (3) NS5B RNA-dependent RNA polymerase.

of the *IL28B* (now renamed *IFNL3*) SNP that code for IFN-λ3 (a type III IFN, the receptors for which are more discretely distributed than IFN-α receptors and more concentrated in hepatocytes) correlated significantly with responsiveness. Homozygotes for the C allele at this locus (C/C) achieved SVRs of ~80%, heterozygotes (C/T) SVRs of ~35%, and homozygotes for the T allele (T/T) SVRs of ~25%.

Side effects of IFN therapy are described in the section on treatment of chronic hepatitis B (see above). Besides ribavirin-associated nasal and chest congestion, pruritus, and precipitation of gout, the most pronounced ribavirin side effect is hemolysis, often requiring dose reduction or addition of erythropoietin therapy (not shown, however, to increase the likelihood of an SVR); therefore, close monitoring of blood counts is crucial, and ribavirin should be avoided in patients with anemia, hemoglobinopathies, coronary artery disease or cerebrovascular disease, or renal insufficiency (the drug is excreted renally) and in pregnancy (the drug is teratogenic, mandating contraception during, and for several months after, therapy in women of child-bearing age [because of their antiproliferative properties, IFNs also are contraindicated during pregnancy]).

For most of the decade prior to 2011, when protease inhibitors were introduced for HCV genotype 1 (see below), the standard of care was a combination of PEG IFN plus ribavirin (unless ribavirin was contraindicated) for all HCV genotypes. Even after the introduction of protease inhibitors for genotypes 1 and 4, however, PEG IFN–ribavirin remained the standard of care for patients with genotypes 2 and 3 until late 2013. Responsiveness to IFN-ribavirin–based therapy was diminished in immunocompromised patients and in patients with HIV-HCV co-infection and contraindicated in patients with decompensated liver disease or end-stage renal disease. The cumbersome nature of IFN-ribavirin–based therapy (injections, complicated laboratory monitoring, side effects and poor tolerability, modest efficacy, variables and patient subsets associated with poor responsiveness, tailored therapy, futility rules, etc.) was supplanted eventually (in 2016) by DAAs for all genotypes (see below). Most of the variables associated with poor responsiveness to IFN-based therapy became irrelevant, and difficult-to-treat patient subpopulations began to experience responses to DAAs that were indistinguishable from responses in standard patients (see below).

Persons with chronic HCV infection suffer increased liver-related mortality, all-cause mortality, and multiple extrahepatic disorders (see above). On the other hand, successful antiviral therapy of chronic hepatitis C resulting in an SVR was shown to improve survival (and to reduce the need for liver transplantation); to lower the risk of liver failure, liver-related death, and all-cause mortality; to slow the progression of chronic hepatitis C; to reverse fibrosis and even cirrhosis; and to improve such HCV-associated extrahepatic disorders as type 2 diabetes and renal disease. Whereas the 10- and 20-year survival in the absence of an SVR is reduced in cirrhotic patients with chronic hepatitis C, survival at these intervals after an SVR has been found to be indistinguishable from that of the general population. In cirrhotic patients (and in those with advanced fibrosis), although successful treatment reduces mortality and liver failure (three- to fourfold 10-year reduction) and reduces the need for liver transplantation and the likelihood of HCC (14-fold 10-year reduction), the risk of liver-related death and HCC persists, albeit at a much reduced level, necessitating continued clinical monitoring and cancer surveillance after SVR in patients with advanced fibrosis and cirrhosis. On the other hand, in the absence of an SVR, IFN-based therapy does not reduce the risk of HCC. Fortunately, PEG IFN–ribavirin nonresponders can now be retreated with DAAs and experience SVR rates comparable to those in treatment-naïve persons (see below).

FIRST-GENERATION PROTEASE INHIBITORS (2011–2013)

The HCV RNA genome encodes a single polyprotein, which is cleaved during and after translation by host and viral-encoded proteases (Fig. 352-2). One protease involved in the cleavage of the viral polyprotein is an NS3/4A viral protein that has serine protease activity. Telaprevir and boceprevir were first-generation serine protease inhibitors that target the genotype 1 NS3/4A. In 2011, telaprevir and boceprevir used in combination with PEG IFN and ribavirin were approved by the FDA as the first oral DAA agents for the treatment of hepatitis C genotype 1 (not other genotypes) in adults with stable liver disease. Although now replaced by more effective, all-oral regimens, these first-in-class agents represented a breakthrough in the treatment of chronic hepatitis C and established milestones against which subsequent therapies could be measured.

Because selection of resistant variants developed rapidly during monotherapy with telaprevir and boceprevir, these drugs had to be used in combination with PEG IFN and ribavirin. Ribavirin, in particular, appeared to reduce relapse rates significantly in protease-inhibitor-based regimens, such that those who could not take or were intolerant to ribavirin were unlikely to benefit from the addition of these agents. Telaprevir and boceprevir regimens consisted of periods of triple therapy (protease inhibitor plus PEG IFN plus ribavirin) and periods of dual therapy (PEG IFN plus ribavirin). Cumbersome periods of "run-in" therapy or late-treatment consolidation therapy with PEG IFN-ribavirin, reliance on early virologic responses to determine duration of therapy ("response-guided therapy"), and futility rules (for stopping therapy based on poor early responsiveness) rendered first-generation DAA treatment regimens complicated and unwieldy.

For patients with HCV genotype 1, protease inhibitors improved the frequency of RVRs and SVRs significantly as compared to PEG IFN plus ribavirin alone. In treatment-naïve patients, telaprevir-based SVRs were achieved in up to 79% of patients who received 12 weeks of triple therapy followed by 12–36 weeks of dual therapy, with higher rates of response (83–92%) observed in those with undetectable RNA at weeks 4 and 12. In studies with boceprevir in treatment-naïve patients, SVRs occurred in 59–66% of patients, and among those with undetectable HCV RNA at 8 weeks, the SVR rate increased to 86–88%. Adding to the complexity of treatment with these protease inhibitors were absolute stopping rules for futility, that is, absence of HCV RNA reductions at critical treatment milestones, which were shown to be invariably predictive of nonresponse.

The first-generation protease inhibitors were successful as well among patients in whom prior PEG IFN plus ribavirin had failed, even in "null responders," who had never experienced even a 2 $\log_{10}$ reduction in HCV RNA while on treatment. In this hardest-to-treat group, telaprevir-based therapy achieved an SVR in 29–33% and boceprevir achieved an SVR in 30–40%.

In a substantial proportion of protease inhibitor nonresponders, resistance-associated substitutions (RASs; previously referred to as resistance-associated variants [RAVs]) could be identified, but these variants were not archived, and wild-type HCV reemerged in almost all cases within 1.5–2 years. SVRs to these protease inhibitors were highest in prior relapsers and treatment-naïve patients (with SVR rates of >75%) and lowest in cirrhotic prior null responders, for whom no benefit accrued over PEG IFN–ribavirin treatment.

Both protease inhibitors had substantial toxicities. Telaprevir was associated with a severe, generalized (trunk and extremities), often confluent, maculopapular, pruritic rash in ~6% of treated patients (that required careful dermatologic monitoring in all patients and systemic corticosteroid therapy in the most severely affected). Other common side effects included pruritus, rectal burning, nausea, diarrhea, fatigue, dysgeusia (altered or unpleasant taste), and anemia, which required close monitoring, could be relatively refractory, and occasionally required transfusion and even hospitalization (especially in cirrhotic prior nonresponders). Anemia occurred in half of boceprevir-treated patients. The other most common side effects of boceprevir were fatigue, nausea, headache, dysgeusia, dry mouth, vomiting, and diarrhea.

Both drugs came with an inconveniently high pill burden and had to be administered every 8 h with food (telaprevir with a 20-g fat meal). Use of protease inhibitors was further complicated by numerous drug-drug interactions. As telaprevir and boceprevir are

both eliminated by and inhibit CYP3A4, these agents could not be administered with other medications that induce CYP3A4 or are dependent on CYP3A4 for elimination. Care had to be taken to examine for any potential interactions between these protease inhibitors and other medications the patient was taking, and a convenient website became available to check for such drug-drug interactions (*www.hep-druginteractions.org*). This website remains updated and of important clinical utility for checking drug-drug interactions for current HCV DAA regimens.

Despite the improvement in SVRs with protease-inhibitor-based regimens for genotype 1 compared to PEG IFN–ribavirin (e.g., in treatment-naïve patients 66–79% vs 38–44%), triple-drug protease inhibitor therapy was hampered by amplified intolerability, the complexity of response-guided regimens and futility stopping rules, the inconvenience of thrice-daily dosing with meals and a high pill burden, the need for PEG IFN injections and ribavirin with all their intolerability, and multiple drug-drug interactions. Moreover, side effects appeared to be more severe and burdensome once these drugs entered practice, especially in cirrhotic nonresponders, in whom studies reported from Europe showed serious adverse events in up to 45% and deaths in up to 3%. All these issues, as well as rapidly accelerating progress on next-generation and all-oral DAA therapy (see below), conspired to temper enthusiasm for these new antivirals; after a brief stint as recommended therapy (2011–2013), these drugs became obsolete and are no longer recommended or available.

DIRECT-ACTING ANTIVIRAL COMBINATIONS OF SECOND-GENERATION PROTEASE INHIBITORS, FIRST-GENERATION POLYMERASE INHIBITORS, AND FIRST-GENERATION NS5A INHIBITORS (2014–2015)

Since late 2013, the number of new antiviral agents for hepatitis C has expanded substantially, and currently, PEG IFN–based treatments have been supplanted by five remaining therapeutic regimens, which are all oral, IFN-free, highly efficacious (>95% SVR), and well tolerated, with high barriers to resistance, simple dosing, low pill burdens, treatment durations as brief as 8–12 weeks, and pangenotypic efficacy **(Table 352-6)**. These drugs are distributed among three classes of DAAs: NS3/4 protease inhibitors (which cleave the single HCV polyprotein into constituent structural and nonstructural proteins [drug name ending in "-previr"]), NS5B nucleoside and nonnucleoside polymerase inhibitors (which interfere with the RNA-dependent RNA polymerase [a replicase] involved in synthesis of viral RNA [drug name ending in "-buvir"]), and NS5A inhibitors (which interfere

TABLE 352-6 Indications and Recommendations for Antiviral Therapy of Chronic Hepatitis C[a]

Standard Indications for Therapy	**Treatment-Naïve**	**Previously Treated with DAA**
All patients with chronic HCV infection (detectable HCV RNA, with or without elevated ALT) except for those with short life expectancies owing to comorbid conditions. Any stage of fibrosis; pretreatment biopsy is no longer embraced and has been supplanted by noninvasive measures of fibrosis, e.g., imaging to determine liver elasticity. **Retreatment Recommended** Relapsers, partial responders, or nonresponders after a previous course of interferon-based therapy or prior direct-acting antiviral therapy **Antiviral Therapy Not Recommended** Pregnancy: No sizable clinical studies of direct-acting antivirals during pregnancy are available. Ribavirin is contraindicated during pregnancy; therefore, any regimen including ribavirin should not be used. Sofosbuvir and sofosbuvir plus ledipasvir are classified as pregnancy category B, but the other direct-acting antivirals do not have a pregnancy classification. Therefore, these therapies are not indicated routinely in pregnancy and should be used, with caution, only if the benefit of treatment outweighs the potential for fetal risk. **Therapeutic Regimens (based on AASLD-IDSA recommendations, *www.hcvguidelines.org*)[b]**	**Simplified treatment regimen[b]** *All genotypes* Sofosbuvir-velpatasvir × 12 weeks Glecaprevir-pibrentasvir × 8 weeks	**Sofosbuvir failure** *All genotypes* Sofosbuvir-velpatasvir-voxilaprevir × 12 weeks *Genotypes 1, 2, 4, 5, or 6 (alternative)* Glecaprevir-pibrentasvir × 16 weeks[e]
	Cirrhosis – compensated[c] *Genotypes 1–6* Glecaprevir-pibrentasvir × 8 weeks *Genotypes 1, 2, 4, 5, or 6* Sofosbuvir-velpatasvir × 12 weeks	**Glecaprevir-pibrentasvir failure** *All genotypes* Glecaprevir-pibrentasvir plus sofosbuvir and weight-based ribavirin × 16 weeks Sofosbuvir-velpatasvir-voxilaprevir × 12 weeks[f]
	Cirrhosis – decompensated Ribavirin-eligible *Genotypes 1–6* Sofosbuvir-velpatasvir with weight-based ribavirin[d] × 12 weeks *Genotypes 1,4, 5, or 6* Ledipasvir-sofosbuvir with ribavirin[e] × 12 weeks Ribavirin-ineligible *Genotypes 1–6* Sofosbuvir-velpatasvir × 24 weeks *Genotypes 1, 4, 5, or 6* Ledipasvir-sofosbuvir × 24 weeks	**Multiple direct-acting antiviral failures** *All genotypes* Glecaprevir-pibrentasvir plus sofosbuvir and weight-based ribavirin × 16 weeks[g] Sofosbuvir-velpatasvir-voxilaprevir plus weight-based ribavirin × 24 weeks **Cirrhosis – decompensated** *All genotypes* Sofosbuvir-velpatasvir plus weight-based ribavirin × 24 weeks *Genotypes 1, 4, 5, or 6* Ledipasvir-sofosbuvir plus ribavirin[e] × 24 weeks
FEATURES ASSOCIATED WITH REDUCED RESPONSIVENESS TO DIRECT-ACTING ANTIVIRAL COMBINATION THERAPY Genotype and subtype (genotype 1a less responsive than genotype 1b for several drugs) Treatment experience Advanced fibrosis (bridging fibrosis, cirrhosis) Reduced adherence		**DECOMPENSATED CIRRHOSIS** **Any protease-inhibitor-containing regimen is CONTRAINDICATED in decompensated cirrhosis (glecaprevir, grazoprevir, voxilaprevir).**

[a]Rapidly evolving new recommendations continue to be issued; for up-to-date treatment recommendations, please see *www.hcvguidelines.org*. [b]Excludes: cirrhosis, prior treatment, pregnancy, hepatitis B surface antigen positive, hepatocellular carcinoma (HCC), or liver transplant. No adjustment required for end-stage renal disease. [c]Child-Pugh class A cirrhosis only; excludes: prior treatment, pregnancy, hepatitis B surface antigen positive, end-stage renal disease, HCC, or liver transplant. After treatment, ongoing surveillance for HCC is required. [d]For Child-Pugh class C, initial low dose of ribavirin 600 mg is recommended with increase as tolerated. [e]Initial dose of ribavirin 600 mg with increase as tolerated. [e]Not recommended for prior NS3/4 protease inhibitor failure or genotype 3. [f]In compensated cirrhosis, the addition of weight-based ribavirin is recommended. [g]Consider extending treatment to 24 weeks if high-risk features (e.g., genotype 3, cirrhosis, or failure following sofosbuvir-glecaprevir-pibrentasvir).

Abbreviations: ALT, alanine aminotransferase; HCV, hepatitis C virus.

with a membrane-associated phosphoprotein essential to the HCV RNA replication complex [drug name ending in "-asvir"]).

The first of the new DAA agents (approved in November 2013) was simeprevir, a second-generation protease inhibitor for genotype 1, followed shortly thereafter (December 2013) by sofosbuvir, a pangenotypic nucleoside polymerase inhibitor. For genotype 1, both of these agents had to be combined with PEG IFN and ribavirin; for genotypes 2 and 3, sofosbuvir was administered with ribavirin, without PEG IFN; however, these treatment regimens have been supplanted by combinations of all-oral, IFN-free DAAs, and ribavirin is rarely needed and retained only for very limited indications.

Simeprevir When simeprevir was used with PEG IFN, its efficacy (genotype 1b > 1a) was similar to that of first-generation protease inhibitors but required only once-a-day dosing without the complexity of response-guided therapy. Similar to first-generation protease inhibitors, however, simeprevir was hampered by many drug-drug interactions, restriction to genotype 1 HCV, side effects, and limited efficacy in patients with a highly prevalent HCV NS3 polymorphism. Little about simeprevir supported its adoption in combination with PEG IFN and ribavirin. On the other hand, the combination of simeprevir (150 mg) along with sofosbuvir (400 mg) for 12 weeks was found to be effective in treatment-naïve (97% SVR_{12}) or treatment-experienced (95% SVR_{12}) patients without cirrhosis and in treatment-naïve (88% SVR_{12}) or treatment-refractory (79% SVR_{12}) patients with cirrhosis. While this all-oral, simeprevir-sofosbuvir regimen was a landmark in the treatment of chronic hepatitis C, simeprevir was eclipsed by more effective DAAs and is no longer in clinical use.

Sofosbuvir Sofosbuvir, which inhibits the NS5B RNA-dependent RNA polymerase, was the first non–protease inhibitor DAA to be approved and had a paradigm-shifting excellent profile—high potency, high barrier to resistance, pangenotypic activity, very well tolerated with limited adverse effects (most commonly mild fatigue, insomnia, headache, and nausea), once-daily oral administration, and relative freedom from major drug-drug interactions. Sofosbuvir has efficacy in all genotypes (1–6); in treatment-naïve subjects and prior nonresponders to PEG IFN–based and protease-inhibitor-based therapy; with PEG IFN–ribavirin or in IFN-free regimens; in combination with ribavirin or with NS5A inhibitors (see below); and for treatment periods as brief as 8–12 weeks. Currently, sofosbuvir is used in combination with one of two NS5A inhibitors and is a component of three of the five currently recommended DAA regimens (Table 352-6).

Paritaprevir-Ritonavir, Ombitasvir, and Dasabuvir The combination of ritonavir (100 mg)–boosted paritaprevir (150 mg), a protease inhibitor; ombitasvir (25 mg), an NS5A inhibitor; and dasabuvir (250 mg), a nonnucleoside NS5B polymerase inhibitor, with or without weight-based ribavirin (total of five drugs), was approved in December 2014 for genotypes 1 and 4. In clinical trials, this combination achieved SVR_{12} rates of 87–100% in treatment-naïve and treatment-experienced patients with genotype 1; without ribavirin, this combination in genotype 1a was ~7% less responsive than in genotype 1b. Therefore, in treatment-naïve patients with genotype 1a, this combination was administered *with* ribavirin for 12 weeks in the absence of cirrhosis (95–97% SVR_{12}) or for 24 weeks in the presence of compensated cirrhosis (94% SVR_{12}), whereas in patients with genotype 1b, the combination did not require ribavirin, and the duration of therapy was 12 weeks for both noncirrhotic and cirrhotic patients (99–100% SVR_{12}). In July 2016, the FDA approved a long-acting formulation of dasabuvir, allowing once-a-day instead of twice-a-day treatment; for genotype 1a, twice-daily ribavirin dosing remained.

This combination was well tolerated with generally mild side effects. Hyperbilirubinemia (primarily unconjugated) and elevations in ALT levels could occur but resolved during or shortly after treatment. Because of occasional hyperbilirubinemia and potential hepatotoxicity (FDA warning letter issued October 2015 regarding hepatic failure/decompensation reported in treated cirrhotic patients), this combination (and all subsequently introduced protease-inhibitor-containing combinations) was contraindicated in patients with decompensated cirrhosis, and treated cirrhotic patients had be monitored closely for decompensation.

Compared to superior regimens that came later (e.g., sofosbuvir-ledipasvir, see below), this regimen had the disadvantage of requiring twice-a-day ribavirin therapy for genotype 1a and of being contraindicated in decompensated cirrhosis; however, it had the advantage of offering a 12-week, ribavirin-free regimen for prior null responders with cirrhosis and providing an option for patients with renal failure. Based on regimen simplicity and superiority, subsequent-generation, ribavirin-free combination DAAs have supplanted paritaprevir-ritonavir, ombitasvir, and dasabuvir; this regimen is no longer recommended by the AASLD; however, it is retained in EASL recommendations as an alternative regimen for genotype 1b only.

Sofosbuvir and Daclatasvir Daclatasvir, an NS5A inhibitor, along with the polymerase inhibitor sofosbuvir, was approved by the FDA in July 2015 for genotype 3 and in February 2016 for genotype 1. At the time of its approval for genotype 3, daclatasvir filled a need inadequately met by other available combination DAAs; however, eventually, recommendation of this combination regimen was extended to genotypes 1–4 in the United States and to all genotypes (1–6) in Europe. Daclatasvir, a 60-mg tablet, and sofosbuvir, a separate 400-mg tablet, were taken once a day for 12–24 weeks.

In clinical trials among treatment-naïve or treatment-experienced patients, SVR_{12} rates for 12 weeks of daclatasvir plus sofosbuvir were 98% for genotype 1 (comparable results in genotypes 1a and 1b), 92% for genotype 2, and 89% for genotype 3. In patients with cirrhosis, SVR_{12} was achieved in 93% with Child-Pugh class A and B but in only 56% with class C decompensated cirrhosis. For patients with genotype 3 and cirrhosis, the combination was effective in treatment-naïve patients (94% SVR_{12}) but less so in prior nonresponders (69% SVR_{12}).

Like other sofosbuvir–NS5A inhibitor combinations, daclatasvir plus sofosbuvir was well tolerated (mild fatigue, headache, nausea, or diarrhea in 5–14%) but could cause severe bradycardia when administered with amiodarone (contraindicated). Responsiveness to daclatasvir-containing drug combination therapy was reduced in cirrhotic patients with genotype 1a and in both cirrhotic and noncirrhotic patients with genotype 3 who had baseline daclatasvir-associated NS5A RASs.

As new combination DAAs were introduced, however, daclatasvir-sofosbuvir was less competitive and no longer filled a niche. This regimen has been supplanted by better, later-generation combination DAAs and is no longer recommended.

CURRENT FIRST-LINE COMBINATIONS OF DIRECT-ACTING ANTIVIRALS

Sofosbuvir-Ledipasvir The DAA combination that has had an early and dominant role in the treatment of hepatitis C is sofosbuvir (400 mg) plus the NS5A inhibitor ledipasvir (90 mg) in a once-a-day, fixed-dose, single pill, approved in October 2014 for genotype 1 and in November 2015 for genotypes 4, 5, and 6. Phase 3 trials were conducted in treatment-naïve noncirrhotic patients, in treatment-naïve cirrhotic and noncirrhotic patients, and in treatment-experienced cirrhotic and noncirrhotic patients treated for 8, 12, or 24 weeks, both with and without ribavirin. In treatment-naïve noncirrhotics, an SVR_{12} was achieved in 97–99% of subjects, and no benefit was observed by extending therapy from 12 to 24 weeks or by adding ribavirin. Moreover, for treatment-naïve, noncirrhotic patients with baseline HCV RNA $<6 \times 10^6$ IU/mL, a treatment duration of 8 weeks was as effective as one of 12 weeks (94–95% SVR_{12}), which may be a consideration for a proportion of patients. In cirrhotic patients, SVR_{12} was achieved in 97–100% of treatment-naïve subjects (no advantage of extending therapy from 12 to 24 weeks or of adding ribavirin); however, for cirrhotic prior nonresponders to IFN-based therapy, 12 weeks of therapy was inferior (86% SVR_{12})

to 24 weeks of therapy (100% SVR_{12}). This combination, which is equally effective in patients with HIV-HCV co-infection and in African-American patients, has been shown to be highly effective in patients with decompensated cirrhosis and in patients with hepatitis C after liver transplantation and after kidney transplantation. Initially, sofosbuvir-ledipasvir was not recommended in patients with advanced renal failure; however, subsequently, the safety and efficacy of sofosbuvir-ledipasvir in patients with advanced renal failure were established, and the combination was approved for this indication (November 2019). All sofosbuvir-containing regimens can be associated with severe bradycardia in patients taking the antiarrhythmic agent amiodarone, especially along with beta blockers; sofosbuvir-containing combinations are contraindicated with amiodarone. Drug-drug interactions are few, but P-glycoprotein inducers, such as St. John's wort and rifampin, and proton pump gastric acid inhibitors, such as omeprazole, may reduce sofosbuvir-ledipasvir concentrations. Generally, responsiveness to sofosbuvir-ledipasvir is not reduced in patients with baseline RASs to these agents, with the exception of treatment-experienced patients who have baseline NS5A RASs (see Table 352-6).

Elbasvir-Grazoprevir Elbasvir (50 mg), an NS5A inhibitor, combined in a single, fixed-dose pill with grazoprevir (100 mg), an NS3/4 protease inhibitor, was approved in January 2016 as a once-a-day (with or without food) treatment for genotypes 1 and 4. In clinical trials, a 12-week course was effective in treatment-naïve and treatment-experienced patients without cirrhosis or with compensated cirrhosis. In treatment-naïve patients, this combination yielded an SVR_{12} in 92% of patients with genotype 1a, 99% with genotype 1b, and 100% with genotype 4 (very small numbers, however); 10 patients with genotype 6 were included, but only 80% achieved SVR_{12}. Cirrhotic and noncirrhotic patients had comparable rates of SVR_{12}, 97% and 94%, respectively. For this drug combination, however, ~11% of patients with genotype 1a harbor NS5A polymorphisms, which may include RASs, at baseline. If present, these NS5A RASs reduce efficacy of elbasvir-grazoprevir (unlike baseline RASs to most of the other combination DAA regimens described above and below) from 99% to 58% in treatment-naïve patients. Therefore, all patients with genotype 1a required baseline RAS testing prior to starting this regimen; when these RASs were present, treatment extension to 16 weeks and the addition of weight-based ribavirin were documented to bring SVR_{12} rates up to expected levels of close to 100%. In treatment-experienced patients, both extending treatment to 16 weeks and adding ribavirin were studied; however, generally, in the absence of baseline NS5A RASs, SVR_{12} rates were not increased over those without ribavirin for 12 weeks (94–97%). Among nonresponders to prior protease inhibitor therapy, even in the absence of baseline NS5A RASs, ribavirin had to be added to a 12-week regimen; in the presence of baseline NS5A RASs, treatment was extended to 16 weeks and ribavirin added. For genotype 1b, NS5A RASs are not an issue, and the only subgroup requiring modification of a 12-week course of therapy were prior nonresponders to protease inhibitor regimens, for whom ribavirin was added. For genotype 4, the recommended regimen for all prior nonresponders (whether to PEG IFN–ribavirin or protease inhibitor regimens) was 16 weeks of elbasvir-grazoprevir plus ribavirin. Now that simpler, improved combination regimens are available, for patients with NS5A RASs, extending the duration of elbasvir-grazoprevir and adding ribavirin have been abandoned (Table 352-6); however, *elbasvir-grazoprevir is one of the currently recommended DAA combinations* (Table 352-6).

This combination is just as effective in patients with HIV-HCV co-infection and in patients with advanced renal failure (including those requiring hemodialysis), but like all protease-inhibitor-including DAA combinations, it is contraindicated in decompensated cirrhosis. In this vein, like other protease inhibitor regimens, elbasvir-grazoprevir can be associated with aminotransferase elevations and potential hepatotoxicity; because these drugs are excreted by the liver, plasma drug concentrations may become elevated substantially in the presence of impaired hepatic function. Therefore, all treated patients should have ALT screening periodically during therapy, and the drug should be stopped for elevations exceeding 10-fold or for elevations of conjugated bilirubin, alkaline phosphatase, or prothrombin time.

Elbasvir-grazoprevir is well tolerated, with only low levels of mild adverse effects (fatigue, headache, or nausea in 5–11%) seen just as frequently in placebo recipients. Both elbasvir and grazoprevir are substrates for CYP3A and are subject to multiple potential drug-drug interactions. Therefore, this combination should not be used with potent CYP3A inducers; conversely, CYP3A and OATP1B1 inhibitors can lead to untoward elevations of plasma elbasvir-grazoprevir concentrations. Checking for potential drug-drug interactions is advisable prior to initiating therapy (*www.hep-druginteractions.org*).

Compared to other available regimens for genotypes 1 and 4, elbasvir-grazoprevir has the disadvantage/inconvenience of requiring baseline NS5A RAS testing but the advantages of a comparable regimen for cirrhotic and noncirrhotic patients, for treatment-naïve and treatment-experienced patients, and for patients with normal renal function and with renal failure. As noted above, its limitations and complexities notwithstanding, elbasvir-grazoprevir remains one of the recommended DAA combinations (albeit not one of the "simplified" treatment algorithms, see below).

Sofosbuvir-Velpatasvir The combination in a single, fixed-dose pill of velpatasvir (100 mg), a highly potent, pangenotypic NS5A inhibitor, and the polymerase inhibitor sofosbuvir (400 mg) was approved in June 2016 for genotypes 1–6 in treatment-naïve and treatment-experienced noncirrhotic and cirrhotic patients. In August 2017, approval was extended to include patients with HCV-HIV co-infection. Ribavirin is not required, including in patients with genotypes 2 and 3, except in patients with decompensated cirrhosis.

In a series of clinical trials, this combination for 12 weeks in the absence of ribavirin was shown to yield a 99% SVR_{12} (range 97–100%) in genotypes 1, 2, 4, 5, and 6 and 95% in genotype 3. Baseline NS5A RASs had no impact on responsiveness.

Prior to the availability of this drug combination, patients with genotype 3, especially those with cirrhosis and prior null response to other therapies, proved to be the most refractory subset of patients. In treatment-naïve patients with genotype 3, 12 weeks of sofosbuvir-velpatasvir (95% SVR_{12}) was superior to 24 weeks of sofosbuvir plus ribavirin (80% SVR_{12}). In patients with genotype 3, the combination of sofosbuvir-velpatasvir for 12 weeks was comparable in noncirrhotic (97% SVR_{12}) and cirrhotic patients (91% SVR_{12}) and in treatment-naïve (97% SVR_{12}) and treatment-experienced (90% SVR_{12}) patients and was superior in all these categories to 24 weeks of sofosbuvir plus ribavirin (87, 66, 86, and 63%, respectively). In cirrhotic null responder patients, most available IFN-free regimens for genotype 3 (including daclatasvir plus sofosbuvir, which had been approved specifically for this genotype) achieved SVR_{12} rates in the range of ~60–75%, while the combination of PEG IFN, ribavirin, and sofosbuvir could boost SVR_{12} to the mid-80% range. For treatment-experienced patients with genotype 3, sofosbuvir-velpatasvir in noncirrhotic and cirrhotic patients had similarly high efficacy (91 and 89% SVR_{12}, respectively); this was the highest recorded SVR_{12} for genotype 3 cirrhotic null responders treated with IFN-free DAA regimens. Finally, in patients with genotypes 1–4 and 6 and with decompensated, class B cirrhosis (55% treatment-experienced), sofosbuvir-velpatasvir plus ribavirin for 12 weeks yielded an SVR_{12} in 94%; this result was better than sofosbuvir-velpatasvir without ribavirin for 12 weeks (83% SVR_{12}) or 24 weeks (86% SVR_{12}).

Like other all-oral DAAs, sofosbuvir-velpatasvir was very well tolerated; in noncirrhotic and compensated cirrhotic patients, mild headache and fatigue were seen in >10% (this occurred in a comparable proportion of placebo recipients), and in patients with decompensated cirrhosis, mild fatigue, headache, nausea, insomnia, diarrhea,

and anemia (ribavirin was part of the regimen) were seen in >10%. Like other sofosbuvir-containing regimens, sofosbuvir-velpatasvir should not be administered along with amiodarone (potential serious bradycardia); in addition, P-glycoprotein inducers and moderate-to-potent CYP3A inducers can reduce plasma levels of sofosbuvir and/or velpatasvir. Checking for drug-drug interactions prior to therapy is advisable (*www.hep-druginteractions.org*). Baseline RASs do not influence responsiveness to this combination. Sofosbuvir-velpatasvir is one of the currently recommended DAA combinations for hepatitis C (Table 352-6). *Because it is so simple and broadly effective across patient subgroups, sofosbuvir-velpatasvir is one of the two combination DAA regimens recommended by the AASLD and EASL as a preferred, simplified treatment algorithm* (Table 352-6).

Sofosbuvir-Velpatasvir-Voxilaprevir Approved in July 2017, the pangenotypic, high-barrier-to-resistance protease inhibitor voxilaprevir (100 mg) added to the polymerase inhibitor–NS5A inhibitor combination of sofosbuvir-velpatasvir yields a very well tolerated *triple-drug* combination with ~97% SVR_{12} across all HCV genotypes and patient subgroups. These include the small percentage of patients with genotype 1 and genotype 3 refractory to previously approved DAA combinations as well as noncirrhotic/cirrhotic, treatment-naïve/treatment-experienced groups, including those who had or who had not received prior NS5A treatment. Efficacy was independent of the number of prior DAA drug classes received, and no effects of baseline NS5A RASs were noted.

The potential for abbreviated (8-week) treatment with this triple combination was explored in a clinical trial involving treatment-naïve patients; however, the shortened duration was inferior to a full 12-week course. The side effect profile for sofosbuvir-velpatasvir-voxilaprevir was similar to that in the placebo arm of clinical trial patients and included mild and uncommon headache, fatigue, nausea, and diarrhea.

Because other DAA regimens are so effective in most patients with chronic hepatitis C, recommendations for sofosbuvir-velpatasvir-voxilaprevir are limited to a small subset of otherwise refractory patients: for treatment-naïve cirrhotic patients with genotype 3 and baseline NS5A velpatasvir RAS Y93H, for treatment-naïve (according to AASLD, not EASL) or IFN-ribavirin–experienced noncirrhotic or cirrhotic patients with genotype 3 (Table 352-6), and for patients with or without compensated cirrhosis and prior, failed NS5A inhibitor–containing therapy (consult *www.hcvguidelines.org*).

This triple-drug combination, like all sofosbuvir-containing combinations, is contraindicated in patients taking amiodarone and, like all protease inhibitor–containing combinations, in patients with decompensated cirrhosis. Concomitant omeprazole, 20 mg, can be taken with this sofosbuvir-containing regimen. Prior to initiating therapy, checking for drug-drug interactions is recommended.

Glecaprevir-Pibrentasvir A regimen of 8 weeks of this single-pill, fixed-dose combination of the protease inhibitor glecaprevir (300 mg) and NS5A inhibitor pibrentasvir (120 mg), two pangenotypic, high-potency DAAs with high barriers to resistance (approved in August 2017), achieves SVR_{12} in close to 100% of treatment-naïve patients with all genotypes, with or without cirrhosis: SVR_{12} of ~99% for genotypes 1, 2, and 4–6 and of 95–98% for genotype 3. Extended treatment for 12 weeks did not increase efficacy. In trials among treatment-experienced patients, treatment with 12 weeks of this DAA combination was just as effective as 16 weeks for all genotypes except genotype 3; however, with increasing numbers of prior treatment courses, SVR_{12} rates fell—100% for patients treated with a protease inhibitor only, 88% for patients treated with an NS5A inhibitor only, and 79% for patients treated previously with both a protease inhibitor and an NS5A inhibitor. Similarly, baseline RASs reduced SVR_{12} rates—from 100% without RASs (or with RASs limited to those reflecting protease inhibitor resistance) to 89% for baseline NS5A RASs.

For retreatment of patients with prior glecaprevir-pibrentasvir failure, 16 weeks of glecaprevir-pibrentasvir plus sofosbuvir are recommended (alternatively, sofosbuvir-velpatasvir-voxilaprevir for 12 weeks [plus ribavirin in cirrhotic patients]). Glecaprevir-pibrentasvir for 16 weeks is recommended as well after failure to respond to the triple-drug combination of sofosbuvir-velpatasvir-voxilaprevir (see below). For retreatment of patients with sofosbuvir-velpatasvir-voxilaprevir failure, 16 weeks of glecaprevir-pibrentasvir plus ribavirin is recommended, as is a repeat course of sofosbuvir-velpatasvir-voxilaprevir plus ribavirin for 24 weeks. For navigating the complexities of treating DAA-refractory patients, checking up-to-date guidelines (*www.hcvguidelines.org*) and referral to a specialized center are advisable.

As is the case for any DAA combination containing a protease inhibitor, glecaprevir-pibrentasvir is contraindicated in decompensated cirrhosis; it has been shown to achieve an SVR_{12} in 98% of patients with stage 4 or 5 renal disease (in treatment-naïve or experienced, cirrhotic or noncirrhotic patients) and is a preferred treatment for patients with severe renal impairment. This DAA combination should be taken with food, and drug-drug interactions should be considered prior to initiating treatment. *Because it is so simple and broadly effective across patient subgroups (8 weeks for all noncirrhotic treatment-naïve patients [including with HIV co-infection]; 12 weeks for all treatment-experienced cirrhotics [including with HIV co-infection] and treatment-naïve cirrhotics with genotype 3 [except treatment-experienced cirrhotic or noncirrhotic genotype 3 {16 weeks}]), glecaprevir-pibrentasvir is one of the two combination DAA regimens recommended by the AASLD and EASL as a preferred, simplified treatment algorithm* (Table 352-6).

Emerging data on the impact of DAAs on the natural history of chronic hepatitis C indicated that, as was documented for IFN-based therapy, successful DAA therapy is associated with a gradual reduction in fibrosis progression and a regression of advanced fibrosis (cirrhosis), improvement in survival among patients with decompensated cirrhosis, a reduction in HCC, and a decline in the number of patients with hepatitis C being referred for liver transplantation. Indeed, early and broad implementation of DAAs in the treatment of chronic hepatitis C has been instrumental in enabling the decline of HCV-related deaths since 2013. Modeling estimates suggest that application of DAA therapies has the potential to result in a 50–70% reduction in the hepatitis C–associated disease burden by 2050.

TREATMENT RECOMMENDATIONS

Because the pace of new drug development and approval has been so rapid, the AASLD and the Infectious Diseases Society of America (IDSA) have been providing a consensus of updated treatment recommendations for patients with hepatitis C; these recommendations, which continue to be revised regularly based on new data, are available online at *www.hcvguidelines.org* and should be consulted before initiating therapy. The EASL issues similar (but not identical) treatment recommendations annually for hepatitis C (*www.easl.eu*), most recently in November 2020.

Prior to therapy, all patients should undergo pretreatment evaluation, which includes HCV RNA, HCV genotype, renal function, hepatitis B status (testing should include HBsAg and anti-HBc), HIV status, and fibrosis stage. Despite the presence of pangenotypic regimens, HCV genotype should still be determined, because the genotype may contribute to decisions about which treatment regimens are indicated and can guide insurance coverage (Table 352-6).

Fibrosis assessment is an especially important element of the pretreatment evaluation: the absence or presence of cirrhosis or advanced fibrosis determines the treatment options from which to select, including the antiviral agents to be used, the duration of therapy, and the now rare need for ribavirin (Table 352-6). In the past, a pretreatment liver biopsy was relied upon to assess histologic grade and stage as well as to identify such histologic factors as steatosis, which can influence adversely responsiveness to therapy. As therapy has improved for patients with a broad range of histologic severity, and as noninvasive measures of the stage of fibrosis (e.g., assessment of liver stiffness by imaging, FIB-4 score [see above]) have

advanced in accuracy and popularity, noninvasive approaches have supplanted histology in almost most cases. As noted above, if cirrhosis or advanced fibrosis is present prior to therapy, the risk of HCC, although reduced substantially by successful therapy, is not eliminated, and twice-yearly posttreatment imaging for HCC surveillance remains indicated even after an SVR. In patients with low-level fibrosis at baseline, achievement of SVR allows cessation of such surveillance.

Several reports have appeared describing hepatitis B reactivation, often severe, during and after DAA therapy in patients co-infected with HCV and HBV who were not being treated for their HBV infections. Therefore, screening for HBV infection is recommended prior to initiating DAA therapy for hepatitis C (which should have been done to determine HBV immunity status as a prelude to recommended hepatitis B vaccination in patients with chronic hepatitis C), and therapy for HBV infection (for those meeting HBV treatment criteria, see above) should be initiated prior to or simultaneously with HCV therapy.

Monitoring of serum HCV RNA levels before, during, and after treatment is crucial in assessing the response to therapy; moreover, the baseline level may contribute to determining the duration of therapy (e.g., in noncirrhotic patients with genotype 1 and HCV RNA $<6 \times 10^6$ IU/mL, 8 [instead of the usual 12] weeks of sofosbuvir-ledipasvir may be a consideration). *The goal of treatment is to eradicate HCV RNA during therapy and to document that the virus remains undetectable for at least 12 weeks after completion of therapy (SVR_{12}).*

Most recent guidelines support a simplified treatment algorithm for patients with HCV infection, leveraging the well tolerated and highly effective pangenotypic regimens. Patients who are eligible for this simplified algorithm must *not* have any of the following clinical characteristics: prior treatment failure, cirrhosis, presence of HBsAg, pregnancy, HCC, or history of liver transplantation. In the absence of any of these features, the patient may be treated with *either* sofosbuvir/velpatasvir for 12 weeks or glecaprevir/pibrentasvir for 8 weeks.

INDICATIONS FOR ANTIVIRAL THERAPY

Patients with chronic hepatitis C who have detectable HCV RNA in serum, whether or not aminotransferase levels are increased, and chronic hepatitis of any grade and stage are candidates for antiviral therapy with DAA agents. The only exception would be patients with short life expectancies, for whom treating hepatitis C would have no influence on longevity. Certainly, for patients with advanced liver disease, early treatment merits a high priority. Although patients with persistently normal aminotransferase activity tend to progress histologically very slowly or not at all, they respond to antiviral therapy just as well as do patients with elevated aminotransferase levels; therefore, such patients are candidates for antiviral therapy. As noted above, antiviral therapy has been shown to improve survival and complication-free survival and to slow progression of and to reverse fibrosis.

Patients who have relapsed after, or failed to respond to, a course of IFN-based (currently no longer encountered commonly) or DAA agent–based therapy are candidates for retreatment with a DAA therapy regimen (Table 352-6). For patients who have failed to respond to a DAA combination, options include increasing the duration of therapy with the failed regimen, adding ribavirin, or changing the drug class (e.g., after failed protease and polymerase inhibitors, switching to an NS5A-containing combination). In the presence of cirrhosis or a need for urgent retreatment, patients who have failed protease inhibitor plus polymerase inhibitor combination therapy or who have failed an NS5A combination are candidates for RAS testing and tailored therapy based on such resistance testing. If reliable RAS testing is not available, adding ribavirin or extending the duration of therapy are options. For prior nonresponders to IFN-based therapy, NS5A inhibitor–containing regimens are highly effective; however, reduced responsiveness can be encountered, especially in cirrhotic patients. The simplest current approach for patients who have not responded to prior DAA therapy containing sofosbuvir is to re-treat with sofosbuvir-velpatasvir-voxilaprevir for 12 weeks or glecaprevir-pibrentasvir for 16 weeks. Additional details for treatment of such patient subgroups can be found at www.hcvguidelines.org; in the small proportion of patients in whom initial DAA courses do not achieve SVR_{12}, referral to an experienced treatment center is advisable. Worth reiterating, protease inhibitors are contraindicated for patients with decompensated cirrhosis, and sofosbuvir-containing regimens are not recommended for patients taking amiodarone (especially with beta blockers) for treatment of cardiac arrhythmias. While sofosbuvir-containing DAA combinations were not recommended initially for patients with advanced renal failure, subsequent studies demonstrated safety and efficacy in this subgroup, and sofosbuvir-containing DAA combinations are now approved for advanced renal failure.

Persons with *acute* hepatitis C are also candidates for antiviral therapy **(Chap. 350)** with the same pangenotypic combination DAA agents and the same duration of treatment approved for chronic hepatitis C. For example, in a trial of a shortened, 6-week course of sofosbuvir-velpatasvir for acute hepatitis C, a 6-week course was less effective than a full 12-week course (81.7 vs 90.5%, respectively). Delaying the initiation of therapy in acute hepatitis C to allow for spontaneous recovery is no longer recommended. While acute hepatitis C should be treated, postexposure prophylaxis after HCV exposure is not recommended currently

In patients with biochemically and histologically mild chronic hepatitis C, the rate of progression is slow; however, such patients respond just as well to antiviral therapy as those with elevated aminotransferase levels and more histologically severe hepatitis. Because of the high cost of DAA treatments, in the past, a higher priority was assigned to patients with advanced fibrosis/cirrhosis; however, this controversial approach was relied upon by some medical insurers and pharmacy benefit management organizations to withhold therapy from patients with low-level fibrosis. Unfortunately, delaying therapy until fibrosis becomes advanced misses the opportunity to prevent all the dire consequences of chronic hepatitis C (liver failure, death/transplantation, HCC), which can be reduced, but not eliminated completely, once advanced fibrosis is established. Therefore, therapy for patients with mild disease is justified as well as cost-effective.

TREATMENT OF UNIQUE POPULATIONS

Decompensated Cirrhosis Patients with compensated cirrhosis can respond to therapy, and their likelihood of a sustained response with DAAs is comparable to that in the absence of cirrhosis. Patients with decompensated cirrhosis, who were not candidates for IFN-based antiviral therapy, respond well to non–protease-inhibitor-containing regimens, and specifically sofosbuvir combined with an NS5A inhibitor, velpatasvir or ledipasvir, with or without ribavirin. As noted above, protease-inhibitor-containing combinations have been associated with potential hepatotoxicity and hepatic decompensation and are contraindicated in this patient subset. Treatment decisions are informed by whether the patient is eligible for ribavirin: in ribavirin-eligible patients, ribavirin is added to a 12-week course of sofosbuvir-NS5A therapy; however, in cases of ribavirin ineligibility, the duration of therapy should be extended to 24 weeks. In cases of prior failure to respond to sofosbuvir-NS5A therapy, the sofosbuvir-NS5A regimen should be repeated but supplemented with ribavirin and extended to 24 weeks (*www.hcvguidelines.org*). Also, patients with decompensated cirrhosis should be referred to a liver transplantation center.

DAAs are highly effective not only for patients with end-stage liver disease awaiting liver transplantation but also for patients with recurrent hepatitis C after liver transplantation. Ideally, patients should be treated prior to liver transplantation. Given the effectiveness of treatment immediately after transplantation (either for donor or recipient HCV infection), however, the utility of treatment may be limited if the patient has a high Model for End-Stage Liver Disease (MELD) score and may soon receive a donor

liver for transplantation. Therefore, advocacy has been expressed for postponing DAA therapy in patients with high-MELD-score (≥18–20), HCV-associated, end-stage liver disease until after liver transplantation; for patients with MELD scores <18–20, pretransplantation DAA therapy is advised. Still, the decision whether to treat pretransplantation or posttransplantation should be individualized thoughtfully for each patient, based on such factors as MELD score, time anticipated prior to availability of a donor organ, relative clinical stability, and comorbidities **(Chap. 356)**. Because DAA therapy is so effective, most transplantation centers are accepting organs from HCV-infected donors, transplanting them into HCV-uninfected recipients, and treating recipients with sofosbuvir-velpatasvir for 12 weeks or glecaprevir-pibrentasvir for 8 weeks after transplantation—with excellent results.

Extrahepatic Manifestations The cutaneous and renal vasculitis of HCV-associated essential mixed cryoglobulinemia **(Chap. 350)** may respond to antiviral therapy, but sustained responses were rare after discontinuation of therapy in the IFN era, and prolonged, potentially indefinite, therapy was recommended. Now that more effective DAAs are available, a 12-week course of sofosbuvir-based combination therapy has been shown to yield an SVR_{12} rate exceeding 80% in cryoglobulinemic vasculitis. Anecdotal reports suggest that IFN-based antiviral therapy may be effective in porphyria cutanea tarda or lichen planus associated with hepatitis C; whether the more appealing DAAs are effective in these groups remains to be documented.

HIV Co-infection In patients with HCV/HIV co-infection, hepatitis C is more progressive and severe than in HCV mono-infected patients. Although patients with HCV/HIV co-infection responded less well to IFN-based antiviral therapy for hepatitis C, they respond as well as patients with HCV infection alone to DAA combination regimens and, generally, should be treated with the same DAA combinations and for the same duration as those for patients (in the absence or presence of cirrhosis) with HCV mono-infection. For patients with HCV/HIV co-infection, an abbreviated, 8-week course of sofosbuvir-ledipasvir for low-level HCV RNA is not recommended, and a full 12 weeks should be given; similarly, for patients with genotype 4, a 12-week course of glecaprevir-pibrentasvir is recommended instead of an 8-week course for treatment-naïve or -experienced patients with or without cirrhosis (Table 352-6). In HCV/HIV-infected patients, ribavirin can potentiate the toxicity of didanosine (e.g., lactic acidosis) and the lipoatrophy of stavudine, and zidovudine can exacerbate ribavirin-associated hemolytic anemia; therefore, these drug combinations should be avoided. In HCV/HIV co-infected persons, the list of potential drug-drug interactions is extensive and should be consulted carefully before beginning DAA treatment (*www.hcvguidelines.org*).

Substance Use Disorder Patients with a history of injection drug use and alcoholism can be treated successfully for chronic hepatitis C, preferably in conjunction with drug and alcohol treatment programs. Moreover, because persons who use injection drugs (PWID), as a source of transmission to others, account disproportionately for perpetuating the spread of HCV infection in the population, the impact of treating people who are actively using injection drugs is amplified by reducing such transmission. In a randomized, controlled clinical trial, treatment with sofosbuvir and velpatasvir for 12 weeks was highly successful in PWID, with SVR_{12} rates of 74–76%. Based on this study, and others, active injection drug use is no longer considered a contraindication to treatment, and indeed, mechanisms to facilitate care of PWID are being sought to address the U.S. and global burden of HCV infection and move toward the World Health Organization goal of HCV elimination by 2030 (see below).

Renal Impairment The approved oral DAA combinations are effective in patients with mild-modest renal impairment and require no dose adjustments. For patients with severe renal impairment (creatinine clearances <30 mL/min), including those undergoing hemodialysis, recommended combinations are 12 weeks of elbasvir-grazoprevir for genotypes 1 and 4 or 12 weeks of glecaprevir-pibrentasvir for all genotypes. Both in severe renal impairment and after kidney transplantation, levels of SVR_{12} in patients treated with these oral DAA combinations have approached 100%. Initially, in patients with severe renal impairment, sofosbuvir-containing combinations were not recommended. Subsequently, however, based on efficacy and safety in a series of clinical trials, sofosbuvir-containing regimens were approved by the FDA in November 2019 for patients with severe renal impairment.

Pregnancy No large clinical studies of the use of DAAs during pregnancy are available. One small study demonstrated the safety and efficacy of sofosbuvir and ledipasvir given for 12 weeks at week 23–24 of gestation. Ribavirin is contraindicated during pregnancy; therefore, any regimen including ribavirin should not be used. Sofosbuvir; sofosbuvir-ledipasvir; and paritaprevir-ritonavir, ombitasvir, and dasabuvir are classified as pregnancy category B; the other DAAs do not have a pregnancy classification. Therefore, these therapies are not indicated routinely in pregnancy and should be used, with caution, only if the benefit of treatment is compelling and justified compared to the potential for fetal risk. Currently, screening all pregnant women for HCV infection is recommended. Breast feeding is not contraindicated in women with HCV infection (unless the mother has a break in the integrity of the nipples or is co-infected with HIV).

CHOOSING AMONG AVAILABLE TREATMENT OPTIONS

Choosing among the number of all-oral DAA combinations approved since 2013 was daunting to treating clinicians. Currently, however, the number of recommended DAA combinations has narrowed to a very manageable few. The most popular of the regimens have been fixed-dose, single-pill, pangenotypic combinations. For simplicity, two "one-size-fits-all" pangenotypic regimens—sofosbuvir-velpatasvir and glecaprevir-pibrentasvir—can be used, for 8–12 weeks in almost all treatment-naïve, noncirrhotic and cirrhotic patients, including those with advanced renal failure and HCV-HIV co-infection. Applicability of the triple-drug combination sofosbuvir-velpatasvir-voxilaprevir is quite limited in treatment-naïve patients, reserved primarily for cirrhotic patients with genotype 3. As noted above, protease-inhibitor-containing DAA regimens (elbasvir-grazoprevir, glecaprevir-pibrentasvir, and sofosbuvir-velpatasvir-voxilaprevir) are contraindicated in decompensated cirrhosis.

APPROACHES TO STEAMLINING DAA TREATMENT

The World Health Organization has set an elimination goal of a 90% reduction in the global prevalence of HCV infection by 2030, and the Viral Hepatitis National Strategic Plan includes a goal of an 80% reduction in the U.S. prevalence of HCV infection by 2030; however, at the current pace of identification and treatment, this ambitious goal is unlikely to be met. To address this shortfall, efforts have been devoted to improving the frequency of screening and diagnosis and to streamlining the process of enrolling persons with HCV infection into treatment programs. Now that DAA regimens have been simplified so dramatically, in-person specialist care is usually not needed (except in complex patients such as those with advanced fibrosis, comorbid conditions, and prior nonresponse to DAA treatment). Programs with an impressive record of success in streamlining the treatment of persons with hepatitis C include those based on telehealth, one-stop screening and treatment initiation, minimal monitoring (dispensing the full course of pills at the beginning of therapy, relying on a limited number of in-person or even all-remote patient contacts during therapy, and involving no HCV RNA or liver test monitoring during treatment and not until 12 weeks after completion of treatment), and collaborative participation on the treatment team of clinicians experienced in managing substance use disorder. The expansion of such programs is anticipated eagerly.

AUTOIMMUNE HEPATITIS

DEFINITION

Autoimmune hepatitis (AIH) is a chronic disorder characterized by continuing hepatocellular necrosis and inflammation, usually with fibrosis, which can progress to cirrhosis and liver failure. The presentation of AIH varies, from asymptomatic liver enzyme abnormalities to severe or even, in its most severe form, marked hepatocellular dropout, multilobular collapse, and clinical features of fulminant hepatitis with high mortality. Based on contemporary estimates of the natural history of AIH, the 10-year survival is 80–98% for treated and 67% for untreated patients. The prominence of extrahepatic features of autoimmunity and seroimmunologic abnormalities in this disorder supports an autoimmune process in its pathogenesis; this concept is reflected in the prior labels *lupoid* and *plasma cell hepatitis*. Similar to other autoimmune diseases, AIH has a strong female predominance, with women accounting for ~75% of all cases. The age distribution is bimodal, with one peak in the early decades (age <30) and the second in middle to late years (often >60). Autoantibodies and other typical features of autoimmunity, however, do not occur in all cases; among the broader categories of "idiopathic" or cryptogenic chronic hepatitis, many, perhaps the majority, are probably autoimmune in origin. Cases in which hepatotropic viruses, metabolic/genetic derangements (including nonalcoholic fatty liver disease), and hepatotoxic drugs have been excluded represent a spectrum of heterogeneous liver disorders of unknown cause, a proportion of which are most likely AIH.

IMMUNOPATHOGENESIS

The weight of evidence suggests that the progressive liver injury in patients with AIH is the result of a cell-mediated immunologic attack directed against liver cells in the setting of a loss of, or failed, immunologic tolerance for self-liver antigens. In all likelihood, predisposition to autoimmunity is inherited, whereas the liver specificity of this injury is triggered by environmental (e.g., chemical, drug [e.g., minocycline], or viral) factors. For example, patients have been described in whom apparently self-limited cases of acute hepatitis A, B, or C led to AIH, presumably because of genetic susceptibility or predisposition. More recently, the emergence of AIH has been reported following—presumably triggered by—COVID-19 and after COVID-19 vaccination, postulated mechanistically to result from the vigorous immune response and loss of immune tolerance in susceptible persons.

Evidence to support an autoimmune pathogenesis in this type of hepatitis includes the following: (1) in the liver, the histopathologic lesions are composed predominantly of cytotoxic T cells and plasma cells; (2) circulating autoantibodies (nuclear, smooth muscle, and others, see below), rheumatoid factor, and hyperglobulinemia are common; (3) other autoimmune disorders—such as autoimmune thyroiditis, rheumatoid arthritis, autoimmune hemolytic anemia, ulcerative colitis, membranoproliferative glomerulonephritis, juvenile diabetes mellitus, vitiligo, celiac disease, and Sjögren's syndrome—occur with increased frequency in patients who have AIH and in their relatives; (4) histocompatibility haplotypes associated with autoimmune diseases, such as HLA-B1, B8, DR3, and DR4 as well as extended haplotype *DRB1*0301* and *DRB1*0401* alleles, are common in patients with AIH; and (5) this type of chronic hepatitis is responsive to glucocorticoid/immunosuppressive therapy, effective in a variety of autoimmune disorders.

Loss of immune tolerance as well as cytotoxic cellular immune responses appear to be important in the pathogenesis of AIH. In vitro studies have suggested that in patients with this disorder, CD4+ T lymphocytes are capable of becoming sensitized to hepatocyte membrane proteins and of destroying liver cells. Molecular mimicry by cross-reacting antigens that contain epitopes similar to liver antigens is postulated to activate these T cells, which infiltrate, and result in injury to, the liver. Abnormalities of immunoregulatory control over cytotoxic lymphocytes (impaired regulatory CD4+CD25+ T-cell influences) may play a role as well. Studies of genetic predisposition to AIH demonstrate that certain haplotypes are associated with the disorder, as enumerated above, as are polymorphisms in cytotoxic T lymphocyte antigens (*CTLA-4*) and tumor necrosis factor α (*TNFA*2*). The precise triggering factors, genetic influences, and cytotoxic and immunoregulatory mechanisms involved in this type of liver injury remain incompletely defined.

Intriguing clues into the pathogenesis of AIH come from the observation that circulating autoantibodies are prevalent in patients with this disorder. Among the autoantibodies described in these patients are antibodies to nuclei (so-called antinuclear antibodies [ANAs], primarily in a homogeneous pattern) and smooth muscle (so-called anti-smooth-muscle antibodies [ASMAs], directed at actin, vimentin, and skeletin), antibodies to F-actin and anti-LKM (see below), antibodies to soluble liver antigen (directed against a uracil-guanine-adenine transfer RNA suppressor protein), antibodies to α-actinin, and antibodies to the liver-specific asialoglycoprotein receptor (or "hepatic lectin") and other hepatocyte membrane proteins. Although some of these provide helpful diagnostic markers, their involvement in the pathogenesis of AIH has not been established.

Humoral immune mechanisms have been shown to play a role in the extrahepatic manifestations of autoimmune and idiopathic hepatitis. Arthralgias, arthritis, cutaneous vasculitis, and glomerulonephritis occurring in patients with AIH appear to be mediated by the deposition of circulating immune complexes in affected tissue vessels, followed by complement activation, inflammation, and tissue injury. While specific viral antigen-antibody complexes can be identified in acute and chronic viral hepatitis, the nature of the immune complexes in AIH has not been defined.

CLINICAL FEATURES

Many of the *clinical features* of AIH are similar to those described for chronic viral hepatitis. The onset of disease may be insidious or abrupt; the disease may present initially like, and be confused with, acute viral hepatitis. The most common symptom, occurring in ~85% of patients, is fatigue. In severe disease, which accounts for 20–25% of cases, jaundice may be present as well. In approximately a quarter of patients, the diagnosis is made in the absence of symptoms, based on abnormal liver laboratory tests. A subset of patients with AIH has distinct features. Such patients are predominantly young to middle-aged women with marked hyperglobulinemia and high-titer circulating ANAs. This is the group with positive lupus erythematosus (LE) preparations (initially labeled *lupoid* hepatitis) in whom other autoimmune features are common. Fatigue, malaise, anorexia, amenorrhea, acne, arthralgias, and jaundice are common. Occasionally, arthritis, maculopapular eruptions (including cutaneous vasculitis), erythema nodosum, colitis, pleuritis, pericarditis, anemia, azotemia, and sicca syndrome (keratoconjunctivitis, xerostomia) occur. In some patients, complications of cirrhosis, such as ascites and edema (associated with portal hypertension and hypoalbuminemia), encephalopathy, hypersplenism, coagulopathy, or variceal bleeding may bring the patient to initial medical attention.

The course of AIH may be variable. In patients with mild disease or limited histologic lesions (e.g., interface hepatitis, labeled in the past as piecemeal necrosis [inflammation and erosion of the limiting place of periportal hepatocytes] without bridging necrosis and fibrosis), progression to cirrhosis may be limited, but, even in this subset, treatment and careful monitoring remain warranted, because, if untreated, up to half can progress to cirrhosis over 15 years. Also, asymptomatic patients, if left untreated, have a lower 10-year overall survival. In North America, cirrhosis at presentation is more common in African Americans than in whites. In those with severe symptomatic AIH (aminotransferase levels >10 times normal, marked hyperglobulinemia, "aggressive" histologic lesions—bridging necrosis or multilobular collapse, cirrhosis), the 6-month mortality without therapy may be as high as 40%. Such severe disease accounts for only 20% of cases; the natural history of milder disease is variable, often accentuated by spontaneous remissions and exacerbations. In a 10-year (2006–2016) national Dutch study, mortality in patients with AIH was higher than that of the general population only in patients with cirrhosis; for patients without cirrhosis, survival was

comparable to that of the general population. Especially poor prognostic signs include the presence histologically of multilobular collapse at the time of initial presentation and failure of serum bilirubin to improve after 2 weeks of therapy. Death may result from hepatic failure, hepatic coma, other complications of cirrhosis (e.g., variceal hemorrhage), and intercurrent infection. In patients with established cirrhosis, HCC may be a late complication **(Chap. 87)** but occurs less frequently than in cirrhosis associated with viral hepatitis.

Laboratory features of AIH are similar to those seen in chronic viral hepatitis. Liver biochemical tests are invariably abnormal but may not correlate with the clinical severity or histopathologic features in individual cases. Many patients with AIH have normal serum bilirubin, alkaline phosphatase, and globulin levels with only minimal aminotransferase elevations. Most commonly, serum AST and ALT levels are increased and fluctuate in the range of 100–1000 units. In severe cases, the serum bilirubin level is moderately elevated (51–171 μmol/L [3–10 mg/dL]). Hypoalbuminemia occurs in patients with very active or advanced disease. Serum alkaline phosphatase levels may be moderately elevated or near normal. In a small proportion of patients, marked elevations of alkaline phosphatase activity occur; in such patients, clinical and laboratory features overlap with those of primary biliary cholangitis **(Chap. 355)**. The prothrombin time is often prolonged, particularly late in the disease or during active phases.

Polyclonal hypergammaglobulinemia (>2.5 g/dL) is common in AIH, as is the presence of rheumatoid factor. As noted above, circulating autoantibodies are also prevalent, most characteristically ANAs in a homogeneous staining pattern. Smooth-muscle antibodies are detected in 63% of cases and, when combined with a positive ANA, have high specificity. Of important note, low-titer ANA or ASMA is observed often in other liver diseases, including metabolic dysfunction–associated steatotic liver disease (in one series, 20% of patients had a positive ANA and 14% had a positive ASMA) and viral hepatitis. Studies of autoantibodies in AIH have led to the recognition of two categories of AIH. *Type I AIH* is the classic syndrome prevalent in North America and northern Europe occurring in young women, associated with marked hyperglobulinemia, lupoid features, circulating ANAs, and HLA-DR3 or HLA-DR4 (especially *B8-DRB1*03*). Also associated with type I AIH are autoantibodies against F-actin and atypical perinuclear antineutrophilic cytoplasmic antibodies (pANCA). Included in the spectrum of type I AIH is a subset of patients who lack ANA and anti-LKM1 but who have circulating antibodies to soluble liver antigen (SLA). Most of these patients are women and have clinical features similar to, or perhaps more severe than, those of other patients with type I AIH. The presence of SLA autoantibodies has been reported to be associated with a worse prognosis.

Type II AIH, often seen in children, more common in Mediterranean populations, and linked to HLA-DRB1 and HLA-DQB1 haplotypes, is associated not with ANA but with anti-LKM. Actually, anti-LKMs represent a heterogeneous group of antibodies. In type II AIH, the antibody is anti-LKM1, directed against cytochrome P450 2D6. This is the same anti-LKM seen in some patients with chronic hepatitis C. Anti-LKM2 is seen in drug-induced hepatitis, and anti-LKM3 (directed against uridine diphosphate glucuronyltransferases) is seen in patients with chronic hepatitis D but has also been observed in type II AIH. Another autoantibody observed in type II AIH is directed against liver cytosol formiminotransferase cyclodeaminase (anti-liver cytosol 1 [LC-1]).

Liver biopsy is imperative to make the diagnosis of AIH. Abnormalities are similar to those described for chronic viral hepatitis, but classic features of AIH include inflammation involving not only the portal tracts but extending beyond the portal tracts (*interface hepatitis*), the presence of plasma cells in the inflammatory infiltrate, and central vein perivenulitis. Necroinflammatory activity characterizes the lobular parenchyma, and evidence of hepatocellular regeneration is reflected by "rosette" formation, the occurrence of thickened liver cell plates, and regenerative "pseudolobules." Septal fibrosis, bridging fibrosis, and cirrhosis are frequent. In patients with early AIH presenting as an acute-hepatitis-like illness, lobular and centrilobular (as opposed to the more common periportal) necrosis has been reported. Bile duct injury and granulomas are uncommon; however, a subgroup of patients with AIH has histologic, biochemical, and serologic features overlapping those of primary biliary cholangitis **(Chap. 355)**.

DIAGNOSTIC CRITERIA

An international group has suggested a set of criteria for establishing a diagnosis of AIH. Exclusion of liver disease caused by genetic disorders, viral hepatitis, drug hepatotoxicity, and alcohol is linked with such inclusive diagnostic criteria as hyperglobulinemia, autoantibodies, and characteristic histologic features. This international group has also suggested a comprehensive diagnostic scoring system that, rarely required for typical cases, may be helpful when typical features are not present. Factors that weigh in favor of the diagnosis include female gender; predominant aminotransferase elevation; presence and level of globulin elevation; presence of nuclear, smooth-muscle, LKM1, and other autoantibodies; concurrent other autoimmune diseases; characteristic histologic features (interface hepatitis, plasma cells, rosettes); HLA-DR3 or DR4 markers; and response to treatment (see below). A more simplified, more specific scoring system relies on four variables: presence of autoantibodies (ANA, ASMA, anti-SLA or LKM), elevated serum IgG level, typical or compatible histologic features, and absence of viral hepatitis markers. Elevated aminotransferase levels are also required for the diagnosis of AIH. Weighing against the diagnosis are predominant alkaline phosphatase elevation, mitochondrial antibodies, markers of viral hepatitis, history of hepatotoxic drugs or excessive alcohol, histologic evidence of bile duct injury, or such atypical histologic features as fatty infiltration, iron overload, and viral inclusions.

DIFFERENTIAL DIAGNOSIS

Early during the course of chronic hepatitis, AIH may resemble typical *acute viral hepatitis or drug-induced liver injury* **(Chap. 350)**. Exclusion of acute viral hepatitis with serologic testing is critical. In adolescence, *Wilson disease* **(Chaps. 355 and 427)** may present with features of chronic hepatitis long before neurologic manifestations become apparent and before the formation of Kayser-Fleischer rings (copper deposition in Descemet's membrane in the periphery of the cornea). In this age group, serum ceruloplasmin and serum and urinary copper determinations plus measurement of liver copper levels establish the correct diagnosis. *Cryptogenic cirrhosis* and *primary biliary cholangitis* **(Chap. 355)** share clinical features with AIH, and both alcohol-associated hepatitis **(Chap. 353)** and metabolic dysfunction–associated steatohepatitis (MASH; formerly nonalcoholic steatohepatitis [NASH], **Chap. 354**) may present with many features common to AIH; historic, biochemical, serologic, and histologic assessments are usually sufficient to allow these entities to be distinguished from AIH. The distinction between autoimmune and chronic viral hepatitis may not be straightforward, especially when viral antibodies occur in patients with autoimmune disease or when autoantibodies occur in patients with viral disease. Furthermore, the presence of extrahepatic features such as arthritis, cutaneous vasculitis, or pleuritis—not to mention the presence of circulating autoantibodies—may cause confusion with *rheumatologic disorders* such as rheumatoid arthritis and systemic LE. The existence of clinical and biochemical features of progressive necroinflammatory liver disease distinguishes chronic hepatitis from these other disorders, which are not associated with severe liver disease. Rarely, hepatic venous outflow obstruction (Budd-Chiari syndrome) may present with features suggestive of AIH, but painful hepatomegaly, ascites, and vascular imaging provide distinguishing diagnostic clues. Other diagnostic considerations would include celiac disease and ischemic liver disease, which would be readily distinguishable by clinical and laboratory features from AIH.

In patients treated with immune checkpoint inhibitors for malignancy, the liver may be one of the autoimmune targets of therapy; the syndrome of immune checkpoint inhibitor (ICI) hepatitis resembles AIH in clinical features (without the female preponderance, however) and response to glucocorticoid-based treatment; however, patients with ICI are less likely to have ANA, which, if present, is low-titer and unlikely to have plasma cell inflammatory infiltrates histologically. Similar to de novo AIH, ICI hepatitis encompasses a spectrum of severity, and some cases may be refractory to standard

therapeutics. Finally, occasionally, features of AIH overlap with features of autoimmune biliary disorders such as primary biliary cholangitis, primary sclerosing cholangitis **(Chaps. 355 and 357)**, or, even more rarely, mitochondrial antibody-negative autoimmune cholangitis. Such overlap syndromes are difficult to categorize, and often response to therapy may be the distinguishing factor that establishes the diagnosis.

TREATMENT

Autoimmune Hepatitis

The mainstay of management in AIH is glucocorticoid therapy, which is highly effective for the induction of remission. Several controlled clinical trials have documented that such therapy leads to symptomatic, clinical, biochemical, and histologic improvement as well as increased survival. A therapeutic response to glucocorticoids can be expected in up to 80% of patients, and recent consensus opinion defines response as a >50% reduction in ALT by 4 weeks of therapy; however, a dramatic reduction within days is uncommon after the initiation of corticosteroids. Although some advocate the use of prednisolone (the hepatic metabolite of prednisone), prednisone is just as effective and is favored by most authorities. A popular regimen in the United States relies on an initiation dose of 60 mg/d. This high dose is tapered successively over the course of a month down to a goal of 10–20 mg/d. In the European literature, successful treatment for AIH has been achieved with a prednisone starting dose of 20 mg. For patients with a mild presentation, budesonide, while inferior to prednisone in AIH, is an alternative first-line corticosteroid with limited systemic effects related to its extensive hepatic first-pass metabolism that achieves similar rates of biochemical response in patients with aminotransferase levels <2× the upper limit of normal.

After an early response to corticosteroids is observed, a steroid-sparing agent should be initiated to maintain remission. Azathioprine, considered first-line treatment for *nonicteric* or severe AIH, should be introduced 7–14 days after corticosteroids are started and a response is observed. Testing for thiopurine *S*-methyltransferase activity is recommended during this period prior to initiation of azathioprine. Dosing of azathioprine may be between 50 and 150 mg, and some experts titrate the dose upward after starting at 50 mg. Once on maintenance azathioprine (typically 1–2 mg/kg per day), prednisone is tapered further to a maintenance dose of 5–10 mg. If the patient achieves full biochemical remission, an attempt to taper prednisone completely is reasonable.

The advantage of this combination approach is a reduction, over the span of an 18-month course of therapy, in serious, life-threatening complications of steroid therapy (e.g., cushingoid features, hypertension, diabetes, osteoporosis) from 66% down to <20%.

Improvement of fatigue, anorexia, malaise, and jaundice tends to occur within days to several weeks; biochemical improvement occurs over the course of several weeks to months, with a fall in serum bilirubin and globulin levels and an increase in serum albumin. Serum aminotransferase levels usually drop promptly, but improvements in AST and ALT alone do not appear to be reliable markers of recovery in individual patients; histologic improvement, characterized by a decrease in mononuclear infiltration and in hepatocellular necrosis, may be delayed for 6–24 months. Still, if interpreted cautiously, aminotransferase levels, and immunoglobulin levels in some, are valuable indicators of relative disease activity, and although recommended, many authorities do *not* advocate for serial liver biopsies to assess therapeutic success or to guide decisions to alter or stop therapy. Therapy should continue for at least 24 months after biochemical remission. After tapering and cessation of therapy, the likelihood of relapse is at least 50%, and in one multicenter study, the rate of relapse was 81% after 3 years. In fact, most (95% of) patients will require treatment at maintenance doses indefinitely. Patients who relapse after completing one course of therapy almost always relapse after subsequent courses; because each relapse increases the risk of cirrhosis, death, and need for liver transplantation, ideally, patients who relapse once should be treated indefinitely.

If azathioprine is not tolerated because of adverse effects (such as marrow suppression, fatigue, or gastrointestinal symptoms), both 6-mercaptopurine (6MP) and mycophenolate mofetil (MMF) are considered second-line alternative agents; if azathioprine is ineffective, MMF (1.5–2.0 g/d in divided doses) is the next drug of choice. While MMF has yet to be compared to azathioprine in a randomized controlled clinical trial, in a recent prospective study, MMF was at least as effective, if not more so, than azathioprine in achieving biochemical remission and may be better tolerated. A downside of MMF that merits consideration is the risk of teratogenicity.

In cases of AIH refractory to standard treatment (azathioprine, 6-MP, or MMF, with or without prednisone) and in whom coexisting other causes for liver disease have been excluded, several additional treatments are options. Tacrolimus has been shown to be effective. Small studies of tacrolimus have shown a decline in aminotransferase levels in up to 80% after 3 months of therapy; however, tacrolimus requires careful trough monitoring and comes with a risk of nephrotoxicity. Treatment with monoclonal anti-CD20 (rituximab), described initially in a small pediatric case series, is another promising option that has been used with increasing frequency in refractory AIH. In one cohort study, rituximab given to patients with refractory AIH (1000-mg IV infusion given twice, 2 weeks apart) achieved remission rates of 95% at 1 year and 71% at 2 years and permitted substantial corticosteroid dose reduction.

When medical therapy fails, including in severe acute AIH refractory to high-dose corticosteroids or when AIH progresses to cirrhosis and end-stage liver disease, liver transplantation is the only recourse **(Chap. 356)**; in patients with severe AIH, failure of the bilirubin to improve after 2 weeks of therapy should prompt early consideration of the patient for liver transplantation. Recurrence of AIH in the new liver occurs rarely in most experiences but in as many as 35–40% of cases in others; nonetheless, 5-year patient and graft survival exceed 80%.

Like all patients with chronic liver disease, patients with AIH should be vaccinated against hepatitis A and B, ideally before immunosuppressive therapy is begun, if practical. Similarly, age- and gender-appropriate vaccinations, such as human papillomavirus, varicella-zoster virus, pneumococcal, and COVID-19, should be administered prior to immunosuppressive therapy. Patients with AIH and cirrhosis should be screened for HCC with ultrasound at 6-month intervals and may merit screening for varices with upper gastrointestinal endoscopy, based on the severity of liver disease **(Chap. 355)**.

353 Alcohol-Associated Liver Disease

Bernd Schnabl

Alcohol-associated liver diseases (ALD) comprise a spectrum of diseases associated with chronic alcohol consumption ranging from alcohol-associated fatty liver disease and steatohepatitis to more advanced liver disease including fibrosis and cirrhosis. Acute alcohol-associated hepatitis is an acute-on-chronic form of ALD that is associated with liver failure and high mortality.

EPIDEMIOLOGY

Approximately 7% of adults in the United States meet criteria for unhealthy drinking, defined as ≥2 drinks per day in women and ≥3 drinks per day in men, or partake in heavy episodic drinking, defined as ≥4 drinks for women and ≥5 drinks for men on a single occasion (1 drink equals ~14 g of ethanol, which is 1 beer, 4 oz of wine, or 1 oz of 80% spirits). The COVID-19 pandemic increased excessive alcohol intake, resulting in a rise in morbidity and mortality linked to ALD. Prevalence of ALD correlates with the amount of alcohol consumption in different regions. Prevalence of alcohol-associated fatty liver disease is 4.7% of the general population in the United States, and 1.5% has stage 2 or greater fibrosis. Liver cirrhosis is the eleventh leading cause of mortality worldwide, causing 1.16 million deaths annually; 48% of cases of cirrhosis can be attributed to alcohol. Among patients with alcohol misuse, 18% had fibrosis, 26% had cirrhosis, and 7% had acute alcohol-associated hepatitis without underlying cirrhosis. In the European population, the annual incidence rate for acute alcohol-associated hepatitis is between 24 and 27 per million persons in women and between 46 and 65 per million persons in men.

PATHOGENESIS

Alcohol in the form of ethanol is rapidly absorbed in the upper gastrointestinal tract and predominantly metabolized in the liver. Ethanol reaches the liver through the portal vein, and the majority of ethanol is oxidized via alcohol dehydrogenase 1 (ADH1) into acetaldehyde in hepatocytes. Chronic alcohol consumption induces the expression of a second ethanol-metabolizing enzyme, cytochrome P450 family 2 subfamily E member 1 (CYP2E1), which also converts ethanol into acetaldehyde. In addition to the direct cellular toxic effects of acetaldehyde, metabolism of ethanol into acetaldehyde causes the generation of reactive oxygen species (ROS), resulting in further injury of hepatocytes via lipid peroxidation and DNA damage. Acetaldehyde is then oxidized into acetate via acetaldehyde dehydrogenase (ALDH). Inherited deficiency of ALDH2 is common in Asian countries and leads to acetaldehyde accumulation after alcohol consumption. These individuals develop nausea and cutaneous flushing. Several mechanisms contribute to the development of hepatic steatosis related to alcohol consumption. Acetate is converted into acetyl-coenzyme A (CoA), which contributes to fatty acid and triglyceride synthesis. Alcohol, in part through epigenetic changes, increases the expression of genes involved in lipogenesis, while genes involved in fatty acid transport and oxidation are suppressed. Alcohol also increases the ratio of reduced nicotinamide adenine dinucleotide (NAD)/oxidized NAD ($NADH/NAD^+$) in hepatocytes, which further reduces mitochondrial β-oxidation. Alcohol can increase fatty acid mobilization in adipose tissue and the intestine, which will lead to hepatic accumulation of fatty acids and increased hepatic steatosis. Overall, the net effect of these processes contributes to accumulation of lipids in the liver.

RISK FACTORS FOR PROGRESSION OF ALD

Daily alcohol consumption or heavy drinking results in hepatic steatosis, but only 10–20% of such individuals will develop progressive liver disease and cirrhosis. Therefore, other cofactors such as behavioral, environmental, and genetic factors play important roles in progression of ALD **(Table 353-1)**. There is a dose-dependent increase, with regard to the amount of alcohol consumed, in the likelihood of developing liver cirrhosis. Women develop ALD at a lower daily alcohol intake. Cigarette smoking is an independent risk factor for alcohol-associated cirrhosis. The drinking pattern, in particular binge drinking and excessive alcohol drinking outside meals, increases the risk of developing progressive ALD. Obesity and metabolic dysfunction–associated steatotic liver disease (MASLD) are frequent cofactors contributing to progression of ALD. A distinct subset of patients within ALD, termed as metabolic ALD (MetALD), now describes patients with MASLD and increased alcohol consumption. Other chronic liver diseases such as viral hepatitis and hemochromatosis can have synergistic effects on ALD. Twin studies demonstrated a genetic predisposition to alcohol-associated liver cirrhosis that is independent from the genetic predisposition to alcohol use disorder. Gene polymorphisms conferring increased risk of alcohol-associated liver cirrhosis have been found in three genes, patatin-like phospholipase domain-containing 3 (*PNPLA3*), membrane bound O-acyltransferase domain-containing 7 (*MBOAT7*), and transmembrane 6 superfamily member 2 (*TM6SF2*), although the molecular mechanism is not well understood. Genetic variants in hydroxysteroid 17-beta dehydrogenase 13 (*HSD17B13*) and Fas-associated factor family member 2 (*FAF2*) are associated with a reduced risk of developing ALD. A subset of patients with alcohol use disorder develop changes in the gut microbiome and increased intestinal permeability. This leads to the passage of microbial components, like bacterial lipopolysaccharide (LPS), through the portal vein into the liver resulting in hepatic inflammation, hepatocyte death, and activation of fibrotic pathways. Ongoing fibrosis resulting from sustained alcohol consumption progresses to cirrhosis accompanied by portal hypertension. Impaired liver regeneration might contribute to the acute onset of alcohol-associated-hepatitis in patients with underlying cirrhosis **(Chap. 355)**.

TABLE 353-1 Factors for Progression of Alcohol-Associated Liver Disease

- Alcohol amount and duration
- Drinking pattern (drinking without meal, binge drinking)
- Genetic factors, especially *PNPLA3* polymorphism
- Female sex
- Smoking
- Obesity and metabolic dysfunction–associated steatotic liver disease (MASLD)
- Chronic liver diseases such as viral hepatitis and hemochromatosis
- Intestinal microbiota

TABLE 353-2 Symptoms and Signs Associated with Alcohol-Associated Cirrhosis and Alcohol-Associated Hepatitis

- Tiredness
- Malnutrition and sarcopenia
- Abdomen: abdominal discomfort, hepatomegaly, splenomegaly, caput medusae, ascites with weight gain, abdominal pain, and shortness of breath
- Skin: spider angioma, palmar erythema, jaundice, ecchymoses
- Eyes: icteric sclerae
- Hands: Dupuytren contracture
- Extremities: edema
- Face: rhinophyma
- Reproductive system: gynecomastia, gonadal atrophy, loss of libido, amenorrhea
- Neurologic:
  - Peripheral neuropathy
  - Alcohol withdrawal: tachycardia, agitation, tremor, seizures, delirium
  - Hepatic encephalopathy: asterixis (flapping tremor), forgetfulness, inversion of sleep/wake pattern, altered consciousness, confusion, lethargy, coma
  - Wernicke-Korsakoff syndrome

CLINICAL FEATURES

The development of alcohol-associated steatosis, steatohepatitis, and cirrhosis is most often clinically silent. Symptoms arise once the patient with alcohol-associated liver cirrhosis decompensates or develops alcohol-associated hepatitis **(Table 353-2)**. Patients with alcohol-associated hepatitis have been drinking heavily (>40 g/d for women and >50–60 g/d for men) for >6 months with <60 days of abstinence before onset of symptoms. They present with rapid onset of jaundice (serum bilirubin >3 mg/dL), often accompanied by fever, malaise, tender hepatomegaly, and clinical signs of hepatic decompensation, such as ascites, bacterial infection, variceal bleeding, and hepatic encephalopathy. Infections occur in 12–26% of patients with severe alcohol-associated hepatitis at the time of admission. Alcohol-associated hepatitis is often accompanied by systemic inflammatory response syndrome (SIRS) and acute kidney injury (AKI) secondary to hepatorenal syndrome.

LABORATORY FINDINGS

Patients with simple hepatic steatosis can present with normal liver function tests. Steatohepatitis is characterized by elevated levels of aspartate aminotransferase (AST) and γ-glutamyl transferase (GGT). Characteristic laboratory parameters for ALD include a ratio of AST to alanine aminotransferase (ALT) of >1, and serum AST is rarely >300 IU/L. Serum bilirubin and international normalized ratio (INR) are typically normal. Elevated bilirubin and INR and low serum albumin and platelet count are common laboratory finings in patients with cirrhosis. Patients with alcohol-associated hepatitis have AST and ALT elevations that do not exceed 400 IU/L, with AST/ALT ratio of >1.5 and serum bilirubin >3 mg/dL.

DIAGNOSIS

The Alcohol Use Disorders Inventory Test (AUDIT) is a validated tool for identifying patients with alcohol use disorder **(Chap. 464)**. Diagnosis of ALD requires exclusion of other liver diseases in heavy drinkers. Alcohol-associated steatosis can be diagnosed by simple ultrasound, magnetic resonance imaging (MRI), or computed tomography (CT). Noninvasive quantification of hepatic fat can be achieved with the

ultrasound technique of controlled attenuation parameter (CAP) or with magnetic resonance proton density fat fraction (MR-PDFF). Liver biopsy is rarely indicated for diagnosing alcohol-associated hepatic steatosis or steatohepatitis. Liver biopsy typically shows hepatocytes with large lipid droplets (macrovesicular steatosis) around pericentral veins (zone 3). Morphologic features of alcohol-associated steatohepatitis include hepatocyte injury and ballooning with Mallory-Denk bodies, necrosis, and lobular inflammation with mononuclear and neutrophilic granulocytes.

Progression of alcohol-associated steatohepatitis to fibrosis can be diagnosed using liver stiffness measurement by techniques such as transient elastography (e.g., FibroScan). Liver stiffness <6 kPa indicates normal liver, whereas cutoffs for each stage of alcohol-associated liver fibrosis have been validated (>8 kPa indicates ≥F3 advanced fibrosis; >12.5 kPa indicates F4 cirrhosis). Fibrosis-4 (Fib-4) score is a serum marker test based on age, AST, ALT, and platelets and can be used to exclude advanced fibrosis or cirrhosis at a threshold value <3.25. Histology shows initially perivenular fibrosis with subsequent extension of collagen fibers into hepatic lobules, described as septal fibrosis. Patients with cirrhosis show liver nodularity on imaging with ultrasound, MRI, or CT scan. Radiologic signs of portal hypertension include ascites, splenomegaly, and portal-systemic collateral vessels. Prognosis and risk of mortality are assessed using Child-Pugh-Turcotte (CPT) or Model for End-Stage Liver Disease (MELD; or sodium-MELD) scores **(Chap. 355)**.

In patients presenting with features suggestive of alcohol-associated hepatitis, imaging is obtained to exclude biliary obstruction and hepatocellular carcinoma (HCC). In addition, other causes of liver disease such as viral hepatitis, Wilson's disease, and severe autoimmune liver disease should be ruled out. Histology shows macrovesicular steatosis, hepatocyte ballooning with Mallory-Denk bodies, megamitochondria, neutrophil infiltration, ductular reaction, bilirubinostasis, and chicken wire fibrosis. The majority of patients with alcohol-associated hepatitis have underlying cirrhosis (80%) **(Chap. 355)**, and 10–20% of patients with a clinical diagnosis of alcohol-associated hepatitis will have other liver diseases on biopsy. Therefore, in the presence of potential confounding factors, including possible ischemic hepatitis (in the setting of, e.g., hypotension, massive gastrointestinal bleeding, recent cocaine use, septic shock), drug-induced liver injury (DILI), autoimmune liver disease, uncertain alcohol use assessment, or atypical laboratory tests (AST <50 IU/L or >400 IU/L, AST/ALT ratio <1.5), a transjugular liver biopsy is recommended to confirm the diagnosis of alcohol-associated hepatitis. Infections need to be assessed routinely with chest x-ray and blood, urine, and ascites cultures in patients presenting with alcohol-associated hepatitis.

TREATMENT

Alcohol-Associated Liver Disease (Fig. 353-1)

To date, the most effective therapy to reduce the progression of and reverse ALD is prolonged alcohol abstinence. In particular, alcohol-associated hepatic steatosis and steatohepatitis are reversible with cessation of alcohol consumption. Thus, treatment of the underlying alcohol use disorder is an integral part for therapy of ALD. There are currently no approved drugs for treatment of alcohol-associated steatosis and steatohepatitis with or without fibrosis.

Patients with alcohol-associated cirrhosis and ongoing alcohol consumption are at risk for decompensation and development of hepatic encephalopathy, ascites, variceal bleeding, hepatorenal syndrome, and HCC **(Chap. 355)**. Patients with cirrhosis should undergo an upper gastrointestinal endoscopy to screen for varices. HCC screening is recommended using liver ultrasonography and serum α-fetoprotein (AFP) every 6 months in patients with cirrhosis. Management of complications of cirrhosis such as variceal bleeding, ascites, hepatic encephalopathy, and HCC does not differ from patients with cirrhosis due to a different etiology **(Chap. 355)**. Liver transplantation for patients with alcohol-associated decompensated cirrhosis or HCC is a definitive

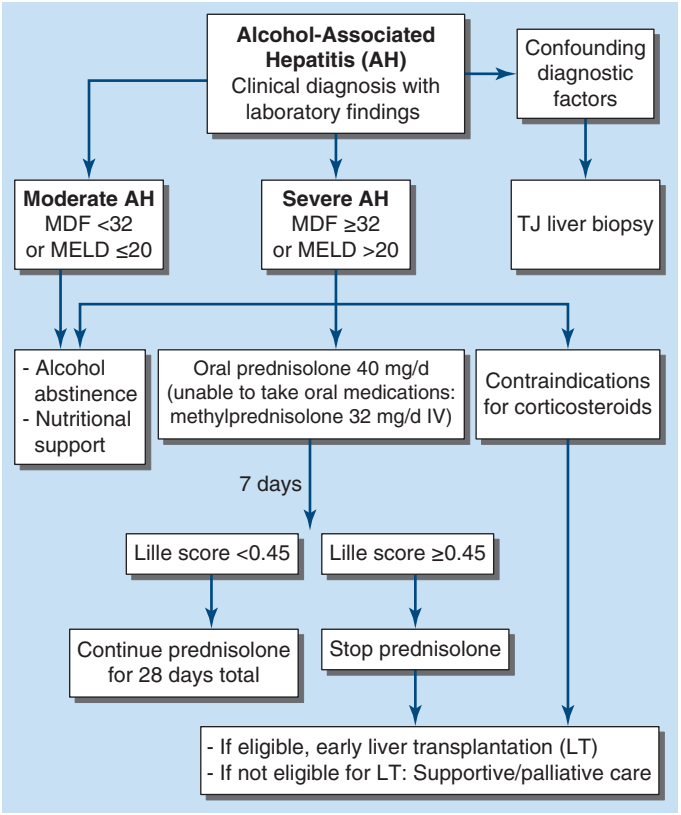

FIGURE 353-1 Treatment algorithm for alcohol-associated hepatitis. In patients with a clinical diagnosis of alcohol-associated hepatitis, confounding factors (see text) need to be ruled out, if necessary, by transjugular (TJ) liver biopsy. Patients with severe alcohol-associated hepatitis (AH), defined as Maddrey discriminant function (MDF) ≥32 or Model for End-Stage Liver Disease (MELD) score >20, without contraindications for glucocorticoids (see text) are candidates for such treatment. Nonresponders or patients with contraindications for treatment should be considered for early liver transplantation (LT) or supportive or palliative care, as clinically appropriate.

therapy and is currently the leading indication for liver transplantation in the United States. Liver transplantation evaluation should be taken into consideration for patients with end-stage liver disease **(Chap. 356)**.

In patients diagnosed with alcohol-associated hepatitis (Fig. 353-1), short-term mortality can be predicted using the Maddrey discriminant function (MDF; calculated as 4.6 × [the prolongation of the prothrombin time above control {seconds}] + serum bilirubin [mg/dL]), MELD score **(Chap. 355)**, or age-bilirubin-INR-creatinine (ABIC) score. Patients with MDF <32 or MELD ≤20 are defined as having moderate alcohol-associated hepatitis. Currently, patients with moderate alcohol-associated hepatitis are treated under a multidisciplinary team including an alcohol use disorder specialist, dietitian for nutritional supplementation for patients with markedly reduced intake, and hepatologist for managing liver disease complications. Enteral nutrition with a goal of 35–40 kcal/kg and supplementation of micronutrients (in particular zinc) and vitamin supplementation (in particular vitamin B_1 and K) are recommended for patients with alcohol-associated hepatitis. Intravenous albumin is preferred for volume expansion. Patients with moderate alcohol-associated hepatitis have a 20% risk of 1-year mortality. MDF ≥32 or MELD >20 identifies patients with severe alcohol-associated hepatitis and high short-term mortality of ~30% at 3 months, who will have a survival benefit with glucocorticoid treatment. Contraindications for glucocorticoid treatment include uncontrolled infections or sepsis, AKI and hepatorenal syndrome, uncontrolled upper gastrointestinal bleeding, concomitant diseases (including viral hepatitis, HCC, pancreatitis, DILI, active tuberculosis, and HIV), multiorgan failure, and shock. Glucocorticoids can be used once infection, sepsis, and gastrointestinal bleeding are adequately controlled.

Glucocorticoid use reduces the risk of death in patients with severe alcohol-associated hepatitis within 28 days of treatment but not in the following 6 months. Oral prednisolone, 40 mg/d for a total duration of 4 weeks, is preferred. For patients unable to take oral medications, methylprednisolone, 32 mg/d IV, is used. The combination of glucocorticoids with *N*-acetylcysteine infusion might add short-term survival benefit at 1 month. Failure of improvement of Lille score (≥0.45) after 7 days of glucocorticoid treatment will determine patients with severe alcohol-associated hepatitis who will unlikely benefit from continued treatment with glucocorticoids. Glucocorticoids should be stopped in nonresponders, and early liver transplantation should be considered. Although short-term prognosis is dependent on liver disease severity at the time of presentation, long-term prognosis (>1 year) largely depends on alcohol abstinence and underlying cirrhosis. Patients with severe alcohol-associated hepatitis that is nonresponsive to medical therapy have high 30-day mortality and are therefore unable to fulfill a minimum of 6 months of alcohol abstinence, which is required in many centers for liver transplantation evaluation. Early liver transplantation can be successfully performed in highly selected patients with an excellent psychosocial profile **(Chap. 356)**. If a nonresponder is ineligible for early liver transplantation, supportive or palliative care should be considered for patients with multiple-organ failure.

354 Metabolic Dysfunction–Associated Steatotic Liver Disease and Steatohepatitis

Manal F. Abdelmalek, Anna Mae Diehl

DISEASE NOMENCLATURE

Under the umbrella term of steatotic liver disease (SLD), metabolic dysfunction–associated steatotic liver disease (MASLD) and metabolic dysfunction–associated steatohepatitis (MASH) now replace the historical terms nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH). The new disease nomenclature emphasizes that SLD in people who do not drink alcohol excessively is strongly associated with metabolic dysfunction while minimizing stigma associated with the terms *nonalcoholic* and *fatty*. Accordingly, people who fulfill the new diagnostic criteria for MASLD/MASH have hepatic steatosis, drink little alcohol (<20 g/d for women and <30 g/d for men) and have one or more cardiometabolic risk factors (e.g., overweight/obesity, hypertension, dyslipidemia, insulin resistance/type 2 diabetes). In addition, a new subcategory of SLD has been generated, termed metabolic and alcohol-associated liver disease (MetALD), for SLD patients who have evidence of metabolic dysfunction but also consume social amounts of alcohol (20–50 g/d for woman; 30–60 g/d for men). Higher amounts of alcohol use, irrespective of the presence of metabolic risk factors, is defined as alcohol-associated liver disease (ALD) **(Chap. 353)**. Epidemiologic data demonstrate almost complete (at least 98%) overlap between the population historically defined as NAFLD/NASH and the population categorized as MASLD/MASH using the new diagnostic criteria.

INCIDENCE, PREVALENCE, AND NATURAL HISTORY

SLD is the most common cause of chronic liver disease in the United States and worldwide. The main causes of SLD are ALD and MASLD. The prevalence of MASLD is rising in parallel with increases in the prevalence of obesity and conditions associated with metabolic syndrome (i.e., insulin resistance, dyslipidemia, central obesity, and hypertension). Hence, MASLD is currently a leading indication for liver transplantation in the United States. While prevalence estimates of MASLD vary based on clinical setting, race/ethnicity, and geographic region, 25–30% of the general U.S. adult population is currently estimated to have MASLD, and at least 3–6% of the group with MASLD is thought to have MASH, i.e., a type of inflammatory liver cell injury that can develop in individuals with metabolic dysfunction–associated steatosis (MASL). Because MASH increases the rate of liver cell death, it can trigger liver scarring (i.e., fibrosis) and, over time, progress to cirrhosis. The prevalence of MASH is increasing as the population ages. For example, a recent study identified MASH in 14% of asymptomatic patients who were ≥50 years of age and undergoing colon cancer screening. With the rise in MASH, the prevalence of clinically significant hepatic fibrosis (hepatic fibrosis ≥ stage 2 [F2]) has increased more than twofold in the past two decades alone. Mirroring the projected rise of MASH, the proportion of patients with advanced hepatic fibrosis (bridging fibrosis [F3] or compensated cirrhosis [F4]) will also increase. Similar to cirrhosis caused by other liver diseases, cirrhosis caused by MASLD increases the risk of hepatic decompensation, hepatocellular carcinoma (HCC), and liver-related morbidity and mortality. In addition, MASLD may be a premalignant condition, increasing the risk for both primary liver cancers and extrahepatic malignancies, even in noncirrhotic livers. MASL, MASH, and MASH-related cirrhosis are not limited to adults. Indeed, these diseases are increasingly documented in children and adolescents. As in adults, weight gain and related insulin resistance are the main risk factors for pediatric MASLD. Thus, the rising incidence and prevalence of childhood obesity is a major contributor to projected future public health burden of liver disease.

Although MASLD typically occurs in the presence of overweight/obese status, it can occur in lean individuals and is particularly common in those with truncal obesity and a paucity of peripheral adipose depots (i.e., lipodystrophy). Ethnic and racial factors influence liver fat accumulation, with documented prevalence of MASLD being lowest in African Americans (~25%), highest in Hispanic and Asian-Indians (~50%), and intermediate in whites (~30%).

MASLD encompasses a spectrum of liver pathology **(Fig. 354-1)** and, thus, has a variable clinical prognosis. The accumulation of triglyceride within hepatocytes in the absence of overt liver injury or inflammation on liver biopsy (i.e., hepatic steatosis) is the most clinically benign extreme of the MASLD spectrum. Although steatotic livers can remain stable for years, they can also reversibly transition to a more clinically dangerous state that is characterized by accumulation of inflammatory cells and injured/dying steatotic hepatocytes (i.e., steatohepatitis, MASH). Like steatosis, MASH can remain stable, wax and wane, or intensify over time. Repeated or protracted bouts of MASH trigger regenerative responses that can become maladaptive, and this increases the risk for progressive liver fibrosis, as well as primary liver cancer. Hence, chronic steatohepatitis is the primary predictor for hepatic fibrosis in MASLD. Fibrosis is a biomarker for defective liver regeneration. As functional hepatic parenchyma is replaced by scar, fibrosis severity increases. Livers with MASLD variably progress from a state of no fibrosis (F0) through stages of minimal fibrosis (F1), significant fibrosis (F2), advanced fibrosis (F3), and ultimately, severe fibrosis/

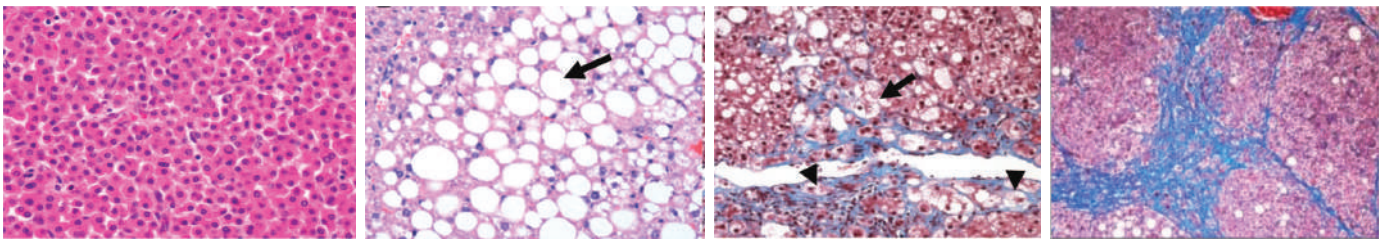

FIGURE 354-1 Histopathologic spectrum of metabolic dysfunction–associated steatotic liver disease (MASLD). MASLD encompasses a dynamic spectrum of liver pathology. ***A.*** Healthy liver. ***B.*** Simple steatosis (*arrow* shows fatty hepatocyte). ***C.*** Metabolic dysfunction–associated steatohepatitis (MASH); note ballooned hepatocyte (*arrow*) near central vein with adjacent blue-stained pericellular fibrosis (arrowheads). ***D.*** Cirrhosis with blue-stained bridging fibrosis surrounding micronodules of liver parenchyma.

cirrhosis (F4). Although cirrhosis is on the opposite end of the clinical spectrum of MASLD, it is important to emphasize that it can regress. Moreover, MASLD patients generally do not manifest symptoms or signs specific for liver disease until cirrhosis has been present for years. Thus, cirrhosis itself is stratified into compensated cirrhosis and decompensated cirrhosis. Both the risk for developing symptoms and signs of liver disease (i.e., decompensating) and the risk for primary liver cancer increase with the duration of cirrhosis.

Fibrosis severity is the primary predictor of liver-related morbidity and mortality in MASLD. As noted next, MASH increases the risk for fibrosis progression. However, the rate at which fibrosis progresses is influenced by many factors, including presence and severity of comorbid diseases (e.g., diabetes mellitus), genetics (e.g., polymorphisms of certain lipid-regulating genes), and environmental factors (e.g., high-fat, high-sugar diets). Meta-analyses of cohorts with longitudinal paired liver biopsies demonstrate an average fibrosis progression rate of one stage every 14 years in people with steatosis, as compared to one stage every 7 years for patients with MASH. Once fibrosis has progressed to stage F2 or higher, patients with MASH are at increased risk for further fibrosis progression and, thus, eventual bad clinical liver outcomes. Therefore, patients with MASH and fibrosis stage ≥F2 have been designated as having "at-risk MASH," a diagnosis that triggers consideration of more regular and intensive monitoring and therapeutic interventions to improve/resolve MASH and hepatic fibrosis. The primary goal of treatment is to prevent fibrosis progression and thereby decrease liver-related and all-cause morbidity and mortality. Among patients with cirrhosis, progression to clinical decompensation ranges from 3 to 20% per year. In addition, once MASLD-related cirrhosis develops, the annual incidence of primary liver cancer can be as high as 1–2% per year. Therefore, the diagnosis of cirrhosis changes clinical management to incorporate biannual screening for primary liver cancer, screening for esophageal varices in accordance to the Baveno criteria, and monitoring for signs or symptoms of hepatic decompensation **(Chap. 355)**.

MOLECULAR AND CELLUAR PATHOGENESIS

The presence and severity of MASL and MASH are governed by imbalances between energy intake and utilization. Excessive energy (i.e., food) intake, coupled with reduced energy expenditure (i.e., physical activity) and a limited capacity for expansion of peripheral adipose depots to accommodate energy surplus, contribute to development of visceral adiposity, insulin resistance, and metabolic disease.

Steatosis Steatotic hepatocytes are characterized by accumulation of triglyceride. Hepatocytes synthesize triglyceride to store fatty acids, and thus, triglycerides accumulate with increases in hepatocyte exposure to free fatty acids that derive from (1) uptake of dietary fatty acids, (2) release of fatty acids from adipose depots, and/or (3) de novo lipogenesis (DNL) within hepatocytes themselves. Fatty acids can also accumulate in hepatocytes when mechanisms that convert/consume fatty acids are impaired because this increases the pool of fatty acids for triglyceride synthesis. Finally, triglycerides accumulate in hepatocytes when export of triglyceride is impaired. Triglycerides provide a relatively safe way for hepatocytes to store lipids, and thus, triglyceride accumulation per se (i.e., steatosis) does not damage the liver. However, steatosis is a biomarker of metabolic dysfunction, and left unchecked, the latter can drive other events that promote lipotoxicity.

Steatohepatitis Lipotoxicity (i.e., lipid-associated injury) distinguishes steatohepatitis from steatosis. Lipotoxicity results from dysregulated processing of fatty acids and/or other precursors/products of lipids that are stored with triglyceride in lipid droplets, leading to accumulation of toxic intermediates and/or by-products. The onset of lipotoxic stress has variable outcomes among individuals and within a given individual over the life span because multiple dynamic factors interact to determine hepatocyte resilience (i.e., the capacity to adapt metabolism in order to prevent, withstand, or repair damage to critical cellular components). Efficient resolution of lipotoxic stress permits recovery from steatohepatitis. However, adaptations that merely enable hepatocytes to survive despite ongoing lipotoxic stress change both the signals they release (e.g., hepatokines, metabolites) and how they respond to signals from other cells (e.g., adipokines, myokines, hormones, neurotransmitters), eventually altering liver morphology and function, as well as systemic metabolic homeostasis. Hepatocytes that succumb to lipotoxicity during steatohepatitis must be replaced, and this triggers regenerative responses that impose additional challenges to energy/metabolic homeostasis. When regenerative responses are defective, functional hepatic parenchyma is progressively replaced by fibrous scar, leading to cirrhosis and eventual hepatic decompensation. Another potentially lethal outcome of maladaptive repair is liver cancer. The risk for cirrhosis and liver cancer increases with the severity and duration of steatohepatitis (i.e., hepatic lipotoxicity).

Dietary sugars, such as fructose, drive DNL and, thus, increase the risk for steatosis, as do diets enriched with saturated versus unsaturated fat. Insulin resistance in peripheral tissues promotes the release of free fatty acids from adipocytes (lipolysis), increasing the substrate for hepatic triglyceride production. Factors that govern energy balance (i.e., fasting and/or frequency and intensity of exercise, activation of brown adipose tissue to energy-consuming thermogenic phenotype, and counterregulatory mechanisms that diminish energy disposal in response to decreased calorie intake) also determine susceptibility to hepatic steatosis. Genetic factors that impact hepatocyte lipid handling (i.e., I148M polymorphism of *PNPLA3*, which impairs lipolysis of triglyceride lipid droplets) and polymorphisms in other genes that play a role in hepatocyte fat metabolism (*TM6SF2*, which influences cholesterol metabolism, and *MBOAT7*, which influences phospholipid metabolism) also influence risk for hepatic steatosis. Recently, loss-of-function variants in *HSD17B13*, a gene that encodes an enzyme that localizes to lipid droplets in hepatocytes, appear to be protective against MASH, progressive fibrosis, and liver cancer. Additional factors including hepatocyte uric acid production, oxidative stress, and cytokine-mediated inflammatory response contribute to the development of MASH. Alterations in gut microbiota that accompany obesity enhance both energy harvest from dietary sources and increase intestinal permeability. Reduced intestinal barrier function increases hepatic exposure to gut-derived products, which stimulate liver cells to generate inflammatory mediators that worsen insulin resistance. Obese adipose depots also produce cytokines (adipokines) that inhibit tissue insulin sensitivity. Insulin resistance promotes hyperglycemia, which drives the pancreas to produce more insulin to maintain glucose

homeostasis. However, hyperinsulinemia promotes lipid uptake, fat synthesis, and fat storage.

Because the severity and duration of lipotoxic liver injury dictate the intensity and duration of repair, the histologic features and outcomes of MASH are variable. Cirrhosis results from futile repair (i.e., progressive accumulation of wound healing cells, fibrous matrix, and abnormal vasculature [scarring]) rather than efficient reconstruction or regeneration of healthy hepatic parenchyma. Primary liver cancers develop when malignantly transformed liver cells escape mechanisms that normally control regenerative growth. The mechanisms responsible for futile repair (cirrhosis) and liver carcinogenesis are not well understood. Because normal liver regeneration is a very complex process, there are multiple opportunities for deregulation and, thus, pathogenic heterogeneity. To date, this heterogeneity has confounded development of both diagnostic tests and treatments for defective/deregulated liver repair (i.e., cirrhosis and cancer). Hence, current strategies focus on circumventing misrepair by preventing and/or reducing lipotoxic liver injury. Human epidemiologic studies have identified factors that modify susceptibility to steatosis, steatohepatitis, and determinants of regenerative capacity and, thus, cirrhosis and liver cancer (see "Disease Modifiers and Risk Factors").

DISEASE MODIFIERS AND RISK FACTORS

Alcohol A diagnosis of MASLD requires demonstration of increased liver fat in an individual who drinks little to no alcohol (i.e., ≤20 g/d for women; ≤30 g/d for men). Epidemiologic studies demonstrate that serum aminotransferase elevations increase as alcohol consumption increases beyond 10 g/d (equivalent to one can of beer, 4 oz of wine, or 1.5 oz [one shot] of distilled spirits). Therefore, thresholds for potentially dangerous alcohol ingestion have been set at more than two drinks (20 g) per day in women and three drinks (30 g) per day in men. Because the combination of metabolic risk factors and higher levels of alcohol consumption may confer higher risk for liver damage and hepatic fibrosis than MASLD alone, a new diagnostic category, MetALD, was recently created to enable more personalized management of these individuals. Hazardous alcohol consumption (≥50 g/d for women; ≥60 g/d for men) is defined as ALD irrespective of the presence of hepatic steatosis and/or metabolic syndrome.

Overweight/Obesity Although MASLD is commonly associated with overweight/obese status, it can occur in lean (body mass index [BMI] <25 kg/m^2 or <23 kg/m^2) individuals. This is particularly common in individuals of Asian ethnicity. Thus, the prevalence of lean MASLD varies geographically (e.g., as low 4% in the United States to as high as 19% in Asia). Regardless of ethnicity, patients with lean MASLD have increased visceral adiposity, insulin resistance, metabolic comorbidities, alterations in gut microbiota contributing to metabolic dysfunction, and/or decreased muscle mass due to sedentary lifestyle.

Metabolic Syndrome The diagnosis of MASLD is closely linked to insulin resistance and the metabolic syndrome **(Chap. 420)**, but MASLD may precede the development of metabolic syndrome components (i.e., truncal obesity, type 2 diabetes mellitus [T2DM], dyslipidemia, hypertension). Android body fat distribution, characterized by increased truncal subcutaneous and visceral fat depots (as opposed to gynoid body fat distribution predominantly in the hips or buttocks), infers an increased risk for MASLD/MASH. T2DM is the strongest risk factor for MASLD acquisition, fibrosis progression, and HCC. The prevalence of MASLD in patients with T2DM ranges from 30 to 75% and conveys a nearly twofold increased risk for NASH with fibrosis compared to patients without impaired glycemic control. Further, the probability of advanced hepatic fibrosis increases with the duration and severity of T2DM. The relationship between MASLD/MASH and T2DM is bidirectional. MASLD is associated with a reduction in insulin sensitivity, increasing the risk for incident T2DM by two- to fivefold. Hence, patients with MASLD should be screened for T2DM. As liver disease progresses, insulin resistance worsens, making control of T2DM more challenging. Effective management of insulin resistance and hyperglycemia may decrease risk for MASH and progressive hepatic fibrosis. In patients without T2DM, MASLD is related to coexistent metabolic risk factors (i.e., increased BMI, hypertriglyceridemia, truncal obesity, hyperinsulinemia). Hypertension (another feature of metabolic syndrome) adds to the risk MASH and fibrosis progression. Whether hypertension per se promotes the development of MASH (or the inverse) or is a consequence of underlying metabolic drivers for MASLD has not been well established. Plasma lipid abnormalities are twice as prevalent in patients with MASLD than in those without MASLD. In addition, the serum lipid subfractions are more atherogenic, further increasing the cardiovascular risk for patients with MASLD/MASH.

Cardiovascular Disease and Obstructive Sleep Apnea Both cardiovascular disease (CVD) and obstructive sleep apnea (OSA) are associated with MASLD, and several studies suggest that the presence of these conditions is associated with MASH and hepatic fibrosis. Given the strong association between MASLD, CVD, and OSA, patients who are known to have these conditions should be screened for MASLD and those who are overweight or obese with metabolic syndrome should be considered at high risk for OSA and CVD.

Endocrine Dysfunction In addition to its strong association with obesity and other metabolic risk factors, higher rates of MASLD have been reported in patients with hypothyroidism, hypogonadism, growth hormone (GH) deficiency, and polycystic ovarian syndrome (PCOS). The presence of MASLD is higher in postmenopausal women compared with premenopausal women, suggesting a role of higher free testosterone levels and/or lower estradiol level in MASH. Likewise, in PCOS, hyperinsulinemia and excess androgen production contribute to a two- to fourfold increase in prevalence of MASLD, MASH with hepatic fibrosis, and T2DM.

Heritable Factors • GENETICS Heritable factors clearly impact susceptibility to hepatic steatosis, MASH, liver fibrosis, and liver cancer. For example, genetic variants on or near *TM6SF2* or *MBOAT7* (genes involved in lipid homeostasis) and palatin-like phospholipase domain-containing 3 gene (*PNPLA3*; a gene that encodes an enzyme involved in intracellular trafficking of lipids) increase the heritability of MASLD. A recent meta-analysis showed that *PNPLA3* exerts a strong influence not only on hepatic fat accumulation but also on the severity of MASH and liver fibrosis. Indeed, twin studies suggest that inheritance accounts for about half the risk for developing cirrhosis.

EPIGENETIC FACTORS Heritable traits that do not result from direct changes in DNA may also influence MASLD pathogenesis and/or progression based on evidence that intrauterine exposures influence susceptibility to obesity and the metabolic syndrome in adolescence. Studies of families with adult-onset obesity have identified genome-wide epigenetic alterations that dysregulate metabolic pathways controlling adiposity, insulin sensitivity, and tissue generation or regeneration. First-degree relatives of probands with MASH cirrhosis have a 12-fold higher risk of advanced fibrosis. Furthermore, the risk of MASLD and advanced fibrosis may be increased among nonrelated household members, likely because of related similar environmental risk factors, lifestyle patterns, and gut microbiota. Whether such epigenetic mechanisms influence susceptibility to MASH and cirrhosis is being investigated.

DIAGNOSIS

Patients with MASLD usually come to medical attention because of incidentally detected abnormalities on abdominal imaging (e.g., steatosis on sonogram or cross-sectional imaging) and/or lab tests (e.g., increased alanine aminotransferase [ALT]). MASLD should be suspected when steatosis is present in the context of metabolic dysfunction (i.e., at least one out of five criteria of metabolic syndrome is present) and the patient drinks little to no alcohol. Confirming MASLD as the diagnosis requires further testing to exclude alternative causes of chronic hepatitis (e.g., viral hepatitis, autoimmune liver disease, iron or copper overload, α_1-antitrypsin deficiency). It is important to note that normal liver enzymes do not exclude MASLD. Also, so-called "normal" ranges for aminotransferases are inflated because they include values

TABLE 354-1 Alternative Causes of Hepatic Steatosis

- Alcohol-related liver disease
- Hepatitis C (particularly genotype 3)
- Inborn errors of metabolism

in people with undiagnosed liver disease. A true normal ALT ranges from 29 to 33 U/L in men and from 19 to 25 U/L in women. Initial evaluation of elevated ALT should include screening for metabolic risk factors, assessment of alcohol intake, and exclusion of other causes of liver disease, as well as a physical examination to identify signs of insulin resistance, metabolic syndrome, and advanced liver disease. In the absence of metabolic syndrome or in the presence of additional signs or symptoms (e.g., diarrhea, iron deficiency anemia, marked elevation of lipoproteins), less common causes of hepatic steatosis or steatohepatitis should be considered in specific clinical contexts **(Table 354-1)**. Medication- or drug-associated steatosis or steatohepatitis **(Table 354-2)** should be excluded with a detailed history.

It is important to emphasize that the liver may not be enlarged and symptoms/signs of liver disease may be absent in patients with MASLD. Further, like serum aminotransferases, other liver tests (e.g., alkaline phosphatase, bilirubin, albumin, prothrombin time) may be completely normal. Because there is yet no one specific blood test for MASLD/MASH, confidence in the diagnosis of MASLD is rendered by identification of a metabolic risk factor(s) in the context of hepatic steatosis. The latter include increased BMI, insulin resistance/T2DM, and other parameters indicative of the metabolic syndrome (e.g., systemic hypertension, dyslipidemia, hyperuricemia/gout, cardiovascular disease) in the patient or first-degree family members. Individuals who have, or have had, pituitary or hypothalamic neoplasms and women with PCOS are also at increased risk for MASLD. Hypothyroidism and OSA may also increase MASLD, presumably by promoting obesity and/or exacerbating the metabolic syndrome.

CLINICAL FEATURES OF MASLD

Most subjects with MASLD are asymptomatic. The diagnosis is often made when abnormal liver aminotransferases or features of fatty liver are noted during an evaluation performed for other reasons. MASLD may also be diagnosed during the workup of vague right upper quadrant abdominal pain, hepatomegaly, or an abnormal-appearing liver at time of abdominal surgery. Obesity is present in 50–90% of subjects. Most patients with MASLD also have other features of the metabolic syndrome. Some have subtle stigmata of chronic liver disease, such as spider angiomata, palmer erythema, or splenomegaly. In a small minority of patients with advanced MASLD, complications of end-stage liver disease (e.g., jaundice, features of portal hypertension such as ascites or variceal hemorrhage) may be the initial findings.

The association of MASLD with obesity, T2DM, hypertriglyceridemia, hypertension, and CVD is well known. Other associations include chronic fatigue, mood alterations, OSA, thyroid dysfunction,

TABLE 354-2 Medications Associated with Hepatic Steatosis and Steatohepatitis

5-Fluorouracil	Macrovesicular steatosis	Unknown
Androgens	Macrovesicular steatosis	Increased hepatic lipid accumulation, impaired glycemic control
Amiodarone	Macrovesicular steatosis, steatohepatitis, and fibrosis	Decreases β-oxidation of fatty acids; increases lipid peroxidation, ROS generation, and lipogenesis
Aspirin (Reye's syndrome) Arrest B oxidation by consuming CoA; increase mi-tochondrial permeability by MPT pore formation	Microvesicular steatosis	Competitively inhibit the enzyme long chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) and β-oxidation of fatty acids; ATP depletion and loss of mitochrondrial membrane potential.
Cocaine	Microvesicular steatosis	Undergoes n-oxidation to produce hepatotoxic products and inhibit β-oxidation
-cycline antibiotics (i.e., doxycycline, minocycline tetracycline	Microvesicular steatosis	Inhibit β-oxidation of fatty acids and VLDL secretion
Fluoxetine	Macrovesicular steatosis	Increased lipid accumulation and intracellular serotonin content
Glucocorticoids	Macrovesicular steatosis	Glucose intolerance and weight gain, inhibit mitochondrial β-oxidation, decrease hepatic triglyceride secretion, and induce lipid peroxidation
L-Asparaginase	Microvesicular steatosis	Inhibition of protein synthesis and export of lipoproteins and lipids
NSAIDs	Microvesicular steatosis	Inhibit β-oxidation of short- and medium-chain fatty acids
Irinotecan	Macrovesicular steatosis	Unknown
Methotrexate	Macrovesicular steatosis, steatohepatitis, fibrosis	Inhibits mitochondrial ETC
NRTIs (i.e., zidovudine, didanosine)	Microvesicular steatosis	Mitochondrial dysfunction by mtDNA depletion and stimulation of autophagy
Pentochemical (i.e., vinyl chloride)	Microvesicular steatosis and steatohepatitis	Unknown
Tamoxifen	Macrovesicular steatosis and steatohepatitis	Promotes de novo fatty acid synthesis and inhibits fatty acid β-oxidation
Valproic acid	Microvesicular steatosis	Inhibit CPT-1 activity, sequestering CoA, arresting ETC and ATP synthesis

Abbreviations: ATP, adenosine triphosphate; CoA, coenzyme A; CPT, carnitine palmitoyl shuttle; ETC, electron transport chain; NRTIs, nucleoside reverse transcriptase inhibitors; NSAIDs, nonsteroidal anti-inflammatory drugs; ROS, reactive oxygen species; VLDL, very-low-density lipoprotein.

PCOS, and chronic pain syndrome. MASLD is an independent risk factor for metabolic syndrome (Chap. 420) and T2DM (Chap. 415). Longitudinal studies suggest that patients with MASH are at two- to threefold increased risk for the development of metabolic syndrome. Similarly, studies have shown that patients with MASH have a higher risk for the development of hypertension and T2DM. The presence of MASLD is also independently associated with endothelial dysfunction, increased carotid intimal thickness, and the number of plaques in carotid and coronary arteries. Such data indicate that MASLD has many deleterious effects on health in general, including patient-reported quality of life.

STAGING AND RISK STRATIFICATION

Establishing the severity of MASLD-related liver injury and related scarring (i.e., staging MASLD) is more difficult than simply diagnosing MASLD. Staging is critically important because staging is necessary to define prognosis and thereby determine treatment recommendations. The goal of staging is to distinguish patients with steatohepatitis from those with steatosis and to identify which of the MASH patients have advanced fibrosis. The 10-year probability of developing liver-related morbidity or mortality is negligible in individuals with steatosis alone, and hence, this subgroup of MASLD patients tends to be managed conservatively (see below). In contrast, more intensive follow-up and therapy are justified in MASH patients, and the subgroup with advanced fibrosis merits the most intensive scrutiny and intervention because their 10-year risk of liver-related morbidity and mortality is increased. Staging approaches can be separated into noninvasive testing (i.e., physical examination, blood testing, and imaging) and invasive approaches (i.e., liver biopsy). Blood test evidence of liver inflammation (e.g., aspartate aminotransferase [AST], ALT) and hepatic dysfunction (e.g., hyperbilirubinemia, hypoalbuminemia, prothrombin time prolongation) or portal hypertension (e.g., thrombocytopenia) and stigmata of portal hypertension on physical examination or imaging studies (e.g., spider angiomata, palmer erythema, splenomegaly, ascites, clubbing, encephalopathy) suggest the diagnosis of advanced MASLD. While liver biopsy has historically been the "gold standard" for establishing the severity of liver injury and fibrosis, the increased sensitivity of new noninvasive approaches for staging liver disease severity has decreased the frequency with which liver biopsy is utilized to guide patient management. Although liver biopsy is safe and seldom complicated by serious adverse sequelae (i.e., bleeding, pain, or inadvertent puncture of other organs), it is impractical for population-based risk assessment. Further, liver biopsy suffers from potential sampling and inter- and intraobserver variability, particularly when tissue cores are suboptimal (<2 cm in length) in quality. Also, examination of tissue at a single point in time is a static depiction of disease activity that cannot otherwise define pathologic process of disease progression or regression. Serial liver biopsies within short intervals of time are generally deemed unacceptable outside of research studies for which MASH resolution and/or fibrosis regression are surrogate endpoints to clinically meaningful outcomes.

Although general population screening for MASLD is not recommended, targeted screening and risk stratification for high-risk groups are advised. Such high-risk groups include those with T2DM, obesity with metabolic complications, a family history of cirrhosis, or significant alcohol use. Clinical practice has been advanced by the emergence of an armamentarium of noninvasive tests (NITs) as surrogates to liver biopsy for screening and risk stratification of high-risk cohorts of patients. Screening and risk stratification in these high-risk groups are a cost-effective approach to identifying those with asymptomatic but clinically significant fibrosis. Early detection allows for interventions (i.e., lifestyle modification, pharmacologic and/or endobariatric or surgical interventions) that may prevent fibrosis progression and, thereby, potentially decrease both liver-related and all-cause mortality. Since the majority of patients with MASLD/MASH are asymptomatic, the primary goal of risk stratification using NITs is to identify patients who are not likely to have advanced fibrosis. NITs can be used singularly or sequentially to optimize predictive value and consist of a simple calculator-based risk score or blood-based or imaging biomarkers (Fig. 354-2). Screening with a Fibrosis-4 (FIB-4) score, a score derived from available clinical and laboratory data, is cost-effective. FIB-4 is calculated using a simple algorithm based on age, ALT, AST, and platelet count and outperforms other calculations (i.e., AST to platelet ratio index, BARD score, NAFLD fibrosis score) in its ability to identify patients with a low probability of advanced fibrosis.

The FIB-4 score is well validated and has an excellent negative predictive value for exclusion of advanced hepatic fibrosis (i.e., low risk,

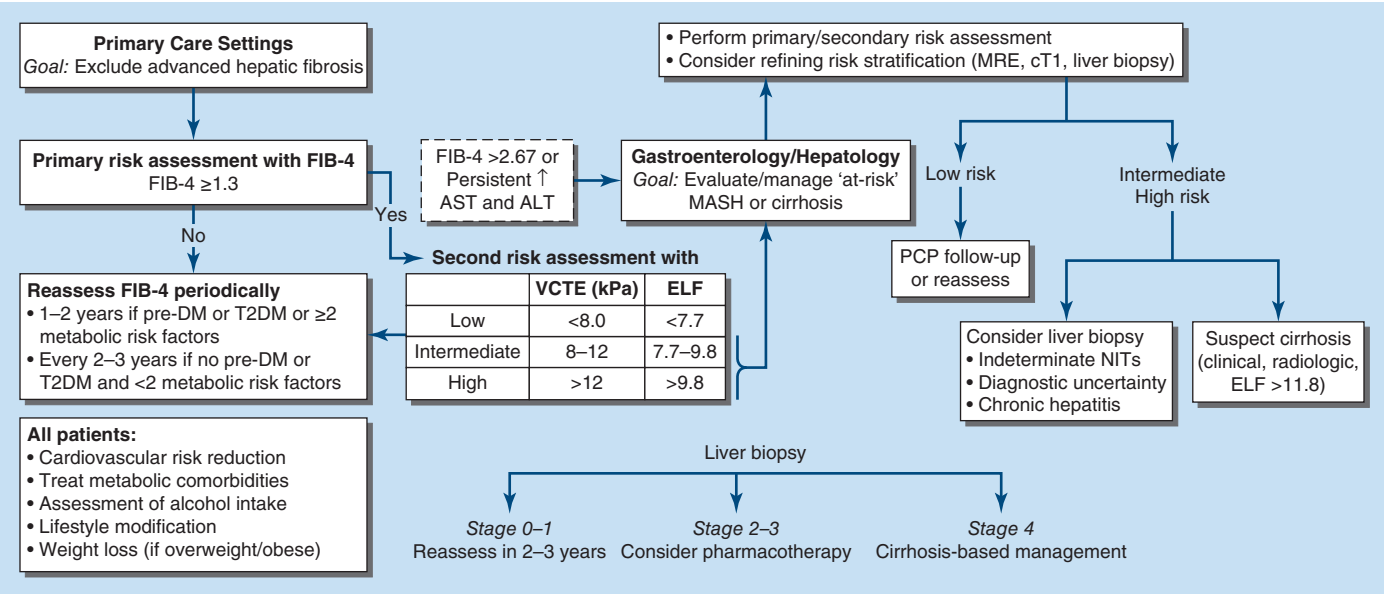

FIGURE 354-2 Algorithm for the evaluation of patients at risk for or with established metabolic dysfunction–associated steatotic liver disease (MASLD) across practice settings. Patients with suspected MASLD based on imaging, metabolic risk factors, or evaluation of liver enzymes should be risk stratified using noninvasive tests for advanced hepatic fibrosis. Empasis in the primary care setting is the exclusion of advanced hepatic fibrosis using a test with high negative predictive value. When the Fibrosis-4 index (FIB-4) is <1.3, patients can be followed in the primary care setting and reassessed every 2–3 years. Patients with metabolic syndrome, prediabetes (pre-DM), or diabetes (T2DM) are at higher risk for fibrosis progression and can be followed with FIB-4 monitoring every 1–2 years. Due to low accuracy in patients older than 65 years and younger than 35 years, a secondary assessment should be done (i.e., elastography for liver stiffness measure or Enhanced Liver Fibrosis ELF]). Referral to a specialist should be considered for persistent elevation of liver enzymes, clinical suspicion of more advanced liver disease, and/or indeterminate or discordant noninvasive tests (NITs). ALT, alanine aminotransferase; AST, aspartate aminotransferase; MASH, metabolic dysfunction–associated steatohepatitis; MRE, magnetic resonance elastography; PCP, primary care physician; VCTE, vibration-controlled elastography.

FIB-4 <1.3). Patients with a low FIB-4 score of <1.3 can be managed in primary care; however, patients with two or more metabolic risk factors, particularly those with prediabetes or T2DM, are at increased risk for fibrosis progression with time and should have repeat assessment of FIB-4 score every 1–2 years with general health assessments. A change in FIB-4 score over time may allow for the prediction of progression to cirrhosis or hepatic decompensation, although the strength as a predictive biomarker is less robust in patients with T2DM.

Patients with a FIB-4 score ≥2.67 may have moderate or high risk for advanced hepatic fibrosis and should undergo further assessment with a secondary NIT, either blood- or imaging-based biomarker. In the primary care setting, as initial secondary tests, either the Enhanced Liver Fibrosis (ELF) panel, vibration-controlled elastography (VCTE), or ultrasound-based methods such as acoustic radiation force impulse (as available) are favored over magnetic resonance elastography (MRE) due to cost considerations. A VCTE-derived liver stiffness measurement (LSM) <8 kPa can be used to rule out advanced fibrosis, especially if used sequentially after FIB-4. LSMs by VCTE between 8 and 12 kPa may be associated with fibrotic MASH, and LSM >12 kPa is associated with a high likelihood of advanced fibrosis, although the positive predictive value is low (range 0.34–0.71). LSM by VCTE may be suggestive of portal hypertension. Changes in LSMs may also be useful in identifying disease progression. An increase in liver stiffness of 20% on either VCTE or MRE may be associated with disease progression and long-term clinical outcomes. Low LSM is most useful for excluding advanced hepatic fibrosis as cirrhosis is extremely unlikely when LSM is low. However, higher LSM must be interpreted with caution since several factors (obesity, nonfasting state, severe hepatic inflammation, hepatic congestion, and/or iron overload) decrease the specificity of the test.

The ELF panel is a proprietary blood test consisting of three elements involved in matrix turnover: hyaluronic acid, tissue inhibitor of metalloproteinase-1, and N-terminal procollagen III peptide. The ELF test is approved by the U.S. Food and Drug Administration (FDA) for prognostication (ELF ≥9.8) of MASLD patients at increased risk of progression to cirrhosis and liver-related clinical events. The ELF test can be ordered, particularly when access to VCTE is limited. If secondary risk assessment with blood- or imaging-based NITs is consistent with an intermediate or high risk of advanced disease, patients should be referred to specialty care for further evaluation and potential consideration of magnetic resonance imaging (MRI)-based tools such as MRE or MRI-corrected T1 (cT1) and/or liver biopsy to further risk stratify patients in whom other NITs have been indeterminate or not consistent with clinical suspicion of liver disease severity. A liver biopsy should be considered when there is diagnostic uncertainty, discordant or indeterminate NITs, discordance between NITs and clinical, radiologic, and/or laboratory features (i.e., thrombocytopenia) suggesting a diagnosis of advanced fibrosis, competing or concomitant diagnoses (e.g., iron overload, autoimmune hepatitis, drug-induced liver injury), or persistent elevation (>6 months) in liver chemistries in the absence of hepatic steatosis or metabolic risk factors. Knowledge of the presence of advanced hepatic fibrosis or cirrhosis changes clinical care and management (i.e., primary and secondary prevention of complications of portal hypertension and screening for HCC), which can decrease risk for liver-related outcomes.

Although abdominal ultrasound is routinely used in clinical practice, ultrasound lacks sufficient sensitivity for lesser degrees (<30%) of steatosis, particularly in those with concomitant obesity. The semiquantitative assessment of steatosis on ultrasound does not exclude the presence of MASH or hepatic fibrosis, although nodular-appearing morphology, splenomegaly, and/or portosystemic collateral vessels may suggest presence of cirrhosis. The controlled attenuation parameter (CAP) typically measured in conjunction with VCTE provides a point-of-care semiquantitative assessment of hepatic steatosis but does not accurately monitor for changes in liver fat. MRI–proton density fat fraction (PDFF) is routinely use in clinical research and increasingly used in tertiary care settings as an accurate, reproducible, and precise NIT for quantification of liver fat content. Although MRI-PDFF is superior to CAP in the diagnosis and quantification of liver fat, it is not a point-of-care test, and enthusiasm for its more routine use is tempered by cost, patient acceptance, and the fact that quantification of hepatic steatosis alone (as opposed to MASH or fibrosis) has not been associated with a clinically meaningful outcome. Other serum and imaging biomarkers are under study for the detection of "at-risk" MASH (steatohepatitis with ≥F2 fibrosis); however, these newer MASH biomarkers are not yet ready for routine clinical practice and require further validation. NIS4, a panel of four serum biomarkers (miR-34a-5p, α_2-macroglobulin, YKL-40, and glycated hemoglobin) and other blood-based markers utilizing lipidomics, metabolomics, or proteomic biomarkers for at-risk MASH are in development.

Although NITs are being validated against liver histology and clinically meaningful outcomes, data regarding the dynamic context to ascertain a treatment response or prognosticate time to outcomes of progression to cirrhosis or hepatic decompensation are still evolving. ALT normalization in response to any treatment intervention (discussed below) may predict MASH resolution. A decrease of ≥17 IU/L in ALT has been associated with higher odds of histologic response in clinical trials. Likewise, improvements in FIB-4, ELF, VCTE, and MRE were correlated with reduction in liver injury and fibrosis. Several studies and a meta-analysis have shown that ≥30% reduction in liver fat content by MRI-PDFF is associated with a fivefold improved likelihood of MASH resolution; however, thresholds for changes in LSM that correlate with improvements in fibrosis are not well established. Although more data and broader validation are needed, emerging data suggest that improvement in NITs may be a reliable surrogate for predicting histologic improvement in response to a therapeutic intervention and associated clinical outcome.

TREATMENT OF MASLD

Treatment approaches are focused on modification of identifiable risk factors and targeted approaches to management of metabolic comorbidities that contribute pathophysiologically to the acquisition and progression of MASLD. For the overwhelming majority of patients, healthy diet and routine physical activity are foundational in the care plan, irrespective of weight loss goals. Thereafter, treatment for MASLD can be divided into the following: (1) therapies that improve cardiometabolic risk and associated comorbidities (e.g., obesity, insulin resistance, T2DM, dyslipidemia); (2) liver-directed therapies, which are typically reserved for those with clinically significant (i.e., at-risk) MASH with ≥F2 fibrosis; and (3) treatment of complications of advanced MASLD/MASH. The subsequent discussion highlights specific therapies for MASH and their impact on MASH disease activity. Generally, treatment(s) of complications of advanced MASLD/MASH, including cirrhosis, portal hypertension, and primary liver cancer, requires tertiary care and multidisciplinary approaches. Approaches to accomplish these objectives are similar to those used in other chronic liver diseases and are covered elsewhere in the textbook.

Lifestyle Modification Lifestyle modification with healthy diet and exercise is foundational in the treatment of MASLD/MASH. For patients with overweight/obese status, even modest amounts of weight loss can be impactful in improving disease activity and clinical outcomes. Weight loss of 3–5% has been demonstrated to improve hepatic steatosis, whereas greater weight loss (>10%) improves MASH and fibrosis. In those with advanced hepatic fibrosis or cirrhosis, moderate- to high-intensity exercise may decrease portal hypertension, sarcopenia, and risk for HCC. Unfortunately, achieving and sustaining weight loss long term is challenging for most patients with insulin resistance, with <10% achieving effective weight loss despite structured interventions at 1 year. However, sustained weight loss improves peripheral insulin sensitivity, cytokine-medicated inflammatory response, both hepatic and nonhepatic tissue stress, and even alterations in gut microbiota that contribute to metabolic dysfunction. A multidisciplinary approach, inclusive of patient and family engagement strategies, behavioral medicine specialists, dieticians, nutritionists, and a multidisciplinary team approach to management of complications of metabolic syndrome, may optimize results.

Modification of dietary macronutrient composition with avoidance of excess saturated fats, refined carbohydrates, and sugar-sweetened beverages (i.e., Western obesogenic diet) is recommended. Excess

fructose consumption increases the risk for MASLD, MASH, and hepatic fibrosis, independent of calorie intake. Various approaches to dietary modification (e.g., low-fat vs low-carbohydrate, saturated vs unsaturated fats, intermittent fasting, Mediterranean diet, Mediterranean green diet, or different intensities of calorie restriction) appear relatively comparable in their ability to improve MASLD/MASH. The Mediterranean diet is often recommended based on long-term adherence, ability to be tailored across different cultures and ethnicities, and benefits with cardiovascular risk reduction. Coffee consumption (at least 3 cups daily) may also be beneficial based on epidemiologic studies and meta-analyses with reduced risk for hepatic fibrosis and HCC. Increased physical activity (i.e., energy expenditure), independent of weight loss, compliments dietary modification. Exercise improves insulin sensitivity, decreases cardiometabolic risk, and should be tailored to a patient's preference and physical ability. Regular moderate exercise at least five times per week for a total of 150 min/week or more intensive exercise for at least 60 min/week can prevent or improve MASLD and associated histologic features of liver injury. A dose-dependent response of exercise in improvement of MASLD/MASH has been observed, although the optimal duration, intensity, and type (aerobic vs resistance) needs to be individualized to patient ability and capacity. For patients with advance liver disease due to MASLD, exercise can improve frailty, sarcopenia, and quality of life in patients with cirrhosis. Changes in dietary composition, when coupled with increased physical activity, may be sufficient to improve MASLD/MASH and/or result in improvements in patients with milder disease activity.

Pharmacologic Therapies *Resmetirom*, a selective thyroid hormone receptor beta (THR-B) agonist, was recently granted accelerated approval by the FDA to treat patients with 'at-risk' MASH (i.e. F2-F3 fibrosis) without cirrhosis. Resmetirom works by mimicking the effects of thyroid hormone in the liver, promoting lipid metabolism, reducing liver fat, and improving liver function. In a 52 week phase randomized controlled trial of resmetirom (80 mg or 100 mg) or placebo in 966 patients with biopsy-proven NASH with fibrosis (MAESTRO-NASH trial) which had not yet advanced to cirrhosis, resmetirom 100 mg and 80 mg were superior to placebo with respect to NASH resolution (30%, 26% and 10%, respectively; p<0.0001) and improvement in liver fibrosis (26%, 24% and 14%, respectively, p<0.0001). Resmetirom was generally well tolerated with the predominant treatment emergent side effects being early treatment transient gastrointestinal symptoms of nausea and loose stools. The MEASTRO-NASH study is ongoing to accrue data on long-term safety and liver-related outcomes including progression to cirrhosis for full FDA approval. Pharmacotherapy for liver disease per se is not recommended for patients with hepatic steatosis without steatohepatitis or fibrosis, but these patients should receive counseling for healthy diet and physical activity. Pharmacotherapy to treat metabolic comorbidities may improve MASLD.

The pipeline for emerging therapies for MASH is robust, with a large number of clinical trials designed to identify effective and safe treatment in progress. For the purpose of reporting trial results acquired prior to change in disease definition and nomenclature, the terms NAFLD and NASH will be utilized with the understanding that overall concordance between NAFLD and MASLD and between NASH and MASH is high.

Because MASLD is strongly associated with the metabolic syndrome **(Chap. 420)** and T2DM **(Chap. 415)**, the efficacy of various insulin-sensitizing agents has been examined.

Metformin, a biguanide anti-hyperglycemic agent, improves hepatic insulin sensitivity and has been evaluated in several small, open-label studies in adults and a larger, prospectively randomized trial in children (dubbed the TONIC study). Although several of the adult NASH studies suggested improvements in aminotransferases and, less consistently, liver histology, metformin did not improve liver histology in the TONIC study of children with NASH. Thus, it is not currently recommended as a treatment for NASH. However, meta-analyses suggest metformin may decrease risk of HCC in patients with T2DM.

Thiazolidinediones, ligands for peroxisome proliferator-activated receptor (PPAR) γ, improve insulin resistance and serum lipids and are approved for the treatment of T2DM. In a randomized controlled trial sponsored by the National Institutes of Health of pioglitazone versus vitamin E versus placebo (PIVENS trial) for the treatment of adults (n = 247) with NASH without prediabetes or T2DM, pioglitazone (30 mg/d) for 18 months resolved NASH compared to placebo (47 vs 21%, respectively; p <.001). In an 18-month study in patients with NASH and prediabetes or T2DM, pioglitazone improved the nonalcoholic activity score (NAS) by ≥2 points with a trend toward fibrosis improvement. The effect of pioglitazone on NASH resolution and fibrosis improvement was subsequently demonstrated in a meta-analysis. The side effects of pioglitazone include weight gain, bone loss in postmenopausal women, potential risk for worsening heart failure in patients with preexisting cardiac dysfunction, and a debated risk of bladder cancer. The use of pioglitazone has been largely usurped in clinical practice by the increasing use of incretin mimetics (e.g., glucagon-like peptide 1 receptor agonists [GLP-1RAs]) and sodium-glucose cotransporter 2 inhibitors (SGLT-2i) because these agents are reasonably well tolerated and have multiple benefits (i.e., improve glycemic control, induce weight loss, and reduce cardiovascular mortality).

*Incretin mimetic*s, drugs that act on the pancreas to optimize insulin and glucagon release, have a beneficial effect on MASH. GLP-1RAs are currently approved for the indication of obesity and T2DM. GLP-1RAs improve lipids, glucose, and weight, and decrease cardiovascular risk, making them attractive agents for treatment of MASH. In a small study of patients with NASH, liraglutide improved steatosis, resolved NASH, and reduced fibrosis progression compared to placebo. In a large randomized, double-blind, placebo-controlled study of daily subcutaneous semaglutide in 320 patients with biopsy-proven NASH (F1–F3) randomized to 0.1, 0.2, or 0.4 mg or placebo for 72 weeks, a dose-dependent response on NASH resolution without worsening of fibrosis (primary endpoint) was observed (59% in 0.4-mg treatment group vs 17% in placebo group, p <.001). Although there was no statistically significant improvement in fibrosis, a protective effect against fibrosis progression was observed. A global phase 3 study of semaglutide for the treatment of NASH-related fibrosis is currently underway. Tirzepatide, a GLP-1/glucose-dependent insulintopic polypeptide receptor agonist approved for the treatment of T2DM, demonstrated significant weight loss (up to 20.9% change in body weight in obese patients without diabetes mellitus compared with 3.1% in the placebo group at week 72). The weight loss was associated with significant reductions in liver fat content, identifying this agent as another potentially effective therapy for MASH.

SGLT-2is increase glucose excretion from the glomerular filtrate and are approved for the treatment of T2DM. SGLT-2is induce mild weight loss (2–3%) and exert cardioprotective benefits. Studies evaluating the efficacy of SGLT-2i in MASH are limited by small sample size and lack of histologic endpoints; however, available data suggest that SGLT-2is improve liver aminotransferases and quantitative measures of hepatic steatosis. Whether this translates into resolution of MASH or improvement in hepatic fibrosis needs to be defined.

Antioxidants have also been evaluated for the treatment of MASLD because oxidant stress is thought to contribute to the pathogenesis of MASH. Vitamin E, an inexpensive yet potent antioxidant, has been examined in several small pediatric and adult studies with varying results. In all of those studies, vitamin E was well tolerated, and most studies showed modest improvements in aminotransferase levels, radiographic features of hepatic steatosis, and/or histologic features of NASH. In the PIVENS study, treatment with RRR-α-tocopherol (the natural form of vitamin E) 800 IU daily for 96 weeks improved histologic features of steatohepatitis without worsening of fibrosis (43% in the vitamin E group vs 19% in the placebo group, p <.04), a finding supported by a meta-analysis showing that vitamin E improves serum aminotransferases and features of NASH on biopsy. Although no study has demonstrated an antifibrotic effect with vitamin E, a retrospective study of patients with NASH and advanced hepatic fibrosis (n = 236) showed that vitamin E use, independent of diabetes status, was associated with lower rate of hepatic decompensation (37 vs 62%, p = .04) and higher transplant-free survival (78 vs 49%, p <.01). Enthusiasm for use of vitamin E for treatment of NASH has been dampened by concerns of the risk-to-benefit ratio for safety (i.e., risk of perioperative

bleeding, hemorrhagic stroke, increased cardiac mortality, and prostate cancer) with long-term efficacy.

Statins are an important class of agents to treat dyslipidemia and decrease cardiovascular risk, even in patients with MASLD/MASH. Statins are safe across the spectrum of MASLD, including in patients with well-compensated cirrhosis. Statins decrease cardiovascular morbidity and mortality; however, they remain underutilized in clinical practice despite the extensive evidence demonstrating safety in patients with chronic liver disease. Statins have beneficial effects on decreasing portal pressure and, thus, decrease risk for hepatic decompensation. Meta-analyses also suggest that long-term statin use may decrease risk for cirrhosis and HCC.

The incidence of liver enzyme elevations in MASLD patients taking statins is also no different than that of healthy controls or patients with other chronic liver diseases. Moreover, several studies have suggested that statins may improve aminotransferases and histology in patients with MASH. Yet, there is continued reluctance to use statins in patients with MASLD. The lack of evidence that statins harm the liver in MASLD patients, combined with the increase risk for cardiovascular morbidity and mortality in MASLD patients, justifies the use of statins to treat dyslipidemia in patients with MASLD, either as monotherapy or in combination with other lipid-lowering agents to achieve therapeutic goals. Limited data exist on the safety and efficacy of statins in patients with decompensated MASLD-related cirrhosis.

Drugs Shown Not to Benefit MASH Ursodeoxycholic acid (a bile acid conjugate used to treat certain cholestatic liver disease), betaine (a metabolite of choline that raises *S*-adenosylmethioine levels and decreases cellular oxidative damage), dipeptidylpeptidase-4 (an insulin-sensitizing agent), and silymarin (a putative antioxidant) are well studied in NASH and should not be used as a treatment for NASH/MASH because they do not offer a meaningful histologic benefit.

Emerging Therapies Many other pharmacotherapies that target dysregulated energy homeostasis, lipotoxicity, cell death, and liver inflammation, processes that are critically involved in the pathogenesis and/or progression of MASH and liver fibrosis, are currently in clinical trials (e.g., probiotics, farnesoid X receptor agonists, fibroblast growth factor agonists, antiapoptotic agents, anticytokine agents, PPAR modulators, thyroid hormone receptor β-selective agonists, stearyl-CoA desaturase-1 inhibitors, DGAT inhibitors, acyl-CoA carboxylase inhibitors, and direct modulators of liver fibrosis). Sufficient data do not yet exist to justify the use of these emerging therapies as MASH treatments in clinical practice. Given that liver disease outcomes in MASH patients are highly heterogeneous, optimal treatment of MASH may need to be individualized by tailoring therapy based on clinical or histologic phenotypes of MASH and/or genetic susceptibility for disease progression.

Bariatric Surgery Obesity, BMI ≥40 kg/m^2 irrespective of metabolic comorbid conditions, or BMI ≥35 kg/m^2 with comorbidities (e.g., T2DM, hypertension, OSA, hypertension) are accepted indications for bariatric surgery. MASLD is increasingly being accepted as the hepatic manifestation of metabolic syndrome and a complication that improves with effective and sustained weight loss. The overwhelming majority of patients undergoing bariatric surgery have MASLD; however, the prevalence of advanced hepatic fibrosis and cirrhosis is low (likely due to presurgical screening of those with chronic liver disease/cirrhosis or variable risk of visceral fat accumulation in patients with larger capacity for peripheral adipose depot stores). Bariatric surgery cures diabetes in a majority of patients, improves MASH and hepatic fibrosis, and decreases both liver-related and all-cause morbidity and mortality. In a prospective study, bariatric surgery resolved the histologic features of MASH and improved hepatic fibrosis in 80% of patients at 1 year; this improvement was maintained in patients who sustained weight loss at 5 years after surgery. Failure to sustain weight, or the regain of weight, following bariatric surgery is associated with persistent MASH. The impact of bariatric surgery is concordant with the degree of weight loss, with malabsorptive procedures being more effective than restrictive surgical procedures that result in substantially less weight loss. While endoscopic bariatric and metabolic procedures are promising as less invasive options, long-term safety and efficacy data are needed. The risk of hepatic decompensation increases in the presence of cirrhosis. At present, bariatric surgery cannot be considered as a primary salvage therapy for patients with compensated MASH cirrhosis. However, it may be safely accomplished at select tertiary care centers for selected patients. Bariatric surgery in the setting of decompensated cirrhosis and/or portal hypertension is associated with increased mortality and should only be consider at high-volume centers with expertise with combined liver transplant and bariatric surgery.

Liver Transplantation Patients with MASLD in whom end-stage liver disease develops should be evaluated for liver transplantation **(Chap. 356)**. The outcomes of liver transplantation in well-selected patients with MASLD are generally good, but comorbid medical conditions associated with MASLD, such as diabetes mellitus, obesity, and CVD, often limit transplant candidacy. MASLD may recur after liver transplantation. The risk factors for recurrent or de novo MASLD after liver transplantation are multifactorial and include hypertriglyceridemia, obesity, diabetes mellitus, and immunosuppressive therapies, particularly glucocorticoids.

GLOBAL HEALTH CONSIDERATIONS

MASLD, the hepatic manifestation of metabolic syndrome, is a potentially progressive liver disease. The global prevalence is 30% with the highest MASLD prevalence in Latin America (44%), Middle East and North Africa (36.5%), and South Asia (33.8%). The rising prevalence globally requires urgent and comprehensive strategies to raise awareness and address all aspects of MASLD on local, regional, and global levels. Although a minority of patients with MASLD will progress to cirrhosis or HCC, given the vast population affected, the total number of patients who are at risk for adverse clinical outcomes is already huge and will increase. Of concern, individuals are increasingly being affected by MASLD at an earlier age, meaning there is more time for them to develop severe complications. The epidemic of chronic liver disease and MASLD-related cirrhosis is anticipated to rise in parallel with diabetes, obesity, and other complications of metabolic dysfunction. MASLD is a huge burden on public health that has received little attention from the global public health community and policymakers. The economic burden directly attributable to MASLD is already enormous (estimated direct medical costs of ~$103 billion/year in the United States and €35 billion/year in the Europe-4 countries: Germany, France, Italy, and United Kingdom) with projections for continued increases in economic burden in the upcoming years. The global impact of MAFLD is projected to increase, with a 178% increase in liver-related deaths by 2030.

A multistakeholder approach for policymakers, health care practitioners, civil society groups, research institutions, and patient advocacy groups could provide a strong foundation for a comprehensive global public health response to MASLD. Despite the global burden, there are large geographical discrepancies in the prevalence of MASLD, which could be attributable to differing socioeconomic milieus, degree of urbanization, and genetic predisposition (i.e., higher prevalence in certain ethnic groups such as Asians, Hispanics, and Native Americans, and lower in others such as African Americans compared to whites). Although all of these variables confound efforts to predict the net impact of this obesity-related liver disease on global health, it seems likely that MASLD will remain a major cause of chronic liver disease worldwide for the foreseeable future. The landscape of emerging therapies for MASLD could potentially turn the tide on the growing epidemic of MASLD-related chronic liver disease once the first liver-directed pharmacotherapy for MASLD achieves FDA approval.

355 Cirrhosis and Its Complications

Alex S. Befeler, Bruce R. Bacon

Cirrhosis is a condition that is defined histopathologically and has a variety of clinical manifestations and complications, some of which can be life-threatening. In the past, it has been thought that cirrhosis was never reversible; however, it has become apparent that when the underlying insult that has caused the cirrhosis has been removed, there can be reversal of fibrosis. This is most apparent with the successful treatment of chronic hepatitis C; however, reversal of fibrosis is also seen in patients with hemochromatosis after iron removal and in patients with alcohol-associated liver disease who have discontinued alcohol use.

Regardless of the cause of cirrhosis, the pathologic features consist of the development of fibrosis to the point that there is architectural distortion with the formation of regenerative nodules. This results in a decrease in hepatocellular mass, and thus function, and an alteration of blood flow. The induction of fibrosis occurs with activation of hepatic stellate cells, resulting in the formation of increased amounts of collagen and other components of the extracellular matrix.

Clinical features of cirrhosis are the result of pathologic changes and mirror the severity of the liver disease. Most hepatic pathologists provide an assessment of grading and staging when evaluating liver biopsy samples. These schemes vary between disease states and have been developed for most conditions, including chronic viral hepatitis, nonalcoholic fatty liver disease, and primary biliary cholangitis. Advanced fibrosis usually includes bridging fibrosis with nodularity designated as stage 3 and cirrhosis designated as stage 4. Patients who have cirrhosis have varying degrees of liver function, and clinicians need to differentiate between those who have stable, compensated cirrhosis and those who have decompensated cirrhosis. Patients who have developed ascites, hepatic encephalopathy, or variceal bleeding are classified as decompensated. They should be considered for liver transplantation, particularly if the decompensations are poorly controlled. Many of the complications of cirrhosis will require specific therapy. *Portal hypertension* is a significant complicating feature of decompensated cirrhosis and is responsible for the development of ascites and bleeding from esophagogastric varices. Loss of hepatocellular function results in jaundice, coagulation disorders, and hypoalbuminemia and contributes to the causes of portosystemic encephalopathy. The complications of cirrhosis are basically the same regardless of the etiology. Nonetheless, it is useful to classify patients by the cause of their liver disease **(Table 355-1)**; patients can be divided into broad groups, including those with alcohol-associated cirrhosis, cirrhosis due to chronic viral hepatitis, biliary cirrhosis, metabolic dysfunction–associated steatotic liver disease (the new consensus term for nonalcoholic fatty liver disease), and other, less common causes, such as cardiac cirrhosis, cryptogenic cirrhosis, and other miscellaneous causes.

TABLE 355-1 Causes of Cirrhosis

Alcohol	Cardiac cirrhosis
Chronic viral hepatitis	Inherited metabolic liver disease
Hepatitis B	Hemochromatosis
Hepatitis C	Wilson's disease
Autoimmune hepatitis	α_1 Antitrypsin deficiency
Metabolic dysfunction-associated steatohepatitis	Cystic fibrosis
Biliary cirrhosis	Cryptogenic cirrhosis
Primary biliary cholangitis	
Primary sclerosing cholangitis	
Autoimmune cholangiopathy	

ALCOHOL-ASSOCIATED CIRRHOSIS

Excessive chronic alcohol use can cause several different types of chronic liver disease, including alcohol-associated fatty liver, alcoholic hepatitis, and alcohol-associated cirrhosis. Furthermore, use of excessive alcohol can contribute to liver damage in patients with other liver diseases, such as hepatitis C, hemochromatosis, and metabolic dysfunction–associated steatotic liver disease. Chronic alcohol use can produce fibrosis in the absence of accompanying inflammation and/or necrosis. Fibrosis can be centrilobular, pericellular, or periportal. When fibrosis reaches a certain degree, there is disruption of the normal liver architecture and replacement of liver cells by regenerative nodules. In alcohol-associated cirrhosis, the nodules are usually <3 mm in diameter; this form of cirrhosis is referred to as *micronodular*. With cessation of alcohol use, larger nodules may form, resulting in a mixed micronodular and macronodular cirrhosis.

Pathogenesis Alcohol is the most commonly used drug in the United States, and >70% of adults drink alcohol each year. Twenty percent have had a binge within the past month, and >7% of adults regularly consume more than four or five drinks five or more times a month. Unfortunately, >14 million adults in the United States meet the diagnostic criteria for alcohol use disorder. In the United States, chronic liver disease is the tenth most common cause of death in adults, and alcohol-associated cirrhosis accounts for ~48% of deaths due to cirrhosis.

Ethanol is mainly absorbed by the small intestine and, to a lesser degree, through the stomach. Gastric alcohol dehydrogenase (ADH) initiates alcohol metabolism. Three enzyme systems account for metabolism of alcohol in the liver. These include cytosolic ADH, the microsomal ethanol oxidizing system (MEOS) utilizing the inducible cytochrome P450 CYP2E1, and peroxisomal catalase. Normally the majority of ethanol oxidation occurs via ADH to form acetaldehyde, which is a highly reactive molecule that may have multiple effects. The MEOS pathway in chronic alcohol use causes induction of CYP2E1, which leads to generation of reactive oxygen species and produces more acetaldehyde. Ultimately, acetaldehyde is metabolized to acetate

by aldehyde dehydrogenase (ALDH). Intake of ethanol increases intracellular accumulation of triglycerides by increasing fatty acid uptake and by reducing fatty acid oxidation and lipoprotein secretion. Protein synthesis, glycosylation, and secretion are impaired. Oxidative damage to hepatocyte membranes occurs due to the formation of reactive oxygen species; acetaldehyde is a highly reactive molecule that combines with proteins and nucleic acids to form acetaldehyde adducts. These adducts may interfere with specific enzyme activities, including microtubular formation and hepatic protein trafficking. With acetaldehyde-mediated hepatocyte damage, certain reactive oxygen species can result in Kupffer cell activation. As a result, profibrogenic cytokines are produced that initiate and perpetuate stellate cell activation, with the resultant production of excess collagen and extracellular matrix. Connective tissue appears in both periportal and pericentral zones and eventually connects portal triads with central veins forming regenerative nodules. Hepatocyte loss occurs, and with increased collagen production and deposition, together with continuing hepatocyte destruction, the liver contracts and shrinks in size. This process generally takes from years to decades to occur and requires repeated insults.

Clinical Features The diagnosis of alcohol-associated liver disease requires an accurate history regarding both amount (>2 drinks per day in women and >3 drinks per day in men) and duration (>12 months) of alcohol consumption. Patients with alcohol-associated liver disease can present with nonspecific symptoms such as vague right upper quadrant abdominal pain, fever, nausea and vomiting, diarrhea, anorexia, and malaise. Alternatively, they may present with complications of chronic liver disease, including ascites, edema, upper gastrointestinal (GI) hemorrhage, jaundice, or encephalopathy. Many cases present incidentally at the time of autopsy or elective surgery. Other patients may be identified during an evaluation of routine laboratory studies that are found to be abnormal. On physical examination, the liver and spleen may be enlarged, with the liver edge being firm and nodular. Other frequent findings include scleral icterus, palmar erythema **(Fig. 355-1)**, spider angiomas **(Fig. 355-2)**, parotid gland enlargement, digital clubbing, muscle wasting, edema, and ascites. Men may have decreased body hair, gynecomastia, and testicular atrophy, which may be a consequence of hormonal abnormalities or a direct toxic effect of alcohol on the testes. In women with advanced disease, menstrual irregularities usually occur including amenorrhea. These changes are often reversible following cessation of alcohol ingestion.

Laboratory tests may be completely normal in patients with early compensated alcohol-associated cirrhosis. Alternatively, in advanced liver disease, many abnormalities usually are present. Patients may be anemic from chronic GI blood loss, nutritional deficiencies, or hypersplenism or as a direct suppressive effect of alcohol on the bone marrow. A unique form of hemolytic anemia (with spur cells and acanthocytes) called *Zieve's syndrome* can occur in patients with severe alcoholic hepatitis. Platelet counts are often reduced early in the disease, reflective of portal hypertension with hypersplenism. Serum total bilirubin can be normal or elevated with advanced disease. Prothrombin times are often prolonged and usually do not respond to administration of parenteral vitamin K. Serum sodium levels are usually normal unless patients have ascites and then can be depressed, largely due to ingestion of excess free water. Serum alanine and aspartate aminotransferases (ALT, AST) are typically elevated but <400 IU/mL, with AST levels being higher than ALT levels, usually by a 2:1 ratio, particularly in patients who continue to drink.

FIGURE 355-1 Palmar erythema. This figure shows palmar erythema in a patient with alcohol-associated cirrhosis. The erythema is peripheral over the palm with central pallor.

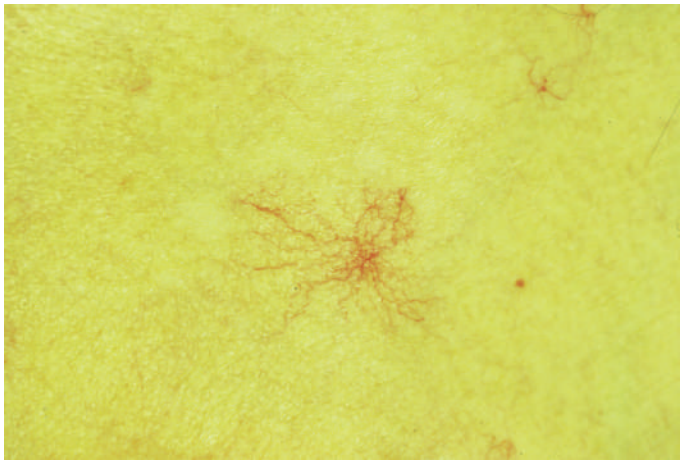

FIGURE 355-2 Spider angioma. This figure shows a spider angioma in a patient with hepatitis C cirrhosis. With release of central compression, the arteriole fills from the center and spreads out peripherally.

Diagnosis Patients who have any of the above-mentioned clinical features, physical examination findings, or laboratory studies in the setting of chronic alcohol consumption should be considered to have alcohol-associated liver disease. Furthermore, other forms of chronic liver disease (e.g., chronic viral hepatitis or metabolic or autoimmune liver diseases) must be considered or ruled out, or if present, an estimate of relative causality along with the alcohol use should be determined. Liver biopsy can be helpful to confirm a diagnosis but generally is not performed unless there is a suspicion of an alternative diagnosis.

In patients who have had complications of cirrhosis and who continue to drink, there is a <50% 5-year survival. In contrast, in patients who remain abstinent, the prognosis is significantly improved, particularly when they have resolution of liver complications; however, some individuals who remain abstinent do not improve and liver transplantation is a viable option.

TREATMENT

Alcohol-Associated Cirrhosis and Alcoholic Hepatitis

Abstinence is the cornerstone of therapy for patients with alcohol-associated liver disease. New clinically available biomarkers of recent alcohol consumption such as phosphatidylethanol (Peth) can be helpful in evaluating abstinence. In addition, patients require good nutrition and long-term medical supervision to manage underlying complications that may develop. Complications such as the development of ascites and edema, variceal hemorrhage, or portosystemic encephalopathy all require specific management and treatment. Liver transplantation can be an effective long-term treatment in those who have been deemed a low enough risk for alcohol relapse and do not respond to other treatments.

Glucocorticoids are occasionally used in patients with severe alcoholic hepatitis in the absence of infection. Short-term survival has been shown to be improved in certain studies and meta-analysis, although 6-month survival is more dependent on abstinence. Treatment is restricted to patients with a discriminant function (DF) value of >32. The DF is calculated as the serum total bilirubin plus the difference in the patient's prothrombin time

compared to upper limit of control (in seconds) multiplied by 4.6. Failure to improve total bilirubin after 7 days predicts treatment failure, and glucocorticoids can be stopped; otherwise, they are continued for 28 days.

There is modest evidence that intravenous *N*-acetylcysteine plus glucocorticoids may have a short-term survival benefit in alcoholic hepatitis if the DF is >32. Other therapies including oral pentoxifylline, inhibitors of tumor necrosis factor (TNF) α, anabolic steroids, propylthiouracil, antioxidants, colchicine, and penicillamine have not shown clear-cut benefits and are not recommended. A variety of nutritional therapies have been tried, both parenteral and enteral feedings; however, there is no clear evidence of improved survival. There is evidence that persons who consume >21.5 kcal/kg body weight per day have better survival, so achieving better caloric intake is recommended. Finally, in highly selected patients with good social support structure who fail other treatments for alcoholic hepatitis, early liver transplant can be an effective treatment.

Cessation of alcohol use is key. Recent experience with medications that reduce craving for alcohol, such as acamprosate calcium and baclofen, have been favorable. Patients may take other necessary medications even in the presence of cirrhosis. Acetaminophen use is often discouraged in patients with liver disease; however, if no more than 2 g of acetaminophen per day are consumed, there generally are no problems unless there is active alcohol use.

CIRRHOSIS DUE TO CHRONIC VIRAL HEPATITIS B OR C

Of patients exposed to the hepatitis C virus (HCV), ~80% develop chronic hepatitis C, and of those, ~20–30% will develop cirrhosis over 20–30 years. Many of these patients have had concomitant alcohol use, and the true incidence of cirrhosis due to hepatitis C alone is unknown. It is expected that an even higher percentage will go on to develop cirrhosis over longer periods of time. In the United States, ~5–6 million people have been exposed to HCV, and ~4–5 million are chronically viremic. Worldwide, ~170 million individuals have hepatitis C, with some areas of the world (e.g., Egypt) having up to 15% of the population infected. HCV is a noncytopathic virus, and liver damage is probably immune-mediated. Progression of liver disease due to chronic hepatitis C is characterized by portal-based fibrosis with bridging fibrosis and nodularity developing, ultimately culminating in the development of cirrhosis. In cirrhosis due to chronic hepatitis C, the liver is small and shrunken with characteristic features of a mixed micro- and macronodular cirrhosis seen on liver biopsy. In addition, an inflammatory infiltrate is found in portal areas with interface hepatitis and occasionally some lobular hepatocellular injury and inflammation. In patients with HCV genotype 3, steatosis is often present.

Similar findings are seen in patients with cirrhosis due to chronic hepatitis B. Of adult patients exposed to hepatitis B, ~5% develop chronic hepatitis B, and ~20% of those patients will go on to develop cirrhosis. Special stains for hepatitis B core (HBc) and hepatitis B surface (HBs) antigen will be positive, and ground-glass hepatocytes signify HBs antigen (HBsAg) may be present. In the United States, there are ~2 million carriers of hepatitis B, whereas in other parts of the world where hepatitis B virus (HBV) is endemic (i.e., Asia, Southeast Asia, sub-Saharan Africa), up to 15% of the population may be infected, having acquired the infection vertically at the time of birth. Thus, >300–400 million individuals are thought to have hepatitis B worldwide. Approximately 25% of these individuals may ultimately develop cirrhosis.

Clinical Features and Diagnosis Patients with cirrhosis due to either chronic hepatitis C or B can present with the usual symptoms and signs of chronic liver disease. Fatigue, malaise, vague right upper quadrant pain, and laboratory abnormalities are frequent presenting features. Diagnosis requires a thorough laboratory evaluation, including quantitative HCV RNA testing and analysis for HCV genotype, or hepatitis B serologies to include HBsAg, HBeAg (hepatitis B e antigen), anti-HBe, and quantitative HBV DNA levels.

TREATMENT

Cirrhosis due to Chronic Viral Hepatitis B or C

Management of complications of cirrhosis revolves around specific therapy for treatment of whatever complications occur (e.g., esophageal variceal hemorrhage, development of ascites and edema, or encephalopathy). In patients with chronic hepatitis B, numerous studies have shown beneficial effects of antiviral therapy, which is effective at viral suppression, as evidenced by reducing aminotransferase levels and HBV DNA levels and improving histology by reducing inflammation and fibrosis. Several clinical trials and case series have demonstrated that patients with decompensated liver disease can become compensated with the use of antiviral therapy directed against hepatitis B. Currently available therapy includes lamivudine, adefovir, telbivudine, entecavir, and tenofovir, with the latter two strongly preferred because of reduced risk of viral resistance. Interferon α can also be used for treating hepatitis B, but it should not be used in cirrhotics **(see Chap. 352)**.

Treatment of patients with cirrhosis due to hepatitis C with direct-acting antiviral protocols is highly successful (>95% cure rate), well tolerated, and usually of short duration (8–12 weeks) **(see Chap. 352)**.

CIRRHOSIS FROM AUTOIMMUNE HEPATITIS AND METABOLIC DYSFUNCTION–ASSOCIATED STEATOTIC LIVER DISEASE

Other causes of posthepatitic cirrhosis include autoimmune hepatitis (AIH) and metabolic dysfunction–associated steatohepatitis (MASH), which was previously called nonalcoholic steatohepatitis. Many patients with AIH present with cirrhosis that is already established. Typically, these patients will not benefit from immunosuppressive therapy with glucocorticoids or azathioprine because the AIH is "burned out." In this situation, liver biopsy does not show a significant inflammatory infiltrate. Diagnosis in this setting requires positive autoimmune markers such as antinuclear antibody (ANA) or anti-smooth-muscle antibody (ASMA). When patients with AIH present with cirrhosis and active inflammation accompanied by elevated liver enzymes, there can be considerable benefit from the use of immunosuppressive therapy.

Patients with MASH are increasingly being found to have progressed to cirrhosis. With the epidemic of obesity that continues in Western countries, more and more patients are identified with metabolic dysfunction–associated steatotic liver disease **(Chap. 354)**. Of these, a significant subset has MASH and can progress to increased fibrosis and cirrhosis. Over the past several years, it has been increasingly recognized that many patients who were thought to have cryptogenic cirrhosis in fact have MASH. As their cirrhosis progresses, they become catabolic and then lose the telltale signs of steatosis seen on biopsy. Management of complications of cirrhosis due to either AIH or MASH is similar to that for other forms of cirrhosis.

BILIARY CIRRHOSIS

Biliary cirrhosis has pathologic features that are different from either alcohol-associated cirrhosis or posthepatitic cirrhosis, yet the manifestations of end-stage liver disease are the same. Cholestatic liver disease may result from necroinflammatory lesions, congenital or metabolic processes, or external bile duct compression. Thus, two broad categories reflect the anatomic sites of abnormal bile retention: *intrahepatic* and *extrahepatic*. The distinction is important for obvious therapeutic reasons. Extrahepatic obstruction may benefit from surgical or endoscopic biliary tract decompression, whereas intrahepatic cholestatic processes will not improve with such interventions and require a different approach.

The major causes of chronic cholestatic syndromes are primary biliary cholangitis (PBC), autoimmune cholangitis (AIC), primary sclerosing cholangitis (PSC), and idiopathic adulthood ductopenia. These syndromes are usually clinically distinguished from each other

by antibody testing, cholangiographic findings, and clinical presentation. However, they all share the histopathologic features of chronic cholestasis, including cholate stasis; copper deposition; xanthomatous transformation of hepatocytes; and irregular, so-called biliary fibrosis. In addition, there may be chronic portal inflammation, interface activity, and chronic lobular inflammation. Ductopenia is a result of progressive disease as patients develop cirrhosis.

PRIMARY BILIARY CHOLANGITIS

PBC is seen in about 100–200 individuals per million, with a strong female preponderance and a median age of ~50 years at the time of diagnosis. The cause of PBC is unknown; it is characterized by portal inflammation and necrosis of cholangiocytes in small- and medium-sized bile ducts. Cholestatic features prevail, and biliary cirrhosis is characterized by an elevated bilirubin level and progressive liver failure. Liver transplantation is the treatment of choice for patients with decompensated cirrhosis due to PBC.

Antimitochondrial antibodies (AMAs) are present in ~95% of patients with PBC. These autoantibodies recognize lipoic acid on the inner mitochondrial membrane proteins that are enzymes of the pyruvate dehydrogenase complex (PDC), the branched-chain 2-oxoacid dehydrogenase complex, and the 2-oxogluterate dehydrogenase complex. These autoantibodies are not pathogenic, but rather are useful markers for making a diagnosis.

Pathology Histopathologic analysis identifies four distinct stages of the disease as it progresses. The earliest lesion is termed *chronic nonsuppurative destructive cholangitis* and is a necrotizing inflammatory process of the portal tracts. Medium and small bile ducts are infiltrated with lymphocytes and undergo duct destruction. Mild fibrosis and sometimes bile stasis can occur. With progression, the inflammatory infiltrate becomes less prominent, but the number of bile ducts is reduced and there is proliferation of smaller bile ductules. Increased fibrosis ensues with the expansion of periportal fibrosis to bridging fibrosis. Finally, cirrhosis, which may be micronodular or macronodular, develops.

Clinical Features Currently, most patients with PBC are middle-aged women diagnosed well before the end-stage manifestations of the disease are present, and as such, most patients are asymptomatic. When symptoms are present, they most prominently include a significant degree of fatigue out of proportion to either the severity of the liver disease or the age of the patient. Pruritus is seen in ~50% of patients at the time of diagnosis, and it can be debilitating. It might be intermittent and usually is most bothersome in the evening. In some patients, pruritus can develop toward the end of pregnancy and can be mistaken for cholestasis of pregnancy. Pruritus that presents prior to the development of jaundice indicates severe disease and a poor prognosis.

Physical examination can show jaundice and other complications of chronic liver disease including hepatomegaly, splenomegaly, ascites, and edema. Other features that are unique to PBC include hyperpigmentation, xanthelasma, and xanthomata, which are related to altered cholesterol metabolism. Hyperpigmentation is evident on the trunk and the arms and is seen in areas of exfoliation and lichenification associated with progressive scratching related to the pruritus. Bone pain resulting from osteopenia or osteoporosis is occasionally seen at diagnosis.

Laboratory Findings Laboratory findings in PBC show cholestatic liver enzyme abnormalities with an elevation in γ-glutamyl transpeptidase and alkaline phosphatase (ALP) along with mild elevations in aminotransferases (ALT and AST). Immunoglobulins, particularly IgM, are typically increased. Hyperbilirubinemia usually is seen once cirrhosis has developed. Thrombocytopenia, leukopenia, and anemia may be seen in patients with portal hypertension and hypersplenism. Liver biopsy shows characteristic features as described above and should be evident to any experienced hepatopathologist. Up to 10% of patients with characteristic PBC will have features of AIH (moderate to severe interphase hepatitis on biopsy, elevated ALT >5× the upper limit of normal, and elevated IgG levels) as well and are defined as having "overlap" syndrome. These patients are usually treated as PBC patients and progress to cirrhosis with the same frequency as typical PBC patients. Some patients require immunosuppressive medications as well.

Diagnosis PBC should be considered in patients with chronic cholestatic liver enzyme abnormalities. AMA testing may be negative in as many as 5–10% of patients with PBC. These patients usually are positive for other PBC-specific autoantibodies including sp100 or gp210, although these tests are not universally available. Liver biopsy is most important in this setting of AMA-negative PBC. In patients who are AMA negative with cholestatic liver enzymes, PSC should be ruled out by way of cholangiography.

TREATMENT

Primary Biliary Cholangitis

Treatment of the typical manifestations of cirrhosis is no different for PBC than for other forms of cirrhosis. Ursodeoxycholic acid (UDCA) has been shown to improve both biochemical and histologic features of the disease, thus slowing but not reversing or curing the disease. Improvement is greatest when therapy is initiated early; the likelihood of significant improvement with UDCA is low in patients with PBC who present with manifestations of cirrhosis. UDCA is given in doses of 13–15 mg/kg per d; the medication is usually well tolerated, although some patients have worsening pruritus with initiation of therapy. A small proportion of patients may have diarrhea or headache as a side effect of the drug. About 30–40% of patients with PBC do not have a satisfactory response to UDCA; more than half of these patients will have significant improvement with obeticholic acid, elafibranor or seladelpar though these medication should be avoided in the setting of cirrhosis with portal hypertension or decompensation. Patients with PBC require long-term follow-up by a physician experienced with the disease. Certain patients may need to be considered for liver transplantation should their liver disease decompensate.

The main symptoms of PBC are fatigue and pruritus. Several therapies have been tried for treatment of fatigue, but none of them has been successful; frequent naps should be encouraged. Pruritus is treated with antihistamines, narcotic receptor antagonists (naltrexone), selective serotonin reuptake inhibitors, and rifampin. Cholestyramine, a bile salt–sequestering agent, has been helpful in some patients but is somewhat tedious and difficult to take. Plasmapheresis has been used rarely in patients with severe intractable pruritus. There is an increased incidence of osteopenia and osteoporosis in patients with cholestatic liver disease, and bone density testing should be performed. Oral calcium and vitamin D are also recommended. Treatment with a bisphosphonate should be instituted when bone disease is identified. Screening for fat-soluble vitamin deficiency (A, D, E, K) should done if total bilirubin is >2 mg/dL.

PRIMARY SCLEROSING CHOLANGITIS

As in PBC, the cause of PSC remains unknown. PSC is a chronic cholestatic syndrome that is characterized by diffuse inflammation and fibrosis involving the entire biliary tree, resulting in chronic cholestasis. This pathologic process ultimately results in obliteration of both the intra- and extrahepatic biliary tree, leading to biliary cirrhosis, portal hypertension, and liver failure. The cause of PSC remains unknown despite extensive investigation into various mechanisms related to bacterial and viral infections, toxins, genetic predisposition, and immunologic mechanisms, all of which have been postulated to contribute to the pathogenesis and progression of this syndrome.

Liver biopsy changes in PSC are not pathognomonic, and establishing the diagnosis of PSC must involve imaging of the biliary tree. Pathologic changes occurring in PSC show bile duct proliferation as well as ductopenia and fibrous cholangitis (pericholangitis). Periductal fibrosis is occasionally seen on biopsy specimens and can be quite

helpful in making the diagnosis. As the disease progresses, biliary cirrhosis is the end-stage manifestation of PSC.

Clinical Features The usual clinical features of PSC are those found in cholestatic liver disease, with fatigue, pruritus, steatorrhea, deficiencies of fat-soluble vitamins, and the associated consequences. As in PBC, the fatigue is profound and nonspecific. Pruritus can often be debilitating and is related to the cholestasis. The severity of pruritus does not correlate with the severity of the disease. Metabolic bone disease, as seen in PBC, can occur with PSC and should be treated (see above).

Laboratory Findings Patients with PSC typically are identified during an evaluation of abnormal liver enzymes. Most patients have at least a twofold increase in ALP and may have elevated aminotransferases as well. Albumin levels may be decreased, and prothrombin times can be prolonged at the time of diagnosis. Some degree of correction of a prolonged prothrombin time may occur with parenteral vitamin K. A small subset of patients has aminotransferase elevations >5× the upper limit of normal and may have features of AIH on biopsy indicating an overlap syndrome between PSC and AIH. Autoantibodies are frequently positive in patients with the overlap syndrome but are typically negative in patients who only have PSC. One autoantibody, the perinuclear antineutrophil cytoplasmic antibody (pANCA), is positive in ~65% of patients with PSC. Sixty to eighty percent of patients with PSC have inflammatory bowel disease, predominately ulcerative colitis (UC); thus, a colonoscopy is recommended at diagnosis.

Diagnosis The definitive diagnosis of PSC requires cholangiographic imaging. Magnetic resonance imaging (MRI) with magnetic resonance cholangiopancreatography (MRCP) is the imaging technique of choice for initial evaluation. Endoscopic retrograde cholangiopancreatography (ERCP) can be considered if the MRCP provided suboptimal images or if there is newly elevated total bilirubin or MRCP evidence of a dominant stricture. Typical cholangiographic findings in PSC are multifocal stricturing and beading involving both the intrahepatic and extrahepatic biliary tree. These strictures are typically short and with intervening segments of normal or slightly dilated bile ducts that are distributed diffusely, producing the classic beaded appearance. The gallbladder and cystic duct can be involved in up to 15% of cases. Gradually, biliary cirrhosis develops, and patients will progress to decompensated liver disease with manifestations of ascites, esophageal variceal hemorrhage, and encephalopathy.

TREATMENT

Primary Sclerosing Cholangitis

There is no specific proven treatment for PSC. Some clinicians use UDCA at "PBC dosages" of 13–15 mg/kg per d with anecdotal improvement, although no study has shown convincing evidence of clinical benefit. A study of high-dose (28–30 mg/kg per d) UDCA found it to be harmful. Endoscopic dilatation of dominant strictures can be helpful, but the ultimate treatment is liver transplantation when decompensated cirrhosis develops. Episodes of cholangitis should be treated with antibiotics and can be an indication for liver transplantation. A dreaded complication of PSC is the development of cholangiocarcinoma, which is a relative contraindication to liver transplantation.

CARDIAC CIRRHOSIS

Definition Patients with long-standing right-sided congestive heart failure may develop chronic liver injury from congestive hepatopathy sometimes resulting in cardiac cirrhosis. This is an increasingly uncommon, if not rare, cause of chronic liver disease given the advances made in the care of patients with heart failure, particularly valvular heart disease, but there has been an increase in patients with congenital heart disease particularly after the Fontan operation.

Etiology and Pathology In the case of long-term right-sided heart failure, there is an elevated venous pressure transmitted via the inferior vena cava and hepatic veins to the sinusoids of the liver, which become dilated and engorged with blood. The liver becomes enlarged and swollen, and with long-term passive congestion and relative ischemia due to poor circulation, centrilobular hepatocytes can become necrotic, leading to pericentral fibrosis. This fibrotic pattern can extend to the periphery of the lobule outward until a unique pattern of fibrosis causing cirrhosis can occur.

Clinical Features Patients typically have signs of congestive heart failure and will manifest an enlarged firm liver on physical examination. ALP levels are characteristically elevated, and aminotransferases may be normal or slightly increased, with AST usually higher than ALT. It is unlikely that patients will develop variceal hemorrhage or encephalopathy.

Diagnosis The diagnosis is usually made in someone with clear-cut cardiac disease who has an elevated ALP and an enlarged liver. Liver biopsy shows a pattern of fibrosis that can be recognized by an experienced hepatopathologist. Differentiation from Budd-Chiari syndrome (BCS) can be made by seeing extravasation of red blood cells in BCS, but not in cardiac hepatopathy. Venoocclusive disease, now termed sinusoidal obstructive syndrome (SOS), can also affect hepatic outflow and has characteristic features on liver biopsy. SOS can be seen under the circumstances of conditioning for bone marrow transplant with radiation and chemotherapy; it can also be seen with the ingestion of certain herbal teas as well as pyrrolizidine alkaloids. This is typically seen in Caribbean countries and rarely in the United States. Treatment is based on management of the underlying cardiac disease.

OTHER TYPES OF CIRRHOSIS

There are several other less common causes of chronic liver disease that can progress to cirrhosis. These include inherited metabolic liver diseases such as hemochromatosis, Wilson's disease, α_1 antitrypsin (α_1AT) deficiency, and cystic fibrosis. For these disorders, the manifestations of cirrhosis are similar, with some minor variations, to those seen in other patients with other causes of cirrhosis.

Hemochromatosis is an inherited disorder of iron metabolism that results in a progressive increase in hepatic iron deposition, which, over time, can lead to a portal-based fibrosis progressing to cirrhosis, liver failure, and hepatocellular cancer. While the frequency of hemochromatosis is relatively common, with genetic susceptibility occurring in 1 in 250 individuals, the frequency of end-stage manifestations due to the disease is relatively low, and <5% of those patients who are genotypically susceptible will go on to develop severe liver disease from hemochromatosis. Diagnosis is made with serum iron studies showing an elevated transferrin saturation and an elevated ferritin level, along with abnormalities identified by *HFE* mutation analysis. Treatment is straightforward, with regular therapeutic phlebotomy.

Wilson's disease is an inherited disorder of copper homeostasis with failure to excrete excess amounts of copper, leading to an accumulation in the liver. This disorder is relatively uncommon, affecting 1 in 30,000 individuals. Wilson's disease typically affects adolescents and young adults. Prompt diagnosis before end-stage manifestations become irreversible can lead to significant clinical improvement. Diagnosis requires determination of ceruloplasmin levels, which are low; 24-h urine copper levels, which are elevated; typical physical examination findings, including Kayser-Fleischer corneal rings; and characteristic liver biopsy findings. Treatment consists of copper-chelating medications.

α_1AT deficiency results from an inherited disorder that causes abnormal folding of the α_1AT protein, resulting in failure of secretion of that protein from the liver. It is unknown how the retained protein leads to liver disease. Patients with α_1AT deficiency at greatest risk for developing chronic liver disease have the ZZ phenotype, but only ~10–20% of such individuals will develop chronic liver disease. Diagnosis is made by determining α_1AT levels and phenotype. Characteristic periodic acid–Schiff (PAS)–positive, diastase-resistant globules are seen on liver biopsy. The only effective treatment is liver transplantation, which is curative.

TABLE 355-2 Complications of Cirrhosis

Portal hypertension	Coagulopathy
Gastroesophageal varices	Factor deficiency
Portal hypertensive gastropathy	Fibrinolysis
Splenomegaly, hypersplenism	Thrombocytopenia
Ascites	Bone disease
Spontaneous bacterial peritonitis	Osteopenia
Acute kidney injury-hepatorenal syndrome	Osteoporosis
Chronic kidney disease-hepatorenal syndrome	Osteomalacia
	Hematologic abnormalities
Hepatic encephalopathy	Anemia
Hepatopulmonary syndrome	Hemolysis
Portopulmonary hypertension	Thrombocytopenia
Malnutrition	Neutropenia

TABLE 355-3 Classification of Portal Hypertension

Prehepatic
Portal vein thrombosis
Splenic vein thrombosis
Massive splenomegaly (Banti's syndrome)
Hepatic
Presinusoidal
Schistosomiasis
Congenital hepatic fibrosis
Sinusoidal
Cirrhosis—many causes
Alcoholic hepatitis
Postsinusoidal
Hepatic sinusoidal obstruction (venoocclusive syndrome)
Posthepatic
Budd-Chiari syndrome
Inferior vena caval webs
Cardiac causes
Restrictive cardiomyopathy
Constrictive pericarditis
Severe congestive heart failure

Cystic fibrosis is an uncommon inherited disorder affecting whites of northern European descent. A biliary-type cirrhosis can occur, and some patients derive benefit from the chronic use of UDCA.

MAJOR COMPLICATIONS OF CIRRHOSIS

These include gastroesophageal variceal hemorrhage, splenomegaly, ascites, hepatic encephalopathy, spontaneous bacterial peritonitis (SBP), hepatorenal syndrome (HRS), and hepatocellular carcinoma (Table 355-2). There are also more rare complications in the pulmonary system including hepatopulmonary syndrome and portopulmonary hypertension.

PORTAL HYPERTENSION

Portal hypertension is defined as the elevation of the hepatic venous pressure gradient (HVPG) to >5 mmHg. The portal venous system normally drains blood from most of the GI tract including the stomach, small and large intestines, spleen, pancreas, and gallbladder. Portal hypertension is caused by a combination of two simultaneously occurring hemodynamic processes: (1) increased intrahepatic resistance to the passage of blood flow through the liver due to cirrhosis, regenerative nodules, and microthrombi, and (2) increased splanchnic blood flow secondary to vasodilation within the splanchnic vascular bed. In more advanced stages, there is also activation of neurohumoral responses and vasoconstrictive systems resulting in sodium and water retention, increased blood volume, and hyperdynamic circulatory system producing more portal hypertension. There is usually an initial stage of compensated cirrhosis with HVPG between 5 and 10 mmHg that can be asymptomatic and last for ≥10 years, but when clinically significant portal hypertension (CSPH) develops (defined as a HVPG ≥10 mmHg), there is substantial risk of decompensation with variceal bleeding, ascites, or hepatic encephalopathy. With decompensation, median mortality is <2 years.

The causes of portal hypertension are usually subcategorized as prehepatic, intrahepatic, and posthepatic (Table 355-3). Prehepatic causes of portal hypertension are those affecting the portal venous system before it enters the liver; they include portal vein thrombosis and splenic vein thrombosis. Posthepatic causes encompass those affecting the hepatic veins and venous drainage to the heart; they include BCS and chronic right-sided cardiac congestion. Intrahepatic causes account for >95% of cases of portal hypertension and are represented by the major forms of cirrhosis. Intrahepatic causes of portal hypertension can be further subdivided into presinusoidal, sinusoidal, and postsinusoidal causes. Postsinusoidal causes include venoocclusive disease, whereas presinusoidal causes include congenital hepatic fibrosis and schistosomiasis. Sinusoidal causes are related to cirrhosis from various causes.

Cirrhosis is overwhelmingly the most common cause of portal hypertension in the United States. Portal vein thrombosis may contribute to portal hypertension and is most often associated with cirrhosis but may be idiopathic or can occur in association with infection, pancreatitis, or abdominal trauma. Coagulation disorders that can lead to the development of portal vein thrombosis include polycythemia vera; essential thrombocytosis; deficiencies in protein C, protein S, antithrombin III, and factor V Leiden; and abnormalities in the gene-regulating prothrombin production. Some patients may have a subclinical myeloproliferative disorder.

Clinical Features The three primary complications of portal hypertension are gastroesophageal varices with hemorrhage, ascites, and hypersplenism. Thus, patients may present with upper GI bleeding, which, on endoscopy, is found to be due to esophageal or gastric varices; with the development of ascites along with peripheral edema; or with an enlarged spleen with associated reduction in platelets and white blood cells on routine laboratory testing.

ESOPHAGEAL VARICES *Variceal hemorrhage* is an immediate life-threatening problem with a 20–30% mortality rate associated with each episode of bleeding. Over the past decade, it has become common practice to screen known cirrhotics with endoscopy to look for esophageal varices. Such screening studies have shown that approximately one-third of patients with histologically confirmed cirrhosis have varices. Approximately 5–15% of cirrhotics per year develop varices, and it is estimated that the majority of patients with cirrhosis will develop varices over their lifetimes. Furthermore, it is anticipated that roughly one-third of patients with varices will develop bleeding. Several factors predict the risk of bleeding, including the severity of cirrhosis (Child-Pugh class, Model for End-Stage Liver Disease [MELD] score); the height of wedged-hepatic vein pressure; the size of the varix; the location of the varix; and certain endoscopic stigmata, including red wale signs, hematocystic spots, diffuse erythema, bluish color, cherry red spots, or white-nipple spots. Patients with tense ascites are also at increased risk for bleeding from varices.

Diagnosis In patients with cirrhosis who are being followed chronically, the development of portal hypertension is usually revealed by the presence of thrombocytopenia; the appearance of an enlarged spleen; or the development of ascites, encephalopathy, and/or esophageal varices with or without bleeding. In previously undiagnosed patients, any of these features should prompt further evaluation to determine the presence of portal hypertension and liver disease. Varices should be identified by endoscopy. Contrasted-enhanced abdominal imaging, either by computed tomography (CT) or MRI, can be helpful in demonstrating a nodular liver and in finding changes of portal hypertension with intraabdominal collateral circulation. Rarely, the HVPG is

measured by interventional radiology. Patients with a gradient >12 mmHg are at risk for variceal hemorrhage.

TREATMENT

Variceal Hemorrhage

Treatment for esophageal varices as a complication of portal hypertension is divided into two main categories: (1) primary prophylaxis and (2) prevention of rebleeding once there has been an initial variceal hemorrhage. Primary prophylaxis requires routine surveillance by endoscopy. Upper endoscopies are recommended at diagnosis of compensated cirrhosis and then every 2 years if the liver disease is active or every 3 years if inactive (alcohol cessation, viral hepatitis eradication). In the absence of thrombocytopenia and with a liver stiffness by transient elastography <20 kPa, high-risk varices are rare and thus screening is not needed. Endoscopy is also recommended at the time of hepatic decompensation. Once varices that are at increased risk for bleeding are identified, usually defined as medium or large varices or small varices with high-risk stigmata or in decompensated cirrhosis, primary prophylaxis can be achieved either through traditional nonselective beta blockade (NSBB) (propranolol or nadolol) titrated with a goal heart rate of 55–60 beats/min with systolic blood pressure >90 mmHg or by variceal band ligation. Carvedilol is becoming the NSBB of choice. Given its additional anti-α_1-adrenergic vasodilating properties, it more effectively lowers portal pressure, lacks the need for heart rate goals, and has emerging data that suggest it can prevent hepatic decompensation and improve survival in persons with CSPH.

Endoscopic variceal ligation (EVL) has been compared to traditional NSBB and carvedilol for primary prophylaxis against variceal bleeding, and EVL appears to have equivalent efficacy at preventing bleeding. NSBBs, especially carvedilol, are generally recommended as first-line treatment for primary prophylaxis of bleeding if tolerated, given their additional benefits. Once primary prophylaxis has been initiated, repeat endoscopy for surveillance of varices is unnecessary.

The approach to patients once they have had a variceal bleed is first to treat the acute bleed, which can be life-threatening, and then to prevent further bleeding. Treatment of acute bleeding requires both fluid and red blood cell replacement to stabilize hemodynamics. A randomized trial of restricted transfusion starting when hemoglobin is <7 g/dL with a goal hemoglobin of 7–9 g/dL, compared to a more liberal strategy, resulted in reduced early rebleeding and mortality. This strategy is recommended, although adjustments should be made based on cardiac risks and hemodynamics. Correcting an elevated prothrombin time with fresh frozen plasma is not recommended unless there is evidence of coagulopathy (bleeding at other sites such as IV lines). The use of vasoconstricting agents, usually somatostatin or octreotide, has been shown to improve initial bleeding control and reduce transfusion requirements and all-cause mortality. Prophylactic antibiotics, usually with ceftriaxone, started prior to endoscopy result in reduced infections, recurrent bleeding, and mortality. Balloon tamponade (Sengstaken-Blakemore tube or Minnesota tube) or placement of self-expandable metal stents can be used in patients who need stabilization prior to endoscopic therapy or as a bridge to transjugular intrahepatic portosystemic shunt (TIPS) after endoscopic failure. Control of bleeding can be achieved in the vast majority of cases; however, bleeding recurs in the majority of patients if definitive endoscopic therapy has not been instituted. Upper endoscopy is used as first-line treatment to diagnose the cause of the bleeding and to control bleeding acutely with EVL. When esophageal varices extend into the proximal stomach or the bleeding varices are entirely within the stomach, band ligation is often unsuccessful. In these situations, consideration for a TIPS should be made. This technique creates a portosystemic shunt by a percutaneous approach using an expandable metal stent, which is advanced under angiographic guidance to the hepatic veins and then through the substance of the liver to create a direct portocaval shunt. Encephalopathy can occur in as many as 20% of patients after TIPS and is particularly problematic in elderly patients and in patients with preexisting encephalopathy. TIPS is usually reserved for individuals who fail or are unable to receive endoscopic therapy, although there is emerging evidence that patients who are highly selected to be at high risk for rebleeding may also benefit. TIPS can sometimes be used as a bridge to transplantation, and all patients requiring TIPS should be considered for transplant evaluation. Some gastric varices are associated with a splenorenal shunt and can be effectively treated with a balloon-occluded retrograde transvenous obliteration (BRTO) of varices sometimes in combination with a TIPS. Prevention of further bleeding is usually accomplished with repeated variceal band ligation until varices are obliterated in combination with NSBB. If recurrent variceal bleeding occurs, then TIPS should be performed for long-term prevention of bleeding. Once a TIPS has been performed, there is no need for further endoscopies for variceal surveillance; however, the TIPS should be periodically monitored with Doppler ultrasound for stenosis **(Fig. 355-3)**.

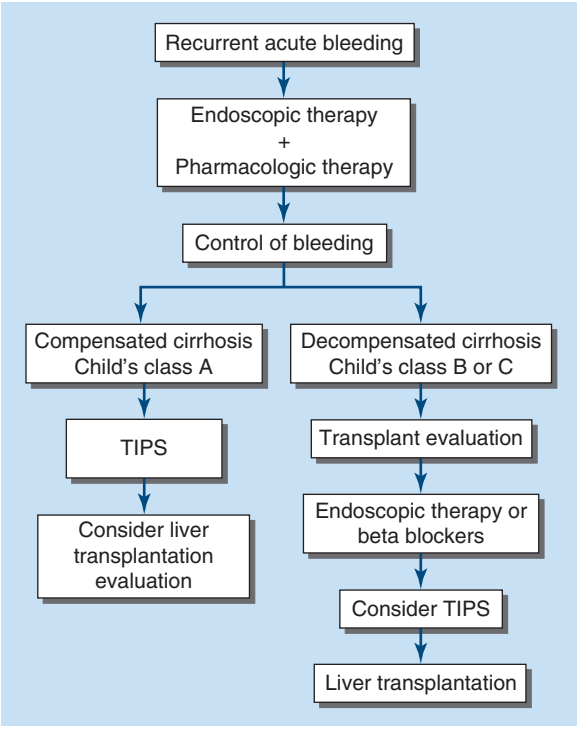

FIGURE 355-3 Management of recurrent variceal hemorrhage. This algorithm describes an approach to management of patients who have recurrent bleeding from esophageal varices. Initial therapy is generally with endoscopic therapy often supplemented by pharmacologic therapy. With control of bleeding, a decision needs to be made as to whether patients should go on to transjugular intrahepatic portosystemic shunt (TIPS; if they are Child's class A) or if they should have TIPS and be considered for transplant (if they are Child's class B or C).

PORTAL HYPERTENSIVE GASTROPATHY

Portal hypertensive gastropathy can cause both acute clinical GI bleeding and chronic bleeding resulting in iron-deficiency anemia. It is associated with all causes of portal hypertension and is diagnosed by characteristic endoscopy findings showing a snakeskin-like mosaic pattern of gastric mucosa often with central red or brown spots. When there is bleeding, treatment is with NSBB and iron repletion. Refractory bleeding may respond to TIPS.

SPLENOMEGALY AND HYPERSPLENISM

Congestive splenomegaly with hypersplenism is common in patients with portal hypertension and is usually the first indication of portal hypertension. Clinical features include the presence of an enlarged spleen on physical examination and the development of thrombocytopenia and leukopenia in patients who have cirrhosis. Some patients will have significant left-sided and left upper quadrant abdominal pain

related to an enlarged spleen. Splenomegaly itself usually requires no specific treatment.

ASCITES

Definition Ascites is the accumulation of fluid within the peritoneal cavity. Overwhelmingly, the most common cause of ascites is portal hypertension related to cirrhosis; however, clinicians should remember that malignant, infectious, and cardiac causes of ascites can be present as well, and careful differentiation of these other causes is obviously important for patient care.

Pathogenesis The presence of portal hypertension contributes to the development of ascites in patients who have cirrhosis (Fig. 355-4). There is an increase in intrahepatic resistance, causing increased portal pressure, but there is also vasodilation of the splanchnic arterial system, which, in turn, results in an increase in portal venous inflow. Both abnormalities result in increased production of splanchnic lymph. Vasodilating factors such as nitric oxide are responsible for the vasodilatory effect. There is activation of the renin-angiotensin-aldosterone system with the development of hyperaldosteronism and activation of the sympathetic nervous system as a consequence of a homeostatic response caused by underfilling of the arterial circulation secondary to arterial vasodilation in the splanchnic vascular bed. The renal effects of increased aldosterone and activation of the sympathetic nervous system lead to sodium retention causing fluid accumulation and expansion of the extracellular fluid volume, resulting in peripheral edema and ascites. Because the retained fluid is constantly leaking out of the intravascular compartment into the peritoneal cavity, the sensation of vascular filling is not achieved, and the process continues. Hypoalbuminemia from decreased synthetic function in a cirrhotic liver results in reduced plasma oncotic pressure and contributes to the loss of fluid from the vascular compartment into the peritoneal cavity.

Clinical Features Patients typically note an increase in abdominal girth that is often accompanied by peripheral edema. The development of ascites is often insidious, and it is surprising that some patients wait so long and become so distended before seeking medical attention. Patients usually have at least 1–2 L of fluid in the abdomen before they are aware that there is an increase. If ascitic fluid is massive, respiratory function can be compromised, causing dyspnea. Hepatic hydrothorax may also contribute to respiratory symptoms. Patients with massive ascites are often malnourished and have muscle wasting and excessive fatigue and weakness.

Diagnosis Diagnosis of ascites is by physical examination and is often aided by abdominal imaging. Patients will have bulging flanks and may have a fluid wave or the presence of shifting dullness. This is determined by taking patients from a supine position to lying on either their left or right side and noting the movement of the dullness to percussion. Subtle amounts of ascites can be detected by ultrasound or CT scanning. Hepatic hydrothorax is more common on the right side and implicates a rent in the diaphragm with free flow of ascitic fluid into the thoracic cavity.

When patients present with ascites for the first time, it is recommended that a diagnostic paracentesis be performed to characterize the fluid. This should include the determination of total protein and albumin content, blood cell counts with differential, and cultures. In the appropriate setting, amylase may be measured and cytology performed. In patients with cirrhosis, the protein concentration of the ascitic fluid is low, usually <2.5 g/dL. The serum ascites-to-albumin gradient (SAAG), calculated by subtracting the fluid albumin level from the serum albumin level, has replaced the description of exudative or transudative fluid. When the SAAG is >1.1 g/dL, the cause of the ascites is most likely due to portal hypertension; this is usually in the setting of cirrhosis. Cardiac ascites can be identified by SAAG >1.1 g/dL and ascites protein >2.5g/dL. When the SAAG is <1.1 g/dL, infectious or malignant causes of ascites should be considered. When ascitic fluid protein is very low, <1.5 g/dL, patients are at increased risk for developing SBP. A high level of red blood cells in the ascitic fluid usually signifies a traumatic tap but can also rarely occur with hepatocellular cancer or a ruptured omental varix. When the absolute level of polymorphonuclear leukocytes is >250/μL, infection is likely.

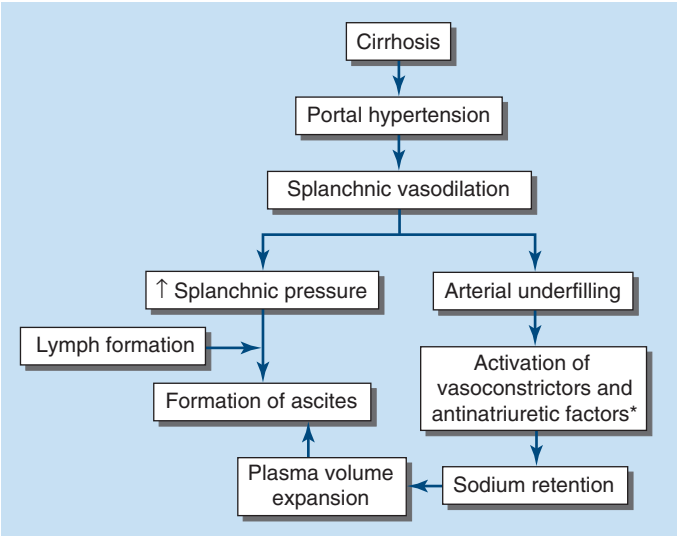

FIGURE 355-4 Development of ascites in cirrhosis. This flow diagram illustrates the importance of portal hypertension with splanchnic vasodilation in the development of ascites. *Antinatriuretic factors include the renin-angiotensin-aldosterone system and the sympathetic nervous system.

TREATMENT

Ascites

Patients with small amounts of ascites can usually be managed with dietary sodium restriction alone. Most average diets in the United States contain 6–8 g of sodium per day, and if patients eat at restaurants or fast-food outlets, the amount of sodium in their diet can exceed this amount. Thus, it is often extremely difficult to get patients to change their dietary habits to ingest 2 g of sodium per day, equivalent to slightly more than three-quarters of a teaspoon of salt, which is the recommended amount. Sodium educational pamphlets are helpful. Often, a simple recommendation is to eat fresh or frozen foods, avoiding canned or processed foods. When a moderate amount of ascites is present, diuretic therapy is usually necessary. Traditionally, spironolactone at 100 mg/d as a single dose is started, and furosemide may be added at 40 mg/d, particularly in patients who have peripheral edema. Failure of the diuretics suggests that patients may not be compliant with a low-sodium diet. If compliance is confirmed and ascitic fluid is not being mobilized, there should be incremental increases in spironolactone to a maximum of 400 mg/d and furosemide to 160 mg/d. If a large amount of ascites is still present on diuretics in patients who are compliant with a low-sodium diet, then they are defined as having *refractory ascites*, and alternative treatment modalities including repeated large-volume paracentesis (LVP) or a TIPS procedure should be considered (Fig. 355-5). After LVP of ≥5 L, IV 25% albumin at a dose of 6–8 g/L of removed ascites should be given to prevent circulatory dysfunction. Multiple studies have shown that TIPS, although effective at managing the ascites, does not improve survival. Unfortunately, TIPS is often associated with an increased frequency of hepatic encephalopathy and must be considered carefully on a case-by-case basis. The prognosis for patients with cirrhosis with ascites is poor, and some studies have shown that <50% of patients survive 2 years after the onset of ascites. Thus, there should be consideration for liver transplantation in patients with ascites. Patients with cirrhosis and ascites are at increased risk for renal failure from certain medications including nonsteroidal anti-inflammatory drugs and aminoglycosides; therefore, these medications should generally be avoided. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers should be used cautiously with close monitoring of blood pressure and renal function.

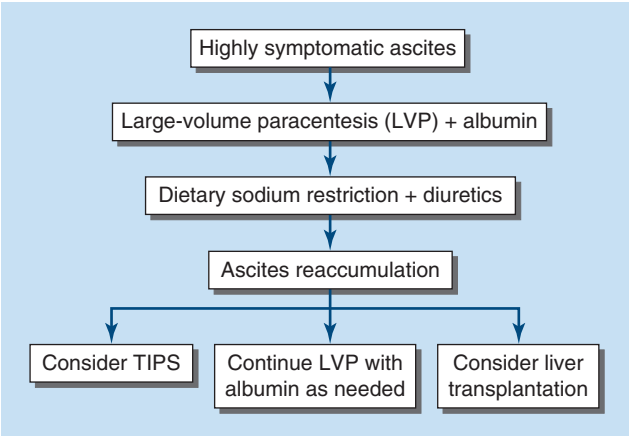

FIGURE 355-5 Treatment of refractory ascites. In patients who develop azotemia in the course of receiving diuretics in the management of their ascites, some will require repeated large-volume paracentesis (LVP), some may be considered for transjugular intrahepatic portosystemic shunt (TIPS), and some would be good candidates for liver transplantation. These decisions are all individualized.

SPONTANEOUS BACTERIAL PERITONITIS

SBP is a common and severe complication of ascites characterized by spontaneous infection of the ascitic fluid without an intraabdominal source. In hospitalized patients with cirrhosis and ascites, SBP can occur in up to 30% of individuals and can have a 25% in-hospital mortality rate. Bacterial translocation is the presumed mechanism for development of SBP, with gut flora traversing the intestine into mesenteric lymph nodes, leading to bacteremia and seeding of the ascitic fluid. The most common organisms are *Escherichia coli* and other gut bacteria; however, gram-positive bacteria, including *Streptococcus viridans*, *Staphylococcus aureus*, and *Enterococcus* spp., can also be found. If more than two organisms are identified, secondary bacterial peritonitis due to a perforated viscus should be considered. The diagnosis of SBP is made when the fluid sample has an absolute neutrophil count >250/μL. Bedside cultures should be obtained by direct injection of ascitic fluid into blood culture bottles. Patients with ascites may present with fever, altered mental status, elevated white blood cell count, abdominal pain or discomfort, and acute kidney injury, or they may present without any of these features. Therefore, it is necessary to have a high degree of clinical suspicion, and peritoneal taps are recommended for cirrhosis patients hospitalized with ascites and cirrhosis complications or signs of infection. Treatment is commonly with intravenous third-generation cephalosporin for 5 days. In addition, intravenous albumin (1.5 g/kg body weight on day 1 and 1.0 g/kg on day 3) has been shown to reduce the risk of renal failure and to improve survival. In patients with variceal hemorrhage, the frequency of SBP is significantly increased, and prophylaxis against SBP is recommended at presentation with upper GI bleeding. Furthermore, in patients who have had an episode of SBP and recovered, quinolone antibiotic prophylaxis should be given to prevent recurrent SBP.

HEPATORENAL SYNDROME

HRS is a form of functional renal failure without renal pathology that occurs in ~10% of patients with advanced cirrhosis or acute liver failure. There are marked disturbances in the arterial renal circulation in patients with HRS; these include an increase in vascular resistance accompanied by a reduction in systemic vascular resistance. The reason for renal vasoconstriction is most likely multifactorial and is poorly understood. The diagnosis is made usually in the presence of a large amount of ascites in patients who have a stepwise progressive increase in creatinine. Acute kidney injury (AKI) is defined by a 0.3-mg/dL rise in creatinine over 48 h or a 50% rise in creatinine from baseline. HRS-AKI, the new term for type 1 HRS, is characterized by a progressive rapid impairment in renal function. Type 2 HRS, now termed HRS–chronic kidney disease (CKD), is characterized by a reduction in glomerular filtration rate with an elevation of serum creatinine level, but it is stable and is associated with a better outcome than that of type 1 HRS.

HRS-AKI requires exclusion of other causes of acute renal failure, most notably volume depletion. Diuretics should be stopped, and infusion of albumin 1 g/kg per d for 48 h without significant improvements is required. Other causes of AKI, including intrinsic (acute tubular necrosis, acute interstitial nephritis, and glomerulonephritis) and obstructive kidney disease, should be excluded. Treatment is with vasoconstrictors such as terlipressin or, if not available, low-dose norepinephrine, which requires intensive care unit monitoring. Midodrine, an α-agonist, along with octreotide and intravenous albumin are also commonly used in the United States but are now third line. If treatment fails, then renal replacement therapy can be initiated. The best therapy for HRS is liver transplantation; recovery of renal function is typical in this setting. In patients with either AKI-HRS or CKD-HRS, the prognosis is poor unless transplant can be achieved.

HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy is a serious complication of chronic liver disease and is broadly defined as an alteration in mental status and cognitive function occurring as a consequence of liver failure. In severe acute liver injury, the development of encephalopathy is a requirement for a diagnosis of acute liver failure and can be seen in association with life-threatening brain edema, which is not a feature in chronic liver disease. Hepatic encephalopathy is much more commonly seen in patients with chronic liver disease. Gut-derived neurotoxins that are not removed by the liver because of vascular shunting and decreased hepatic mass reach the brain and cause the symptoms known as hepatic encephalopathy. Ammonia levels are typically elevated, but the correlation between severity of liver disease and height of ammonia levels is often poor, and most hepatologists do not rely on ammonia levels to make a diagnosis or follow clinical progress. Other compounds and metabolites that may contribute to the development of encephalopathy include certain false neurotransmitters and mercaptans.

Clinical Features In acute liver failure, changes in mental status can occur rapidly. Brain edema can be seen in these patients, with severe encephalopathy associated with swelling of the gray matter. Cerebral herniation is a feared complication of brain edema in acute liver failure, and treatment to decrease edema is with hypertonic saline or mannitol.

In patients with cirrhosis, encephalopathy is often found as a result of precipitating events such as volume depletion, gastrointestinal bleeding, hyponatremia, infection, or constipation. Patients may be confused or exhibit a change in personality. They may be quite violent and difficult to manage; alternatively, patients may be very sleepy and difficult to rouse. If patients have ascites, this should be tapped to rule out infection. Evidence of GI bleeding should be sought, and patients should be appropriately hydrated. Electrolytes should be measured, and abnormalities corrected. In patients presenting with encephalopathy, asterixis is often present. Asterixis can be elicited by having patients extend their arms and bend their wrists back. Patients who are encephalopathic have a "liver flap"—that is, a sudden forward movement of the wrist. This requires patients to be able to cooperate with the examiner. Alternative causes for altered mental status should also be considered.

The diagnosis of hepatic encephalopathy is clinical and requires an experienced clinician to recognize and put together all the various features. Often when patients have encephalopathy for the first time, they (and/or their caregivers) are unaware of what is transpiring, but once they have been through the experience, they can identify when this is developing in subsequent situations and can often self-medicate to prevent the development or worsening of encephalopathy.

TREATMENT

Hepatic Encephalopathy

Treatment is multifactorial and includes management of the above-mentioned precipitating factors. Sometimes hydration and correction of electrolyte imbalance are all that is necessary. In the past, restriction of dietary protein was used; however, the negative impact of that maneuver on overall nutrition is thought to outweigh the

benefit, and it is thus strongly discouraged. The mainstay of treatment for encephalopathy is to use lactulose, a nonabsorbable disaccharide, which results in colonic acidification. Catharsis ensues, contributing to the elimination of nitrogenous products in the gut that are responsible for the development of encephalopathy. The goal of lactulose therapy is to promote two to three soft stools per day. Patients are asked to titrate their amount of ingested lactulose to achieve the desired effect. Lactulose is usually continued after the initial episode of encephalopathy. Poorly absorbed antibiotics are often used as adjunctive therapies for patients who have a difficult time with lactulose or in those with recurrent episodes. Rifaximin has replaced neomycin and metronidazole (because of their significant toxicity). The dose is 550 mg twice daily and is very effective in preventing recurrent encephalopathy. In patients with recurrent symptoms despite treatment, closure of large portosystemic shunts can be helpful. Zinc supplementation is sometimes helpful and is relatively harmless. The development of encephalopathy in patients with chronic liver disease is a poor prognostic sign, but this complication can be managed in the vast majority of patients.

ACUTE-ON-CHRONIC LIVER FAILURE

Acute-on-chronic liver failure (ACLF) is a recently recognized clinical syndrome that is characterized by acutely decompensating cirrhosis with associated failure of one or more organ systems, including liver, kidneys, brain, lung, circulatory system, and coagulation. It occurs in the setting of chronic liver disease almost always with cirrhosis and is a major cause of mortality in persons with cirrhosis. ACLF is precipitated by either direct injury to the liver (most commonly from alcoholic hepatitis and less often from new or flaring viral hepatitis, autoimmune hepatitis, or drug-induced liver injury) or systemic effects (most commonly bacterial or fungal infection and less often GI bleeding or the postoperative state), resulting in a marked systemic inflammatory response followed by organ failure and is analogous to sepsis syndrome. Mortality at 28 days ranges from 20 to 70% and increases with the number of organ failures. Clinicians should search for and treat precipitating causes of ACLF, determine if intensive care unit (ICU) care is needed, and consider immediate referral for liver transplantation. Complications of cirrhosis should be treated as described elsewhere in this chapter. If after 3–7 days of ICU support, there continue to be four or more organ failures and liver transplantation is not an option, consideration for a transition to palliative care is recommended.

LIVER-LUNG SYNDROMES

Hepatopulmonary syndrome (HPS) is characterized by arterial hypoxemia in a patient with cirrhosis without significant lung disease. The liver disease causes intrapulmonary vascular dilations, resulting in blood shunting past alveoli and significant ventilation-perfusion mismatch. Clinical symptoms include dyspnea and platypnea. HPS is common, occurring in 4–32% of patients with cirrhosis; however, it is often mild. Diagnosis involves demonstrating hypoxemia, without evidence of significant lung disease, and shunt on bubble echocardiography. Treatment is with oxygen supplementation and liver transplantation.

Portopulmonary hypertension (PPHT) is pulmonary hypertension in a patient with portal hypertension. The portal hypertension results in the production of vasoconstrictor substances that affect the pulmonary artery. Many patients are asymptomatic, especially early in the disease; however, they later can develop dyspnea on exertion and fatigue. PPHT is rare, occurring in ~5% of patients with advanced cirrhosis. Diagnosis includes initial identification on echocardiogram and confirmation on right heart catheterization showing elevated mean pulmonary artery pressure, elevated pulmonary vascular resistance, and normal pulmonary capillary wedge pressure. Prognosis is poor, although liver transplantation after effective reduction in pulmonary artery pressure with vasodilatory medications can be effective.

MALNUTRITION IN CIRRHOSIS

Because the liver is principally involved in the regulation of protein and energy metabolism in the body, patients with decompensated cirrhosis often develop malnutrition, insufficient intake of nutrients, which manifests clinically as sarcopenia, a loss in muscle mass and function resulting in frailty, decreased physical reserve, and increased susceptibility to health stressors. In the setting of cirrhosis and subsequent hepatic decompensation, patients become more catabolic with increased energy needs but often have decreased caloric intake due to anorexia, early satiety, ascites, restrictive diets (low sodium, potassium, and fluid) and hepatic encephalopathy. Obesity and edema may mask underlying sarcopenia. Lack of physical activity can further exacerbate the sarcopenia and resulting frailty. Sarcopenia and frailty have been associated with increased resource utilization and risk of death and poorer quality of life. Guidelines recommend (1) education for patients and families both with asymptomatic compensated and symptomatic decompensated cirrhosis on appropriate nutritional intake (both calories and protein) and the benefits of regular exercise; (2) periodic clinical assessments for malnutrition, sarcopenia, and frailty with increasing frequency as the patient decompensates; and (3) early referrals to registered dietician and physical therapy to develop a personalized therapeutic plan. Generally, patients with cirrhosis should consume 35 kcal/kg per d based on actual weight with estimated discounting for edema and ascites and 1.2–1.5 g/kg per d of protein based upon ideal body weight. Caloric intake goals should be reduced for patients with body mass index over 35 kg/m^2. Multiple small meals are recommended throughout waking hours to minimize muscle wasting during the fasted state. Relaxation in sodium restriction should be considered in those who are not meeting caloric intake goals. Optimization of care for hepatic encephalopathy and ascites is also beneficial. General exercise recommendations include 150–300 min of aerobic exercise a week and 2 days of muscle-strengthening exercises per week, though these recommendations should be tailored, particularly in decompensated cirrhosis.

ABNORMALITIES IN COAGULATION

Coagulation disorders in cirrhosis are poorly understood, and typical clinical measures of coagulation, such as the prothrombin time and international normalized ratio, are not reliable measures of clotting ability. There is decreased synthesis of both pro- and anticoagulant factors and thus some rebalancing in coagulation; however, the coagulation cascade can easily tip toward thrombosis or bleeding. In addition, patients may have thrombocytopenia from hypersplenism due to portal hypertension and some platelet dysfunction, which is counterbalanced with increased von Willebrand factor. Adequate thrombin formation can occur with platelet levels from cirrhosis patients >50,000–60,000/L. Synthesis of vitamin K–dependent clotting factors II, VII, IX, and X is diminished in patients with chronic cholestatic syndromes because absorption of vitamin K requires good bile flow. Intravenous or intramuscular vitamin K can quickly correct this abnormality. Overall, the status of coagulation in a cirrhotic patient needs to be judged clinically rather than relying on current laboratory tests. Standard prophylaxis for deep venous thrombosis when hospitalized is generally recommended. Routine correction of international normalized ratio before procedures or with variceal bleeding is generally not required.

BONE DISEASE IN CIRRHOSIS

Osteoporosis is common in patients with chronic cholestatic liver disease because of malabsorption of vitamin D and decreased calcium ingestion. The rate of bone resorption exceeds that of new bone formation in patients with cirrhosis, resulting in bone loss. Dual-energy x-ray absorptiometry (DEXA) is a useful method for determining osteoporosis or osteopenia. When a DEXA scan shows osteoporosis, treatment with bisphosphonates is effective.

HEMATOLOGIC ABNORMALITIES IN CIRRHOSIS

Numerous hematologic manifestations of cirrhosis are present, including anemia from a variety of causes including hypersplenism, hemolysis, iron deficiency, and perhaps folate deficiency from malnutrition. Macrocytosis is a common abnormality in red blood cell morphology seen in patients with chronic liver disease, and neutropenia may be a result of hypersplenism.

356 Liver Transplantation

Emily D. Bethea, Raymond T. Chung, Jules L. Dienstag

Liver transplantation—the replacement of the native, diseased liver by a normal organ (allograft)—has matured from an experimental procedure reserved for desperately ill patients to an accepted, lifesaving operation applied more optimally in the natural history of end-stage liver disease. The preferred and technically most advanced approach is *orthotopic transplantation*, in which the native organ is removed and the donor organ is inserted in the same anatomic location. Pioneered in the 1960s by Thomas Starzl at the University of Colorado and, later, at the University of Pittsburgh and by Roy Calne in Cambridge, England, liver transplantation is now performed routinely worldwide. Success measured as 1-year survival has improved from ~30% in the 1970s to >90% today. These improved prospects for prolonged survival resulted from refinements in operative technique, improvements in organ procurement and preservation, advances in immunosuppressive therapy, and, perhaps most influentially, more enlightened patient selection and timing. Despite the perioperative morbidity and mortality, the technical and management challenges of the procedure, and its costs, liver transplantation has become the approach of choice for selected patients whose chronic or acute liver disease is progressive, life-threatening, and unresponsive to medical therapy. Based on the current level of success, the number of liver transplants has continued to grow each year; in 2022, 9528 patients received liver allografts in the United States—8925 deceased donor (94%) and 603 living donor (6%). Still, the demand for new livers continues to outpace availability; as of September 2023, 10,285 patients in the United States were on a waiting list for a donor liver.

INDICATIONS

Potential candidates for liver transplantation are children and adults who, in the absence of contraindications (see below), suffer from severe, irreversible liver disease for which alternative medical or surgical treatments have been exhausted or are unavailable. *Timing of the operation is of critical importance*. Indeed, improved timing and better patient selection are felt to have contributed more to the increased success of liver transplantation in the 1980s and beyond than all the impressive technical and immunologic advances combined. Although the disease should be advanced, and although opportunities for spontaneous or medically induced stabilization or recovery should be allowed, the procedure should be done sufficiently early to give the surgical procedure a fair chance for success. Ideally, transplantation should be considered in patients with end-stage liver disease who are experiencing or have experienced a life-threatening complication of hepatic decompensation or whose quality of life has deteriorated to unacceptable levels. Although patients with well-compensated cirrhosis can survive for many years, many patients with quasi-stable chronic liver disease have much more advanced disease than may be apparent. As discussed below, the better the status of the patient prior to transplantation, the higher will be its anticipated success rate. The decision about *when* to transplant is complex and requires the combined judgment of an experienced team of hepatologists, transplant surgeons, anesthesiologists, and specialists in support services, not to mention the well-informed consent of the patient and the patient's family.

TRANSPLANTATION IN CHILDREN

Indications for transplantation in children are listed in Table 356-1. The most common is *biliary atresia*. *Inherited or genetic disorders of metabolism* associated with liver failure constitute another major indication for transplantation in children and adolescents. In Crigler-Najjar disease type I and in certain hereditary disorders of the urea cycle and of amino acid or lactate-pyruvate metabolism, transplantation may be the only way to prevent impending deterioration of central nervous system function, despite the fact that the native liver is structurally normal. Combined heart and liver transplantation has yielded dramatic improvement in cardiac function and in cholesterol levels in children with homozygous familial hypercholesterolemia; combined liver and

TABLE 356-1 Indications for Liver Transplantation

CHILDREN	ADULTS
Biliary atresia	Primary biliary cholangitis
Neonatal hepatitis	Primary sclerosing cholangitis
Congenital hepatic fibrosis	Caroli's disease[a]
Alagille's syndrome[b]	Secondary biliary cirrhosis
Byler's disease[c]	Autoimmune hepatitis
Inherited disorders of metabolism	Hemochromatosis-associated cirrhosis
Wilson's disease	α_1 Antitrypsin deficiency
Tyrosinemia	Metabolic dysfunction–associated steatohepatitis (MASH)[d]
Glycogen storage diseases	Alcohol-associated cirrhosis
Lysosomal storage diseases	Severe alcohol-associated hepatitis
Protoporphyria	Cryptogenic cirrhosis
Crigler-Najjar disease type I	Chronic viral hepatitis with cirrhosis
Familial hypercholesterolemia	Hepatic venous outflow obstruction (Budd-Chiari syndrome)
Primary hyperoxaluria type I	Acute liver failure (ALF)
Hemophilia	Hepatocellular carcinoma
	Select cases for the following indications:
	Hepatic adenomas
	Familial amyloidosis
	Hepatic epithelioid hemangioendothelioma (HEHE)
	Erythropoietic protoporphyria (EPP)
	Metastatic neuroendocrine tumors
	Polycystic liver disease

[a]Multiple cystic dilatations of the intrahepatic biliary tree. [b]Arteriohepatic dysplasia, with paucity of bile ducts, and congenital malformations, including pulmonary stenosis. [c]Intrahepatic cholestasis, progressive liver failure, and mental and growth retardation. [d]Formerly nonalcoholic steatohepatitis (NASH).

kidney transplantation has been successful in patients with primary hyperoxaluria type I. In hemophiliacs with transfusion-associated hepatitis and liver failure, liver transplantation has been associated with recovery of normal factor VIII synthesis.

TRANSPLANTATION IN ADULTS

Liver transplantation is indicated for end-stage *cirrhosis* of all causes (Table 356-1). In *sclerosing cholangitis* and *Caroli's disease* (multiple cystic dilatations of the intrahepatic biliary tree), recurrent infections and sepsis associated with inflammatory and fibrotic obstruction of the biliary tree may be an indication for transplantation. Because prior biliary surgery complicates and is a relative contraindication for liver transplantation, surgical diversion of the biliary tree has been all but abandoned for patients with sclerosing cholangitis. Currently, the most common indication for liver transplantation is steatotic liver disease (SLD), which encompasses alcohol-associated liver disease (ALD) and metabolic dysfunction–associated steatotic liver disease (MASLD), formerly known as nonalcoholic fatty liver disease (NAFLD). Patients with alcohol-associated cirrhosis can be considered as candidates for transplantation if they meet strict criteria for abstinence and reform; however, these criteria still do not prevent return to alcohol use in up to a quarter of cases. In highly selected cases in a limited but growing number of centers, transplantation for severe *acute* alcohol-associated hepatitis has been performed with success; however, because patients with acute alcohol-associated hepatitis are still actively using alcohol and because continued alcohol use remains a concern, acute alcohol-associated hepatitis is not a routine indication for liver transplantation. Patients with chronic hepatitis C have early allograft and patient survival comparable to those of other subsets of patients after transplantation; however, they have historically experienced a higher frequency of allograft failure beyond 5 years due to universal reinfection and progressive fibrosis in cases of recurrent hepatitis C is insidiously progressive, with allograft cirrhosis and failure occurring at a higher frequency beyond 5 years. Fortunately, with the introduction of highly effective direct-acting antiviral (DAA) agents targeting hepatitis C virus (HCV), allograft outcomes have improved substantially. In patients with chronic hepatitis B, in the absence of measures to prevent recurrent hepatitis B, survival after transplantation is reduced by ~10–20%; however, prophylactic use of hepatitis B immune globulin (HBIg) during and after transplantation increases the success of transplantation to a level comparable to that seen in patients with nonviral causes of liver decompensation. Specific oral antiviral drugs (e.g., entecavir, tenofovir disoproxil fumarate, tenofovir alafenamide) **(Chap. 352)** can be used both for prophylaxis against and for treatment of recurrent hepatitis B, facilitating further the management of patients undergoing liver transplantation for end-stage hepatitis B; most transplantation centers rely on antiviral drugs with or without HBIg to manage patients with hepatitis B. Issues of disease recurrence are discussed in more detail below. In patients who undergo transplantation for *hepatic vein thrombosis* (*Budd-Chiari syndrome*), postoperative anticoagulation is essential, as is the treatment of any myeloproliferative disorder. Patients with acute liver failure are candidates for liver transplantation, provided a donor organ can be located quickly, before life-threatening complications—including cerebral edema—set in. Patients with nonmetastatic primary hepatobiliary tumors—primary hepatocellular carcinoma (HCC), cholangiocarcinoma, hepatoblastoma, angiosarcoma, epithelioid hemangioendothelioma, and multiple or massive hepatic adenomata—have undergone liver transplantation; however, for some hepatobiliary malignancies, overall survival is significantly lower than that for other categories of liver disease. Most transplantation centers have reported 5-year recurrence-free survival rates in patients with unresectable HCC for single tumors <5 cm in diameter or for three or fewer lesions all <3 cm comparable to those seen in patients undergoing transplantation for nonmalignant indications. Consequently, liver transplantation is currently restricted to patients whose hepatic malignancies meet these criteria. Expanded criteria for patients with HCC continue to be evaluated in exploratory clinical trials. Because the likelihood of recurrent cholangiocarcinoma is very high, only highly selected patients with limited disease are being evaluated for transplantation after intensive chemotherapy and radiation.

CONTRAINDICATIONS

Absolute contraindications for transplantation include life-threatening systemic diseases, uncontrolled extrahepatic bacterial or fungal infections, preexisting advanced cardiovascular or pulmonary disease, multiple uncorrectable life-threatening congenital anomalies, metastatic malignancy, and active drug or alcohol use disorders **(Table 356-2)**. Because carefully selected patients in their sixties and even seventies have undergone transplantation successfully, advanced age per se is no longer considered an absolute contraindication; however, in older patients, a more thorough preoperative evaluation should be undertaken to exclude ischemic cardiac disease and other comorbid conditions. Still, advanced age (>70 years) should be considered a *relative contraindication*—that is, a factor to be considered with other relative contraindications. Other relative contraindications include extensive portal vein thrombosis, preexisting renal disease not associated with liver disease (which may prompt consideration of combined liver and kidney transplantation), intrahepatic or biliary sepsis, severe hypoxemia (PO_2 <50 mmHg) resulting from right-to-left intrapulmonary shunts, portopulmonary hypertension with high mean pulmonary artery pressures (>35 mmHg), uncontrolled psychiatric conditions, and lack of sufficient social supports. Any one of these relative contraindications may be insufficient in and of itself to preclude transplantation. For example, the problem of portal vein thrombosis may be overcome in certain cases by constructing a graft from the donor liver portal vein to the recipient's superior mesenteric vein. Now that combination antiretroviral therapy has dramatically improved the survival of persons with HIV infection **(Chap. 208)** and because end-stage liver disease caused by chronic hepatitis C and B has emerged as a serious source of morbidity and mortality in the HIV-infected population, liver transplantation has now been performed successfully in selected HIV-positive persons who have excellent control of HIV infection. Selected patients with CD4+ T-cell counts >100/μL and with pharmacologic suppression of HIV viremia have undergone transplantation for end-stage liver disease. HIV-infected persons who have received liver allografts for end-stage liver disease resulting from chronic hepatitis B have experienced survival rates comparable to those of HIV-negative persons undergoing transplantation for the same indication. In contrast, until recently, recurrent HCV infection in the allograft has limited long-term success in persons with HCV-related end-stage

TABLE 356-2 Contraindications to Liver Transplantation

ABSOLUTE	RELATIVE
Uncontrolled extrahepatobiliary infection	Advanced age[a]
Active, untreated sepsis	Prior extensive hepatobiliary surgery
Life-limiting congenital anomalies	Extensive portal vein thrombosis
Cholangiocarcinoma (except those tumors that fit into protocols)	Renal failure not attributable to liver disease (consider dual organ transplantation)
Advanced cardiopulmonary disease	Extrahepatobiliary malignancy Severe obesity Severe malnutrition/wasting Medical noncompliance
AIDS	HIV seropositivity with failure to control HIV viremia or CD4 <100/μL
Life-threatening systemic diseases	Severe hypoxemia secondary to right-to-left intrapulmonary shunts (PO_2 <50 mmHg) Severe pulmonary hypertension (mean pulmonary artery pressure >35 mmHg)
Active substance use disorder	Uncontrolled psychiatric disorder

[a]For patients 70 years and older, comprehensive assessment to exclude concurrent comorbidities, in particular cardiovascular compromise, is indicated.

liver disease. Again, the availability of DAA agents targeting HCV (see below and Chap. 352) has improved allograft outcomes substantially.

TECHNICAL CONSIDERATIONS

DECEASED-DONOR SELECTION

Deceased-donor livers for transplantation are procured primarily from victims of head trauma, termed donation after brain death (DBD). Cardiovascular and respiratory functions in these donors are maintained artificially until the liver can be removed. Organs from brain-dead donors up to age 60 are acceptable if the following criteria are met: hemodynamic stability, adequate oxygenation, absence of bacterial or fungal infection, absence of abdominal trauma, and absence of hepatic dysfunction. Historically serologic exclusion of infections with hepatitis B virus (HBV), HCV, and HIV was required, but organs from donors infected with HBV, HCV, and HIV are now used in select cases when matched appropriately with the recipient after thorough informed consent and antiviral medication planning. Transplantation of organs procured from deceased donors who have succumbed to cardiac death, termed donation after circulatory death (DCD), can be performed successfully under selected circumstances, when ischemic time is minimized and liver histology preserved. Encouraging improvements in normothermic ex vivo liver perfusion techniques may make broader use of these organs possible. Compatibility in ABO blood group and organ size between donor and recipient are important considerations in donor selection; however, ABO-incompatible, split-liver, or reduced-donor-organ allografts can be performed in emergencies or marked donor scarcity. Tissue typing for human leukocyte antigen (HLA) matching is not required, and preformed cytotoxic HLA antibodies do not preclude liver transplantation. Following perfusion with cold electrolyte solution, the donor liver is removed and packed in ice. The use of University of Wisconsin (UW) solution, rich in lactobionate and raffinose, has permitted the extension of cold ischemic time up to 20 h; however, 12 h may be a more reasonable limit. Improved techniques for harvesting multiple organs from the same donor have increased the availability of donor livers, but the availability of donor livers is far outstripped by the demand. Currently in the United States, all donor livers are distributed through a nationwide organ-sharing network (United Network for Organ Sharing [UNOS]) designed to allocate available organs based on regional considerations and recipient acuity. Recipients who have the highest disease severity generally have the highest priority, but allocation strategies that balance highest urgency against best outcomes continue to evolve to distribute deceased-donor organs most effectively. Allocation based on the Child-Turcotte-Pugh (CTP) score, which uses five clinical variables (encephalopathy stage, ascites, bilirubin, albumin, and prothrombin time) and waiting time, has been replaced by allocation based on urgency alone, calculated using the Model for End-Stage Liver Disease (MELD) score. The MELD score is based on a mathematical model that includes serum bilirubin, albumin, sodium, creatinine, and prothrombin time expressed as international normalized ratio (INR); gender assigned at birth is included in the MELD calculation for females (Table 356-3). The MELD scale is continuous with scores ranging between 6 and 40; higher values correlate with increased illness severity. On the lower end of this scale, the value of proceeding to transplantation is limited, because liver recipients with MELD scores <15 experience higher posttransplantation mortality rates than similarly classified patients who remain on the waiting list. The MELD score has undergone modifications over time, including the development of MELD-Na in 2016 and MELD-3.0 in 2023 to improve model accuracy in predicting short-term survival and prioritizing allocation. Neither waiting time (except as a tie breaker between two potential recipients with the same MELD scores) nor posttransplantation outcome is taken into account, but use of the MELD score has been shown to reduce waiting list mortality, to reduce waiting time prior to transplantation, to be the best predictor of pretransplantation mortality, to satisfy the prevailing view that medical need should be the decisive determinant, and to eliminate both the subjectivity inherent in the CTP scoring system (presence and degree of ascites and hepatic encephalopathy) and the differences in waiting times among different regions of the country.

TABLE 356-3 United Network for Organ Sharing (UNOS) Liver Transplantation Waiting List Criteria

Status 1	Acute liver failure (including primary graft nonfunction and hepatic artery thrombosis)[a]
The Model for End-Stage Liver Disease (MELD) score, on a continuous scale, determines allocation of the remainder of donor organs[b].	
Candidates who are **at least 18 years old** at the time of registration receive an initial MELD score equal to: 1.33 (if female) $+ [4.56 \times \log_e(\text{bilirubin})] + [0.82 \times (137 - \text{sodium})] - [0.24 \times (137 - \text{sodium}) \times \log_e(\text{bilirubin})] + [9.09 \times \log_e(\text{INR})] + [11.14 \times \log_e(\text{creatinine})] + [1.85 \times (3.5 - \text{albumin})] - [1.83 \times (3.5 - \text{albumin}) \times \log_e(\text{creatinine})] + 6$ Candidates who are currently **at least 12 years** old and were less than 18 years old at the time of registration receive a MELD score equal to: $[4.56 \times \log_e(\text{bilirubin})] + [0.82 \times (137 - \text{sodium})] - [0.24 \times 137 - \text{sodium}) \times \log_e(\text{bilirubin})] + [9.09 \times \log_e(\text{INR})] + 11.14 \times \log_e(\text{creatinine})] + [1.85 \times (3.5 - \text{albumin})] - [1.83 \times (3.5 - \text{albumin})] - [1.83 \times (3.5 - \text{albumin}) \times \log_e(\text{creatinine})] + 7.33$ The **PELD calculator is for candidates under the age of 12.**	
Online calculators to determine MELD scores are available, such as the following: *https://optn.transplant.hrsa.gov/resources/allocation-calculators/meld-calculator/*	

[a]For children <18 years of age, status 1 includes acute or chronic liver failure plus hospitalization in an intensive care unit or inborn errors of metabolism. Status 1 is retained for those persons with acute liver failure and supersedes the MELD score. MELD scale is continuous, with 34 levels ranging between 6 and 40 (scores above 40 are categorized as 40). [b]In certain cases, the natural MELD score may not represent the severity of illness or need for transplantation; in such cases, an exception MELD score may be granted if select criteria are met upon review by the National Liver Review Board (NLRB): *https://optn.transplant.hrsa.gov/professionals/by-topic/guidance/liver-review-board-guidance/*.

The highest priority (status 1) continues to be reserved for patients with acute liver failure (ALF) or complications following transplantation such as primary graft nonfunction and hepatic artery thrombosis. Because candidates for liver transplantation who have HCC may not be sufficiently decompensated to compete for donor organs based on urgency criteria alone, and because protracted waiting for deceased-donor organs often results in tumor growth beyond acceptable limits for transplantation, such patients are assigned disease-specific MELD exception points. In addition to HCC, other disease-specific MELD exceptions are evaluated on a regular basis and updated by the National Liver Review Board (NLRB) (Table 356-3).

LIVING-DONOR TRANSPLANTATION

Occasionally, especially for liver transplantation in children, one deceased-donor organ can be split between two recipients (one adult and one child). A more viable alternative, transplantation of the right lobe of the liver from a healthy adult donor into an adult recipient, has gained increased popularity. Living-donor transplantation of the left lobe (left lateral segment), introduced in the early 1990s to alleviate the extreme shortage of donor organs for small children, accounts currently for approximately one-third of all liver transplantation procedures in children. Driven by the shortage of deceased-donor organs, living-donor transplantation involving the more sizable right lobe is being considered with increasing frequency in adults; however, living-donor liver transplantation cannot be expected to solve the donor organ shortage; 603 such procedures were done in 2023, representing only ~6% of all liver transplant operations done in the United States.

Living-donor transplantation can reduce waiting time and cold ischemia time; is done under elective, rather than emergency, circumstances; and is lifesaving in recipients who cannot afford to wait for a deceased donor. The downside, of course, is the risk to the healthy donor (a mean of 10 weeks of medical disability; biliary complications in ~5%; postoperative complications such as wound infection, small-bowel obstruction, and incisional hernias in 9–19%; and death in 0.2–0.4%) as well as the increased frequency of biliary (15–32%) and vascular (10%) complications in the recipient. Potential donors must participate voluntarily without coercion, and transplantation teams should go to great lengths to exclude subtle coercive or inappropriate psychological factors as well as outline carefully to both donor and

recipient the potential benefits and risks of the procedure. Donors for the procedure should be 18–65 years old; have a compatible blood type with the recipient; have no serious chronic medical problems or history of major abdominal surgery; and pass an exhaustive series of clinical, biochemical, and serologic evaluations to unearth disqualifying medical disorders. The recipient should meet the same UNOS criteria for liver transplantation as recipients of a deceased donor allograft.

SURGICAL TECHNIQUE

Removal of the recipient's native liver is technically difficult, particularly in the presence of portal hypertension with its associated collateral circulation and extensive varices and especially in the presence of scarring from previous abdominal operations. The combination of portal hypertension and coagulopathy (elevated prothrombin time and thrombocytopenia) may translate into large blood-product transfusion requirements. After the portal vein and infrahepatic and suprahepatic inferior vena cava are dissected, the hepatic artery and common bile duct are dissected. Then the native liver is removed and the donor organ inserted. During the anhepatic phase, coagulopathy, hypoglycemia, hypocalcemia, and hypothermia are encountered and must be managed by the anesthesiology team. Caval, portal vein, hepatic artery, and bile duct anastomoses are performed in succession, the last by end-to-end suturing of the donor and recipient common bile ducts **(Fig. 356-1)** or by choledochojejunostomy to a Roux-en-Y loop if the recipient common bile duct cannot be used for reconstruction (e.g., in sclerosing cholangitis). A typical transplant operation lasts 8 h, with a range of 6–18 h. Because of excessive bleeding, large volumes of blood, blood products, and volume expanders may be required during surgery; however, blood requirements have fallen sharply with improvements in surgical technique, blood-salvage interventions, and experience.

As noted above, emerging alternatives to orthotopic liver transplantation include split-liver grafts, in which one donor organ is divided and inserted into two recipients, and living-donor procedures, in which part of the left (for children), the left (for children or small adults), or the right (for adults) lobe of the liver is harvested from a living donor for transplantation into the recipient. In the adult procedure, once the right lobe is removed from the donor, the donor right hepatic vein is anastomosed to the recipient right hepatic vein remnant, followed by donor-to-recipient anastomoses of the portal vein and then the hepatic artery. Finally, the biliary anastomosis is performed, duct-to-duct if practical or via Roux-en-Y anastomosis. Heterotopic liver transplantation, in which the donor liver is inserted without removal of the native liver, has met with very limited success and acceptance, except in a very small number of centers. Areas of research with the potential to overcome the shortage of donor organs include hepatocyte transplantation and xenotransplantation with genetically modified organs of nonhuman origin (e.g., swine).

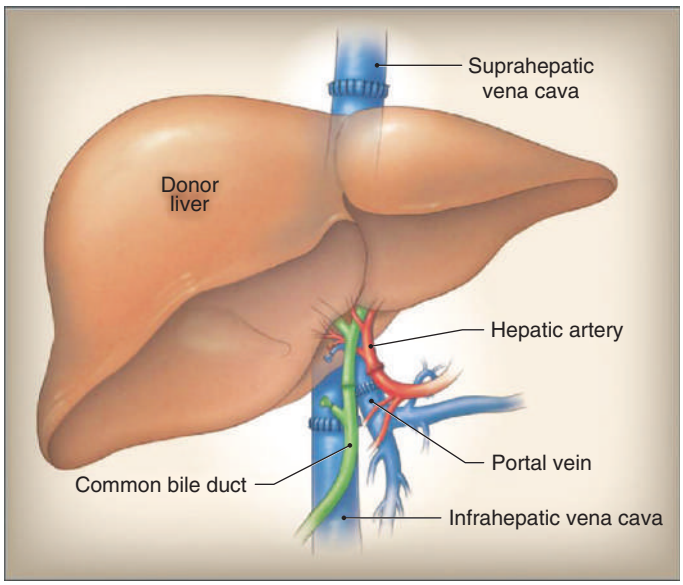

FIGURE 356-1 The anastomoses in orthotopic liver transplantation. The anastomoses are performed in the following sequence: (1) suprahepatic and infrahepatic vena cava, (2) portal vein, (3) hepatic artery, and (4) common bile duct-to-duct anastomosis. *(Reproduced with permission from S Vilarinho, RP Lifton: Liver transplantation: From inception to clinical practice. 150:1096, 2012.)*

POSTOPERATIVE COURSE AND MANAGEMENT

IMMUNOSUPPRESSIVE THERAPY

The introduction in 1980 of cyclosporine as an immunosuppressive agent contributed substantially to the improvement in survival after liver transplantation. Cyclosporine, a calcineurin inhibitor, blocks early activation of T cells and is specific for T-cell functions that result from the interaction of the T cell with its receptor and that involve the calcium-dependent signal transduction pathway. As a result, the activity of cyclosporine leads to inhibition of lymphokine gene activation, blocking interleukins 2, 3, and 4, tumor necrosis factor α, and other lymphokines. Cyclosporine also inhibits B-cell functions. This process occurs without affecting rapidly dividing cells in the bone marrow, which may account for the reduced frequency of posttransplantation systemic infections. The most common and important side effect of cyclosporine therapy is nephrotoxicity. Cyclosporine causes dose-dependent renal tubular injury and direct renal artery vasospasm. Following renal function is therefore important in monitoring cyclosporine therapy and is perhaps even a more reliable indicator than blood levels of the drug. Nephrotoxicity is reversible and can be managed by dose reduction. Other adverse effects of cyclosporine therapy include hypertension, hyperkalemia, tremor, hirsutism, glucose intolerance, and gingival hyperplasia.

Tacrolimus, a macrolide lactone antibiotic isolated from a Japanese soil fungus, *Streptomyces tsukubaensis*, has the same mechanism of action as cyclosporine but is 10–100 times more potent. Initially applied as "rescue" therapy for patients in whom rejection occurred despite the use of cyclosporine, tacrolimus was shown to be associated with a reduced frequency of acute, refractory, and chronic rejection. Although patient and graft survival are the same with these two drugs, the advantage of tacrolimus in minimizing episodes of rejection, reducing the need for additional glucocorticoid doses, and lowering the likelihood of bacterial and cytomegalovirus (CMV) infection has simplified the management of patients undergoing liver transplantation. In addition, the oral absorption of tacrolimus is more predictable than that of cyclosporine. As a result, tacrolimus has now supplanted cyclosporine for primary immunosuppression, and most centers rely on oral rather than IV administration from the outset.

Although more potent than cyclosporine, tacrolimus is also more toxic and more likely to be discontinued for adverse events. The toxicity of tacrolimus is similar to that of cyclosporine; nephrotoxicity and neurotoxicity are the most commonly encountered adverse effects, and neurotoxicity (tremor, seizures, hallucinations, psychoses, coma) is more likely and more severe in tacrolimus-treated patients. Both drugs can cause diabetes mellitus, but tacrolimus does not cause hirsutism or gingival hyperplasia. Because of overlapping toxicity between cyclosporine and tacrolimus, especially nephrotoxicity, and because tacrolimus reduces cyclosporine clearance, these two drugs should not be used together. Because 99% of tacrolimus is metabolized by the liver, hepatic dysfunction reduces its clearance; in primary graft nonfunction (when, for technical reasons or because of ischemic damage prior to its insertion, the allograft is defective and does not function normally from the outset), tacrolimus doses have to be reduced substantially, especially in children. Both cyclosporine and tacrolimus are metabolized by the cytochrome P450 IIIA system, and therefore, drugs that induce cytochrome P450 (e.g., phenytoin, phenobarbital, carbamazepine, rifampin) reduce available levels of cyclosporine and tacrolimus, and drugs that inhibit cytochrome P450 (e.g., erythromycin, fluconazole, ketoconazole, clotrimazole, itraconazole, verapamil, diltiazem, danazol, metoclopramide, the HIV protease inhibitor ritonavir, and the HCV protease inhibitors glecaprevir [cyclosporine only] and

grazoprevir) increase cyclosporine and tacrolimus blood levels. Indeed, itraconazole is used occasionally to help boost tacrolimus levels. Like azathioprine, cyclosporine and tacrolimus appear to be associated with a risk of lymphoproliferative malignancies (see below), which may occur earlier after cyclosporine or tacrolimus than after azathioprine therapy. Because of these side effects, combinations of cyclosporine or tacrolimus with prednisone and an antimetabolite (azathioprine or mycophenolic acid, see below)—all at reduced doses—are preferable regimens for immunosuppressive therapy.

Mycophenolic acid, a nonnucleoside purine metabolism inhibitor derived as a fermentation product from several *Penicillium* species, is another immunosuppressive drug being used for patients undergoing liver transplantation. Mycophenolate has been shown to be better than azathioprine, when used with other standard immunosuppressive drugs, in preventing rejection after renal transplantation and has been adopted widely as well for use in liver transplantation. The most common adverse effects of mycophenolate are bone marrow suppression and gastrointestinal complaints.

In patients with pretransplantation renal dysfunction or renal deterioration that occurs intraoperatively or immediately postoperatively, tacrolimus or cyclosporine therapy may not be practical; under these circumstances, induction or maintenance of immunosuppression with antithymocyte globulin (ATG; thymoglobulin) or monoclonal antibodies to T cells (basiliximab, daclizumab) may be appropriate. Therapy with some of these agents (ATG) has also been effective in reversing acute rejection in the posttransplantation period and is the standard treatment for acute rejection that fails to respond to methylprednisolone boluses. Available data support the use of thymoglobulin induction to delay calcineurin inhibitor use and its attendant nephrotoxicity. IV infusions of thymoglobulin may be complicated by fever and chills, which can be ameliorated by premedication with antipyretics and a low dose of glucocorticoids.

Sirolimus, an inhibitor of the mammalian target of rapamycin (mTOR), blocks later events in T-cell activation and is another agent approved for use in solid-organ transplantation. Sirolimus, however, is not used early in the posttransplantation course, because it impairs wound healing and is associated with an increased frequency of hepatic artery thrombosis in the first 30 days after transplantation. In patients with calcineurin inhibitor–related nephrotoxicity, conversion to sirolimus has been demonstrated to be effective in preventing rejection with accompanying improvements in renal function. Because of its profound antiproliferative effects, sirolimus has also been suggested to be a useful immunosuppressive agent in patients with a prior or current history of malignancy, such as HCC. Side effects include hyperlipidemia, peripheral edema, oral ulcers, and interstitial pneumonitis. Everolimus is a hydroxyethyl derivative of sirolimus that, when used in conjunction with low-dose tacrolimus, also provides successful protection against acute rejection, with decreased renal impairment compared to that associated with standard tacrolimus dosing. Everolimus and sirolimus share a similar adverse event profile. The most important principle of immunosuppression is that the ideal approach strikes a balance between immunosuppression and immunologic competence. In general, given sufficient immunosuppression, acute liver allograft rejection is nearly always reversible. On one hand, incompletely treated acute rejection predisposes to the development of chronic rejection, which can threaten graft survival. On the other hand, if the cumulative dose of immunosuppressive therapy is too large, the patient may succumb to opportunistic infection. Data show a benefit to minimizing the use of glucocorticoids, a mainstay of immunosuppressive regimens, as cases allow. In select conditions, such as hepatitis C, early steroid withdrawal and initiation of DAAs can avert recurrent allograft hepatitis successfully. Patients who undergo liver transplantation for autoimmune diseases such as autoimmune hepatitis are less likely to achieve freedom from glucocorticoids, although, in many cases, immunosuppression can be narrowed to a dual-agent regimen of a calcineurin inhibitor and an antimetabolite.

POSTOPERATIVE COMPLICATIONS

Complications of liver transplantation can be divided into nonhepatic and hepatic categories (Tables 356-4 and 356-5). In addition, both immediate postoperative and late complications are encountered. As a rule, patients who undergo liver transplantation have been chronically ill for protracted periods and may be malnourished and wasted. The impact of such chronic illness and the multisystem failure that

TABLE 356-4 Nonhepatic Complications of Liver Transplantation

CATEGORY	COMPLICATION
Cardiovascular instability	Arrhythmias
	Congestive heart failure
	Cardiomyopathy
Pulmonary compromise	Pneumonia
	Pulmonary capillary vascular permeability
	Fluid overload
Renal dysfunction	Prerenal azotemia
	Hypoperfusion injury (acute tubular necrosis)
	Drug nephrotoxicity
	↓ Renal blood flow secondary to ↑ intraabdominal pressure
Hematologic	Anemia secondary to gastrointestinal and/or intraabdominal bleeding
	Hemolytic anemia, aplastic anemia
	Thrombocytopenia
Infection	Bacterial: early, common postoperative infections
	Fungal/parasitic: late, opportunistic infections
	Viral: late, opportunistic infections, recurrent hepatitis
Neuropsychiatric	Seizures
	Metabolic encephalopathy
	Depression
	Difficult psychosocial adjustment
Diseases of donor	Infectious
	Malignant
Malignancy	B-cell lymphoma (posttransplantation lymphoproliferative disorders)
	De novo neoplasms (particularly squamous cell skin carcinoma)

TABLE 356-5 Hepatic Complications of Liver Transplantation

Hepatic Dysfunction Common after Major Surgery	
Prehepatic	Pigment load
	Hemolysis
	Blood collections (hematomas, abdominal collections)
Intrahepatic	
Early	Hepatotoxic drugs and anesthesia
	Hypoperfusion (hypotension, shock, sepsis)
	Benign postoperative cholestasis
Late	Transfusion-associated hepatitis
	Exacerbation of primary hepatic disease
Posthepatic	Biliary obstruction
	↓ Renal clearance of conjugated bilirubin (renal dysfunction)
Hepatic Dysfunction Unique to Liver Transplantation	
Primary graft nonfunction	
Vascular compromise	Portal vein obstruction
	Hepatic artery thrombosis
	Anastomotic leak with intraabdominal bleeding
Bile duct disorder	Stenosis, obstruction, leak
Rejection	
Recurrent primary hepatic disease	

accompanies liver failure continue to require attention in the postoperative period. Because of the massive fluid losses and fluid shifts that occur during the operation, patients may remain fluid overloaded during the immediate postoperative period, straining cardiovascular reserve; this effect can be amplified in the face of transient renal dysfunction and pulmonary capillary vascular permeability. Continuous monitoring of cardiovascular and pulmonary function, measures to maintain the integrity of the intravascular compartment and to treat extravascular volume overload, and scrupulous attention to potential sources and sites of infection are of paramount importance. Cardiovascular instability may also result from the electrolyte imbalance that may accompany reperfusion of the donor liver as well as from restoration of systemic vascular resistance following implantation. Pulmonary function may be compromised further by paralysis of the right hemidiaphragm associated with phrenic nerve injury. The hyperdynamic state with increased cardiac output that is characteristic of patients with liver failure reverses rapidly after successful liver transplantation.

Other immediate management issues include renal dysfunction. Prerenal azotemia, acute kidney injury associated with hypoperfusion (acute tubular necrosis), and renal toxicity caused by antibiotics, tacrolimus, or cyclosporine are encountered frequently in the postoperative period, sometimes necessitating dialysis. Hemolytic-uremic syndrome can be associated with cyclosporine and tacrolimus. Occasionally, postoperative intraperitoneal bleeding may be sufficient to increase intraabdominal pressure, which, in turn, may reduce renal blood flow; this effect is rapidly reversible when abdominal distention is relieved by exploratory laparotomy to identify and ligate the bleeding site and to remove intraperitoneal clot.

Anemia may also result from acute upper gastrointestinal bleeding or from transient hemolytic anemia, which may be autoimmune, especially when blood group O livers are transplanted into blood group A or B recipients. This autoimmune hemolytic anemia is mediated by donor intrahepatic lymphocytes that recognize red blood cell A or B antigens on recipient erythrocytes. Transient in nature, this process resolves once the donor liver is repopulated by recipient bone marrow–derived lymphocytes; the hemolysis can be treated by transfusing blood group O red blood cells and/or by administering higher doses of glucocorticoids. Transient thrombocytopenia is also encountered commonly. Aplastic anemia, a late occurrence, is rare but has been reported in almost 30% of patients who underwent liver transplantation for acute, severe hepatitis of unknown cause.

Bacterial, fungal, or viral infections are common and may be life-threatening postoperatively. Early after transplant surgery, common postoperative infections predominate—pneumonia, wound infections, infected intraabdominal collections, urinary tract infections, and IV line infections—rather than opportunistic infections; these infections may involve the biliary tree and liver as well. Beyond the first postoperative month, the toll of immunosuppression becomes evident, and opportunistic infections—CMV, herpes viruses, fungal infections (*Aspergillus*, *Candida*, cryptococcal disease), mycobacterial infections, parasitic infections (*Pneumocystis*, *Toxoplasma*), and bacterial infections (*Nocardia*, *Legionella*, *Listeria*)—predominate. Rarely, early infections represent those transmitted with the donor liver, either infections present in the donor or infections acquired during procurement processing. De novo viral hepatitis infections acquired from the donor organ or, almost unheard of now, from transfused blood products occur after typical incubation periods for these agents (well beyond the first month). Obviously, infections in an immunosuppressed host demand early recognition and prompt management; prophylactic antibiotic therapy is administered routinely in the immediate postoperative period. Use of sulfamethoxazole with trimethoprim reduces the incidence of postoperative *Pneumocystis jirovecii* pneumonia. Antiviral prophylaxis for CMV with ganciclovir should be administered in patients at high risk (e.g., when a CMV-seropositive donor organ is implanted into a CMV-seronegative recipient).

Neuropsychiatric complications include seizures (commonly associated with cyclosporine and tacrolimus toxicity), metabolic encephalopathy, depression, and difficult psychosocial adjustment. Rarely, diseases are transmitted by the allograft from the donor to the recipient. In addition to viral and bacterial infections, malignancies of donor origin have occurred. Posttransplantation lymphoproliferative disorders, especially B-cell lymphoma, are a recognized complication associated with immunosuppressive drugs such as azathioprine, tacrolimus, and cyclosporine (see above). Epstein-Barr virus has been shown to play a contributory role in some of these tumors, which may regress when immunosuppressive therapy is reduced. De novo neoplasms appear at increased frequency after liver transplantation, particularly squamous cell carcinomas of the skin. Routine screening should be performed.

Long-term complications after liver transplantation attributable primarily to immunosuppressive medications include diabetes mellitus and osteoporosis (associated with glucocorticoids and calcineurin inhibitors) as well as hypertension, hyperlipidemia, and chronic renal insufficiency (associated with cyclosporine and tacrolimus). Monitoring and treating these disorders are routine components of posttransplantation care; in some cases, they respond to changes in immunosuppressive regimen, while in others, specific treatment of the disorder is introduced. Data from a large U.S. database showed that the prevalence of renal failure was 18% at year 5 and 25% at year 10 after liver transplantation. Similarly, the high frequency of diabetes, hypertension, hyperlipidemia, obesity, and the metabolic syndrome renders patients susceptible to cardiovascular disease after liver transplantation; although hepatic complications account for most of the mortality after liver transplantation, renal failure and cardiovascular disease are the other leading causes of late mortality after liver transplantation.

HEPATIC COMPLICATIONS

Hepatic dysfunction after liver transplantation is similar to the hepatic complications encountered after major abdominal and cardiothoracic surgery; however, in addition, hepatic complications include primary graft failure, vascular compromise, failure or stricture of the biliary anastomoses, and rejection. As in nontransplantation surgery, postoperative jaundice may result from prehepatic, intrahepatic, and posthepatic sources. *Prehepatic* sources represent the massive hemoglobin pigment load from transfusions, hemolysis, hematomas, ecchymoses, and other collections of blood. *Early intrahepatic* liver injury includes effects of hepatotoxic drugs and anesthesia; hypoperfusion injury associated with hypotension, sepsis, and shock; and benign postoperative cholestasis. *Late intrahepatic* sources of liver injury include exacerbation of primary disease. *Posthepatic* sources of hepatic dysfunction include biliary obstruction and reduced renal clearance of conjugated bilirubin. Hepatic complications unique to liver transplantation include primary graft failure associated with ischemic injury to the organ during harvesting; vascular compromise associated with thrombosis or stenosis of the portal vein or hepatic artery anastomoses; vascular anastomotic leak; stenosis, obstruction, or leakage of the anastomosed common bile duct; recurrence of primary hepatic disorder (see below); and rejection.

ALLOGRAFT REJECTION

Despite the use of immunosuppressive drugs, rejection of the transplanted liver still occurs in a proportion of patients, beginning 1–2 weeks after surgery. Clinical signs suggesting rejection may include fever, right upper quadrant pain, and reduced bile pigment and volume. Leukocytosis may occur, but the most reliable indicators are increases in serum bilirubin and aminotransferase levels. Because these tests lack specificity, and because patients can be asymptomatic, distinguishing among rejection, biliary obstruction, primary graft nonfunction, vascular compromise, viral hepatitis, CMV infection, drug hepatotoxicity, and recurrent primary disease may prove difficult. Radiographic visualization of the biliary tree and/or percutaneous liver biopsy often help to establish the correct diagnosis. Morphologic features of acute rejection include a mixed portal cellular infiltrate, bile duct injury, and/or endothelial inflammation ("endothelialitis"); some of these findings are reminiscent of graft-versus-host disease, primary biliary cholangitis, or recurrent allograft hepatitis C. As soon as allograft rejection is suspected, treatment consists of increased immunosuppression, most commonly IV methylprednisolone in repeated boluses; if this fails to abort rejection, consideration is given to thymoglobulin. Caution

should be exercised when managing acute rejection with pulse glucocorticoids in patients with HCV infection, because of the high risk of triggering recurrent allograft hepatitis C; however, the availability of DAAs for HCV can obviate this concern effectively.

Chronic rejection is a relatively rare outcome that can follow repeated bouts of acute rejection or that occurs unrelated to preceding rejection episodes. Morphologically, chronic rejection is characterized by progressive cholestasis, focal parenchymal necrosis, mononuclear infiltration, vascular lesions (intimal fibrosis, subintimal foam cells, fibrinoid necrosis), and fibrosis. This process may be reflected as ductopenia—the vanishing bile duct syndrome, which is more common in patients undergoing liver transplantation for autoimmune liver disease. Reversibility of chronic rejection is limited; in patients with therapy-resistant chronic rejection, retransplantation has yielded encouraging results.

OUTCOME

SURVIVAL

The survival rate for patients undergoing liver transplantation has improved steadily since 1983. One-year survival rates have increased from ~70% in the early 1980s to 85–90% from 2003 to the present time. Currently, the 5-year survival rate exceeds 60%. An important observation is the relationship between clinical status before transplantation and outcome. For patients who undergo liver transplantation when their level of compensation is high (e.g., still working or only partially disabled), a 1-year survival rate of >85% is common. For those whose level of decompensation mandates continuous in-hospital care prior to transplantation, the 1-year survival rate is ~70%, whereas for those who are so decompensated that they require life support in an intensive care unit, the 1-year survival rate is ~50%. Since the adoption by UNOS in 2002 of the MELD system for organ allocation, posttransplantation survival has been found to be affected adversely for candidates with MELD scores >25, considered high disease severity. Thus, irrespective of allocation scheme, high disease severity before transplantation corresponds to diminished posttransplantation survival. Another important distinction in survival has been drawn between high- and low-risk patient categories. For patients who do not fit any "high-risk" designations, 1- and 5-year survival rates of 85% and 80%, respectively, have been recorded. In contrast, among patients in high-risk categories—cancer, fulminant hepatitis, age >65, concurrent renal failure, respirator dependence, portal vein thrombosis, and history of a portacaval shunt or multiple right upper quadrant operations—survival statistics fall into the range of 60% at 1 year and 35% at 5 years. Survival after retransplantation for primary graft nonfunction is ~50%. Causes of failure of liver transplantation vary with time. Failures within the first 3 months result primarily from technical complications, postoperative infections, and hemorrhage. Transplant failures after the first 3 months are more likely to result from infection, rejection, or recurrent disease (such as malignancy, viral hepatitis, or return to alcohol use).

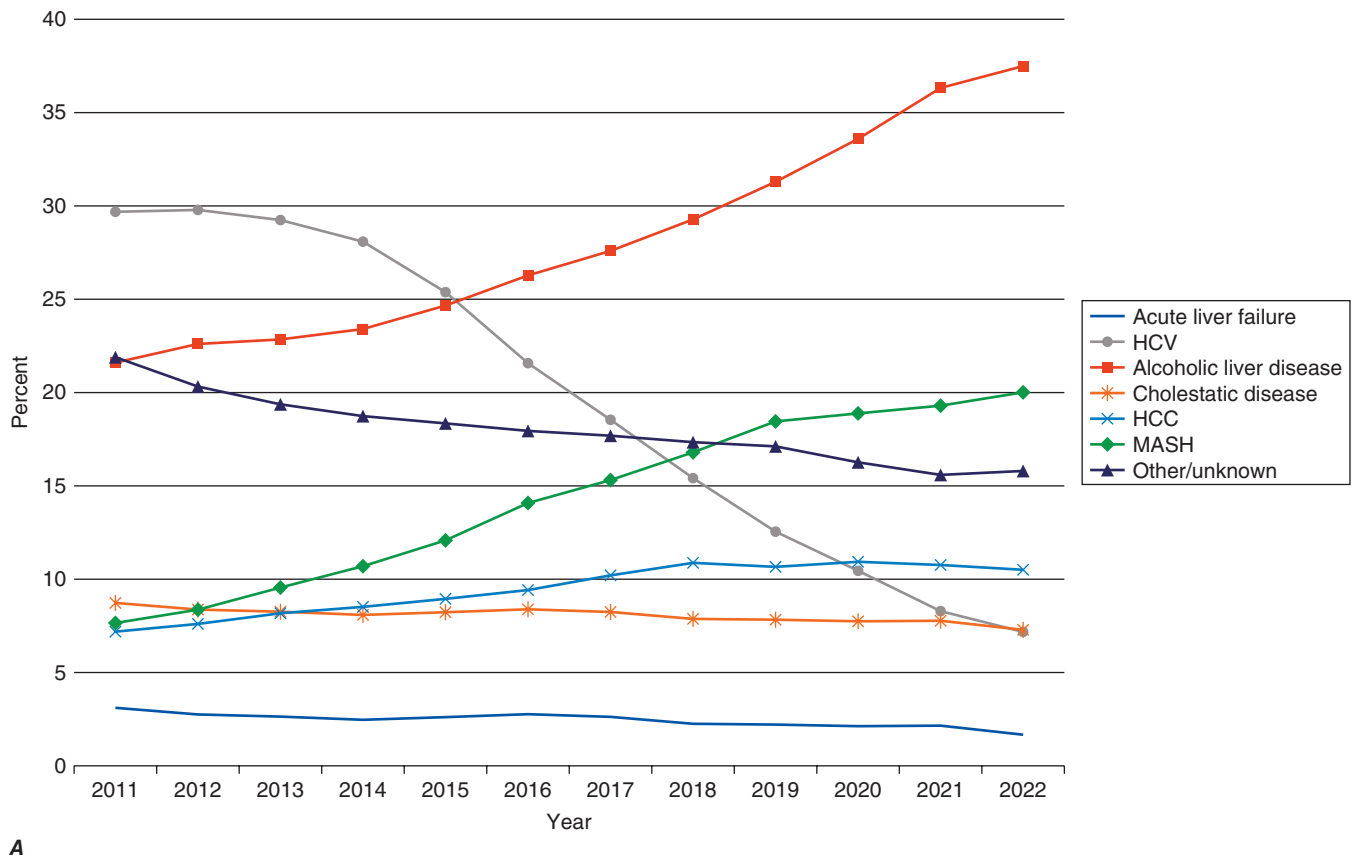
RECURRENCE OF PRIMARY DISEASE

Features of autoimmune hepatitis, primary sclerosing cholangitis, and primary biliary cholangitis overlap with those of rejection or posttransplantation bile duct injury. Autoimmune hepatitis and sclerosing cholangitis can recur after liver transplantation. Similarly, reports of recurrent primary biliary cholangitis after liver transplantation have appeared; however, the histologic features of primary biliary cholangitis and chronic rejection are virtually indistinguishable and occur as frequently in patients with primary biliary cholangitis as in patients undergoing transplantation for other reasons. The presence of a florid inflammatory bile duct lesion is highly suggestive of the recurrence of primary biliary cholangitis, but even this lesion can be observed in acute rejection. Hereditary disorders such as Wilson's disease and α_1 antitrypsin deficiency have not recurred after liver transplantation; however, recurrence of disordered iron metabolism has been observed in some patients with hemochromatosis. Hepatic vein thrombosis (Budd-Chiari syndrome) may recur; this can be minimized by treating underlying myeloproliferative disorders and by anticoagulation. Because cholangiocarcinoma recurs almost invariably, few centers now offer transplantation to such patients; however, a few highly selected patients with operatively confirmed stage I or II cholangiocarcinoma who undergo liver transplantation combined with neoadjuvant chemoradiation may experience excellent outcomes. In patients with intrahepatic HCC who meet criteria for transplantation, 1- and 5-year survivals are similar to those observed in patients undergoing liver transplantation for nonmalignant disease. Finally, metabolic disorders such as MASLD are seen de novo and recur frequently, especially if the underlying metabolic predisposition is not altered.

Hepatitis A can recur after transplantation for fulminant hepatitis A, but such acute reinfection has no serious clinical sequelae. In fulminant hepatitis B, recurrence is not the rule; however, in the absence of any prophylactic measures, hepatitis B usually recurs after transplantation for end-stage chronic hepatitis B. Before the introduction of prophylactic antiviral therapy, immunosuppressive therapy sufficient to prevent allograft rejection led inevitably to marked increases in hepatitis B viremia, regardless of pretransplantation levels. Overall graft and patient survival were poor, and some patients experienced a rapid recapitulation of severe injury—severe chronic hepatitis or even fulminant hepatitis—after transplantation. Also recognized in the era before availability of antiviral regimens was *fibrosing cholestatic hepatitis*, rapidly progressive liver injury associated with marked hyperbilirubinemia, substantial prolongation of the prothrombin time (both out of proportion to relatively modest elevations of aminotransferase activity), and rapidly progressive liver failure. This lesion has been suggested to represent a "choking off" of the hepatocyte by an overwhelming density of HBV proteins. Complications such as sepsis and pancreatitis were also observed more frequently in patients undergoing liver transplantation for hepatitis B prior to the introduction of antiviral therapy. The introduction of long-term prophylaxis with HBIg revolutionized liver transplantation for chronic hepatitis B. Preoperative hepatitis B vaccination, preoperative or postoperative interferon (IFN) therapy, or short-term (≤2 months) HBIg prophylaxis has not been shown to be effective, but a retrospective analysis of data from several hundred European patients followed for 3 years after transplantation has shown that long-term (≥6 months) prophylaxis with HBIg is associated with a lowering of the risk of HBV reinfection from ~75 to 35% and a reduction in mortality from ~50 to 20%.

As a result of long-term HBIg use following liver transplantation for chronic hepatitis B, similar improvements in outcome have been observed in the United States, with 1-year survival rates between 75 and 90%. Currently, with HBIg prophylaxis, the outcome of liver transplantation for chronic hepatitis B is indistinguishable from that for chronic liver disease unassociated with chronic hepatitis B; essentially, medical concerns regarding liver transplantation for chronic hepatitis B have been eliminated. Passive immunoprophylaxis with HBIg is begun during the anhepatic stage of surgery, repeated daily in the postoperative days for high-risk patients (active viremia at the time of transplantation and/or co-infection with hepatitis D or HIV), and then continued with infusions that are given either at regular intervals of 4–6 weeks or, alternatively, when antibody to hepatitis B surface (anti-HBs) levels fall below a threshold of 100 mIU/mL. The current approach in most centers is to continue HBIg indefinitely in select high-risk cases, which can add ~$20,000 per year to the cost of care, and to transition to maintenance with antiviral alone in low-risk-hepatitis B liver allograft recipients. Still, "breakthrough" HBV infection occurs occasionally.

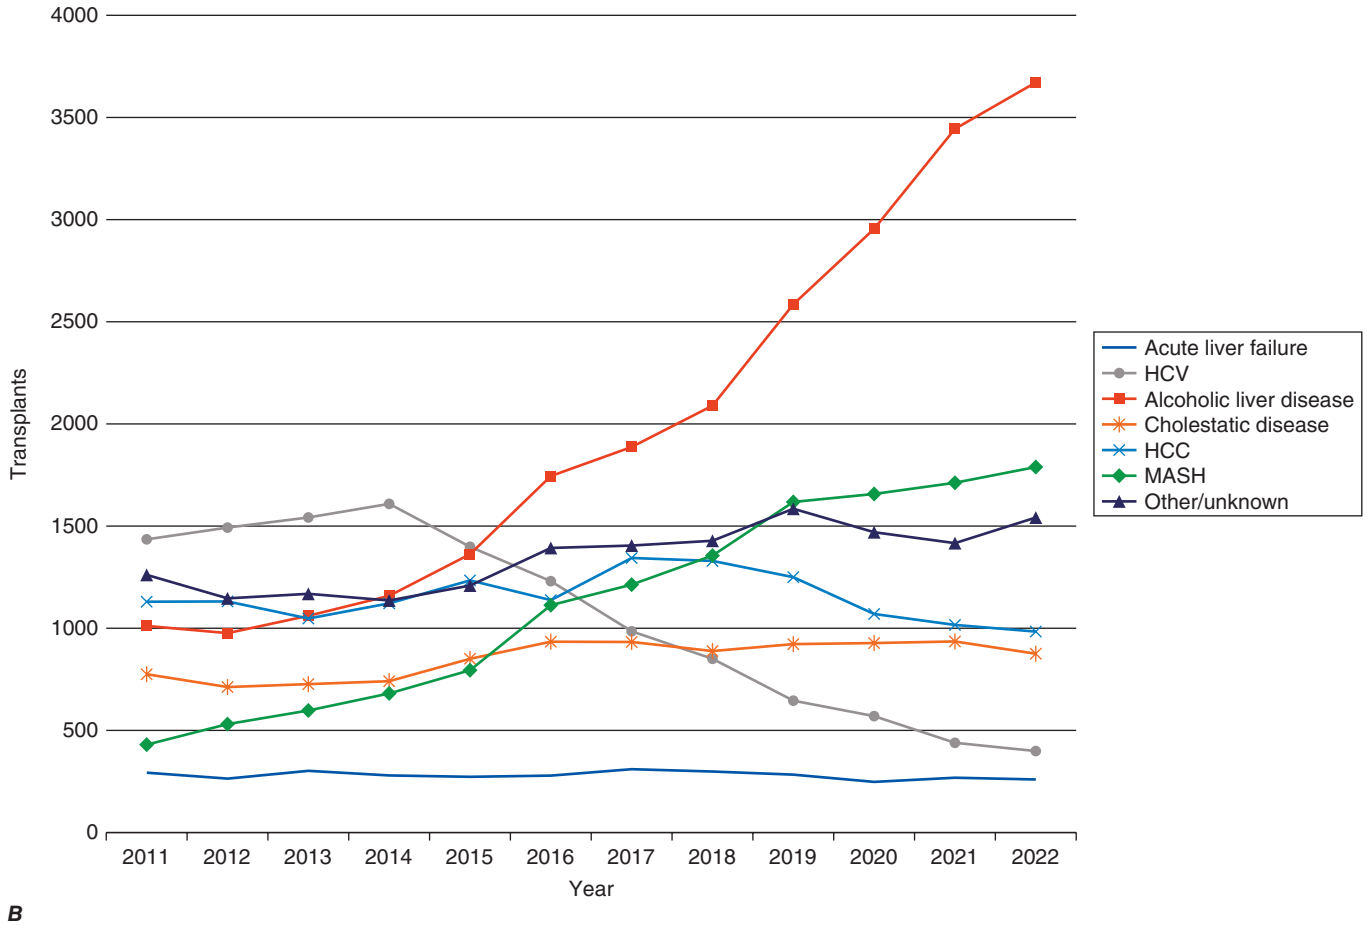
Further improving the outcome of liver transplantation for chronic hepatitis B is the current availability of such antiviral drugs as entecavir, tenofovir disoproxil fumarate, and tenofovir alafenamide (Chap. 352). When these drugs are administered to patients with decompensated liver disease, a proportion improves sufficiently to postpone imminent liver transplantation. In addition, antiviral therapy can be used to prevent recurrence of HBV infection when administered *prior to* transplantation; to treat hepatitis B that recurs *after* transplantation, including in patients who break through HBIg prophylaxis; and to reverse the course of otherwise fatal fibrosing cholestatic hepatitis. Clinical trials have shown that entecavir or tenofovir antiviral therapy reduces the level of HBV replication substantially, sometimes even resulting in clearance of hepatitis B surface antigen (HBsAg); reduces alanine aminotransferase (ALT) levels; and improves histologic features of necrosis



and inflammation. Currently, most liver transplantation centers combine HBIg plus one of the high-barrier-to-resistance oral nucleoside (entecavir) or nucleotide analogues (tenofovir). In low-risk patients with no detectable hepatitis B viremia at the time of transplantation, results from a number of clinical trials have suggested that antiviral prophylaxis can suffice, without HBIg or with a finite duration of HBIg, to prevent recurrent HBV infection of the allograft. In patients documented at the time of liver transplantation to have undetectable HBV DNA in serum and covalently closed circular DNA in the liver (i.e., with low risk for recurrence of HBV infection), results of a clinical trial suggested that, after receipt of 5 years of combined therapy, both HBIg and oral-agent therapy can be withdrawn sequentially (over two 6-month periods) with a success rate, as monitored over a median of 6 years after withdrawal, of 90% and an anti-HBs seroconversion rate of 60% (despite transient reappearance of HBV DNA and/or HBsAg in some of these patients).

Antiviral prophylactic approaches applied to patients undergoing liver transplantation for chronic hepatitis B are being used as well for patients without hepatitis B who receive organs from donors with antibody to hepatitis B core antigen (anti-HBc) but who do not have detectable HBsAg. Patients who undergo liver transplantation for chronic hepatitis B plus D are less likely to experience recurrent liver injury than patients undergoing liver transplantation for hepatitis B alone; still, such co-infected patients would also be offered standard posttransplantation prophylactic antiviral therapy for hepatitis B.

Until recently, the most common indication for liver transplantation was end-stage liver disease resulting from chronic hepatitis C **(Fig. 356-2)**. For patients undergoing liver transplantation for hepatitis C, because of an aggressive natural history of recurrent allograft hepatitis C, graft and patient survival were diminished substantially compared to other indications for transplantation.



The approval over the last decade of several DAA agents and of IFN-free DAA regimens against HCV has had a major impact on the management and outcome of both pretransplantation and posttransplantation HCV infection. Such therapeutic approaches (1) permit the clearance of viremia in a substantial proportion of decompensated cirrhotics, thereby preventing recurrent allograft infection and even improving the clinical status of most of these patients, delaying or obviating the need for liver replacement; and (2) achieve sustained virologic responses in a much higher proportion of persons with allograft HCV infection, because of improvements in antiviral treatment efficacy and tolerability. Ideally, patients should be treated prior to liver transplantation. This approach has already reduced the numbers of patients with HCV infection referred for liver transplantation and led to delisting of others. A concern, however, is that eradication of HCV infection will reduce the MELD score and lower the priority for a donor organ in some patients who still require transplantation because of continued hepatic decompensation and profound reduction in quality of life (a situation referred to as MELD purgatory). In addition, elimination of HCV infection prior to transplantation, historically, would have disqualified such patients as recipients of donor livers from persons with HCV infection, contracting the potential donor pool and limiting accessibility to donor organs and timely transplantation. With the advent of highly effective DAAs, however, allografts from HCV-infected donors are being transplanted into both HCV-infected and HCV-uninfected recipients, who can be treated posttransplantation with DAAs. Thus, earlier concerns about the potential impact of pretransplantation DAA treatment on limiting the donor pool are no longer an issue. The approach to HCV treatment should be individualized thoughtfully for each patient, based on such factors as MELD score, time anticipated prior to availability of a donor organ, relative clinical stability, and comorbidities.

DAA combinations that are being used successfully against allograft HCV include ledipasvir plus sofosbuvir; velpatasvir plus sofosbuvir; and grazoprevir plus pibrentasvir. (For updated guidelines, see *www.hcvguidelines.org*.) In patients with recurrent HCV infection after

FIGURE 356-2 (*Continued*)

liver transplantation, each of these regimens has yielded response rates approaching those seen in compensated nontransplant patient populations.

Historically, small numbers of allograft recipients have succumbed to early HCV-associated liver injury, and a syndrome reminiscent of fibrosing cholestatic hepatitis (see above) has been observed rarely. Currently, however, the routine use of DAA regimens early after transplantation, before the onset of these variant presentations, has already had a profound impact on the frequency of severe recurrent allograft hepatitis C.

Patients who undergo liver transplantation for end-stage alcohol-associated cirrhosis are at risk of a return to drinking again after transplantation, a potential source of recurrent alcohol-associated liver injury. Currently, alcohol-associated liver disease is the most common indication for liver transplantation, accounting for 40% of all liver transplantation procedures, and most transplantation centers screen candidates carefully for predictors of continued abstinence. Return to alcohol use is more likely in patients whose sobriety prior to transplantation was <6 months. For abstinent patients with alcohol-associated cirrhosis, liver transplantation can be undertaken successfully, with outcomes comparable to those for other categories of patients with chronic liver disease, when coordinated by a team approach that includes substance use counseling.

The syndemic of hazardous alcohol consumption, opioid use, and obesity continues to influence important changes in liver disease epidemiology, health disparities, indications for transplant (Fig. 356-2), and disease recurrence.

POSTTRANSPLANTATION QUALITY OF LIFE

Full rehabilitation is achieved in most patients who survive the early postoperative months and escape chronic rejection or unmanageable infection. Psychosocial maladjustment interferes with medical compliance in a small number of patients, but most manage to adhere to immunosuppressive regimens, which must be continued indefinitely. In one study, 85% of patients who survived their transplant operations returned to gainful activities. In fact, some women have conceived and carried pregnancies to term after transplantation without demonstrable injury to their infants.

357 Diseases of the Gallbladder and Bile Ducts

Norton J. Greenberger*, Gustav Paumgartner*, Daniel S. Pratt

PHYSIOLOGY OF BILE PRODUCTION AND FLOW

BILE SECRETION AND COMPOSITION

Bile formed in hepatocytes is secreted into a complex network of canaliculi lined by hepatocytes that flow into the canals of Hering lined partially by hepatocytes and partially by cholangiocytes, leading to small bile ductules and larger bile ducts lined by cholangiocytes that run with lymphatics and branches of the portal vein and hepatic artery in portal tracts situated between hepatic lobules. These interlobular bile ducts coalesce to form larger septal bile ducts that join to form the right and left hepatic ducts, which in turn, unite to form the common hepatic duct. The common hepatic duct is joined by the cystic duct of the gallbladder to form the common bile duct (CBD), which enters the duodenum (often after joining the main pancreatic duct) through the ampulla of Vater.

Hepatic bile is an isotonic fluid with an electrolyte composition resembling blood plasma. The electrolyte composition of gallbladder bile differs from that of hepatic bile because most of the inorganic anions, chloride, and bicarbonate have been removed by reabsorption across the gallbladder epithelium. As a result of water reabsorption, total solute concentration of bile increases from 3–4 g/dL in hepatic bile to 10–15 g/dL in gallbladder bile.

Major solute components of bile by moles percent include bile acids (80%), phospholipids (lecithins, cephalins, and sphingomyelin) (16%), and unesterified cholesterol (4.0%). In the lithogenic state, the cholesterol value can be as high as 8–10%. Other constituents include conjugated bilirubin; proteins (all immunoglobulins, albumin, metabolites of hormones, and other proteins metabolized in the liver); electrolytes; mucus; heavy metals; and, often, drugs and their metabolites.

The total daily basal secretion of hepatic bile is ~500–600 mL. Many substances taken up or synthesized by the hepatocyte are secreted into the bile canaliculi. The canalicular membrane forms microvilli and is associated with microfilaments of actin, microtubules, and other contractile elements. Prior to their secretion into the bile, many substances are taken up into the hepatocyte, while others, such as phospholipids, a portion of primary bile acids, and some cholesterol, are synthesized de novo in the hepatocyte. Three mechanisms are important in regulating bile flow: (1) active transport of bile acids from hepatocytes into the bile canaliculi, (2) active transport of other organic anions, and (3) cholangiocellular secretion. The last is a secretin-mediated and cyclic AMP–dependent mechanism that results in the secretion of a bicarbonate-rich fluid into the bile ducts.

Active vectorial trans-hepatocellular movement of bile acids from the portal blood into the bile canaliculi is driven by a set of transport systems at the basolateral (sinusoidal) and the canalicular apical plasma membrane domains of the hepatocyte. Two sinusoidal bile salt uptake systems have been cloned in humans, the Na^+/taurocholate cotransporter (NTCP, SLC10A1) and the organic anion–transporting proteins (OATP1B1/1B3), which also transport a large variety of non–bile salt organic anions. Several ATP-dependent canalicular transport systems, "export pumps" (ATP-binding cassette transport proteins, also known as ABC transporters), have been identified, the most important of which are the bile salt export pump (BSEP, ABCB11); the anionic conjugate export pump (MRP2, ABCC2), which mediates the canalicular excretion of various amphiphilic conjugates formed by phase II conjugation (e.g., bilirubin mono- and diglucuronides and drugs); the multidrug export pump (MDR1, ABCB1) for hydrophobic cationic compounds; and the phospholipid export pump (MDR3, ABCB4). Two hemitransporters, ABCG5/G8, functioning as a couple, constitute the canalicular cholesterol and phytosterol transporter. F1C1 (ATP8B1) is an aminophospholipid transferase ("flippase") essential for maintaining the lipid asymmetry of the canalicular membrane. The canalicular membrane also contains ATP-independent transport systems such as the Cl/HCO_3 anion exchanger isoform 2 (AE2, SLC4A2) for canalicular bicarbonate secretion. For most of these transporters, genetic defects have been identified that are associated with various forms of cholestasis or defects of biliary excretion. F1C1 (ATP8B1) is defective in progressive familial intrahepatic cholestasis type 1 (PFIC1) and benign recurrent intrahepatic cholestasis type 1 (BRIC1) and results in ablation of all other ATP-dependent transporter functions. BSEP (ABCB11) is defective in PFIC2 and BRIC2. Mutations of MRP2 (ABCC2) cause the Dubin-Johnson syndrome, an inherited form of conjugated hyperbilirubinemia (Chap. 349). A defective MDR3 (ABCB4) results in PFIC3. ABCG5/G8, the canalicular half transporters for cholesterol and other neutral sterols, are defective in sitosterolemia. The cystic fibrosis transmembrane regulator (CFTR, ABCC7), located on bile duct epithelial cells but not on canalicular membranes, is defective in cystic fibrosis, which is associated with impaired cholangiocellular pH regulation during ductular bile formation and chronic cholestatic liver disease, occasionally resulting in biliary cirrhosis.

THE BILE ACIDS

The primary bile acids, cholic acid and chenodeoxycholic acid (CDCA), are synthesized in hepatocytes from cholesterol, conjugated with glycine or taurine, and secreted into the bile canaliculus. Secondary bile acids, including deoxycholate and lithocholate, are formed in the colon as bacterial metabolites of the primary bile acids. However, lithocholic acid is much less efficiently absorbed from the colon than deoxycholic acid. Another secondary bile acid, found in low concentration, is ursodeoxycholic acid (UDCA), a stereoisomer of CDCA. In healthy subjects, the ratio of glycine to taurine conjugates in bile is ~3:1.

Bile acids are detergent-like molecules that in aqueous solutions and above a critical concentration of ~2 m*M* form molecular aggregates called *micelles*. Cholesterol alone is sparingly soluble in aqueous environments, and its solubility in bile depends on both the total lipid concentration and the relative molar percentages of bile acids and lecithin. Normal ratios of these constituents favor the formation of solubilizing *mixed micelles*, while abnormal ratios promote the precipitation of cholesterol crystals in bile via an intermediate liquid crystal phase.

In addition to facilitating the biliary excretion of cholesterol, bile acids facilitate the normal intestinal absorption of dietary fats, mainly cholesterol, and fat-soluble vitamins, via a micellar transport mechanism (Chap. 336). Bile acids also serve as a major physiologic driving force for hepatic bile flow and aid in water and electrolyte transport in the small bowel and colon.

Bile acids also function as hormones binding to nuclear (farnesoid X receptor [FXR]) and G protein–coupled (TGR5) receptors that regulate bile acid metabolism and their enterohepatic circulation.

ENTEROHEPATIC CIRCULATION

Bile acids are efficiently conserved under normal conditions. Unconjugated, and to a lesser degree also conjugated, bile acids are absorbed by *passive diffusion* along the entire gut. Quantitatively much more important for bile salt recirculation, however, is the *active transport* mechanism for conjugated bile acids in the distal ileum (Chap. 336). The reabsorbed bile acids enter the portal bloodstream and are taken up rapidly by hepatocytes, reconjugated, and resecreted into bile (enterohepatic circulation).

The normal bile acid pool size is ~2–4 g. During digestion of a meal, the bile acid pool undergoes at least one or more enterohepatic cycles, depending on the size and composition of the meal. Normally, the bile acid pool circulates ~5–10 times daily. Intestinal reabsorption of the pool is ~95% efficient; therefore, daily fecal loss of bile acids is in the range of 0.2–0.4 g. In the steady state, this fecal loss is compensated by an equal daily synthesis of bile acids by the liver, and thus, the size

*Deceased.

of the bile acid pool is maintained. Bile acids in the intestine stimulate the release of fibroblast growth factor 19 (FGF19), which suppresses the hepatic synthesis of bile acids from cholesterol by inhibiting the rate-limiting enzyme cytochrome P450 7A1 (CYP7A1). FGF19 also promotes gallbladder relaxation. While the loss of bile salts in stool is usually matched by increased hepatic synthesis, the maximum rate of synthesis is ~5 g/d, which may be insufficient to replete the bile acid pool size when there is pronounced impairment of intestinal bile salt reabsorption.

The expression of ABC transporters in the enterohepatic circulation and of the rate-limiting enzymes of bile acid and cholesterol synthesis are regulated in a coordinated fashion by nuclear receptors, which are ligand-activated transcription factors. The hepatic BSEP (ABCB11) is upregulated by the FXR that also represses bile acid synthesis. The expression of the cholesterol transporter, ABCG5/G8, is upregulated by the liver X receptor (LXR), which is an oxysterol sensor.

GALLBLADDER AND SPHINCTERIC FUNCTIONS

In the fasting state, the sphincter of Oddi (SOD) offers a high-pressure zone of resistance to bile flow from the CBD into the duodenum. Its tonic contraction serves to (1) prevent reflux of duodenal contents into the pancreatic and bile ducts and (2) promote filling of the gallbladder. The major factor controlling the evacuation of the gallbladder is the peptide hormone cholecystokinin (CCK), which is released from the duodenal mucosa in response to the ingestion of fats and amino acids. CCK produces (1) powerful contraction of the gallbladder, (2) decreased resistance of the SOD, and (3) enhanced flow of biliary contents into the duodenum.

Hepatic bile is "concentrated" within the gallbladder by energy-dependent transmucosal absorption of water and electrolytes. Almost the entire bile acid pool may be sequestered in the gallbladder following an overnight fast for delivery into the duodenum with the first meal of the day. The normal capacity of the gallbladder is ~30 mL.

DISEASES OF THE GALLBLADDER

CONGENITAL ANOMALIES

Anomalies of the biliary tract are not uncommon and include abnormalities in number, size, and shape (e.g., agenesis of the gallbladder, duplications, rudimentary or oversized "giant" gallbladders, and diverticula). *Phrygian cap* is a clinically innocuous entity in which a partial or complete septum (or fold) separates the fundus from the body. Anomalies of position or suspension are not uncommon and include left-sided gallbladder, intrahepatic gallbladder, retrodisplacement of the gallbladder, and "floating" gallbladder. The latter condition predisposes to acute torsion, volvulus, or herniation of the gallbladder.

GALLSTONES

Epidemiology and Pathogenesis Gallstones are quite prevalent in most Western countries. Gallstone formation increases after age 50. In the United States, the prevalence is highest in Native Americans followed by Hispanics, non-Hispanic whites, and black Americans. The prevalence is higher in women than men across all ages.

Gallstones form because of abnormal bile composition. They are divided into two major types: cholesterol stones and pigment stones. Cholesterol stones account for >90% of all gallstones in Western industrialized countries. Cholesterol gallstones usually contain >50% cholesterol monohydrate plus an admixture of calcium salts, bile pigments, proteins, and fatty acids. Pigment stones are composed primarily of calcium bilirubinate; they contain <20% cholesterol and are classified into "black" and "brown" types, the latter forming secondary to chronic biliary infection.

CHOLESTEROL STONES AND BILIARY SLUDGE Cholesterol is essentially water-insoluble and requires aqueous dispersion into either micelles or vesicles, both of which require the presence of a second lipid to solubilize the cholesterol. Cholesterol and phospholipids are secreted into bile as unilamellar bilayered vesicles, which are converted into mixed micelles consisting of bile acids, phospholipids, and cholesterol by the action of bile acids. If there is an excess of cholesterol in relation to phospholipids and bile acids, unstable, cholesterol-rich vesicles remain, which aggregate into large multilamellar vesicles from which cholesterol crystals precipitate (Fig. 357-1).

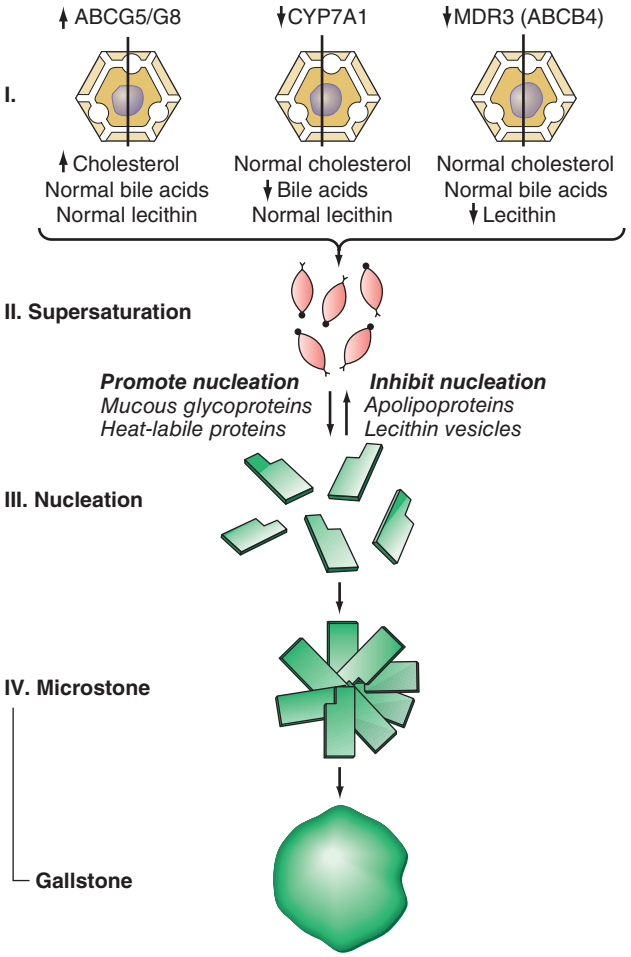

FIGURE 357-1 Scheme showing pathogenesis of cholesterol gallstone formation. Conditions or factors that increase the ratio of cholesterol to bile acids and phospholipids (lecithin) favor gallstone formation. ABCB4, ATP-binding cassette transporter; ABCG5/8, ATP-binding cassette (ABC) transporter G5/G8; CYP7A1, cytochrome P450 7A1; MDR3, multidrug resistance protein 3, also called phospholipid export pump.

There are several important mechanisms in the formation of lithogenic (stone-forming) bile. The most important is increased biliary secretion of cholesterol. This may occur in association with obesity, the metabolic syndrome, high-caloric and cholesterol-rich diets, or drugs (e.g., clofibrate) and may result from increased activity of hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme of hepatic cholesterol synthesis, and increased hepatic uptake of cholesterol from blood. In patients with gallstones, dietary cholesterol *increases* biliary cholesterol secretion. This does not occur in nongallstone patients on high-cholesterol diets. In addition to environmental factors such as high-caloric and cholesterol-rich diets, genetic factors play an important role in gallstone disease. A large study of symptomatic gallstones in Swedish twins provided strong evidence for a role of genetic factors in gallstone pathogenesis. Genetic factors accounted for 25%, shared environmental factors for 13%, and individual environmental factors for 62% of the phenotypic variation among monozygotic twins. A single nucleotide polymorphism of the gene encoding the hepatic cholesterol transporter ABCG5/G8 has been found in 21% of patients with gallstones, but only in 9% of the general population. It is thought to cause a gain of function of the cholesterol transporter and to contribute to cholesterol hypersecretion. A high prevalence of gallstones is found among first-degree relatives of gallstone carriers and in certain ethnic populations such as American Indians, Chilean Indians, and Chilean Hispanics. A common genetic

trait has been identified for some of these populations by mitochondrial DNA analysis. In some patients, impaired hepatic conversion of cholesterol to bile acids may also occur, resulting in an increase of the lithogenic cholesterol/bile acid ratio. Although most cholesterol stones have a polygenic basis, there are rare monogenic (Mendelian) causes. Mutations in the *CYP7A1* gene have been described that result in a deficiency of the enzyme cholesterol 7-hydroxylase, which catalyzes the initial step in cholesterol catabolism and bile acid synthesis. The homozygous state is associated with hypercholesterolemia and gallstones. Because the phenotype is expressed in the heterozygote state, mutations in the *CYP7A1* gene may contribute to the susceptibility to cholesterol gallstone disease in the population. Mutations in the *MDR3* (ABCB4) gene, which encodes the phospholipid export pump in the canalicular membrane of the hepatocyte, may cause defective phospholipid secretion into bile, resulting in cholesterol supersaturation of bile and formation of cholesterol gallstones in the gallbladder and in the bile ducts. Thus, an excess of biliary cholesterol in relation to bile acids and phospholipids is primarily due to hypersecretion of cholesterol, but hyposecretion of bile acids or phospholipids may contribute. An additional disturbance of bile acid metabolism that is likely to contribute to supersaturation of bile with cholesterol is enhanced conversion of cholic acid to deoxycholic acid, with replacement of the cholic acid pool by an expanded deoxycholic acid pool. It may result from enhanced dehydroxylation of cholic acid and increased absorption of newly formed deoxycholic acid. An increased deoxycholate secretion is associated with hypersecretion of cholesterol into bile. A recent study suggested a role for the gut microbiota as an environmental factor contributing to gallstone formation through an influence on cholesterol and bile acid metabolism.

While supersaturation of bile with cholesterol is an important prerequisite for gallstone formation, it is generally not sufficient by itself to produce cholesterol precipitation in vivo. Most individuals with supersaturated bile do not develop stones because the time required for cholesterol crystals to nucleate and grow is longer than the time bile remains in the gallbladder.

An important mechanism is *nucleation* of cholesterol monohydrate crystals, which is greatly accelerated in human lithogenic bile. Accelerated nucleation of cholesterol monohydrate in bile may be due to either an *excess of pronucleating factors* or a *deficiency of antinucleating factors*. Mucin and certain nonmucin glycoproteins, principally immunoglobulins, appear to be pronucleating factors, while apolipoproteins A-I and A-II and other glycoproteins appear to be antinucleating factors. Pigment particles may possibly play a role as nucleating factors. In a genome-wide analysis of serum bilirubin levels, the uridine diphosphate-glucuronyltransferase 1A1 (*UGT1A1*) Gilbert's syndrome gene variant was associated with the presence of gallstone disease. Because most gallstones associated with the *UGT1A1* variant were cholesterol stones, this finding points to the role of pigment particles in the pathogenesis of gallbladder stones. Cholesterol monohydrate crystal nucleation and crystal growth probably occur within the mucin gel layer. Vesicle fusion leads to liquid crystals, which, in turn, nucleate into solid cholesterol monohydrate crystals. Continued growth of the crystals occurs by direct nucleation of cholesterol molecules from supersaturated unilamellar or multilamellar biliary vesicles.

A third important mechanism in cholesterol gallstone formation is *gallbladder hypomotility*. If the gallbladder emptied all supersaturated or crystal-containing bile completely, stones would not be able to grow. A high percentage of patients with gallstones exhibits abnormalities of gallbladder emptying. Ultrasonographic studies show that gallstone patients display an increased gallbladder volume during fasting and after a test meal (residual volume) and that fractional emptying after gallbladder stimulation is decreased. The incidence of gallstones is increased in conditions associated with infrequent or impaired gallbladder emptying such as fasting, parenteral nutrition, or pregnancy and in patients using drugs that inhibit gallbladder motility.

Biliary sludge is a thick, mucous material that, upon microscopic examination, reveals lecithin-cholesterol liquid crystals, cholesterol monohydrate crystals, calcium bilirubinate, and mucin gels. Biliary sludge typically forms a crescent-like layer in the most dependent portion of the gallbladder and is recognized by characteristic echoes on ultrasonography (see below). The presence of biliary sludge implies two abnormalities: (1) the normal balance between gallbladder mucin secretion and elimination has become deranged, and (2) nucleation of biliary solutes has occurred. That biliary sludge may be a precursor form of gallstone disease is evident from several observations. In one study, 96 patients with gallbladder sludge were followed prospectively by serial ultrasound studies. In 18%, biliary sludge disappeared and did not recur for at least 2 years. In 60%, biliary sludge disappeared and reappeared; in 14%, gallstones (8% asymptomatic, 6% symptomatic) developed; and in 6%, severe biliary pain with or without acute pancreatitis occurred. In 12 patients, cholecystectomies were performed, 6 for gallstone-associated biliary pain and 3 in symptomatic patients with sludge but without gallstones who had prior attacks of pancreatitis; the latter did not recur after cholecystectomy. It should be emphasized that biliary sludge can develop with disorders that cause gallbladder hypomotility; that is, surgery, burns, total parenteral nutrition, pregnancy, and oral contraceptives—all of which are associated with gallstone formation. However, the presence of biliary sludge implies supersaturation of bile with either cholesterol or calcium bilirubinate.

Two other conditions are associated with cholesterol-stone or biliary-sludge formation: pregnancy and rapid weight reduction through a very-low-calorie diet. There appear to be two key changes during pregnancy that contribute to a "cholelithogenic state": (1) a marked increase in cholesterol saturation of bile during the third trimester and (2) sluggish gallbladder contraction in response to a standard meal, resulting in impaired gallbladder emptying. That these changes are related to pregnancy per se is supported by several studies that show reversal of these abnormalities quite rapidly after delivery. During pregnancy, gallbladder sludge develops in 20–30% of women and gallstones in 5–12%. Although biliary sludge is a common finding during pregnancy, it is usually asymptomatic and often resolves spontaneously after delivery. Gallstones, which are less common than sludge and frequently associated with biliary colic, may also disappear after delivery because of spontaneous dissolution related to bile becoming unsaturated with cholesterol postpartum.

Approximately 10–20% of persons with rapid weight reduction achieved through very-low-calorie dieting develop gallstones. In a study involving 600 patients who completed a 3-month, 520-kcal/d diet, UDCA in a dosage of 600 mg/d proved highly effective in preventing gallstone formation; gallstones developed in only 3% of UDCA recipients, compared to 28% of placebo-treated patients. In obese patients treated by gastric banding, 500 mg/d of UDCA reduced the risk of gallstone formation from 30 to 8% within a follow-up of 6 months.

To summarize, cholesterol gallstone disease occurs because of several defects, which include (1) bile supersaturation with cholesterol, (2) nucleation of cholesterol monohydrate with subsequent crystal retention and stone growth, and (3) abnormal gallbladder motor function with delayed emptying and stasis. Other important factors known to predispose to cholesterol-stone formation are summarized in **Table 357-1**.

PIGMENT STONES Black pigment stones are composed of either pure calcium bilirubinate or polymer-like complexes with calcium and mucin glycoproteins. They are more common in patients who have chronic hemolytic states (with increased conjugated bilirubin in bile); cirrhosis, especially related to alcohol; Gilbert's syndrome; or cystic fibrosis. Gallbladder stones in patients with ileal diseases, ileal resection, or ileal bypass generally are also black pigment stones. Enterohepatic recycling of bilirubin in ileal disease states contributes to their pathogenesis. Brown pigment stones are composed of calcium salts of unconjugated bilirubin with varying amounts of cholesterol and protein. They are caused by the presence of increased amounts of unconjugated, insoluble bilirubin in bile that precipitates to form stones. Deconjugation of an excess of soluble bilirubin mono- and diglucuronides may be mediated by endogenous β-glucuronidase but may also occur by spontaneous hydrolysis. Sometimes, the enzyme is also produced when bile is chronically infected by bacteria, and such

TABLE 357-1 Predisposing Factors for Cholesterol and Pigment Gallstone Formation

Cholesterol Stones

1. Demographic/genetic factors: Prevalence highest in North American Indians, Chilean Indians, and Chilean Hispanics, greater in Northern Europe and North America than in Asia, lowest in Japan; familial disposition; hereditary aspects
2. Obesity, metabolic syndrome: Normal bile acid pool and secretion but increased biliary secretion of cholesterol
3. Rapid weight loss: Mobilization of tissue cholesterol leads to increased biliary cholesterol secretion while enterohepatic circulation of bile acids is decreased
4. Female sex hormones
   a. Estrogens stimulate hepatic lipoprotein receptors, increase uptake of dietary cholesterol, and increase biliary cholesterol secretion
   b. Natural estrogens, other estrogens, and oral contraceptives lead to decreased bile salt secretion and decreased conversion of cholesterol to cholesteryl esters
5. Pregnancy: Impaired gallbladder emptying caused by progesterone combined with the influence of estrogens, which increase biliary cholesterol secretion
6. Increasing age: Increased biliary secretion of cholesterol, decreased size of bile acid pool, decreased secretion of bile salts
7. Gallbladder hypomotility leading to stasis and formation of sludge
   a. Total parenteral nutrition
   b. Fasting
   c. Pregnancy
   d. Drugs such as octreotide
8. Clofibrate therapy: Increased biliary secretion of cholesterol
9. Decreased bile acid secretion
   a. Genetic defect of the *CYP7A1* gene
10. Decreased phospholipid secretion: Genetic defect of the *MDR3* gene
11. Miscellaneous
    a. High-calorie, high-fat diet
    b. Spinal cord injury

Pigment Stones

1. Demographic/genetic factors: Asia, rural setting (presumed due to increased prevalence of parasitic biliary infections; the incidence has been dropping with time)
2. Chronic hemolysis (example: sickle cell disease)
3. Alcohol related liver cirrhosis
4. Ineffective erythropoiesis (example: pernicious anemia)
5. Cystic fibrosis
6. Chronic biliary tract infection, parasite infections
7. Increasing age
8. Ileal disease, ileal resection or bypass

TABLE 357-2 Diagnostic Evaluation of the Gallbladder

DIAGNOSTIC ADVANTAGES	DIAGNOSTIC LIMITATIONS	COMMENT
Ultrasound		
Rapid Accurate identification of gallstones (>95%) Simultaneous scanning of GB, liver, bile ducts, pancreas "Real-time" scanning allows assessment of GB volume, contractility Not limited by jaundice, pregnancy May detect very small stones	Bowel gas Massive obesity Ascites	Procedure of choice for detection of stones
Plain Abdominal X-Ray		
Low cost Readily available	Relatively low yield Contraindicated in pregnancy	Pathognomonic findings in: calcified gallstones, limey bile, porcelain GB, emphysematous cholecystitis, gallstone ileus
Cholescintigraphy (HIDA, DISIDA, etc.)		
Accurate identification of cystic duct obstruction Simultaneous assessment of bile ducts	Contraindicated in pregnancy Serum bilirubin >103–205 μmol/L (6–12 mg/dL) Cholecystogram of low resolution	Indicated for confirmation of suspected acute cholecystitis; less sensitive and less specific in chronic cholecystitis; useful in the diagnosis of acalculous cholecystopathy, especially if given with CCK to assess GB emptying

Abbreviations: CCK, cholecystokinin; DISIDA, diisopropyl iminodiacetic acid; GB, gallbladder; HIDA, hydroxyl iminodiacetic acid.

stones are brown. Pigment stone formation is frequent in Asia and is often associated with parasitic infections in the gallbladder and biliary tree (Table 357-1).

Diagnosis Procedures of potential use in the diagnosis of cholelithiasis and other diseases of the gallbladder are detailed in **Table 357-2**. Ultrasonography of the gallbladder is very accurate in the identification of cholelithiasis and has replaced oral cholecystography (OCG) **(Fig. 357-2*A*)**. Stones as small as 1.5 mm in diameter may be confidently identified provided that firm criteria are used (e.g., acoustic "shadowing" of opacities that are within the gallbladder lumen and that change with the patient's position [by gravity]). In major medical centers, the false-negative and false-positive rates for ultrasound in gallstone patients are ~2–4%. Biliary sludge is material of low echogenic activity that typically forms a layer in the most dependent position of the gallbladder. This layer shifts with postural changes but fails to produce acoustic shadowing; these two characteristics distinguish sludges from gallstones. Ultrasound can also be used to assess the emptying function of the gallbladder.

The plain abdominal film may detect gallstones containing sufficient calcium to be radiopaque (10–15% of cholesterol and ~50% of pigment stones). Plain radiography may also be of use in the diagnosis of emphysematous cholecystitis, porcelain gallbladder, limey bile, and gallstone ileus.

OCG was historically a useful procedure for the diagnosis of gallstones but has been replaced by ultrasound and is now regarded as obsolete. It may be used to assess the patency of the cystic duct and gallbladder emptying function. Further, OCG can also delineate the size and number of gallstones and determine whether they are calcified, useful information if medical dissolution is being considered.

Radiopharmaceuticals such as ^{99m}Tc-labeled *N*-substituted iminodiacetic acids (HIDA and DISIDA) are rapidly extracted from the blood and are excreted into the biliary tree in high concentration even in the presence of mild to moderate serum bilirubin elevations. Failure to image the gallbladder in the presence of biliary ductal visualization may indicate cystic duct obstruction, acute or chronic cholecystitis, or surgical absence of the organ. Such scans have application in the diagnosis of acute cholecystitis and may play a role in the detection of a postcholecystectomy bile leak.

Symptoms of Gallstone Disease Gallstones usually produce symptoms by causing inflammation or obstruction following their migration into the cystic duct or CBD. The most specific and characteristic symptom of gallstone disease is biliary colic that is a constant and often long-lasting pain (see below). Obstruction of the cystic duct or CBD by a stone produces increased intraluminal pressure and distention of the viscus that cannot be relieved by repetitive biliary contractions. The resultant visceral pain is characteristically a severe,

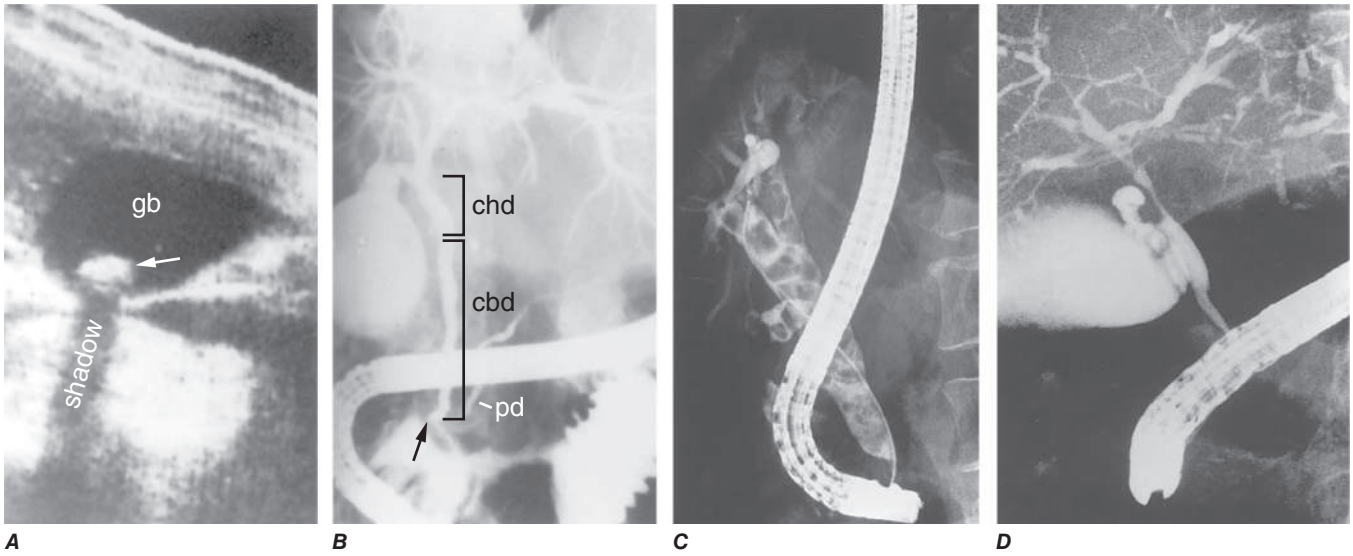

FIGURE 357-2 Examples of ultrasound and radiologic studies of the biliary tract. ***A.*** An ultrasound study showing a distended gallbladder (GB) containing a single large stone (*arrow*), which casts an acoustic shadow. ***B.*** Endoscopic retrograde cholangiopancreatogram (ERCP) showing normal biliary tract anatomy. In addition to the endoscope and large vertical gallbladder filled with contrast dye, the common hepatic duct (CHD), common bile duct (CBD), and pancreatic duct (PD) are shown. The *arrow* points to the ampulla of Vater. ***C.*** Endoscopic retrograde cholangiogram (ERC) showing choledocholithiasis. The biliary tract is dilated and contains multiple radiolucent calculi. ***D.*** ERCP showing sclerosing cholangitis. The CBD shows areas that are strictured and narrowed.

steady ache or fullness in the epigastrium or right upper quadrant (RUQ) of the abdomen with frequent radiation to the interscapular area, right scapula, or shoulder.

Biliary colic begins quite suddenly and may persist with severe intensity for 30 min to 5 h, subsiding gradually or rapidly. It is steady rather than intermittent, as would be suggested by the word *colic*, which must be regarded as a misnomer, although it is in widespread use. An episode of biliary pain persisting beyond 5 h should raise the suspicion of acute cholecystitis (see below). Nausea and vomiting frequently accompany episodes of biliary pain. An elevated level of serum bilirubin and/or alkaline phosphatase suggests a common duct stone. Fever or chills (rigors) with biliary pain usually imply a complication, that is, cholecystitis, pancreatitis, or cholangitis. Complaints of short-lasting, vague epigastric fullness, dyspepsia, eructation, or flatulence, especially following a fatty meal, should not be confused with biliary pain. Such symptoms are frequently elicited from patients with or without gallstone disease but are not specific for biliary calculi. Biliary colic may be precipitated by eating a fatty meal, by consumption of a large meal following a period of prolonged fasting, or by eating a normal meal; it is frequently nocturnal, occurring within a few hours of retiring.

Natural History Gallstone disease discovered in an asymptomatic patient or in a patient whose symptoms are not referable to cholelithiasis is a common clinical problem. Sixty to 80% of persons with asymptomatic gallstones remain asymptomatic over follow-up periods of up to 25 years. The probability of developing symptoms within 5 years after diagnosis is 2–4% per year and decreases in the years thereafter to 1–2%. The yearly incidence of complications is about 0.1–0.3%. Patients remaining asymptomatic for 15 years were found to be unlikely to develop symptoms during further follow-up, and most patients who did develop complications from their gallstones experienced *prior* warning symptoms. Similar conclusions apply to diabetic patients with silent gallstones. Decision analysis has suggested that (1) the cumulative risk of death due to gallstone disease while on expectant management is small, and (2) prophylactic cholecystectomy is not warranted.

Complications requiring cholecystectomy are much more common in gallstone patients who have developed symptoms of biliary pain. Patients found to have gallstones at a young age are more likely to develop symptoms from cholelithiasis than are patients >60 years at the time of initial diagnosis. Patients with diabetes mellitus and gallstones may be somewhat more susceptible to septic complications, but the magnitude of risk of septic biliary complications in diabetic patients is incompletely defined.

TREATMENT

Gallstones

SURGICAL THERAPY

In asymptomatic gallstone patients, the risk of developing symptoms or complications requiring surgery is quite small (see above). Thus, a recommendation for cholecystectomy in a patient with gallstones should probably be based on assessment of three factors: (1) the presence of symptoms that are frequent enough or severe enough to interfere with the patient's general routine; (2) the presence of a prior complication of gallstone disease, that is, history of acute cholecystitis, pancreatitis, gallstone fistula, etc.; or (3) the presence of an underlying condition predisposing the patient to increased risk of gallstone complications (e.g., a previous attack of acute cholecystitis regardless of current symptomatic status). Patients with very large gallstones (>3 cm in diameter) and patients harboring gallstones in a congenitally anomalous gallbladder might also be considered for prophylactic cholecystectomy. Although young age is a worrisome factor in asymptomatic gallstone patients, few authorities would now recommend routine cholecystectomy in young patients with silent stones. Laparoscopic cholecystectomy is a minimal-access approach for the removal of the gallbladder together with its stones. Its advantages include a markedly shortened hospital stay, minimal disability, and decreased cost, and it is the procedure of choice for most patients referred for elective cholecystectomy.

From several studies involving >4000 patients undergoing laparoscopic cholecystectomy, the following key points emerge: (1) complications develop in ~4% of patients, (2) conversion to laparotomy occurs in 5%, (3) the death rate is remarkably low (i.e., <0.1%), and (4) the rate of bile duct injuries is low (i.e., 0.2–0.6%) and comparable with open cholecystectomy. These data indicate why laparoscopic cholecystectomy has become the "gold standard" for treating symptomatic cholelithiasis.

MEDICAL THERAPY—GALLSTONE DISSOLUTION

In carefully selected patients with a functioning gallbladder and with radiolucent stones <10 mm in diameter, complete dissolution can be achieved in ~50% of patients within 6 months to 2 years. For

good results within a reasonable time period, this therapy should be limited to radiolucent stones <5 mm in diameter. The dose of UDCA should be 10–15 mg/kg per d. Stones >10 mm in size rarely dissolve. Pigment stones are not responsive to UDCA therapy. Probably ≤10% of patients with *symptomatic* cholelithiasis are candidates for such treatment. However, in addition to the vexing problem of recurrent stones (30–50% over 3–5 years of follow-up), there is also the factor of taking a drug for up to 2 years and perhaps indefinitely. The advantages and success of laparoscopic cholecystectomy have largely reduced the role of gallstone dissolution to patients who wish to avoid or are not candidates for elective cholecystectomy. However, patients with cholesterol gallstone disease who develop recurrent choledocholithiasis after cholecystectomy should be on long-term treatment with UDCA.

ACUTE AND CHRONIC CHOLECYSTITIS

Acute Cholecystitis Acute inflammation of the gallbladder wall usually follows obstruction of the cystic duct by a stone. Inflammatory response can be evoked by three factors: (1) *mechanical inflammation* produced by increased intraluminal pressure and distention with resulting ischemia of the gallbladder mucosa and wall, (2) *chemical inflammation* caused by the release of lysolecithin (due to the action of phospholipase on lecithin in bile) and other local tissue factors, and (3) *bacterial inflammation*, which may play a role in 50–85% of patients with acute cholecystitis. The organisms most frequently isolated by culture of gallbladder bile in these patients include *Escherichia coli*, *Klebsiella* spp., *Streptococcus* spp., and *Clostridium* spp.

Acute cholecystitis often begins as an attack of biliary pain that progressively worsens. Approximately 60–70% of patients report having experienced prior attacks that resolved spontaneously. As the episode progresses, however, the pain of acute cholecystitis becomes more generalized in the right upper abdomen. As with biliary colic, the pain of cholecystitis may radiate to the interscapular area, right scapula, or shoulder. Peritoneal signs of inflammation such as increased pain with jarring or on deep respiration may be apparent. The patient is anorectic and often nauseated. Vomiting is relatively common and may produce symptoms and signs of vascular and extracellular volume depletion. Jaundice is unusual early in the course of acute cholecystitis but may occur when edematous inflammatory changes involve the bile ducts and surrounding lymph nodes.

A low-grade fever is characteristically present, but shaking chills or rigors are not uncommon. The RUQ of the abdomen is almost invariably tender to palpation. An enlarged, tense gallbladder is palpable in 25–50% of patients. Deep inspiration or cough during subcostal palpation of the RUQ usually produces increased pain and inspiratory arrest (Murphy's sign). Localized rebound tenderness in the RUQ is common, as are abdominal distention and hypoactive bowel sounds from paralytic ileus, but generalized peritoneal signs and abdominal rigidity are usually lacking, in the absence of perforation.

The diagnosis of acute cholecystitis is usually made on the basis of a characteristic history and physical examination. The triad of sudden onset of RUQ tenderness, fever, and leukocytosis is highly suggestive. Typically, leukocytosis in the range of 10,000–15,000 cells per microliter with a left shift on differential count is found. The serum bilirubin is mildly elevated (<85.5 μmol/L [5 mg/dL]) in fewer than half of patients, whereas about one-fourth have modest elevations in serum aminotransferases (usually less than a fivefold elevation). Ultrasound will demonstrate calculi in 90–95% of cases and is useful for detection of signs of gallbladder inflammation including thickening of the wall, pericholecystic fluid, and dilatation of the bile duct. The radionuclide (e.g., HIDA) biliary scan may be confirmatory if bile duct imaging is seen without visualization of the gallbladder.

Approximately 75% of patients treated medically have remission of acute symptoms within 2–7 days following hospitalization. In 25%, however, a complication of acute cholecystitis will occur despite conservative treatment (see below). In this setting, prompt surgical intervention is required. Of the 75% of patients with acute cholecystitis who undergo remission of symptoms, ~25% will experience a recurrence of cholecystitis within 1 year, and 60% will have at least one recurrent bout within 6 years. In view of the natural history of the disease, acute cholecystitis is best treated by early surgery whenever possible. Mirizzi's syndrome is a rare complication in which a gallstone becomes impacted in the cystic duct or neck of the gallbladder causing compression of the CBD, resulting in CBD obstruction and jaundice. Ultrasound shows gallstone(s) lying outside the hepatic duct. Endoscopic retrograde cholangiopancreatography (ERCP) **(Fig. 357-2*B*)**, percutaneous transhepatic cholangiography (PTC), or magnetic resonance cholangiopancreatography (MRCP) will usually demonstrate the characteristic extrinsic compression of the CBD. Surgery consists of removing the cystic duct, diseased gallbladder, and impacted stone. The preoperative diagnosis of Mirizzi's syndrome is important to avoid CBD injury.

ACALCULOUS CHOLECYSTITIS In 5–14% of patients with acute cholecystitis, calculi obstructing the cystic duct are not found at surgery. In >50% of such cases, an underlying explanation for acalculous inflammation is not found. An increased risk for the development of acalculous cholecystitis is especially associated with prolonged fasting, with serious trauma or burns, in the postpartum period following prolonged labor, and with orthopedic and other nonbiliary major surgical operations in the postoperative period. It may possibly complicate periods of prolonged parenteral hyperalimentation. For some of these cases, biliary sludge in the cystic duct may be responsible. Other precipitating factors include vasculitis, obstructing adenocarcinoma of the gallbladder, diabetes mellitus, torsion of the gallbladder, "unusual" bacterial infections of the gallbladder (e.g., *Leptospira*, *Streptococcus*, *Salmonella*, or *Vibrio cholerae*), and parasitic infestation of the gallbladder. Acalculous cholecystitis may also be seen with a variety of other systemic disease processes (e.g., sarcoidosis, cardiovascular disease, tuberculosis, syphilis, actinomycosis).

Although the clinical manifestations of acalculous cholecystitis are indistinguishable from those of calculous cholecystitis, the setting of acute gallbladder inflammation complicating severe underlying illness is characteristic of acalculous disease. Ultrasound or computed tomography (CT) examinations demonstrating a large, tense, static gallbladder without stones and with evidence of poor emptying over a prolonged period may be diagnostically useful in some cases. The complication rate for acalculous cholecystitis exceeds that for calculous cholecystitis. Successful management of acute acalculous cholecystitis appears to depend primarily on early diagnosis and surgical intervention, with meticulous attention to postoperative care.

ACALCULOUS CHOLECYSTOPATHY Disordered motility of the gallbladder can produce recurrent biliary pain in patients without gallstones. Infusion of an octapeptide of CCK can be used to measure the gallbladder ejection fraction during cholescintigraphy. The surgical findings have included abnormalities such as chronic cholecystitis, gallbladder muscle hypertrophy, and/or a markedly narrowed cystic duct. Some of these patients may well have had antecedent gallbladder disease. The following criteria can be used to identify patients with acalculous cholecystopathy: (1) recurrent episodes of typical RUQ pain characteristic of biliary tract pain, (2) abnormal CCK cholescintigraphy demonstrating a gallbladder ejection fraction of <40%, and (3) infusion of CCK reproducing the patient's pain. An additional clue would be the identification of a large gallbladder on ultrasound examination. Importantly, it should be noted that SOD dysfunction can also give rise to recurrent RUQ pain and CCK-scintigraphic abnormalities.

EMPHYSEMATOUS CHOLECYSTITIS So-called emphysematous cholecystitis is thought to begin with acute cholecystitis (calculous or acalculous) followed by ischemia or gangrene of the gallbladder wall and infection by gas-producing organisms. Bacteria most frequently cultured in this setting include anaerobes, such as *Clostridium welchii* or *C. perfringens*, and aerobes, such as *E. coli*. This condition occurs most frequently in elderly men and in patients with diabetes mellitus. The clinical manifestations are essentially indistinguishable from those of nongaseous cholecystitis. The diagnosis is usually made on plain

abdominal film by finding gas within the gallbladder lumen, dissecting within the gallbladder wall to form a gaseous ring, or in the pericholecystic tissues. The morbidity and mortality rates with emphysematous cholecystitis are considerable. Prompt surgical intervention coupled with appropriate antibiotics is mandatory.

Chronic Cholecystitis Chronic inflammation of the gallbladder wall is almost always associated with the presence of gallstones and is thought to result from repeated bouts of subacute or acute cholecystitis or from persistent mechanical irritation of the gallbladder wall by gallstones. The presence of bacteria in the bile occurs in >25% of patients with chronic cholecystitis. The presence of infected bile in a patient with *chronic* cholecystitis undergoing elective cholecystectomy probably adds little to the operative risk. Chronic cholecystitis may be asymptomatic for years, which may progress to symptomatic gallbladder disease or to acute cholecystitis or may present with complications (see below).

Complications of Cholecystitis • **EMPYEMA AND HYDROPS** Empyema of the gallbladder usually results from progression of acute cholecystitis with persistent cystic duct obstruction to superinfection of the stagnant bile with a pus-forming bacterial organism. The clinical picture resembles that of cholangitis with high fever; severe RUQ pain; marked leukocytosis; and often, prostration. Empyema of the gallbladder carries a high risk of gram-negative sepsis and/or perforation. Emergency surgical intervention with proper antibiotic coverage is required as soon as the diagnosis is suspected.

Hydrops or mucocele of the gallbladder may also result from prolonged obstruction of the cystic duct, usually by a large solitary calculus. In this instance, the obstructed gallbladder lumen is progressively distended, over a period of time, by mucus (mucocele) or by a clear transudate (hydrops) produced by mucosal epithelial cells. A visible, easily palpable, nontender mass sometimes extending from the RUQ into the right iliac fossa may be found on physical examination. The patient with hydrops of the gallbladder frequently remains asymptomatic, although chronic RUQ pain may also occur. Cholecystectomy is indicated, because empyema, perforation, or gangrene may complicate the condition.

GANGRENE AND PERFORATION Gangrene of the gallbladder results from ischemia of the wall and patchy or complete tissue necrosis. Underlying conditions often include marked distention of the gallbladder, vasculitis, diabetes mellitus, empyema, or torsion resulting in arterial occlusion. Gangrene usually predisposes to perforation of the gallbladder, but perforation may also occur in chronic cholecystitis without premonitory warning symptoms. *Localized perforations* are usually contained by the omentum or by adhesions produced by recurrent inflammation of the gallbladder. Bacterial superinfection of the walled-off gallbladder contents results in abscess formation. Most patients are best treated with cholecystectomy, but some seriously ill patients may be managed with cholecystostomy and drainage of the abscess. *Free perforation* is less common but is associated with a mortality rate of ~30%. Such patients may experience a sudden transient relief of RUQ pain as the distended gallbladder decompresses; this is followed by signs of generalized peritonitis.

FISTULA FORMATION AND GALLSTONE ILEUS Fistula formation into an adjacent organ adherent to the gallbladder wall may result from inflammation and adhesion formation. Fistulas into the duodenum are most common, followed in frequency by those involving the hepatic flexure of the colon, stomach or jejunum, abdominal wall, and renal pelvis. Clinically "silent" biliary-enteric fistulas occurring as a complication of acute cholecystitis have been found in up to 5% of patients undergoing cholecystectomy. Asymptomatic cholecystoenteric fistulas may sometimes be diagnosed by finding gas in the biliary tree on plain abdominal films. Barium contrast studies or endoscopy of the upper gastrointestinal tract or colon may demonstrate the fistula. Treatment in the symptomatic patient usually consists of cholecystectomy, CBD exploration, and closure of the fistulous tract.

Gallstone ileus refers to mechanical intestinal obstruction resulting from the passage of a large gallstone into the bowel lumen. The stone customarily enters the duodenum through a cholecystoenteric fistula at that level. The site of obstruction by the impacted gallstone is usually at the ileocecal valve, provided that the more proximal small bowel is of normal caliber. Most patients do not give a history of either prior biliary tract symptoms or complaints suggestive of acute cholecystitis or fistula formation. Large stones, >2.5 cm in diameter, are thought to predispose to fistula formation by gradual erosion through the gallbladder fundus. Diagnostic confirmation may occasionally be found on the plain abdominal film (e.g., small-intestinal obstruction with gas in the biliary tree [pneumobilia] and a calcified, ectopic gallstone) or following an upper gastrointestinal series (cholecystoduodenal fistula with small-bowel obstruction at the ileocecal valve). Laparotomy with stone extraction (or propulsion into the colon) remains the procedure of choice to relieve obstruction. Evacuation of large stones within the gallbladder should also be performed. In general, the gallbladder and its attachment to the intestines should be left alone.

LIMEY (MILK OF CALCIUM) BILE AND PORCELAIN GALLBLADDER Calcium salts in the lumen of the gallbladder in sufficient concentration may produce calcium precipitation and diffuse, hazy opacification of bile or a layering effect on plain abdominal roentgenography. This so-called limey bile, or milk of calcium bile, is usually clinically innocuous, but cholecystectomy is often performed, especially when it occurs in a hydropic gallbladder. In the entity called *porcelain gallbladder*, calcium salt deposition within the wall of a chronically inflamed gallbladder may be detected on the plain abdominal film. In the past, cholecystectomy was advised in all patients with porcelain gallbladder because there was felt to be a high incidence of carcinoma of the gallbladder associated with this condition, an association challenged by a number of studies. Two patterns of gallbladder wall calcification have now been appreciated: complete intramural calcification and selective mucosal calcification. The incidence of cancer in those with selective intramural calcification is higher than those with complete mucosal wall calcification, but the risk is very small. As such, the need for cholecystectomy for porcelain gallbladder is not absolute; close surveillance in these patients is also acceptable.

TREATMENT

Acute Cholecystitis

MEDICAL THERAPY

Although surgical intervention remains the mainstay of therapy for acute cholecystitis and its complications, a period of in-hospital stabilization may be required before cholecystectomy. Oral intake is eliminated, nasogastric suction may be indicated, extracellular volume depletion and electrolyte abnormalities are repaired, and analgesia is provided. Intravenous antibiotic therapy is indicated in patients with severe acute cholecystitis, even though bacterial superinfection of bile may not have occurred in the early stages of the inflammatory process. Antibiotic therapy is guided by the most common organisms likely to be present including *E. coli*, *Klebsiella*, *Enterococcus*, *Enterobacter*, and *Streptococcus*. Effective antibiotics include piperacillin plus tazobactam, imipenem, meropenem, ceftriaxone plus metronidazole, and levofloxacin plus metronidazole **(Chap. 166)**. Postoperative complications of wound infection, abscess formation, and sepsis are reduced in antibiotic-treated patients.

SURGICAL THERAPY

The optimal timing of surgical intervention in patients with acute cholecystitis depends on stabilization of the patient. The clear trend is toward earlier surgery, and this is due in part to requirements for shorter hospital stays. Urgent (emergency) cholecystectomy or percutaneous cholecystostomy is probably appropriate in most patients in whom a complication of acute cholecystitis such as empyema, emphysematous cholecystitis, or perforation is suspected or confirmed. Patients with uncomplicated acute cholecystitis should undergo early elective laparoscopic cholecystectomy,

ideally within 48–72 h after diagnosis. The complication rate is not increased in patients undergoing early as opposed to delayed (>6 weeks after diagnosis) cholecystectomy. Delayed surgical intervention is probably best reserved for (1) patients in whom the overall medical condition imposes an unacceptable risk for early surgery and (2) patients in whom the diagnosis of acute cholecystitis is in doubt. Thus, early cholecystectomy (within 72 h) is the treatment of choice for most patients with acute cholecystitis. Mortality figures for emergency cholecystectomy in most centers range from 1 to 3%, whereas the mortality risk for early elective cholecystectomy is ~0.5% in patients under age 60. Of course, the operative risks increase with age-related diseases of other organ systems and with the presence of long- or short-term complications of gallbladder disease. Seriously ill or debilitated patients with cholecystitis may be managed with percutaneous drainage (a cholecystostomy tube), transpapillary drainage (an endoscopically placed transpapillary drainage catheter via the cystic duct), or transmural drainage (an endoscopically placed covered, lumen-apposing stent). Elective cholecystectomy may then be done at a later date.

Postcholecystectomy Complications Early complications following cholecystectomy include atelectasis and other pulmonary disorders, abscess formation (often subphrenic), external or internal hemorrhage, biliary-enteric fistula, and bile leaks. Jaundice may indicate absorption of bile from an intraabdominal collection following a biliary leak or mechanical obstruction of the CBD by retained calculi, intraductal blood clots, or extrinsic compression.

Overall, cholecystectomy is a very successful operation that provides total or near-total relief of preoperative symptoms in 75–90% of patients. The most common cause of persistent postcholecystectomy symptoms is an overlooked symptomatic nonbiliary disorder (e.g., reflux esophagitis, peptic ulceration, pancreatitis, or—most often—irritable bowel syndrome). In a small percentage of patients, however, a disorder of the extrahepatic bile ducts may result in persistent symptomatology. These so-called postcholecystectomy syndromes may be due to (1) biliary strictures, (2) retained biliary calculi, (3) cystic duct stump syndrome, (4) stenosis or dyskinesia of the SOD, or (5) bile salt–induced diarrhea or gastritis.

CYSTIC DUCT STUMP SYNDROME In the absence of cholangiographically demonstrable retained stones, symptoms resembling biliary pain or cholecystitis in the postcholecystectomy patient have frequently been attributed to disease in a long (>1 cm) cystic duct remnant (cystic duct stump syndrome). Careful analysis, however, reveals that postcholecystectomy complaints are attributable to other causes in almost all patients in whom the symptom complex was originally thought to result from the existence of a long cystic duct stump. Accordingly, considerable care should be taken to investigate the possible role of other factors in the production of postcholecystectomy symptoms before attributing them to cystic duct stump syndrome.

SOD STENOSIS, SOD DYSKINESIA, AND BILIARY DYSKINESIA Symptoms of biliary colic accompanied by signs of recurrent, intermittent biliary obstruction may be produced by acalculous cholecystopathy, SOD stenosis, or SOD dyskinesia. SOD stenosis is thought to result from acute or chronic inflammation of the papilla of Vater or from glandular hyperplasia of the papillary segment. Five criteria have been used to define SOD stenosis: (1) upper abdominal pain, usually RUQ or epigastric; (2) abnormal liver tests; (3) dilatation of the CBD upon MRCP or ERCP examination; (4) delayed (>45 min) drainage of contrast material from the duct; and (5) increased basal pressure of the SOD. Treatment consists of endoscopic or surgical sphincteroplasty to ensure wide patency of the distal portions of both the bile and pancreatic ducts. The greater the number of the preceding criteria present, the greater is the likelihood that a patient does have a degree of SOD sufficient to justify correction. The factors usually considered as indications for sphincterotomy include (1) prolonged duration of symptoms, (2) lack of response to symptomatic treatment, (3) presence of severe disability, and (4) the patient's choice of sphincterotomy over surgery (given a clear understanding on the patient's part of the risks involved in both procedures).

Biliary SOD disorders are characterized by three criteria: (1) biliary pain, (2) absence of bile duct stones or other abnormalities, and (3) elevated liver enzymes or a dilated CBD, but not both. In this setting, either hepatobiliary scintigraphy or SOD manometry can support the diagnosis. Importantly, the presence of both elevated liver enzymes and a dilated CBD should raise the question of obstruction. Proposed mechanisms to account for SOD dysfunction include spasm of the sphincter, denervation sensitivity resulting in hypertonicity, and abnormalities in the sequencing or frequency rates of the sphincteric-contraction waves. When thorough evaluation has failed to demonstrate another cause for the pain and when cholangiographic and manometric criteria suggest a diagnosis of SOD dyskinesia, medical treatment with nitrites or anticholinergics to attempt pharmacologic relaxation of SOD has been proposed but not evaluated in detailed studies. Endoscopic biliary sphincterotomy (EBS) or surgical sphincterotomy may be indicated in patients who fail to respond to a 2- to 3-month trial of medical therapy, especially if SOD pressures are elevated. Approximately 45% of such patients have long-term pain relief after EBS. EBS has become the procedure of choice for removing bile duct stones and for other biliary and pancreatic problems.

BILE SALT–INDUCED DIARRHEA AND GASTRITIS Postcholecystectomy patients may develop symptoms of dyspepsia, which have been attributed to duodenogastric reflux of bile. However, firm data linking these symptoms to bile gastritis after surgical removal of the gallbladder are lacking. Cholecystectomy induces persistent changes in gut transit, and these changes effect a noticeable modification of bowel habits. Cholecystectomy shortens gut transit time by accelerating passage of the fecal bolus through the colon with marked acceleration in the right colon, thus causing an increase in colonic bile acid output and a shift in bile acid composition toward the more diarrheagenic secondary bile acids, that is, deoxycholic acid. Diarrhea that is severe enough, that is, three or more watery movements per day, can be classified as postcholecystectomy diarrhea, and this occurs in 5–10% of patients undergoing elective cholecystectomy. Treatment with bile acid–sequestering agents such as cholestyramine or colestipol is often effective in ameliorating troublesome diarrhea.

THE HYPERPLASTIC CHOLECYSTOSES

The term *hyperplastic cholecystoses* is used to denote a group of disorders of the gallbladder characterized by excessive proliferation of normal tissue components.

Adenomyomatosis is characterized by a benign proliferation of gallbladder surface epithelium with glandlike formations, extramural sinuses, transverse strictures, and/or fundal nodule ("adenoma" or "adenomyoma") formation.

Cholesterolosis is characterized by abnormal deposition of lipid, especially cholesteryl esters, within macrophages in the lamina propria of the gallbladder wall. In its diffuse form ("strawberry gallbladder"), the gallbladder mucosa is brick red and speckled with bright yellow flecks of lipid. The localized form shows solitary or multiple "cholesterol polyps" studding the gallbladder wall. Cholesterol stones of the gallbladder are found in nearly half the cases. Cholecystectomy is only indicated in adenomyomatosis or cholesterolosis when biliary symptoms are present.

The prevalence of gallbladder polyps in the adult population is 3–6% with a marked male predominance. Types of gallbladder polyps include cholesterol polyps, adenomyomas, inflammatory polyps, and adenomas (rare). No significant changes have been found over a 5-year period in asymptomatic patients with gallbladder polyps <6 mm and few changes in polyps 7–9 mm. Currently, cholecystectomy is recommended in symptomatic patients as well as in asymptomatic patients >50 years whose polyps are >10 mm or associated with gallstones or polyp growth on serial ultrasonography. A recent consensus conference of the Society of Radiologists in Ultrasound recommends that patients with polyps between 10 and 14 mm and low-risk radiologic features could be monitored instead of undergoing cholecystectomy.

DISEASES OF THE BILE DUCTS

CONGENITAL ANOMALIES

Biliary Atresia and Hypoplasia Atretic and hypoplastic lesions of the extrahepatic and large intrahepatic bile ducts are the most common biliary anomalies of clinical relevance encountered in infancy. The clinical picture is one of severe obstructive jaundice during the first month of life, with pale stools. When biliary atresia is suspected on the basis of clinical, laboratory, and imaging findings, the diagnosis is confirmed by surgical exploration and operative cholangiography. Approximately 10% of cases of biliary atresia are treatable with Roux-en-Y choledochojejunostomy, with the Kasai procedure (hepatic portoenterostomy) being attempted in the remainder in an effort to restore some bile flow. Most patients, even those having successful biliary-enteric anastomoses, eventually develop chronic cholangitis, extensive hepatic fibrosis, and portal hypertension.

Choledochal Cysts Cystic dilatation may involve the free portion of the CBD, that is, choledochal cyst, or may present as diverticulum formation in the intraduodenal segment. In the latter situation, chronic reflux of pancreatic juice into the biliary tree can produce inflammation and stenosis of the extrahepatic bile ducts, leading to cholangitis or biliary obstruction. Because the process may be gradual, ~50% of patients present with onset of symptoms after age 10. The diagnosis may be made by ultrasound, abdominal CT, MRCP, or cholangiography. Only one-third of patients show the classic triad of abdominal pain, jaundice, and an abdominal mass. Ultrasonographic detection of a cyst separate from the gallbladder should suggest the diagnosis of choledochal cyst, which can be confirmed by demonstrating the entrance of extrahepatic bile ducts into the cyst. Surgical treatment involves excision of the "cyst" and biliary-enteric anastomosis. Patients with choledochal cysts are at increased risk for cholangiocarcinoma.

Congenital Biliary Ectasia Dilatation of intrahepatic bile ducts may involve either the major intrahepatic radicles (Caroli's disease), the inter- and intralobular ducts (congenital hepatic fibrosis), or both. In Caroli's disease, clinical manifestations include recurrent cholangitis, abscess formation in and around the affected ducts, and, often, brown pigment gallstone formation within portions of ectatic intrahepatic biliary radicles. Ultrasound, MRCP, and CT are of great diagnostic value in demonstrating cystic dilatation of the intrahepatic bile ducts. Treatment with ongoing antibiotic therapy is usually undertaken in an effort to limit the frequency and severity of recurrent bouts of cholangitis. Progression to secondary biliary cirrhosis with portal hypertension, extrahepatic biliary obstruction, cholangiocarcinoma, or recurrent episodes of sepsis with hepatic abscess formation is common.

CHOLEDOCHOLITHIASIS

Pathophysiology and Clinical Manifestations Passage of gallstones into the CBD occurs in ~10–15% of patients with cholelithiasis. The incidence of common duct stones increases with increasing age of the patient, so up to 25% of elderly patients may have calculi in the common duct at the time of cholecystectomy. Undetected duct stones are left behind in ~1–5% of cholecystectomy patients. The overwhelming majority of bile duct stones are cholesterol stones formed in the gallbladder, which then migrate into the extrahepatic biliary tree through the cystic duct. Primary calculi arising de novo in the ducts are usually brown pigment stones developing in patients with (1) hepatobiliary parasitism or chronic, recurrent cholangitis; (2) congenital anomalies of the bile ducts (especially Caroli's disease); (3) dilated, sclerosed, or strictured ducts; or (4) an *MDR3* (ABCB4) gene defect leading to impaired biliary phospholipids secretion (low phospholipid–associated cholesterol cholelithiasis). Common duct stones may remain asymptomatic for years, may pass spontaneously into the duodenum, or (most often) may present with biliary colic or a complication.

Complications • **CHOLANGITIS** Cholangitis may be acute or chronic, and symptoms result from inflammation, which usually is caused by at least partial obstruction to the flow of bile. Bacteria are present on bile culture in ~75% of patients with acute cholangitis early in the symptomatic course. The characteristic presentation of acute cholangitis involves biliary pain, jaundice, and spiking fevers with chills (Charcot's triad). Blood cultures are frequently positive, and leukocytosis is typical. *Nonsuppurative acute cholangitis* is most common and may respond relatively rapidly to supportive measures and to treatment with antibiotics. In *suppurative acute cholangitis*, however, the presence of pus under pressure in a completely obstructed ductal system leads to symptoms of severe toxicity—mental confusion, bacteremia, and septic shock. Response to antibiotics alone in this setting is relatively poor, multiple hepatic abscesses are often present, and the mortality rate approaches 100% unless prompt endoscopic or surgical relief of the obstruction and drainage of infected bile are carried out. Endoscopic management of bacterial cholangitis is as effective as surgical intervention. ERCP with endoscopic sphincterotomy is safe and the preferred initial procedure for both establishing a definitive diagnosis and providing effective therapy.

OBSTRUCTIVE JAUNDICE Gradual obstruction of the CBD over a period of weeks or months usually leads to initial manifestations of jaundice or pruritus without associated symptoms of biliary colic or cholangitis. Painless jaundice may occur in patients with choledocholithiasis but is much more characteristic of biliary obstruction secondary to malignancy of the head of the pancreas, bile ducts, or ampulla of Vater.

In patients whose obstruction is secondary to choledocholithiasis, associated chronic calculous cholecystitis is very common, and the gallbladder in this setting may be unable to distend. The absence of a palpable gallbladder in most patients with biliary obstruction from duct stones is the basis for Courvoisier's law, that is, that the presence of a palpably enlarged gallbladder suggests that the biliary obstruction is secondary to an underlying malignancy rather than to calculous disease. Biliary obstruction causes progressive dilatation of the intrahepatic bile ducts as intrabiliary pressures rise. Hepatic bile flow is suppressed, and reabsorption and regurgitation of conjugated bilirubin into the bloodstream lead to jaundice accompanied by dark urine (bilirubinuria) and light-colored (acholic) stools.

CBD stones should be suspected in any patient with cholecystitis whose serum bilirubin level is >85.5 μmol/L (5 mg/dL). The maximum bilirubin level is seldom >256.5 μmol/L (15.0 mg/dL) in patients with choledocholithiasis unless concomitant hepatic or renal disease or another factor leading to marked hyperbilirubinemia exists. Serum bilirubin levels ≥342.0 μmol/L (20 mg/dL) should suggest the possibility of neoplastic obstruction. The serum alkaline phosphatase level is almost always elevated in biliary obstruction. A rise in alkaline phosphatase often precedes clinical jaundice and may be the only abnormality in routine liver function tests. There may be a two- to tenfold elevation of serum aminotransferases, especially in association with acute obstruction. Following relief of the obstructing process, serum aminotransferase elevations usually return rapidly to normal, while the serum bilirubin level may take 1–2 weeks to return to normal. The alkaline phosphatase level usually falls slowly, lagging behind the decrease in serum bilirubin.

PANCREATITIS The most common associated entity discovered in patients with nonalcoholic acute pancreatitis is biliary tract disease. Biochemical evidence of pancreatic inflammation complicates acute cholecystitis in 15% of cases and choledocholithiasis in >30%, and the common factor appears to be the passage of gallstones through the common duct. Coexisting pancreatitis should be suspected in patients with symptoms of cholecystitis who develop (1) back pain or pain to the left of the abdominal midline, (2) prolonged vomiting with paralytic ileus, or (3) a pleural effusion, especially on the left side. Surgical treatment of gallstone disease is usually associated with resolution of the pancreatitis.

SECONDARY BILIARY CIRRHOSIS Secondary biliary cirrhosis may complicate prolonged or intermittent duct obstruction with or without recurrent cholangitis. Although this complication may be seen in patients with choledocholithiasis, it is more common in cases of

prolonged obstruction from stricture. Once established, secondary biliary cirrhosis may be progressive even after correction of the obstructing process, and increasingly severe hepatic cirrhosis may lead to portal hypertension, hepatic failure and death. Prolonged biliary obstruction may also be associated with clinically relevant deficiencies of the fat-soluble vitamins A, D, E, and K.

Diagnosis and Treatment The diagnosis of choledocholithiasis is made by cholangiography (Table 357-3), either preoperatively by endoscopic retrograde cholangiogram (ERC) (Fig. 357-2*C*) or MRCP or intraoperatively at the time of cholecystectomy. As many as 15% of patients undergoing cholecystectomy will prove to have CBD stones. When CBD stones are suspected prior to laparoscopic cholecystectomy, preoperative ERCP with endoscopic papillotomy and stone extraction is the preferred approach. It not only provides stone clearance but also defines the anatomy of the biliary tree in relationship to the cystic duct. CBD stones should be suspected in gallstone patients who have any of the following risk factors: (1) a history of jaundice or pancreatitis, (2) abnormal tests of liver function, and (3) ultrasonographic or MRCP evidence of a dilated CBD or stones in the duct. Alternatively, if intraoperative cholangiography reveals retained stones, postoperative ERCP can be carried out. The need for preoperative ERCP is expected to decrease further as laparoscopic techniques for bile duct exploration improve.

The widespread use of laparoscopic cholecystectomy and ERCP has decreased the incidence of complicated biliary tract disease and the need for choledocholithotomy and T-tube drainage of the bile ducts. EBS followed by spontaneous passage or stone extraction is the treatment of choice in the management of patients with common duct stones, especially in elderly or poor-risk patients.

TRAUMA, STRICTURES, AND HEMOBILIA

Most benign strictures of the extrahepatic bile ducts result from surgical trauma and occur in about 1 in 500 cholecystectomies. Strictures may present with bile leak or abscess formation in the immediate postoperative period or with biliary obstruction or cholangitis as long as

TABLE 357-3 Diagnostic Evaluation of the Bile Ducts

DIAGNOSTIC ADVANTAGES	DIAGNOSTIC LIMITATIONS	CONTRAINDICATIONS	COMPLICATIONS	COMMENT
Ultrasound				
Rapid Simultaneous scanning of GB, liver, bile ducts, pancreas Accurate identification of dilated bile ducts Not limited by jaundice, pregnancy Guidance for fine-needle biopsy	Bowel gas Massive obesity Ascites Barium Partial bile duct obstruction Poor visualization of distal CBD	None	None	Initial procedure of choice in investigating possible biliary tract obstruction
Computed Tomography				
Simultaneous scanning of GB, liver, bile ducts, pancreas Accurate identification of dilated bile ducts, masses Not limited by jaundice, gas, obesity, ascites High-resolution image Guidance for fine-needle biopsy	Extreme cachexia Movement artifact Ileus Partial bile duct obstruction	Pregnancy	Reaction to iodinated contrast, if used	Indicated for evaluation of hepatic or pancreatic masses or for assessing for complications related to gallstones (pancreatitis) Procedure of choice in investigating possible biliary obstruction if diagnostic limitations limit US
Magnetic Resonance Cholangiopancreatography				
Noninvasive modality for visualizing pancreatic and biliary ducts Has excellent sensitivity for bile duct dilatation, biliary stricture, and intraductal abnormalities Can identify pancreatic duct dilatation or stricture, pancreatic duct stenosis, and pancreas divisum	Cannot offer therapeutic intervention High cost	Claustrophobia Certain metals (iron)	None	First choice to assess for choledocholithiasis given comparable sensitivity and specificity to ERCP
Endoscopic Retrograde Cholangiopancreatography				
Simultaneous pancreatography Best visualization of distal biliary tract Bile or pancreatic cytology Endoscopic sphincterotomy and stone removal Biliary manometry	Gastroduodenal obstruction Roux-en-Y biliary-enteric anastomosis	Pregnancy Acute pancreatitis Severe cardiopulmonary disease	Pancreatitis Cholangitis, sepsis Infected pancreatic pseudocyst Perforation (rare) Hypoxemia, aspiration	Cholangiogram of choice if there is believed to be a need for intervention: Diagnosed or high clinical probability of choledocholithiasis Biliary stricture requiring sampling and stenting Need for sphincterotomy such as sphincter of Oddi dysfunction
Percutaneous Transhepatic Cholangiogram				
Best when bile ducts dilated Best visualization of proximal biliary tract May be used to obtain bile cytology/culture Allows for percutaneous transhepatic drainage	Nondilated or sclerosed ducts	Pregnancy Uncorrectable coagulopathy Massive ascites Hepatic abscess	Bleeding Hemobilia Bile peritonitis Bacteremia, sepsis	Indicated for the drainage of obstructed and infected ducts when ERCP is contraindicated or failed
Endoscopic Ultrasound				
Most sensitive method to detect ampullary stones and exclude pathology in the head of the pancreas				Excellent for detecting choledocholithiasis

Abbreviations: CBD, common bile duct; ERCP, endoscopic retrograde cholangiopancreatography; GB, gallbladder; US, hepatobiliary ultrasound.

2 years or more following the inciting trauma. The diagnosis is established by percutaneous or endoscopic cholangiography. Endoscopic brushing of biliary strictures may be helpful in establishing the nature of the lesion and is more accurate than bile cytology alone. When positive exfoliative cytology is obtained, the diagnosis of a neoplastic stricture is established. This procedure is especially important in patients with primary sclerosing cholangitis (PSC) who are predisposed to the development of cholangiocarcinomas. Successful operative correction of non-PSC bile duct strictures by a skillful surgeon with duct-to-bowel anastomosis is usually possible, although mortality rates from surgical complications, recurrent cholangitis, or secondary biliary cirrhosis are high.

Hemobilia may follow traumatic or operative injury to the liver or bile ducts, intraductal rupture of a hepatic abscess or aneurysm of the hepatic artery, biliary or hepatic tumor hemorrhage, or mechanical complications of choledocholithiasis or hepatobiliary parasitism. Diagnostic procedures such as liver biopsy, PTC, and transhepatic biliary drainage catheter placement may also be complicated by hemobilia. Patients often present with a classic triad of biliary pain, obstructive jaundice, and melena or occult blood in the stools. The diagnosis is sometimes made by cholangiographic evidence of blood clot in the biliary tree, but selective angiographic verification may be required. Although minor episodes of hemobilia may resolve without intervention, arteriography and transcatheter embolization or surgical ligation of the bleeding vessel may be required.

EXTRINSIC COMPRESSION OF THE BILE DUCTS

Partial or complete biliary obstruction may be produced by extrinsic compression of the ducts. The most common cause of this form of obstructive jaundice is carcinoma of the head of the pancreas. Biliary obstruction may also occur as a complication of either acute or chronic pancreatitis or involvement of lymph nodes in the porta hepatis by lymphoma or metastatic carcinoma. The latter should be distinguished from cholestasis resulting from massive replacement of the liver by tumor.

HEPATOBILIARY PARASITISM

Infestation of the biliary tract by adult helminths or their ova may produce a chronic, recurrent pyogenic cholangitis with or without multiple hepatic abscesses, ductal stones, or biliary obstruction. This condition is relatively rare but does occur in inhabitants of southern China and elsewhere in Southeast Asia. The organisms most commonly involved are trematodes or flukes, including *Clonorchis sinensis*, *Opisthorchis viverrini* or *Opisthorchis felineus*, and *Fasciola hepatica*. The biliary tract also may be involved by intraductal migration of adult *Ascaris lumbricoides* from the duodenum or by intrabiliary rupture of hydatid cysts of the liver produced by *Echinococcus* spp. The diagnosis is made by cholangiography and the presence of characteristic ova on stool examination. When obstruction is present, the treatment of choice is laparotomy under antibiotic coverage, with common duct exploration and a biliary drainage procedure.

SCLEROSING CHOLANGITIS

PSC is characterized by a progressive, inflammatory, sclerosing, and obliterative process affecting the extrahepatic and/or the intrahepatic bile ducts. PSC is strongly associated with inflammatory bowel disease, especially ulcerative colitis.

Immunoglobulin G4 (IgG4)–associated cholangitis is a biliary disease of unknown etiology that presents with biochemical and cholangiographic features indistinguishable from PSC, is often associated with autoimmune pancreatitis and other fibrosing conditions and is characterized by elevated serum IgG4 and infiltration of IgG4-positive plasma cells in bile ducts and liver tissue. All patients diagnosed with sclerosing cholangitis should have a serum IgG4 level checked to rule out IgG4 disease as a cause of secondary sclerosing cholangitis, particularly if they do not have inflammatory bowel disease. Glucocorticoids are the initial treatment of choice. Relapse is common after steroid withdrawal, especially with proximal strictures. Steroid-sparing agents such as azathioprine or rituximab may be needed after relapse or for inadequate response **(Chap. 359)**.

Patients with PSC often present with signs and symptoms of chronic or intermittent biliary obstruction: RUQ abdominal pain, pruritus, jaundice, or acute cholangitis. Late in the course, complete biliary obstruction, secondary biliary cirrhosis, hepatic failure, and/or portal hypertension with bleeding varices may occur. The diagnosis is established by finding multifocal, diffusely distributed strictures with intervening segments of normal or dilated ducts, producing a beaded appearance on cholangiography **(Fig. 357-2*D*)**. The cholangiographic technique of choice in suspected cases is MRCP. When a diagnosis of sclerosing cholangitis has been established, causes of secondary sclerosing should be considered before reaching a diagnosis of PSC. Patients with PSC should undergo testing for associated diseases, especially inflammatory bowel disease, if that diagnosis has not already been established.

Small duct PSC is defined by the presence of chronic cholestasis and hepatic histology consistent with PSC in a patient with IBD, but with normal findings on cholangiography. Small duct PSC is found in ~5% of patients with PSC and is associated with a significantly better long-term prognosis. However, such patients may progress to classic PSC and/or end-stage liver disease with consequent necessity of liver transplantation.

In patients with AIDS, cholangiopancreatography may demonstrate a broad range of biliary tract changes as well as pancreatic duct obstruction and occasionally pancreatitis **(Chap. 208)**. Further, biliary tract lesions in AIDS include infection and cholangiopancreatographic changes of sclerosing cholangitis. Changes noted include (1) diffuse involvement of intrahepatic bile ducts alone, (2) involvement of both intra- and extrahepatic bile ducts, (3) ampullary stenosis, (4) stricture of the intrapancreatic portion of the CBD, and (5) pancreatic duct involvement. Associated infectious organisms include *Cryptosporidium*, *Mycobacterium avium-intracellulare*, cytomegalovirus, *Microsporidia*, and *Isospora*. ERCP sphincterotomy can provide significant pain reduction in patients with AIDS-associated papillary stenosis.

TREATMENT

Primary Sclerosing Cholangitis

There is no proven medical therapy for PSC. Therapy to treat pruritus associated with PSC includes cholestyramine, rifampin, fenofibrate/bezafibrate, sertraline, and naltrexone. Antibiotics are useful when bacterial cholangitis complicates the clinical picture. Vitamin D and calcium supplementation may be used as initial therapy to help prevent the loss of bone mass frequently seen in patients with chronic cholestasis. In cases where high-grade biliary obstruction (dominant strictures) has occurred, balloon dilatation is preferred over stenting due to the higher complication rate associated with stenting including pancreatitis and cholangitis. Only rarely is surgical intervention indicated. PSC is a progressive disease with a median survival of 12–18 years following the diagnosis, regardless of therapy. Four variables (age, serum bilirubin level, histologic stage, and splenomegaly) predict survival in patients with PSC and serve as the basis for a risk score. PSC is a common indication for liver transplantation.

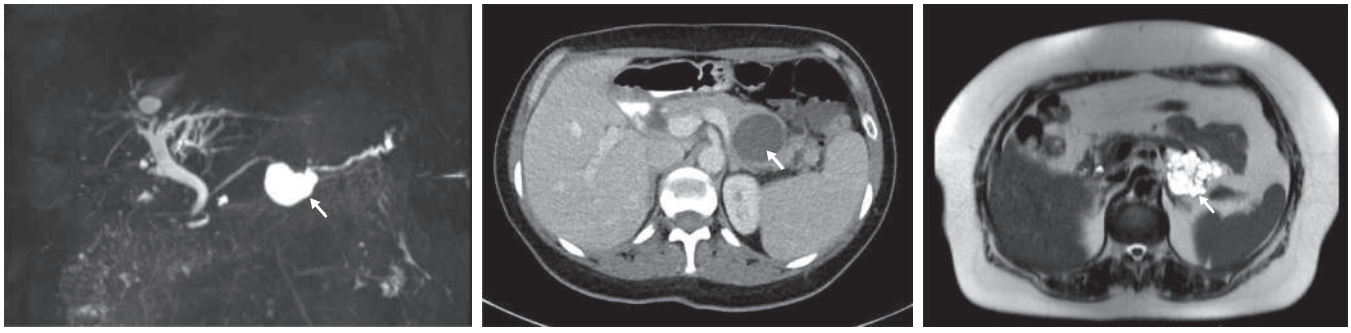
358 Approach to the Patient with Pancreatic Disease

Somashekar G. Krishna, Darwin L. Conwell, Phil A. Hart

GENERAL CONSIDERATIONS



Globally, pancreatic disorders, including acute and chronic pancreatitis, pancreatic cysts, and pancreatic cancer, are challenging to manage and associated with a high burden on health care resources. While the relationships between these diseases are multifaceted, there is ongoing scientific progress and a growing understanding in this field. Acute pancreatitis is one of the most common reasons for hospitalizations in gastroenterology, and there is increasing evidence of sequelae including diabetes, exocrine pancreas insufficiency, and chronic pancreatitis. In elderly patients, acute pancreatitis may serve as an early symptom of pancreatic cancer. Chronic pancreatitis, an irreversible disease of the pancreas, associated with poor quality of life due to abdominal pain and associated exocrine insufficiency, is also an established risk factor for pancreatic cancer. Pancreatic cysts, mostly incidental, are increasingly detected on cross-sectional abdominal imaging studies. Although only a small proportion of pancreatic cysts can progress to pancreatic cancer, the diagnostic uncertainty can introduce unwanted anxiety to patients and treating physicians. Meanwhile, with persistently high mortality rates, the incidence of pancreatic adenocarcinoma is increasing and is the seventh leading cause of cancer-related death in the industrialized world and the third most common in the United States.

As emphasized in **Chap. 359**, the etiologies and clinical manifestations of pancreatitis are quite varied. Although it is well-appreciated that acute pancreatitis is frequently secondary to biliary tract disease or alcohol abuse, it can also be caused by medications, genetic mutations, and trauma. In ~30% of patients with acute pancreatitis and 25–40% of patients with chronic pancreatitis, the etiology is initially unexplained.

The global pooled incidence of acute pancreatitis is ~33.7 cases (95% confidence interval [CI], 23.3–48.8) with 1.16 deaths (95% CI, 0.85–1.6) per 100,000 person-years. The global pooled incidence of chronic pancreatitis is ~9.6 cases (95% CI, 7.9–11.8) with 0.09 attributable deaths (95% CI, 0.02–0.5) per 100,000 person-years. In the United States, the number of patients admitted to the hospital with acute pancreatitis is increasing, with estimated rates of almost 300,000 annually, whereas the number of patients hospitalized for chronic pancreatitis is decreasing, with recent estimates of ~13,000 admissions per year. Chronic pancreatitis has an annual prevalence of 42–73 cases per 100,000 adults in the United States, although higher prevalence rates (0.04–5%) have been noted among adults at autopsy. Together, acute and chronic pancreatic disease costs an estimated $3 billion annually in health care expenditures. During the COVID-19 pandemic, it was noted that the infection was associated with elevated pancreas enzyme serum levels and presumed acute pancreatitis, though causal relationships have not been definitively established.

The diagnosis of acute pancreatitis is generally defined based on a combination of laboratory, imaging, and clinical symptoms. The diagnosis of chronic pancreatitis, especially in mild disease, is hampered by the relative inaccessibility of the pancreas to direct examination and the nonspecificity of the associated abdominal pain. Many patients with chronic pancreatitis do not have elevated blood amylase or lipase levels. Some patients with chronic pancreatitis develop signs and symptoms of exocrine pancreatic insufficiency (EPI), and thus, objective evidence for pancreatic disease can be demonstrated. However, there is a large reservoir of pancreatic exocrine function. Maldigestion of fat and protein becomes evident only when more than 90% of the pancreas is functionally damaged or obstructed. Noninvasive, indirect tests of pancreatic exocrine function (e.g., fecal elastase) are much more likely to give abnormal results in patients with obvious advanced pancreatic disease (i.e., pancreatic calcification, steatorrhea, or diabetes mellitus) than in patients with occult disease. Invasive, direct tests of pancreatic secretory function (e.g., secretin stimulation test) are the most sensitive and specific tests to detect early chronic pancreatic disease when imaging is equivocal or normal.

The increasing utilization of cross-sectional imaging modalities with their improved resolution has contributed to a high prevalence (2–5% with computed tomography [CT] scans, 20–30% with magnetic resonance imaging [MRI]) of incidentally detected pancreatic cysts. The most common cyst type encountered is an intraductal papillary mucinous neoplasm (IPMN), which is classified as a precancerous mucinous cyst. In the absence of high-risk features, radiographic surveillance is typically recommended **(Fig. 358-1)**. Mucinous cystic neoplasms (MCNs) are relatively less common and occur almost exclusively in women. Among the neoplastic cysts, serous cystadenomas have a negligible risk of progression to malignancy. Other infrequent neoplastic cysts include neuroendocrine tumors and solid pseudopapillary neoplasms. The most commonly encountered benign cyst is a pseudocyst, which can occur in patients with a history of acute

A ***B*** ***C***

FIGURE 358-1 ***A.*** Side-branch intraductal papillary mucinous neoplasm (magnetic resonance imaging [MRI] with magnetic resonance cholangiopancreatography [MRCP]). T2-weighted MRCP image demonstrates a dominant, lobulated, hyperintense cystic structure (*arrow*) within the posterior body of the pancreas. The pancreatic duct upstream from the cyst is dilated and irregular. Endoscopic ultrasound and fine-needle aspiration of cyst fluid were consistent with a mucinous cyst. Surgical histopathology revealed an infiltrating moderately differentiated adenocarcinoma, 0.3 cm, arising in a background of an intraductal papillary mucinous neoplasm (IPMN). ***B.*** Mucinous cystic neoplasm (computed tomography [CT] scan). In the tail of the pancreas, there is a well-circumscribed hypodense cyst (*arrow*) without any nodular enhancing components. Endoscopic ultrasound and fine-needle aspiration of cyst fluid were suggestive of a mucinous cyst. Surgical histopathology revealed a mucinous cystic neoplasm (3.4 cm) with low-grade dysplasia. The stroma of the cyst demonstrated diffuse positivity for progesterone receptor and focal positivity for CD10 (ovarian stroma), confirming the diagnosis. ***C.*** Serous cystadenoma (MRI). A lobulated microcystic cyst (*arrow*) is observed in the tail of the pancreas. Neither a communication with the main pancreatic duct nor intracystic soft tissue enhancing nodular components were observed. However, the cyst continued to increase in size, and a distal pancreatectomy was performed. Histopathology revealed a serous microcystic adenoma. *(Courtesy of Dr. Z.K. Shah, The Ohio State University Wexner Medical Center; with permission.)*

or chronic pancreatitis. The challenges with accurately predicting the risk of malignant transformation of precancerous pancreatic cysts has contributed to the growing number of patients on imaging surveillance protocols placing a burden on health care systems in industrialized nations.

TESTS USEFUL IN THE DIAGNOSIS OF PANCREATIC DISEASE

Several tests are of value in the evaluation of pancreatic disease. Examples of specific tests and their usefulness in the diagnosis of acute and chronic pancreatitis are summarized in Table 358-1 and Fig. 358-2. At some

TABLE 358-1 Tests Useful in the Diagnosis of Acute and Chronic Pancreatitis and Pancreatic Neoplasms

TEST	PRINCIPLE	COMMENT
Pancreatic Enzymes in Body Fluids		
Serum lipase	Pancreatic inflammation leads to increased serum enzyme levels	Enzyme measurement of choice for the diagnosis of acute pancreatitis; increased specificity if the level is more than three times the upper limit of normal (3× ULN)
Amylase		
1. Serum	Pancreatic inflammation leads to increased serum enzyme levels	Simple; increased specificity if the level is >3× ULN; may be falsely normal in patients with hypertriglyceridemic pancreatitis
2. Urine	Renal clearance of amylase is increased in acute pancreatitis	Infrequently used
3. Ascitic fluid	Disruption of gland or main pancreatic duct leads to increased amylase concentration	Can help establish source of ascites; false positives occur with intestinal obstruction and perforated ulcer; can also measure lipase
4. Pleural fluid	Exudative pleural effusion with pancreatitis	False positives occur with carcinoma of the lung and esophageal perforation
Studies Pertaining to Pancreatic Structure		
Radiologic and radionuclide tests		
1. Plain film of the abdomen or upper gastrointestinal x-rays	Can demonstrate large calcifications in chronic pancreatitis	Infrequently used
1. Ultrasonography (US)	Can provide limited information on edema, inflammation, calcification, pseudocysts, and mass lesions	Simple, noninvasive; sequential studies quite feasible; useful in diagnosis of gallstones; pancreas visualization limited by interference from overlying bowel gas
2. Computed tomography (CT) scan	Permits detailed visualization of pancreas and surrounding structures, pancreatic fluid collection, pseudocyst; assessment of necrosis or interstitial disease	Useful in the diagnosis of pancreatic calcification, dilated pancreatic ducts, and pancreatic tumors; may not be able to distinguish between inflammatory and neoplastic mass lesions; multiphasic CT scans are the preferred imaging modality for staging pancreatic cancer; IV contrast is needed for characterization of most features
3. Magnetic resonance imaging (MRI) and cholangiopancreatography (MRCP)	Permits noninvasive detailed evaluation of the pancreatic parenchyma, biliary and pancreatic ducts, adjacent soft tissues, and vascular structures.	Has mostly replaced ERCP for diagnostic assessment of the pancreatic duct; more sensitive than CT scan for detection of mild pancreatitis, necrosis, choledocholithiasis, pancreatic ductal abnormalities, and cystic neoplasms; no exposure to ionizing radiation
4. Endoscopic ultrasonography (EUS) and fine-needle aspiration/biopsy (FNA/B)	High-frequency transducer used with EUS produces very-high-resolution images permitting focused evaluation of pancreatic parenchyma and biliary and pancreatic ducts, and FNA/B provides targeted tissue acquisition	Can be used to assess gallstones, choledocholithiasis, chronic pancreatitis, pancreatic masses, and cystic neoplasms; FNA/B facilitates diagnostic and therapeutic management of pancreatic diseases
5. Endoscopic retrograde cholangiopancreatography (ERCP)	Cannulation of pancreatic and/or common bile duct permits visualization of pancreaticobiliary ductal system	Primarily a therapeutic procedure; invasive with risks for iatrogenic complications
Tests of Exocrine Pancreatic Function		
Direct stimulation of the pancreas with analysis of duodenal contents		
1. Secretin test	Secretin leads to increased output of pancreatic juice and HCO_3^-; pancreatic secretory response is related to the functional mass of pancreatic tissue; involves duodenal intubation and fluoroscopic placement of gastroduodenal tube	Sensitive to detect occult disease; poorly defined normal enzyme response; large secretory reserve capacity of the pancreas; rarely performed
2. Endoscopic pancreatic function test (ePFT)	Secretin-stimulated collection of pancreatic juice performed during upper endoscopy; replaces need for tube placement in the duodenum	Sensitive to detect occult disease; high negative predictive value for chronic pancreatitis; requires sedation
3. EUS-ePFT	Combines endosonographic evaluation of the pancreas and endoscopic collection of pancreatic juice	Single endoscopic evaluation of pancreatic structure and function
4. Secretin-stimulated MRCP	Combines imaging evaluation of the pancreas and a semiquantitative estimation of pancreatic juice output in the duodenum	Improved visualization of pancreatic ductal anatomy; functional evaluation is less accurate than ePFT; noninvasive
Measurement of intraluminal digestion products		
1. Stool fat determination	Lack of lipolytic enzymes brings about impaired fat digestion; quantitative 72-h stool collection and estimation are more reliable than qualitative analysis of a random stool sample	Reliable reference standard for defining severity of fat malabsorption; does not distinguish between pancreatic and nonpancreatic cause of malabsorption
Measurement of pancreatic enzymes in feces		
1. Fecal elastase	Pancreatic secretion of proteolytic enzymes; not degraded in intestine	Diagnostic accuracy is highest when the pretest probability is high and the value is <100 μg/g; false positives will occur in patients with nonformed stools

	• **Clinical signs and symptoms suggestive of chronic pancreatic disease:** abdominal pain, nausea, weight loss, steatorrhea, malabsorption, history of alcohol abuse, recurrent pancreatitis, fatty-food intolerance • Perform history, physical examination, review of laboratory studies; consider fecal elastase measurement
Step 1	• **Contrast-enhanced CT scan** • *CP diagnostic criteria*: calcifications in combination with atrophy and/or dilated duct • Diagnostic criteria met; no further imaging needed • Inconclusive or nondiagnostic results; continue to step 2
Step 2	• **MRI and MRCP, with or without secretin enhancement (sMRCP)** • *CP diagnostic criteria*: Cambridge class III,[a] dilated duct, atrophy of gland, filling defects in duct suggestive of stones • Diagnostic criteria met; no further imaging needed • Inconclusive or nondiagnostic results; continue to step 3
Step 3	• **EUS with quantification of parenchymal and ductal criteria** • *CP diagnostic criteria*: ≥5 EUS CP criteria • Diagnostic criteria met; no further imaging needed • Inconclusive or nondiagnostic results; continue to step 4
Step 4	• **Pancreas function test (with secretin)—endoscopic (ePFT) collection method preferred; consider combining ePFT with EUS** • *CP diagnostic criteria*: peak [bicarbonate] <80 mEq/L • Diagnostic criteria met; no further imaging needed • Inconclusive or nondiagnostic results require monitoring of signs and symptoms and repeat testing in 6 months–1 year

FIGURE 358-2 A stepwise diagnostic approach to the patient with suspected chronic pancreatitis (CP). Endoscopic ultrasonography (EUS) and magnetic resonance imaging (MRI) with secretin-stimulated magnetic resonance cholangiopancreatography (sMRCP/MRCP) are appropriate diagnostic alternatives to endoscopic retrograde cholangiopancreatography (ERCP). CT, computed tomography; ePFT, endoscopic pancreas function test. [a]Cambridge classification of pancreatic duct findings: class 0: normal—visualization of complete normal ductal anatomy; class I: equivocal—normal main duct, 1–3 abnormal side branches; class II: mild—normal main duct, >3 abnormal side branches; class III—dilated and irregular main duct, >3 abnormal side branches, small (<10 mm) cysts; class IV—irregular main duct, intraductal calculi, strictures, obstruction with dilation, or large (>10 mm) cysts.

institutions, pancreatic function tests are available and performed if the diagnosis of chronic pancreatitis remains a possibility after noninvasive tests (i.e., ultrasound, CT scan, MRI with magnetic resonance cholangiopancreatography [MRCP]) or invasive tests (i.e., endoscopic retrograde cholangiopancreatography [ERCP], endoscopic ultrasound [EUS]) have given normal or inconclusive results. In this regard, tests using *direct* stimulation of the pancreas with secretin are the most sensitive.

Pancreatic Enzymes in Body Fluids The serum amylase and lipase levels are widely used as screening tests for acute pancreatitis in the patient with acute abdominal pain or back pain. Lipase is more specific for the pancreas, and values greater than three times the upper limit of normal (3× ULN) in combination with epigastric pain strongly suggest the diagnosis of acute pancreatitis. In acute pancreatitis, the serum amylase and lipase are usually elevated within 24 h of onset and remain so for 3–7 days. Levels usually return to normal within 7 days unless there is pancreatic ductal disruption, ductal obstruction, or pseudocyst formation. Approximately 85% of patients with acute pancreatitis have threefold or greater elevated serum lipase and amylase levels. The values may be normal if (1) there is a delay (2–5 days) before blood samples are obtained, (2) the underlying disorder is chronic pancreatitis rather than acute pancreatitis, or (3) hypertriglyceridemia is present. Patients with hypertriglyceridemia and acute pancreatitis have been found to have spuriously low levels of amylase and perhaps lipase activity. In the absence of objective evidence of pancreatitis by abdominal ultrasound, contrast-enhanced CT scan, MRI with MRCP, or EUS, mild to moderate elevations of amylase and/or lipase are not helpful in making a diagnosis of chronic pancreatitis.

It should be noted that the serum amylase can be elevated in other conditions (Table 358-2), in part because the enzyme is found in many organs. In addition to the pancreas and salivary glands, small quantities of amylase are found in the tissues of the fallopian tubes, lung, thyroid, and tonsils and can be produced by various tumors (carcinomas of the lung, esophagus, breast, and ovary). Isoamylase determinations do not accurately distinguish elevated blood amylase levels from pancreatic or nonpancreatic sources. In patients with unexplained hyperamylasemia, the measurement of macroamylase can avoid numerous tests in patients with this rare disorder.

Elevation of ascitic fluid amylase occurs in acute pancreatitis as well as in (1) ascites due to disruption of the main pancreatic duct or a leaking pseudocyst and (2) other abdominal disorders that simulate pancreatitis (e.g., intestinal obstruction, intestinal infarction, or perforated peptic ulcer). Elevation of pleural fluid amylase can occur in acute pancreatitis, chronic pancreatitis, carcinoma of the lung, and esophageal perforation. Serum lipase is the single best enzyme to measure for the diagnosis of acute pancreatitis. It is important to acknowledge that levels are often mildly elevated in the setting of renal disease, so determining whether a patient with renal failure and abdominal pain has pancreatitis remains a challenging clinical problem. One study found that serum amylase levels were elevated in patients with renal dysfunction only when creatinine clearance was <0.8 mL/s (<50 mL/min). In such patients, the serum amylase level was invariably <500 IU/L in the absence of objective evidence of acute pancreatitis. In that study, serum lipase and trypsin levels paralleled serum amylase values. With these limitations in mind, the recommended screening test for acute pancreatitis in renal disease is serum lipase, but a high index of clinical suspicion is needed based on symptoms. Elevations in serum lipase >3× ULN due to nonpancreatic etiology can be observed in hepatobiliary or gastrointestinal malignancies, septicemia, liver cirrhosis, systemic lupus erythematosus, severe head injury, chronic alcoholism, diabetes mellitus, and post-ERCP without any associated evidence of pancreatitis.

COVID-19 infection has been associated with asymptomatic elevations of both amylase and lipase. In a systematic review of 21 studies involving 36,496 patients during the COVID-19 pandemic, the pooled prevalence of hyperlipasemia (>3 × ULN) and hyperamylasemia (>3 × ULN) was 5.6% (95% CI, 2.8–9.3%) and 4.0% (95% CI, 0.9–8.7%), respectively. Importantly, the overall prevalence of acute pancreatitis in this cohort was 1.7%. Abnormal levels of amylase and lipase were more closely associated with the severity of COVID-19 than a diagnosis of acute pancreatitis.

Studies Pertaining to Pancreatic Structure • **RADIOLOGIC TESTS** Plain films of the abdomen rarely provide useful information related to pancreatic disease and have been superseded by more detailed imaging studies (ultrasound, EUS, CT, and MRI with MRCP).

TABLE 358-2 Causes of Hyperamylasemia

Pancreatic Disease

I. Pancreatitis
  A. Acute
  B. Chronic: ductal obstruction
  C. Complications of pancreatitis
    1. Pancreatic pseudocyst
    2. Ascites caused by pancreatic duct disruption
    3. Pancreatic necrosis
II. Pancreatic trauma
III. Pancreatic adenocarcinoma

Nonpancreatic Disorders

I. Renal insufficiency
II. Salivary gland lesions
  A. Mumps
  B. Calculus
  C. Irradiation sialadenitis
  D. Maxillofacial surgery
III. "Tumor" hyperamylasemia
  A. Carcinoma of the lung, esophagus, breast, or ovary
IV. Macroamylasemia
V. Burns
VI. Diabetes mellitus, particularly when ketoacidosis is present
VII. Pregnancy
VIII. Renal transplantation
IX. COVID-19 infection
X. Cerebral trauma
XI. Drugs: opiates

Other Abdominal Disorders

I. Biliary tract disease: cholecystitis, choledocholithiasis
II. Intraabdominal disease
  A. Perforated or penetrating peptic ulcer
  B. Intestinal obstruction or inflammation
  C. Ruptured ectopic pregnancy
  D. Peritonitis
  E. Aortic aneurysm
  F. Postoperative hyperamylasemia

Ultrasonography (US) can provide important information in the initial emergency ward evaluation of patients with acute pancreatitis, chronic pancreatitis, pseudocysts, and pancreatic adenocarcinoma. Sonographic changes can indicate the presence of edema, inflammation, and calcification (not obvious on plain films of the abdomen), as well as gallstones, biliary dilation, pseudocysts, and mass lesions. In acute pancreatitis, the pancreas is characteristically enlarged. In pancreatic pseudocyst, the usual appearance is primarily that of a smooth, round fluid collection. Pancreatic adenocarcinoma distorts the usual landmarks, and mass lesions >3.0 cm are usually detected as localized, solid lesions. US is often the initial investigation for patients with suspected pancreatic disease. However, obesity and excess intestinal bowel gas can interfere with pancreatic imaging, limiting its sensitivity.

CT with intravenous contrast is the best imaging study for the assessment of complications of acute and chronic pancreatitis. It is especially useful in the detection of pancreatic and peripancreatic acute fluid collections, fluid-containing lesions such as pseudocysts, walled-off necrosis **(see Chap. 359, Figs. 359-1, 359-2, and 359-4)**, and pancreatic neoplasms. Acute pancreatitis is characterized by (1) enlargement of the pancreas, (2) distortion of the pancreatic contour with peripancreatic stranding of adjacent fat tissue, and/or (3) the presence of pancreatic fluid that has a different attenuation coefficient than normal pancreas. When possible, CT scans should ideally be performed with oral and intravenous contrast to detect areas of pancreatic necrosis. The major benefit of CT scan in acute pancreatitis is the diagnosis of pancreatic necrosis in patients not responding to conservative management within 72 h. It may take 48–72 h to develop perfusion defects indicative of pancreatic necrosis. Therefore, if acute pancreatitis is confirmed with serology and physical examination findings, CT scan in the first 3 days is not recommended to minimize risk of contrast-induced nephropathy and unnecessary health care costs. Improved imaging technology and increased resolution are facilitated by multiphasic CT scans using multidetector technology (MDCT) in which a pancreas protocol consisting of dual-phase scanning with intravenous contrast is utilized for the detection and staging of pancreatic cancers. While the sensitivity of MDCT for detecting smaller (≤2 cm) lesions is lower, the reported overall sensitivity for pancreatic cancers is 76–97%. The contraindications to using intravenous contrast include renal failure (serum creatinine >2 mg/dL) and a history of severe allergic reaction to iodinated contrast agents. In situations where EUS is not available, CT-guided percutaneous aspiration or biopsy of a pancreatic mass can be performed. Prior to the major advance of EUS-guided fine-needle aspiration (FNA), CT-guided biopsy was utilized in the preceding decades and is regarded as a safe procedure.

MRI and MRCP provide excellent imaging of the bile duct, pancreatic duct, and pancreas parenchyma in both acute pancreatitis and chronic pancreatitis. MRI is more sensitive than transabdominal US and CT scans and comparable to EUS for the detection of choledocholithiasis. Similar to CT, MRI can evaluate for the severity of acute pancreatitis. Moreover, T2-weighted MRI of fluid collections can differentiate necrotic debris from fluid in suspected walled-off necrosis, and T1 imaging can diagnose hemorrhage in suspected pseudoaneurysm rupture. In chronic pancreatitis, secretin-enhanced MRCP is a method to enhance the evaluation of major and minor ductal changes. While imaging is comparable to CT for evaluating pancreatic mass lesions, MRI with MRCP is the preferred imaging modality for evaluating pancreatic cystic lesions. Nephrogenic systemic fibrosis has been described in patients with chronic renal failure following exposure to the gadolinium contrast, but incidence rates are extraordinarily low with contemporary contrast agents.

EUS produces high-resolution images of the bile duct, pancreatic parenchyma, and pancreatic duct with a transducer fixed to an endoscope that can be directed onto the surface of the pancreas through the stomach or duodenum. EUS is not beneficial for the evaluation of pancreas during acute pancreatitis. It is preferable to perform EUS after the resolution of acute pancreatitis (~4 weeks) to detect any predisposing factors, including malignancy, choledocholithiasis, pancreatic divisum, or ampullary lesions. EUS can be combined with ERCP in a single session and is increasingly preferred for the diagnosis and management of choledocholithiasis in acute pancreatitis and pancreatic neoplasm with biliary obstruction. EUS has been studied as a diagnostic modality for chronic pancreatitis. Criteria for abnormalities on EUS in severe chronic pancreatic disease have been developed. There is general agreement that the presence of five or more of the nine criteria listed in **Table 358-3** is highly predictive of chronic pancreatitis in the correct clinical context. The sensitivity of EUS (81%; 95% CI, 70–89%) to diagnose chronic pancreatitis is comparable to that of MRI/MRCP (78%; 95% CI, 69–85%) and better than CT (75%; 95% CI, 66–83%); however, nonspecific changes are commonly seen in the pancreas that may be attributable to cigarette smoking, diabetes, or normal aging. EUS also facilitates the delivery of nerve-blocking agents via fine-needle injection in patients suffering from pancreatic pain from chronic pancreatitis (celiac plexus block) or cancer (celiac plexus neurolysis). When

TABLE 358-3 Endoscopic Ultrasonographic Criteria for Chronic Pancreatitis (Total Criteria = 9)

DUCTAL	PARENCHYMAL
Stones	Echogenic strands
Hyperechoic main duct margins	Echogenic foci
Main duct irregularity	Lobular contour
Main duct dilatation	Cysts
Visible side branches	

clinically suspected, EUS imaging is more sensitive than MDCT for the detection of pancreatic malignancy and permits fine-needle aspiration/biopsy (FNA/B). Currently, EUS-guided FNA/B is the diagnostic modality of choice for the acquisition of diagnostic tissue and cyst fluid in patients with pancreatic masses and cystic lesions, respectively.

Although a pancreatogram during ERCP is the most specific and sensitive test for evaluating the ductal anatomy, EUS and MRI/MRCP have largely replaced ERCP in the diagnostic evaluation of pancreatic disease to avoid the risk of complications. Therefore, ERCP is primarily of therapeutic value after CT, EUS, or MRI/MRCP has detected abnormalities requiring endoscopic treatment. ERCP is the most sensitive modality for the detection of bile duct stones. In the management of acute biliary pancreatitis, ERCP should not be unduly delayed in patients with high clinical suspicion of biliary obstruction. In chronic pancreatitis, ERCP abnormalities in the main pancreatic duct and side branches have been outlined by the Cambridge classification (Fig. 358-2). The presence of ductal stenosis and irregularity can make it difficult to distinguish chronic pancreatitis from pancreatic adenocarcinoma. It is important to be aware that ERCP changes interpreted as indicating chronic pancreatitis actually may be due to the effects of aging on the pancreatic duct, sequelae of a recent attack of acute pancreatitis, or changes secondary to placement of pancreatic duct stent. Pancreatic adenocarcinoma is characterized by stenosis or obstruction of either the pancreatic duct or the common bile duct; both ductal systems are often abnormal (double-duct sign). When indicated, ERCP permits acquisition of diagnostic tissue as in biopsy of ampullary lesions or biliary brushings for distal bile duct strictures. Elevated serum amylase levels after ERCP have been reported in the majority of patients, and clinical pancreatitis has been reported in 5–10% of patients. Historically, pancreatic duct stents were commonly placed to prevent post-ERCP pancreatitis. Recent data, however, have revealed that the periprocedural administration of rectal indomethacin can decrease the incidence of post-ERCP pancreatitis. In a randomized multicenter study, it was demonstrated that the combination of rectal indomethacin with prophylactic pancreatic duct stents was more effective than indomethacin alone in preventing post-ERCP pancreatitis in high-risk patients.

TESTS OF EXOCRINE PANCREATIC FUNCTION

Pancreatic function tests (Table 358-1) can be divided into the following:

1. *Direct stimulation of the pancreas* by IV administration of secretin followed by collection and measurement of duodenal contents: The secretin test, used to detect diffuse pancreatic disease, is based on the physiologic principle that the pancreatic secretory response is directly related to the functional mass of pancreatic tissue. In the standard assay, secretin is given IV in a dose of 0.2 μg/kg of synthetic human secretin as a bolus. Normal values for the standard secretin test are (1) volume output >2 mL/kg per h, (2) bicarbonate (HCO_3^-) concentration >80 mmol/L, and (3) HCO_3^- output >10 mmol/L in 1 h. The most reproducible measurement, giving the highest level of discrimination between normal subjects and patients with chronic pancreas dysfunction, appears to be the maximal bicarbonate concentration. A cutoff point <80 mmol/L is considered abnormal and suggestive of reduced secretory function that is most commonly observed in early chronic pancreatitis.
2. There may be a dissociation between the results of the secretin test and other tests of absorptive function. For example, patients with chronic pancreatitis often have abnormally low outputs of HCO_3^- after secretin but have normal fecal fat excretion. The secretin test directly measures the secretory capacity of ductular epithelium, whereas fecal fat excretion indirectly reflects intraluminal lipolytic activity. Steatorrhea does not occur until intraluminal levels of lipase are markedly reduced, underscoring the fact that only small amounts of enzymes are necessary for intraluminal digestive activities. It must be emphasized that an abnormal secretin test result suggests that pancreatic ductal secretory function is abnormal. This is an early abnormality in chronic pancreatitis but should not be considered diagnostic and must be interpreted within the proper clinical context.
3. *Measurement of fecal pancreatic enzymes* such as elastase: Measurement of *intraluminal digestion products* (i.e., undigested muscle fibers, stool fat, and fecal nitrogen) is discussed in **Chap. 336**. The amount of human elastase in stool reflects the pancreatic output of this proteolytic enzyme. Decreased fecal elastase-1 (FE-1) activity in stool is a test to detect severe EPI in patients with chronic pancreatitis and cystic fibrosis. FE-1 levels >200 μg/g are normal, levels of 100–200 μg/g are considered mild-moderate EPI, and levels <100 μg/g are severe EPI. Although the test is simple and noninvasive, it can yield false-positive results if stools are not formed and should not generally be used for the evaluation of a patient with diarrhea. False-positive results have also been observed in diabetes and irritable bowel syndrome.

Tests useful in the diagnosis of EPI and the differential diagnosis of malabsorption are also discussed in Chaps. 336 and 359.

BIOCHEMISTRY AND PHYSIOLOGY OF PANCREATIC EXOCRINE SECRETION

GENERAL CONSIDERATIONS

The pancreas secretes 1500–3000 mL of isosmotic alkaline (pH >8) fluid per day containing ~20 enzymes. Pancreatic secretions provide the enzymes and bicarbonate needed to perform the major digestive activity of the gastrointestinal tract and produce an optimal pH for the function of these enzymes.

REGULATION OF PANCREATIC SECRETION

Secretions from the exocrine pancreas are highly regulated by neurohormonal systems in a phasic manner (cephalic, gastric, and intestinal phases). *Gastric acid* is the stimulus for the release of secretin from the duodenal mucosa (S cells), which stimulates the secretion of water and electrolytes from pancreatic ductal cells. Release of cholecystokinin (CCK) from the duodenal and proximal jejunal mucosa (Ito cells) is largely triggered by long-chain fatty acids, essential amino acids (tryptophan, phenylalanine, valine, methionine), and gastric acid itself. CCK evokes an enzyme-rich secretion from acinar cells in the pancreas. The *parasympathetic nervous system* (via the vagus nerve) exerts significant control over pancreatic secretion, particularly during the cephalic phase. Secretion evoked by secretin and CCK depends on the permissive roles of vagal afferent and efferent pathways. This is particularly true for enzyme secretion, whereas water and bicarbonate

secretions are heavily dependent on the hormonal effects of secretin and to a lesser extent CCK. Also, vagal stimulation affects the release of vasoactive intestinal peptide (VIP), a secretin agonist. Pancreatic exocrine secretion is also influenced by inhibitory neuropeptides including somatostatin, pancreatic polypeptide, peptide YY, neuropeptide Y, enkephalin, pancreastatin, calcitonin gene–related peptides, glucagon, and galanin. Pancreatic polypeptide and peptide YY may act primarily on nerves outside the pancreas, while somatostatin acts at multiple sites.

WATER AND ELECTROLYTE SECRETION

Bicarbonate is the ion of primary physiologic importance in pancreatic secretions. The ductal cells secrete bicarbonate predominantly derived from plasma (93%) more so than from intracellular metabolism (7%). Bicarbonate enters the duct lumen through the sodium bicarbonate cotransporter with depolarization caused by chloride efflux through the cystic fibrosis transmembrane conductance regulator (CFTR). Secretin and VIP bind at the basolateral surface and cause an increase in secondary messenger intracellular cyclic AMP and act on the apical surface of the ductal cells opening the CFTR to promote secretion. CCK, acting as a neuromodulator, markedly potentiates the stimulatory effects of secretin. Acetylcholine also plays an important role in ductal cell secretion. Intraluminal bicarbonate secreted from the ductal cells helps neutralize gastric acid, increases the solubility of fatty acids and bile acids, maintains an optimal pH for pancreatic and brush border enzymes, and prevents intestinal mucosal damage.

ENZYME SECRETION

The acinar cell is highly compartmentalized for the production and secretion of pancreatic enzymes. Proteins synthesized by the rough endoplasmic reticulum are processed in the Golgi apparatus and then targeted to the appropriate site: zymogen granules, lysosomes, or other cell compartments. The zymogen granules migrate to the apical region of the acinar cell awaiting the appropriate neural or hormonal stimulatory response. The pancreas secretes amylolytic, lipolytic, and proteolytic enzymes into the duct lumen. *Amylolytic enzymes*, such as amylase, hydrolyze starch to oligosaccharides and the disaccharide maltose. The *lipolytic enzymes* include lipase, phospholipase A_2, and cholesterol esterase. Bile salts inhibit lipase in isolation, but colipase, another constituent of pancreatic secretion, binds to lipase and prevents this inhibition. Bile salts activate phospholipase A and cholesterol esterase. *Proteolytic enzymes* include endopeptidases (trypsin, chymotrypsin), which act on internal peptide bonds of proteins and polypeptides; exopeptidases (carboxypeptidases, aminopeptidases), which act on the free carboxyl- and amino-terminal ends of peptides, respectively; and elastase. The proteolytic enzymes are secreted as inactive zymogen precursors. Ribonucleases (deoxyribonucleases, ribonuclease) are also secreted. *Enterokinase*, an enzyme found in the duodenal mucosa ("brush border"), cleaves the lysine-isoleucine bond of trypsinogen to form trypsin. Trypsin then activates the other proteolytic zymogens and phospholipase A_2 in a cascade. The nervous system initiates pancreatic enzyme secretion. The neurologic stimulation is cholinergic, involving extrinsic innervation by the vagus nerve and subsequent innervation by intrapancreatic cholinergic nerves. The stimulatory neurotransmitters are acetylcholine and gastrin-releasing peptides. These neurotransmitters activate calcium-dependent secondary messenger systems, resulting in the release of zymogens into the pancreas duct. VIP is present in intrapancreatic nerves and potentiates the effect of acetylcholine. In contrast to other species, there are no CCK receptors on acinar cells in humans. CCK in physiologic concentrations contributes to pancreatic secretion by stimulating afferent vagal and intrapancreatic nerves.

AUTOPROTECTION OF THE PANCREAS

Autodigestion of the pancreas is prevented by (1) the packaging of pancreatic proteases in the precursor (proenzyme) form, (2) intracellular calcium homeostasis (low intracellular calcium in the cytosol of the acinar cell promotes the destruction of spontaneously activated trypsin), (3) acid-base balance, and (4) the synthesis of protective protease inhibitors serine protease inhibitor, Kazal type 1 (SPINK1) which can bind and inactivate ~20% of intracellular trypsin activity. Chymotrypsin C can also lyse and inactivate trypsin. These protease inhibitors are found in acinar cells, pancreatic secretions, and the α_1- and α_2-globulin fractions of plasma. Loss of any of these four protective mechanisms leads to premature enzyme activation, autodigestion, and ultimately acute pancreatitis.

ENTEROPANCREATIC AXIS AND FEEDBACK INHIBITION

Pancreatic enzyme secretion is controlled, at least in part, by a negative feedback mechanism induced by the presence of active serine proteases in the duodenum and nutrients in the distal small intestine. For example, perfusion of the duodenal lumen with phenylalanine (stimulates early digestion) causes a prompt increase in plasma CCK levels as well as increased secretion of chymotrypsin and other pancreatic enzymes. However, simultaneous perfusion with trypsin (stimulates late digestion) blunts both responses. Conversely, perfusion of the duodenal lumen with protease inhibitors leads to enzyme hypersecretion. Available evidence supports the concept that the duodenum contains a peptide called *CCK-releasing factor* (CCK-RF) that is involved in stimulating CCK release. It appears that serine proteases inhibit pancreatic secretion by inactivating a CCK-releasing peptide in the lumen of the small intestine. Thus, the integrative result of both bicarbonate and enzyme secretion depends on a feedback process for both bicarbonate and pancreatic enzymes. Acidification of the duodenum releases secretin, which stimulates vagal and other neural pathways to activate pancreatic duct cells, which secrete bicarbonate. This bicarbonate then neutralizes the duodenal acid, and the feedback loop is completed. Dietary proteins bind proteases, thereby leading to an increase in free CCK-RF. CCK is then released into the blood in physiologic concentrations, acting primarily through the neural pathways (vagal-vagal). This leads to acetylcholine-mediated pancreatic enzyme secretion. Proteases continue to be secreted from the pancreas until the protein within the duodenum is digested. At this point, pancreatic protease secretion is reduced to basic levels, thus completing this step in the feedback process. Additional hormonal feedback inhibition of pancreatic enzyme secretion occurs via peptide YY and glucagon-like peptide-1 following lipid or carbohydrate exposure to the ileum.

ACUTE PANCREATITIS

GENERAL CONSIDERATIONS

Recent U.S. estimates indicate that acute pancreatitis is one of the most common principal gastrointestinal diagnoses, accounting for almost 300,000 hospitalizations annually. The annual incidence ranges from 15–45/100,000 persons, depending on the distribution of etiologies (e.g., alcohol, gallstones, metabolic factors, drugs; **Table 359-1**) and country of study. The median length of hospital stay is 4 days, with a median hospital cost of ~$6000 and a mortality of ~1%. The estimated annual cost approaches $3 billion. Hospitalization rates increase with age and are higher among African Americans. Globally, there is a steady increase in the incidence of acute pancreatitis, most prominently in North America and Europe. Thus, the incidence of acute pancreatitis continues to rise and is associated with substantial health care costs.

ETIOLOGY AND PATHOGENESIS

There are many causes of acute pancreatitis (Table 359-1), and the mechanisms by which each of these conditions triggers pancreatic inflammation have not been fully elucidated. Gallstones and alcohol account for 80–90% of identified cases of acute pancreatitis in the United States. Gallstones are the leading cause of acute pancreatitis in most series (30–60%). The risk of acute pancreatitis in patients with at least one gallstone <5 mm in diameter is fourfold greater than patients with larger stones. Alcohol is the second most common cause, responsible for 15–30% of cases in the United States. The incidence of pancreatitis in individuals with heavy alcohol use is surprisingly low (5/100,000), indicating that in addition to the amount of alcohol

TABLE 359-1 Causes of Acute Pancreatitis

Common Causes
Gallstones (including microlithiasis)
Heavy alcohol use
Severe hypertriglyceridemia
Endoscopic retrograde cholangiopancreatography (ERCP), especially after therapeutic intervention
Idiopathic
Uncommon Causes
Drugs (azathioprine, 6-mercaptopurine, sulfonamides, estrogens, tetracycline, valproic acid, 5-aminosalicylic acid [5-ASA], dipeptidyl peptidase-4 [DPP4] inhibitors)
Connective tissue disorders and thrombotic thrombocytopenic purpura (TTP)
Pancreatic cancer
Hypercalcemia
Periampullary diverticulum
Pancreas divisum[a]
Hereditary pancreatitis
Cystic fibrosis
Renal failure
Infections (mumps, coxsackievirus, cytomegalovirus, echovirus, parasites)
Autoimmune (e.g., type 1 and type 2)
Trauma (especially blunt abdominal trauma)
Postoperative (abdominal and nonabdominal operations)
Causes to Consider in Patients With Recurrent Bouts of Acute Pancreatitis Without an Obvious Etiology
Occult disease of the biliary tree or pancreatic ducts, especially microlithiasis/biliary sludge
Alcohol abuse
Metabolic: Hypertriglyceridemia, hypercalcemia
Anatomic: Pancreas divisum[a]
Pancreatic cancer
Intraductal papillary mucinous neoplasm (IPMN)
Hereditary pancreatitis
Cystic fibrosis
Idiopathic

[a]Pancreas divisum is not believed to cause acute pancreatitis in isolation of another disease precipitant.

ingested, other factors affect a person's susceptibility to pancreatic injury, such as cigarette smoking and genetic predisposition. Acute pancreatitis occurs in 5–10% of patients following endoscopic retrograde cholangiopancreatography (ERCP); however, this risk can be decreased with proper patient selection and the use of a prophylactic pancreatic duct stent and/or rectal nonsteroidal anti-inflammatory drugs (NSAIDs; indomethacin). Risk factors for post-ERCP pancreatitis include minor papilla sphincterotomy, suspected functional sphincter dysfunction (previously termed sphincter of Oddi dysfunction), prior history of post-ERCP pancreatitis, age <60 years, more than two contrast injections into the pancreatic duct, and endoscopist experience.

Hypertriglyceridemia is the cause of acute pancreatitis in 1–4% of cases; serum triglyceride levels are usually >1000 mg/dL. Most patients with hypertriglyceridemic pancreatitis have undiagnosed or uncontrolled diabetes mellitus. An additional subset has an underlying derangement in lipid metabolism, probably unrelated to pancreatitis. Such patients are prone to recurrent episodes of pancreatitis and increased severity. Any factor (e.g., alcohol or medications, such as oral contraceptives) that causes an abrupt increase in serum triglycerides can potentially precipitate a bout of acute pancreatitis. Patients with a deficiency of apolipoprotein CII have an increased incidence of pancreatitis; apolipoprotein CII activates lipoprotein lipase, which is important in clearing chylomicrons from the bloodstream. Although frequently entertained, <2% of cases of acute pancreatitis are drug related. Drugs cause pancreatitis either by a hypersensitivity reaction or by the generation of a toxic metabolite, although in some cases, it is not clear which of these mechanisms is operative (Table 359-1). Increased attention has been directed toward a potential increased risk for acute pancreatitis in patients taking glucagon-like peptide-1 receptor agonists (GLP-1RA) and dipeptidyl peptidase-4 (DPP4) inhibitors. The most recent metanalysis of cardiovascular outcome trials does support an increased risk with DPP4 inhibitors, but not with GLP-1RA medications. When used for treating hyperglycemia, it is important to be conscious that >10% of individuals with diabetes will have elevated amylase or lipase levels irrespective of medication use.

Pathologically, acute pancreatitis ranges from *interstitial pancreatitis* (pancreas blood supply maintained), which is generally self-limited, to *necrotizing pancreatitis* (pancreas blood supply interrupted). Autodigestion is a currently accepted pathogenic theory resulting when proteolytic enzymes (e.g., trypsinogen, chymotrypsinogen, proelastase) and lipolytic enzymes (such as phospholipase A_2) are activated in the pancreas acinar cell compartment rather than the intestinal lumen. Several factors (e.g., endotoxins, exotoxins, viral infections, ischemia, oxidative stress, lysosomal calcium, direct trauma) are believed to facilitate premature activation of trypsin, which can activate other enzymes. Spontaneous activation of trypsin also can occur, resulting in autodigestion.

ACTIVATION OF PANCREATIC ENZYMES IN THE PATHOGENESIS OF ACUTE PANCREATITIS

Several studies have suggested that pancreatitis is a disease that evolves in three phases. The *initial phase* is characterized by intrapancreatic digestive enzyme activation and acinar cell injury. Trypsin activation appears to be mediated by lysosomal hydrolases such as cathepsin B that become colocalized with digestive enzymes in intracellular organelles; it is currently believed that acinar cell injury is the consequence of trypsin activation. The *second phase* of pancreatitis involves the activation, chemoattraction, and sequestration of leukocytes and macrophages in the pancreas, resulting in an enhanced intrapancreatic inflammatory reaction. Neutrophil depletion induced by prior administration of an antineutrophil serum has been shown to reduce the severity of experimentally induced pancreatitis. There is also evidence to support the concept that neutrophils can activate trypsinogen. Thus, intrapancreatic acinar cell activation of trypsinogen could be a two-step process (i.e., an early neutrophil-independent and a later neutrophil-dependent phase). The *third phase* of pancreatitis is due to the effects of activated proteolytic enzymes and cytokines, released by the inflamed pancreas, on distant organs. Activated proteolytic enzymes, especially trypsin, not only digest pancreatic and peripancreatic tissues but also activate other enzymes such as elastase and phospholipase A_2. The active enzymes and cytokines then digest cellular membranes and cause proteolysis, edema, interstitial hemorrhage, vascular damage, coagulation necrosis, fat necrosis, and cellular necrosis in the parenchyma. Cellular injury and death result in the liberation of bradykinin peptides, vasoactive substances, and histamine that can produce vasodilation, increased vascular permeability, and edema with profound effects on other organs. The systemic inflammatory response syndrome (SIRS) and acute respiratory distress syndrome (ARDS), as well as multiorgan failure, may occur because of this cascade producing local and distant effects.

Several genetic factors can increase the susceptibility and/or modify the severity of pancreatic injury in acute pancreatitis, recurrent acute pancreatitis, and chronic pancreatitis. The major genetic susceptibility factors center on the control of trypsin activity within the pancreatic acinar cell, in part because they were identified as candidate genes linked to intrapancreatic trypsin control. Six genetic variants have been identified as being associated with susceptibility to pancreatitis. The genes that have been identified include (1) cationic trypsinogen gene (*PRSS1*), (2) *SPINK1*, (3) the cystic fibrosis transmembrane conductance regulator gene (*CFTR*), (4) the chymotrypsin C gene (*CTRC*), (5) the calcium-sensing receptor (*CASR*), and (6) claudin-2 (*CLDN2*). Among these variants, only *PRSS1* mutations are sufficient

to precipitate acute pancreatitis in the absence of other risk factors, whereas the other variants are disease modifiers. Investigations for other genetic variants are in progress, so it is expected this list will be expanded in the future.

APPROACH TO THE PATIENT

Abdominal Pain

Abdominal pain is the major symptom of acute pancreatitis. Pain may vary from mild discomfort to severe, constant, and incapacitating distress. Characteristically, the pain, which is steady and boring in character, is located in the epigastrium region and may radiate to the back, chest, flanks, and lower abdomen. Nausea, vomiting, and abdominal distention due to gastric and intestinal hypomotility are also frequent complaints.

Physical examination frequently reveals a distressed and anxious patient. Low-grade fever, tachycardia, and hypotension are common. Shock is not unusual and may result from (1) hypovolemia secondary to exudation of blood and plasma proteins into the retroperitoneal space; (2) increased formation and release of kinin peptides, which cause vasodilation and increased vascular permeability; and (3) systemic effects of proteolytic and lipolytic enzymes released into the circulation. Jaundice occurs infrequently; when present, it may be a consequence of extrinsic compression due to peripancreatic edema, a pancreatic head mass, or intraductal obstruction from a common bile duct stone or sludge. Erythematous skin nodules ("pancreatic panniculitis") due to subcutaneous fat necrosis are possible, but rarely occur. There are pulmonary findings in 10–20% of patients, including basilar rales, atelectasis, and pleural effusion, the latter most frequently left-sided. Abdominal tenderness and muscle rigidity are present to a variable degree, but compared with the intense pain, these signs may be less impressive. Bowel sounds are usually diminished or absent. An enlarged pancreas from an acute fluid collection, walled-off necrosis, or a pseudocyst may be palpable in the upper abdomen later in the course of the disease (i.e., 4–6 weeks). A faint blue discoloration around the umbilicus (Cullen's sign) may occur as the result of hemoperitoneum, and a blue-red-purple or green-brown discoloration of the flanks (Turner's sign) reflects tissue breakdown of hemoglobin from severe necrotizing pancreatitis with hemorrhage; both findings are rare but reflect an increased clinical severity.

LABORATORY DATA

Serum amylase and lipase values greater than three times the upper limit of normal are strongly supportive of the diagnosis if alternate etiologies, including gut perforation, ischemia, and infarction, are excluded. However, it should be noted that there is no correlation between the severity of pancreatitis and the degree of serum lipase and amylase elevations or serial trends. After 3–7 days, even with continuing evidence of pancreatitis, total serum amylase values tend to return to normal. However, pancreatic lipase levels may remain elevated for 7–14 days. It should be recognized that amylase elevations in serum and urine occur in many conditions other than pancreatitis **(see Chap. 358, Table 358-2)**. Importantly, patients with *acidemia* (arterial pH ≤7.32) may have spurious elevations in serum amylase. This finding explains why patients with diabetic ketoacidosis may have marked elevations in serum amylase without any other evidence of acute pancreatitis. On the other hand, serum amylase levels can be spuriously low in severe hypertriglyceridemia. Serum lipase activity increases in parallel with amylase activity and is more specific than amylase, making it the preferred test. A serum lipase measurement can be instrumental in differentiating a pancreatic or nonpancreatic cause for hyperamylasemia.

Leukocytosis (15,000–20,000 leukocytes/μL) occurs frequently. Patients with more severe disease may show hemoconcentration with hematocrit values >44% and prerenal azotemia (elevated blood urea nitrogen [BUN]) resulting from loss of plasma into the retroperitoneal space and peritoneal cavity. In fact, one study reported that a combination of admission BUN and a change in BUN at 48 h was a strong predictor of mortality (area under the curve [AUC] 0.91).

Hemoconcentration may be the harbinger of more severe disease, whereas azotemia is a significant risk factor for mortality. *Hyperglycemia* is common and is due to multiple factors, including decreased insulin release, increased glucagon release, and increased output of adrenal glucocorticoids and catecholamines. *Hypocalcemia* occurs in ~25% of patients, and its pathogenesis is incompletely understood. Although earlier studies suggested that the response of the parathyroid gland to a decrease in serum calcium is impaired, subsequent observations have failed to confirm this phenomenon. Intraperitoneal saponification of calcium by fatty acids in areas of fat necrosis occurs occasionally, with large amounts (up to 6.0 g) dissolved or suspended in ascitic fluid. Such "soap formation" may also be significant in patients with pancreatitis, mild hypocalcemia, and little or no obvious ascites. *Hyperbilirubinemia* (serum bilirubin >4.0 mg/dL) occurs in ~10% of patients. However, jaundice is usually transient, and serum bilirubin levels return to normal in 4–7 days. Serum alkaline phosphatase and transaminase levels may also be transiently elevated and parallel serum bilirubin values. Elevations of alanine aminotransferase (ALT) >3× the upper limit of normal are strongly associated with a gallstone etiology in patients with acute pancreatitis. Approximately 5–10% of patients have *hypoxemia* (arterial PO_2 ≤60 mmHg), which may herald the onset of ARDS. Finally, the electrocardiogram is occasionally abnormal in acute pancreatitis with ST-segment and T-wave abnormalities simulating myocardial ischemia.

An abdominal ultrasound is recommended as the initial diagnostic imaging modality and is most useful for evaluating gallstones and common bile duct dilation.

The Revised Atlanta Criteria have clearly outlined the morphologic features of acute pancreatitis on computed tomography (CT) scan as follows: (1) interstitial pancreatitis, (2) necrotizing pancreatitis, (3) acute pancreatic fluid collection, (4) pancreatic pseudocyst, (5) acute necrotic collection (ANC), and (6) walled-off necrosis (WON) **(Table 359-2** and **Fig. 359-1)**. Radiologic studies useful in the diagnosis of acute pancreatitis are discussed in **Chap. 358** and listed in **Table 358-1**.

DIAGNOSIS

Any severe acute pain in the abdomen or back should raise the possibility of acute pancreatitis. The diagnosis is established by two of the following three criteria: (1) typical abdominal pain in the epigastrium that may radiate to the back, (2) threefold or greater elevation in serum lipase and/or amylase, and (3) confirmatory findings of acute pancreatitis on cross-sectional abdominal imaging. Although not required for diagnosis, markers of severity may include hemoconcentration (hematocrit >44%), admission azotemia, SIRS, and signs of organ failure **(Table 359-3)**.

The *differential diagnosis* should include the following disorders: (1) perforated viscus, especially peptic ulcer; (2) acute cholecystitis and biliary colic; (3) acute intestinal obstruction; (4) mesenteric vascular occlusion; (5) renal colic; (6) inferior myocardial infarction; (7) dissecting aortic aneurysm; (8) connective tissue disorders with vasculitis; (9) pneumonia; and (10) diabetic ketoacidosis. It may be difficult to differentiate acute cholecystitis from acute pancreatitis, because an elevated serum amylase may be found in both disorders. Pain of biliary tract origin is more right sided or epigastric than periumbilical or left upper quadrant and can be more severe; ileus is usually absent. Ultrasound is helpful in establishing the diagnosis of cholelithiasis and cholecystitis. Intestinal obstruction due to mechanical factors can be differentiated from pancreatitis by the history of crescendo-decrescendo pain, findings on abdominal examination, and CT of the abdomen showing changes characteristic of anatomic obstruction. Acute mesenteric vascular occlusion is usually suspected in elderly debilitated patients with leukocytosis, abdominal distention, and bloody diarrhea, confirmed by CT or magnetic resonance angiography. Vasculitides secondary to systemic lupus erythematosus and polyarteritis nodosa may be confused with pancreatitis, especially because pancreatitis may develop as a complication of these diseases. Diabetic ketoacidosis is often accompanied

TABLE 359-2 Revised Atlanta Definitions of Morphologic Features of Acute Pancreatitis

	DEFINITION	COMPUTED TOMOGRAPHY FEATURES
Types of Acute Pancreatitis		
Interstitial pancreatitis	Acute inflammation of the pancreatic parenchyma and peripancreatic tissues, but without recognizable tissue necrosis	Pancreatic parenchyma enhancement by IV contrast agent and without peripancreatic necrosis
Necrotizing pancreatitis	Inflammation associated with pancreatic parenchymal and/or peripancreatic necrosis	Lack of pancreatic parenchymal enhancement by IV contrast agent and/or presence of findings of peripancreatic necrosis (see below—ANC and WON)
Morphologic Features		
Acute pancreatic fluid collection	Peripancreatic fluid associated with interstitial edematous pancreatitis with no associated peripancreatic necrosis. This term applies only to areas of peripancreatic fluid seen within the first 4 weeks after onset of interstitial edematous pancreatitis and without the features of a pseudocyst.	Occurs in the setting of interstitial pancreatitis Homogeneous collection with fluid density Confined by normal peripancreatic fascial planes No definable wall encapsulating the collection Adjacent to pancreas (no intrapancreatic extension)
Pancreatic pseudocyst	An encapsulated collection of fluid with a well-defined wall usually outside the pancreas with minimal or no necrosis. This usually occurs >4 weeks after onset of interstitial edematous pancreatitis.	Well circumscribed, usually round or oval Homogeneous fluid density No solid component Well-defined wall; that is, completely encapsulated Maturation usually requires >4 weeks after onset of acute interstitial pancreatitis
Acute necrotic collection (ANC)	A collection containing variable amounts of both fluid and necrosis associated with necrotizing pancreatitis; the necrosis can involve the pancreatic parenchyma and/or the peripancreatic tissues.	Occurs in the setting of acute necrotizing pancreatitis Heterogeneous and nonliquid density of varying degrees in different locations (some appear homogeneous early in their course) No definable wall encapsulating the collection Location—intrapancreatic and/or extrapancreatic
Walled-off necrosis (WON)	A mature, encapsulated collection of pancreatic and/or peripancreatic necrosis that has developed a well-defined inflammatory wall. WON usually occurs >4 weeks after onset of acute necrotizing pancreatitis.	Heterogeneous with liquid and nonliquid density with varying degrees of loculations (some may appear homogeneous) Well-defined wall; that is, completely encapsulated Location—intrapancreatic and/or extrapancreatic Maturation usually requires >4 weeks after onset of acute necrotizing pancreatitis

Source: Data from P Banks et al: Gut 62:102, 2013.

by abdominal pain and elevated total serum amylase levels, thus closely mimicking acute pancreatitis; however, the serum lipase level is often not elevated in diabetic ketoacidosis, and pancreas imaging is normal.

CLINICAL COURSE, DEFINITIONS, AND CLASSIFICATIONS

The Revised Atlanta Criteria define (1) phases of acute pancreatitis, (2) severity of acute pancreatitis, and (3) radiographic definitions, as outlined below.

Phases of Acute Pancreatitis Two clinical phases of acute pancreatitis have been defined, early (<2 weeks) and late (>2 weeks), which primarily describe the hospital course of the disease. In the *early phase* of acute pancreatitis, which lasts 1–2 weeks, severity is defined by clinical parameters rather than morphologic findings. Most patients exhibit SIRS, and if this persists, patients are predisposed to organ failure. Three organ systems should be assessed to define organ failure: respiratory, cardiovascular, and renal. Organ failure is defined as a score of 2 or more for one of these three organ systems using the modified Marshall scoring system. Persistent organ failure (>48 h) is the most important clinical finding regarding the severity of the acute pancreatitis episode. CT imaging is usually not needed or recommended during the first 48 h of admission in acute pancreatitis.

The *late phase* is characterized by a protracted course of illness and may require imaging to evaluate for local complications. The critical clinical parameter of severity, as in the early phase, is persistent organ failure. These patients may require supportive measures such as renal dialysis, ventilator support, or need for supplemental nutrition. The radiographic feature of greatest importance to recognize in this phase is the development of necrotizing pancreatitis on CT imaging. Necrosis is associated with prolonged hospitalization and, if infected, may require intervention (percutaneous, endoscopic, or, rarely, surgical).

Severity of Acute Pancreatitis Three classes of severity have been defined: mild, moderately severe, and severe. *Mild acute pancreatitis* is without local complications or organ failure. Most patients with interstitial acute pancreatitis have mild pancreatitis. In mild acute pancreatitis, the disease is self-limited, usually within 3–7 days after onset. Oral intake can be resumed if the patient is hungry, has normal bowel function, and is without nausea and vomiting. Typically, a clear or full liquid diet has been recommended for the initial meal; however, a low-fat solid diet is advised early in mild acute pancreatitis.

Moderately severe acute pancreatitis is characterized by transient organ failure (i.e., it resolves in <48 h) or local or systemic complications in the absence of persistent organ failure. These patients may or may not have necrosis but may develop a local complication such as a fluid collection, which often requires a prolonged hospitalization >1 week. As with mild acute pancreatitis, the mortality rate for these patients remains low.

Severe acute pancreatitis is characterized by persistent organ failure (>48 h), involving one or more organs. A CT scan or magnetic resonance imaging (MRI) should be obtained to assess for necrosis and/or complications. If a local complication is encountered, management is dictated by clinical symptoms, evidence of infection, the maturity of fluid collection, and clinical stability of the patient. Prophylactic antibiotics are no longer recommended for severe acute pancreatitis.

Imaging in Acute Pancreatitis Two types of pancreatitis are recognized on imaging as *interstitial* or *necrotizing* based on pancreatic perfusion. CT imaging with IV contrast is best evaluated 3–5 days into hospitalization if patients are not responding to supportive care to assess for local complications such as necrosis. Recent studies report the overutilization of CT imaging within 72 h for acute pancreatitis, including those with a mild severity of disease. The Revised Atlanta Criteria outline the terminology for local complications and fluid collections along with a CT imaging template to guide reporting of findings. Local morphologic features are summarized in Table 359-2. *Interstitial pancreatitis* occurs in 90–95% of admissions for acute pancreatitis and is characterized by diffuse gland enlargement, homogenous contrast enhancement, and mild inflammatory changes or peripancreatic

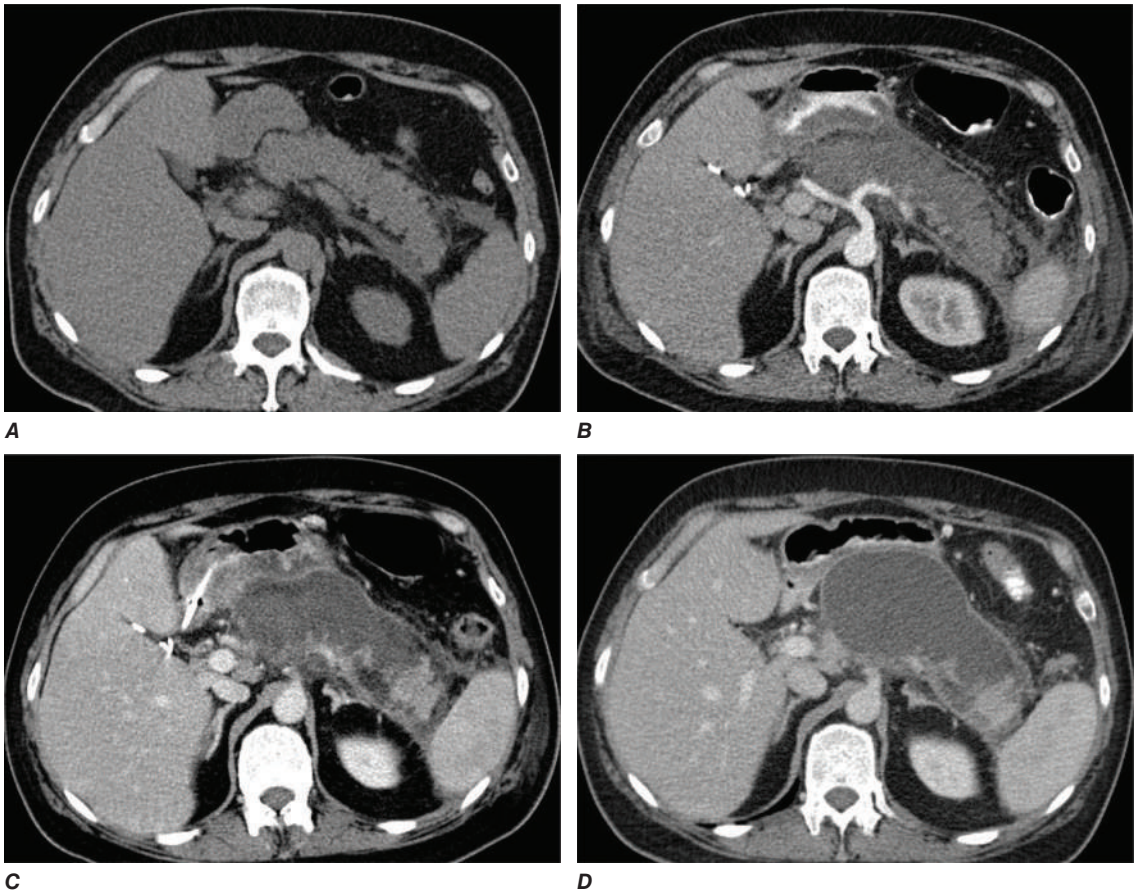

FIGURE 359-1 Evolution of changes of acute necrotizing pancreatitis on computed tomography (CT). ***A.*** CT scan of the abdomen without IV contrast performed on admission for a patient with acute gallstone pancreatitis, showing mild peripancreatic stranding. ***B.*** Contrast-enhanced CT scan of the abdomen performed on the same patient 1 week after admission shows extensive intrapancreatic necrosis, evidenced by the lack of contrast enhancement in the pancreatic body with minimal enhancement noted at the distal most aspect of the pancreatic tail. ***C.*** Contrast-enhanced CT scan of the abdomen performed on the same patient 2 weeks after admission demonstrates a semiorganized, heterogeneous fluid collection, referred to as an acute necrotic collection. On this image, a small area of viable pancreatic parenchyma is seen at the tail of the pancreas. ***D.*** Contrast-enhanced CT scan of the abdomen performed on the same patient 5 weeks after admission demonstrates a well-encapsulated fluid collection, essentially replacing the pancreas, referred to as walled-off necrosis.

stranding. Symptoms generally resolve with a week of hospitalization. *Necrotizing pancreatitis* occurs in 5–10% of acute pancreatitis admissions and may not evolve until after several days of hospitalization. It is characterized by lack of pancreatic parenchymal enhancement by intravenous contrast agent and/or presence of peripancreatic necrosis. The natural history of pancreatic and peripancreatic necrosis is variable because it may remain solid or liquefy, remain sterile or become infected, and persist or resolve over time. Importantly, those with only extrapancreatic necrosis have a more favorable prognosis than patients with pancreatic necrosis (with or without extrapancreatic necrosis). CT identification of local complications, particularly necrosis, is critical in patients who are not responding to therapy because patients with necrosis are at the greatest risk of mortality **(Figs.** 359-1 and **359-2)**. The median prevalence of organ failure is >50% in necrotizing pancreatitis and is slightly higher in infected versus sterile necrosis. With single-organ system failure, the mortality is 3–10%, but increases to nearly 50% with multiorgan failure.

ACUTE PANCREATITIS MANAGEMENT

The management of patients with acute pancreatitis from the time of diagnosis in the emergency ward to hospital discharge is briefly reviewed, highlighting salient features based on severity and complications. It is important to recognize that 85–90% of cases of acute pancreatitis are self-limited and subside spontaneously, usually within 3–7 days after onset, and do not exhibit organ failure or local complications.

The management of acute pancreatitis begins in the emergency ward. After a diagnosis has been confirmed, early and aggressive fluid resuscitation is critical. Additionally, intravenous analgesics are administered, severity is assessed, and a search for etiologies that may impact acute care is begun. Patients who do not respond to aggressive fluid resuscitation in the emergency ward should be considered for admission to a step-down or intensive care unit for further intensive monitoring and management, including hemodynamic monitoring and management of organ failure, if present.

Fluid Resuscitation and Monitoring Response to Therapy The most important treatment intervention for acute pancreatitis is early, intravenous fluid resuscitation to prevent systemic complications from the secondary systemic inflammatory response. The patient is initially made NPO to minimize nutrient-induced stimulation of the pancreas and is given intravenous narcotic analgesics to control abdominal pain and supplemental oxygen (as needed).

Lactated Ringer's solution has been shown to decrease systemic inflammation (lower C-reactive protein levels from admission) and may be a better crystalloid than normal saline. Aggressive intravenous fluids have historically been promoted including an initial bolus of approximately 15–20 mL/kg (1050–1400 mL), followed by 2–3 mL/kg per h (200–250 mL/h), to maintain urine output >0.5 mL/kg per hour. However, a recent randomized controlled trial demonstrated that this hydration strategy is associated with an increased risk of fluid overload (based on signs or symptoms) compared to a less aggressive strategy (10 mL/kg bolus, followed by 1.5 mL/kg per h) without an improvement in clinical outcomes. Irrespective of the initial fluid management strategy, serial bedside evaluations are required every 6–8 h to assess vital signs, oxygen saturation, and change in physical examination to optimize fluid resuscitation. A *targeted resuscitation strategy* with measurement of hematocrit and BUN every 8–12 h is recommended to ensure the adequacy of fluid resuscitation and monitor response

TABLE 359-3 Severity Assessment of Acute Pancreatitis

Risk Factors for Increased Severity
• Age >60 years
• Obesity, BMI >30 kg/m^2
• Comorbid disease (based on Charlson comorbidity index)
Markers of Severity at Admission or Within 24 h
• SIRS—defined by presence of 2 or more criteria:
• Core temperature <36° or >38°C
• Heart rate >90 beats/min
• Respirations >20/min or PCO_2 <32 mmHg
• White blood cell count >12,000/μL, <4000/μL, or 10% bands
• APACHE II (≥8 at 24 h)
• Hemoconcentration (hematocrit >44%)
• Admission BUN (>20 mg/dL)
• BISAP score (≥3 present)
• (B) BUN >25 mg/dL
• (I) Impaired mental status
• (S) SIRS: ≥2 of 4 present
• (A) Age >60 years
• (P) Pleural effusion
• Organ failure (Modified Marshall score) (≥1 present):
• Cardiovascular: systolic BP <90 mmHg, heart rate >130 beats/min
• Pulmonary: PaO_2 <60 mmHg
• Renal: serum creatinine >2.0 mg/dL
Markers of Severity during Hospitalization
• Elevated C-reactive protein (CRP) (variable thresholds >100 mg/L reported)
• Persistent organ failure (≥48 h)
• Pancreatic or extrapancreatic necrosis

Abbreviations: APACHE II, Acute Physiology and Chronic Health Evaluation II; BISAP, Bedside Index of Severity in Acute Pancreatitis; BMI, body mass index; BP, blood pressure; BUN, blood urea nitrogen; SIRS, systemic inflammatory response syndrome.

to therapy, noting that a less aggressive resuscitation strategy may be sufficient in milder forms of pancreatitis. Importantly, a rising BUN during hospitalization is associated not only with inadequate hydration but also higher in-hospital mortality.

A decrease in hematocrit and BUN during the first 12–24 h is strong evidence that an adequate volume of fluids is being administered. Adjustments in fluid resuscitation may be required in patients with cardiac, pulmonary, or renal disease.

Assessment of Severity and Hospital Triage Severity of acute pancreatitis should be determined in the emergency ward to assist in patient triage to a regular hospital ward, step-down unit, or intensive care unit. The Bedside Index of Severity in Acute Pancreatitis (BISAP) incorporates five clinical and laboratory parameters obtained within the first 24 h of hospitalization (Table 359-3)—BUN >25 mg/dL, impaired mental status (Glasgow coma scale score <15), SIRS, age >60 years, and pleural effusion on radiography—that can be useful in assessing severity. The presence of three or more of these factors was associated with substantially increased risk for in-hospital mortality among patients with acute pancreatitis. In addition, an elevated hematocrit and admission BUN are also associated with more severe acute pancreatitis. Incorporating these indices with the overall patient response to initial fluid resuscitation in the emergency ward can be useful in triaging patients to the appropriate hospital acute care setting.

In general, patients with lower BISAP scores, hematocrit, and admission BUN levels tend to respond to initial management and can be safely triaged to a regular hospital ward for ongoing care. If SIRS is not present at 24 h, the patient is unlikely to develop organ failure or necrosis. Conversely, patients with persistent SIRS at 24 h or underlying comorbid illnesses (e.g., chronic obstructive pulmonary disease, congestive heart failure) should be considered for a step-down unit setting if available. Patients with higher BISAP scores and elevations in hematocrit and admission BUN who do not respond to initial fluid resuscitation and exhibit evidence of respiratory failure, hypotension, or organ failure should be considered for direct admission to an intensive care unit.

Special Considerations Based on Etiology A careful history, review of medications, selected laboratory studies (liver profile, serum triglycerides, serum calcium), and abdominal ultrasound are recommended in the emergency ward to assess for etiologies that may impact acute management. An abdominal ultrasound is the initial imaging modality of choice and will evaluate the gallbladder, common bile duct, and pancreatic head.

GALLSTONE PANCREATITIS Patients with evidence of ascending cholangitis (including sepsis with evidence of biliary obstruction on laboratory or imaging studies) should undergo ERCP within 24–48 h of admission. Patients with gallstone pancreatitis are at increased risk of recurrence, and consideration should be given to performing a cholecystectomy during the same admission in mild acute pancreatitis. An alternative for patients who are not surgical candidates would be to perform an endoscopic biliary sphincterotomy before discharge.

HYPERTRIGLYCERIDEMIA Serum triglycerides >1000 mg/dL are associated with acute pancreatitis. Initial therapy should focus on the treatment of hyperglycemia with intravenous insulin, which often corrects hypertriglyceridemia. In contrast to the standard nutritional management of acute pancreatitis, patients should remain fasting for the initial 24–36 h to promote the resolution of severe triglyceride elevations.

Mortele, Brigham and Women's Hospital; with permission.)*

Adjunct therapies may also include heparin or plasmapheresis, but there is no compelling evidence these measures improve clinical outcomes. Outpatient therapies include control of diabetes if present, administration of lipid-lowering agents, weight loss, and avoidance of drugs that elevate lipid levels.

Other potential etiologies that may impact acute hospital care include *hypercalcemia* and *post-ERCP pancreatitis*. Treatment of hyperparathyroidism or malignancy is effective at reducing serum calcium. Pancreatic duct stenting and/or rectal indomethacin administration are effective at decreasing the risk of pancreatitis after ERCP. Drugs that cause pancreatitis should be discontinued. Multiple drugs have been implicated, but only about 30 have been rechallenged (Class 1A) and found to be causative.

Nutritional Therapy A low-fat solid diet can be administered to subjects with mild acute pancreatitis once they are able to eat. Enteral nutrition should be considered 2–3 days after admission in subjects with more severe pancreatitis instead of total parenteral nutrition (TPN). Enteral feeding maintains gut barrier integrity, limits bacterial translocation, is less expensive, and has fewer complications than TPN. While there may be physiologic advantages of jejunal feeding, gastric feeding is safe, and the benefits of jejunal over gastric feeding remain under investigation.

Management of Local Complications (Table 359-4) Patients exhibiting signs of clinical deterioration despite aggressive fluid resuscitation and hemodynamic monitoring should be assessed for local complications, including necrosis, pseudocyst formation, pancreas duct disruption, peripancreatic vascular complications, and extrapancreatic infections. A multidisciplinary team approach is recommended, including gastroenterology, surgery, interventional radiology, and intensive care specialists; consideration should be made for transfer to a tertiary pancreas center of excellence if these services are not available.

NECROSIS The management of necrosis requires a multidisciplinary team approach. Percutaneous fine-needle aspiration of necrosis with Gram stain and culture was previously performed to evaluate for infected pancreatic necrosis in those with sustained leukocytosis, fever, or organ failure. However, the current use of this technique varies depending on institutional preference, with many abandoning this diagnostic test to avoid potentially contaminating an otherwise sterile collection, particularly when culture results will not lead to a clinical decision to de-escalate antimicrobial therapy. Even though there is currently no role for *prophylactic antibiotics* in necrotizing pancreatitis, *empiric antibiotics* should be considered in those with clinical decompensation. Prophylactic antibiotics do not lead to improved survival and may promote the development of opportunistic fungal infections. Repeated CT or MRI imaging should also be considered with any change in clinical course to monitor for complications (e.g., thromboses, hemorrhage, abdominal compartment syndrome).

In general, *sterile necrosis* is most often managed conservatively unless complications arise. Once a diagnosis of *infected necrosis* is established and an organism identified, targeted antibiotics should be instituted. Pancreatic drainage and/or debridement (necrosectomy) should be considered for definitive management of *infected necrosis*, but management decisions are ultimately influenced by the clinical response since almost two-thirds of patients respond to antibiotic treatment with or without drainage. Symptomatic local complications as outlined in the Revised Atlanta Criteria typically require definitive therapy.

A step-up approach (percutaneous or endoscopic transgastric/transduodenal drainage followed, if necessary, by endoscopic or, rarely, surgical necrosectomy) is the current treatment paradigm. Randomized trials have reported advantages to an initial endoscopic approach compared to an initial surgical necrosectomy approach in patients requiring intervention for symptomatic WON. Taken together, a more conservative approach to the management of infected pancreatic necrosis has evolved under the close supervision of a multidisciplinary team. If conservative therapy can be safely implemented, it is recommended to do so for 4–6 weeks to allow the pancreatic collections to either resolve or evolve to develop a more organized boundary (i.e., to "wall off") since interventions are generally safer and more technically straightforward.

PSEUDOCYST The incidence of pseudocyst is low, and most acute collections resolve over time. Less than 10% of patients have persistent fluid collections after 4 weeks that would meet the definition of a pseudocyst. Only symptomatic collections require intervention with endoscopic or surgical drainage.

Fat necrosis
Subcutaneous tissues (erythematous nodules)
Bone
Miscellaneous (mediastinum, pleura, nervous system)

PANCREATIC DUCT DISRUPTION Pancreatic duct disruption may present with symptoms of increasing abdominal pain or shortness of breath in the setting of an enlarging fluid collection resulting in pancreatic ascites (ascitic fluid has high amylase level). Diagnosis can be confirmed on magnetic resonance cholangiopancreatography (MRCP) or ERCP. Placement of a bridging pancreatic stent for at least 6 weeks is >90% effective at resolving the leak with or without parenteral nutrition and octreotide. Nonbridging stents are less effective (25–50%) but may be useful in combination with parenteral nutrition and octreotide prior to surgical evaluation.

PERIVASCULAR COMPLICATIONS Perivascular complications may include *splenic vein thrombosis* with gastric varices and pseudoaneurysms, as well as *portal and superior mesenteric vein thromboses*. *Gastric varices* rarely bleed but can be life-threatening. Similarly, life-threatening bleeding from a ruptured *pseudoaneurysm* can be diagnosed and treated with mesenteric angiography and embolization.

EXTRAPANCREATIC INFECTIONS Hospital-acquired infections occur in up to 20% of patients with acute pancreatitis. Patients should be continually monitored for the development of pneumonia, urinary tract infection, and line infection. Continued culturing of urine, monitoring of chest x-rays, and routine changing of intravenous lines are important during hospitalization.

Follow-Up Care Hospitalizations for moderately severe and severe acute pancreatitis can be prolonged and last weeks to months and often involve periods of intensive care unit admission and outpatient rehabilitation or subacute nursing care. Follow-up evaluation should assess for development of diabetes, exocrine pancreatic insufficiency, recurrent cholangitis, or infected fluid collections. As mentioned previously, cholecystectomy should be performed during the initial hospitalization for acute gallstone pancreatitis with mild clinical severity. For patients with necrotizing gallstone pancreatitis, the timing of cholecystectomy needs to be individualized.

RECURRENT ACUTE PANCREATITIS

Approximately 25% of patients who have had an attack of acute pancreatitis will experience a recurrence. The two most common etiologic factors are alcohol and cholelithiasis. In patients with recurrent pancreatitis without an obvious cause, the differential diagnosis should consider occult biliary tract disease, including microlithiasis, hypertriglyceridemia, pancreatic cancer, and hereditary pancreatitis (Table 359-1). In one small series, up to two-thirds of patients with recurrent acute pancreatitis without an initially apparent cause had occult gallstone disease attributed to microlithiasis. Genetic defects as in hereditary pancreatitis and cystic fibrosis mutations can result in recurrent pancreatitis. Other diseases of the biliary tree and pancreatic ducts that can cause acute pancreatitis include choledochocele; ampullary tumors; pancreas divisum; and pancreatic duct stones, stricture, and tumors. Approximately 2–4% of patients with pancreatic cancer present with acute pancreatitis.

PANCREATITIS IN PATIENTS WITH AIDS

The incidence of acute pancreatitis is theoretically increased in patients with AIDS for two reasons: (1) the high incidence of infections involving the pancreas such as infections with cytomegalovirus, *Cryptosporidium*, and the *Mycobacterium avium* complex; and (2) the frequent use of medications such as pentamidine, trimethoprim-sulfamethoxazole, and protease inhibitors. The incidence has been markedly reduced due to advances in therapy, including the disuse of didanosine (Chap. 208).

CHRONIC PANCREATITIS AND EXOCRINE PANCREATIC INSUFFICIENCY

PATHOPHYSIOLOGY

Chronic pancreatitis is a disease process characterized by irreversible damage to the pancreas, in contrast to the reversible changes noted in acute pancreatitis (Table 359-4). The events that initiate and then perpetuate the inflammatory process in the pancreas are becoming more clearly understood. Irrespective of the mechanism of injury, it is apparent that stellate cell activation leads to cytokine expression and production of extracellular matrix proteins that contribute to acute and chronic inflammation and collagen deposition in the pancreas. This condition is defined by the presence of histologic abnormalities, including chronic inflammation, fibrosis, and progressive destruction (atrophy) of both exocrine and endocrine tissue. A number of etiologies have been associated with chronic pancreatitis resulting in the cardinal manifestations of the disease such as abdominal pain, steatorrhea, weight loss, diabetes mellitus, and, less commonly, pancreatic cancer (Table 359-5).

Even in individuals in whom alcohol is believed to be the primary cause of chronic pancreatitis, other factors are likely required for the development and progression of disease, which explains why not all heavy consumers of alcohol develop pancreatic disease. Importantly, there is a strong association between smoking and chronic pancreatitis. Cigarette smoke leads to an increased susceptibility to pancreatic autodigestion and predisposes to dysregulation of duct cell CFTR function. Smoking is an independent, dose-dependent risk factor for chronic pancreatitis and recurrent acute pancreatitis. Both continued alcohol and smoking exposure are associated with disease progression, including pancreatic fibrosis and calcifications.

Characterization of pancreatic stellate cells (PSCs) has added insight into the underlying cellular responses behind development of chronic pancreatitis. Specifically, PSCs are believed to play a role in maintaining normal pancreatic architecture that shifts toward fibrogenesis in those who develop chronic pancreatitis. It is believed that alcohol or additional stimuli lead to matrix metalloproteinase–mediated destruction of normal collagen in pancreatic parenchyma, which later allows for pancreatic

remodeling. Proinflammatory cytokines, tumor necrosis factor α (TNF-α), interleukin 1 (IL-1), and interleukin 6 (IL-6), as well as oxidant complexes, can induce PSC activity with subsequent new collagen synthesis. In addition to being stimulated by cytokines, oxidants, or growth factors, PSCs also possess transforming growth factor β (TGF-β)–mediated self-activating autocrine pathways that may explain disease progression in chronic pancreatitis even after removal of noxious stimuli.

ETIOLOGIC CONSIDERATIONS

Among adults in the United States, heavy alcohol use is the most common cause of clinically apparent chronic pancreatitis. As many as 25% of adults in the United States with chronic pancreatitis have the *idiopathic* form, including a subset of patients who do not develop clinical manifestations until later in life (referred to as idiopathic late-onset chronic pancreatitis). Recent investigations have indicated that up to 15% of patients with chronic pancreatitis previously classified as having idiopathic pancreatitis may have an underlying genetic predisposition (Table 359-5).

The prototypical genetic defect was identified in the cationic trypsinogen gene (*PRSS1*) by studying several large families with chronic pancreatitis. Additional pathogenic and nonpathogenic mutations have been identified in this gene. The defect prevents the destruction of prematurely activated trypsin and allows it to be resistant to the intracellular protective effect of trypsin inhibition. It is hypothesized that this continual activation of digestive enzymes within the gland leads to acute injury and, finally, chronic pancreatitis. Since the initial discovery of the *PRSS1* mutation defect, other genetic disease modifiers have been identified (Table 359-5).

The *CFTR* gene functions as a cyclic AMP–regulated chloride channel. In patients with cystic fibrosis, the high concentration of macromolecules can block the pancreatic ducts. It must be appreciated, however, that there is a great deal of heterogeneity in relationship to the *CFTR* gene defect. More than 1700 putative mutations of the *CFTR* gene have been identified. The large number and different classes of *CFTR* mutations have hampered attempts to elucidate the relationship between the genotype and pancreatic manifestations. The ability to detect *CFTR* mutations has led to the recognition that the clinical spectrum of the disease is broader than initially thought. Studies have clarified the association between mutations of the *CFTR* gene and another monosymptomatic form of cystic fibrosis (i.e., chronic pancreatitis). It is estimated that in patients with idiopathic pancreatitis, the frequency of a single *CFTR* mutation is 11 times the expected frequency and the frequency of two mutant alleles is 80 times the expected frequency. In these studies, patients were adults when the diagnosis of pancreatitis was made; none had any clinical evidence of pulmonary disease, and sweat test results were not diagnostic of cystic fibrosis. The prevalence of such mutations is unclear, and further studies are needed. In addition, the therapeutic and prognostic implication of these findings with respect to managing pancreatitis remains to be determined. *CFTR* mutations are common in the general population, so it is unclear whether the *CFTR* mutation alone can lead to pancreatitis as an autosomal recessive disease. A study evaluated 39 patients with idiopathic chronic pancreatitis to assess the risk associated with these mutations. Patients with two *CFTR* mutations (compound heterozygotes) demonstrated *CFTR* function at a level between that seen in typical cystic fibrosis and cystic fibrosis carriers and had a 40-fold increased risk of pancreatitis. The presence of a separate genetic mutation (*N34S SPINK1*) increased the risk 20-fold. A combination of two *CFTR* mutations and an *N34S SPINK1* mutation increased the risk of pancreatitis 900-fold. Knowledge of the genetic defects and downstream alterations in protein expression has led to the development of novel therapies in children with cystic fibrosis that potentiate the CFTR channel, resulting in improvement in lung function, quality of life, and weight gain. Some studies have shown that use of CFTR modulators may reduce the frequency of acute pancreatitis in heterozygous carriers. Table 359-5 lists other recognized causes of chronic pancreatitis.

AUTOIMMUNE PANCREATITIS (TABLE 359-6)

Autoimmune pancreatitis (AIP) refers to a form of chronic pancreatitis with distinct histopathology and several unique differences in the clinical phenotype. Currently, two subtypes of AIP are recognized, type 1 AIP and idiopathic duct-centric chronic pancreatitis (IDCP, also referred to as type 2 AIP). Type 1 AIP is identified as the pancreatic manifestation of a multiorgan syndrome currently referred to as IgG4-related disease **(Chap. 380)**. The characteristic histopathologic findings of type 1 AIP include lymphoplasmacytic infiltrate, storiform fibrosis, and abundant IgG4 cells. IDCP is histologically defined by the presence of granulocytic infiltration of the duct wall (termed a granulocytic epithelial lesion [GEL]) but without IgG4-positive cells. Type 1 AIP is often associated with involvement of other organs in the setting of IgG4-related disease, including bilateral submandibular gland enlargement, characteristic renal lesions, retroperitoneal fibrosis, and stricturing of the extrapancreatic biliary tree. In contrast, IDCP is a pancreas-specific disorder that is associated with inflammatory bowel disease in ~10% of patients. AIP is not a common cause of idiopathic recurrent acute pancreatitis.

Jaundice, weight loss, and new-onset diabetes are the most common presenting symptoms. Elevated serum IgG4 levels are supportive of the diagnosis (elevated in two-thirds of patients with type 1 AIP) but have a low positive predictive value when used in isolation of other clinical findings. CT imaging demonstrates abnormalities in the majority of patients with either diffuse or focal enlargement during active disease, unless the gland is atrophic due to previous disease **(Fig. 359-3)**. The presence of an inflammatory rim, termed a capsule sign, is highly specific (but not sensitive) for AIP. ERCP or MRCP reveals strictures in the bile duct in more than one-third of patients with AIP, including some patients with isolated intrahepatic bile duct strictures (type 1 AIP only), which can mimic primary sclerosing cholangitis, and is referred to as IgG4-related sclerosing cholangitis (previously termed IgG4-associated cholangitis).

The Mayo Clinic HISORt criteria provide a helpful mnemonic to remember the key diagnostic features of this disease, including (1) *h*istology; (2) *i*maging; (3) *s*erology (elevated serum IgG4 levels); (4) *o*ther organ involvement; and (5) *r*esponse to glucocorticoid *t*herapy. These diagnostic criteria have been harmonized with those from other countries to develop the International Consensus Diagnostic Criteria for AIP, which are the most comprehensive criteria. Glucocorticoids have shown efficacy in alleviating symptoms, decreasing the size of

TABLE 359-6 Comparison of the Autoimmune Pancreatitis (AIP) Subtypes

	TYPE 1 AIP	TYPE 2 AIP
Age at diagnosis, mean	Seventh decade	Fifth decade
Male sex	75%	50%
Serum IgG4 elevation	~66%	~25%
Other organ involvement	50%	No[a]
Histologic findings:		
Lymphoplasmacytic Infiltration	++	++
Periductal inflammation	++	++
Storiform fibrosis	++	+
Obliterative phlebitis	++	+
Granulocytic epithelial lesion (GEL)	–	+++
IgG4 tissue staining	Abundant (≥10 cells/hpf)	Scant (<10 cells/hpf)
Response to steroids	~100%	~100%
Risk for relapse	Moderate to high (20–60%)	Low (<10%)
Associated with IgG4-RD	Yes	No

[a]Inflammatory bowel disease is seen in ~10–20% of patients with idiopathic duct-centric chronic pancreatitis but may also occur in type 1 AIP.

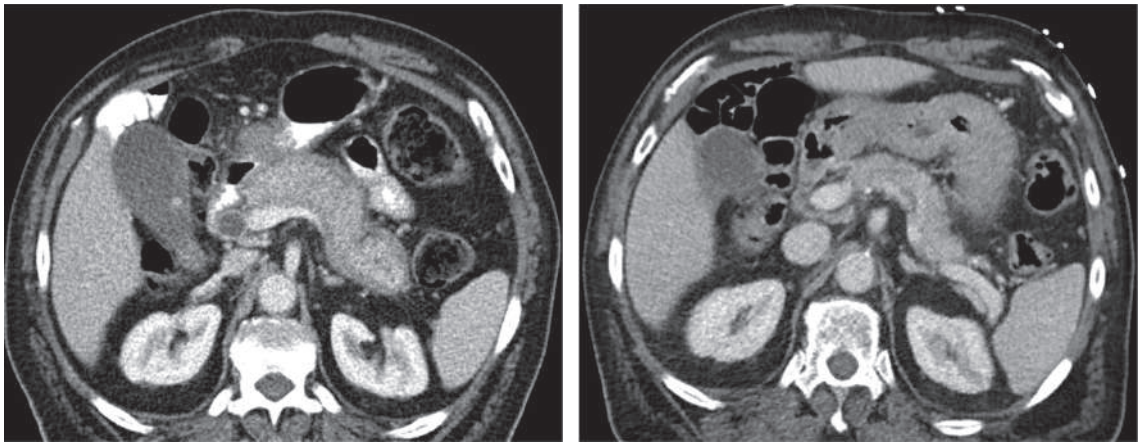

FIGURE 359-3 Imaging features of the pancreatic parenchyma in a patient with type 1 autoimmune pancreatitis on computed tomography (CT). ***A.*** Contrast-enhanced CT scan of the abdomen demonstrates diffuse pancreatic enlargement and a hypoechoic rim (capsule sign) in a patient who presented with jaundice. The serum IgG4 level was elevated to 942 mg/dL (reference range 4–86 mg/dL), so the patient was diagnosed with definitive type 1 autoimmune pancreatitis. ***B.*** Contrast-enhanced CT scan of the abdomen following a treatment course with high-dose steroids demonstrates return to normal size of the pancreas, reappearance of normal lobulations along the margin, and absence of the hypoechoic rim.

the pancreas, and reversing histopathologic features in patients with AIP. Patients typically respond dramatically to glucocorticoid therapy within a 2- to 4-week period. Prednisone is usually administered at an initial dose of 40 mg/d for 4 weeks followed by a taper of the daily dosage by 5 mg per week based on monitoring of clinical parameters. Relief of symptoms, liver biochemistries, and abnormal imaging of the pancreas and bile ducts are followed to assess for treatment response. A poor response to glucocorticoids should raise suspicion of an alternate diagnosis, such as pancreatic cancer. A prior multicenter international study examined >1000 patients with AIP. Clinical remission was achieved in 99% of type 1 AIP and 92% of type 2 AIP patients with steroids. However, disease relapse occurred in 31 and 9% of patients with type 1 and type 2 AIP, respectively. Patients with multiple relapses have been managed with immunomodulators (e.g., azathioprine, 6-mercaptopurine, or mycophenolate mofetil) with variable success. Management with B-cell depletion therapy (e.g., rituximab) is likely the most effective treatment option for patients with recurrent relapses with other therapies under investigation. The appearance of interval cancers following a diagnosis of AIP is uncommon.

Clinical Features of Chronic Pancreatitis Patients with chronic pancreatitis primarily seek medical attention due to abdominal pain or symptoms of maldigestion. The abdominal pain may be variable in location, severity, and frequency. The pain can be constant or intermittent with pain-free intervals. Eating may exacerbate the pain, leading to a fear of eating with consequent weight loss. The spectrum of abdominal pain ranges from mild to quite severe, with narcotic dependence as a frequent consequence. There is often a disparity between the reported severity of abdominal pain and the physical findings, which primarily consist of nonfocal abdominal tenderness. Patients with chronic abdominal pain may or may not experience symptoms of maldigestion, such as chronic diarrhea, steatorrhea, and/or weight loss. Fat-soluble vitamin deficiencies are increasingly recognized. Importantly, there is an exceedingly high prevalence of metabolic bone disease in chronic pancreatitis, with ~65% of patients having either osteopenia or osteoporosis. Patients with chronic pancreatitis have impaired quality of life and develop significant morbidity, requiring frequent health encounters.

The diagnosis of early or mild chronic pancreatitis can be challenging because there is no accurate biomarker for the disease. In contrast to acute pancreatitis, the serum amylase and lipase levels are usually not strikingly elevated in chronic pancreatitis. Rather, low serum pancreatic enzyme levels are moderately specific for a diagnosis of chronic pancreatitis but have poor sensitivity. Elevation of serum bilirubin and alkaline phosphatase may indicate cholestasis secondary to common bile duct stricture caused by chronic inflammation or fibrosis. The cumulative prevalence of exocrine pancreatic insufficiency is >80%. The presence of overt steatorrhea in a patient with chronic pancreatitis is highly suggestive of this complication. However, in those with milder symptoms, additional testing, such as a random fecal elastase-1 level (on a formed stool specimen) may be needed to confirm the diagnosis of exocrine pancreatic insufficiency. The radiographic evaluation of a patient with suspected chronic pancreatitis usually proceeds from a noninvasive to more invasive approach. Abdominal CT imaging **(Fig. 359-4)** is the initial modality of choice, followed by MRI, endoscopic ultrasound, and pancreas function testing. In addition to excluding a pseudocyst and pancreatic cancer, CT imaging may show calcifications, dilated pancreatic or biliary ducts, or an atrophic pancreas. Although abdominal CT scanning and MRI greatly aid in the diagnosis of pancreatic disease, the diagnostic test with the best sensitivity is the direct pancreatic function test using secretin. The secretin test becomes abnormal when ≥60% of the pancreatic exocrine function has been lost and usually correlates well with the onset of chronic abdominal pain. The role of endoscopic ultrasonography (EUS) in diagnosing early chronic pancreatitis is still evolving. A total of nine endosonographic features have been described in chronic pancreatitis. The presence of five or more features is considered diagnostic of chronic pancreatitis. EUS is not a specific enough test for detecting early chronic pancreatitis alone **(Chap. 358)** and may show positive features in patients with diabetes, patients with a history of cigarette smoking, or even in normal aging individuals. Recent data suggest that EUS can be combined with endoscopic pancreatic function testing (EUS-ePFT) during a single endoscopy to screen for chronic pancreatitis in patients with chronic abdominal pain. Diffuse calcifications noted on plain film of the abdomen usually indicate significant damage to the pancreas and are pathognomonic for chronic pancreatitis. While patterns of calcification are not specific for an etiology, patients with tropical pancreatitis (often associated with a *SPINK1* mutation) characteristically have bulky calcifications.

Complications of Chronic Pancreatitis There are a number of disease-related complications from chronic pancreatitis in addition to the aforementioned abdominal pain and exocrine pancreatic insufficiency **(Table 359-7)**. The lifetime prevalence of chronic pancreatitis–related diabetes exceeds 80%. Although most patients develop hyperglycemia due to insulin deficiency caused by loss of islet cells, diabetic ketoacidosis and diabetic coma are uncommon. Likewise, end-organ damage (retinopathy, neuropathy, nephropathy) is also uncommon. Nondiabetic retinopathy may be due to vitamin A and/or zinc deficiency. Osteoporosis and osteopenia are increasingly recognized in chronic pancreatitis and likely related to a combination of shared risk factors (e.g., alcohol use, cigarette smoking), vitamin D deficiency, and detrimental effects on the bone from chronic inflammation. Gastrointestinal bleeding may occur from peptic ulceration, gastritis, a pseudocyst

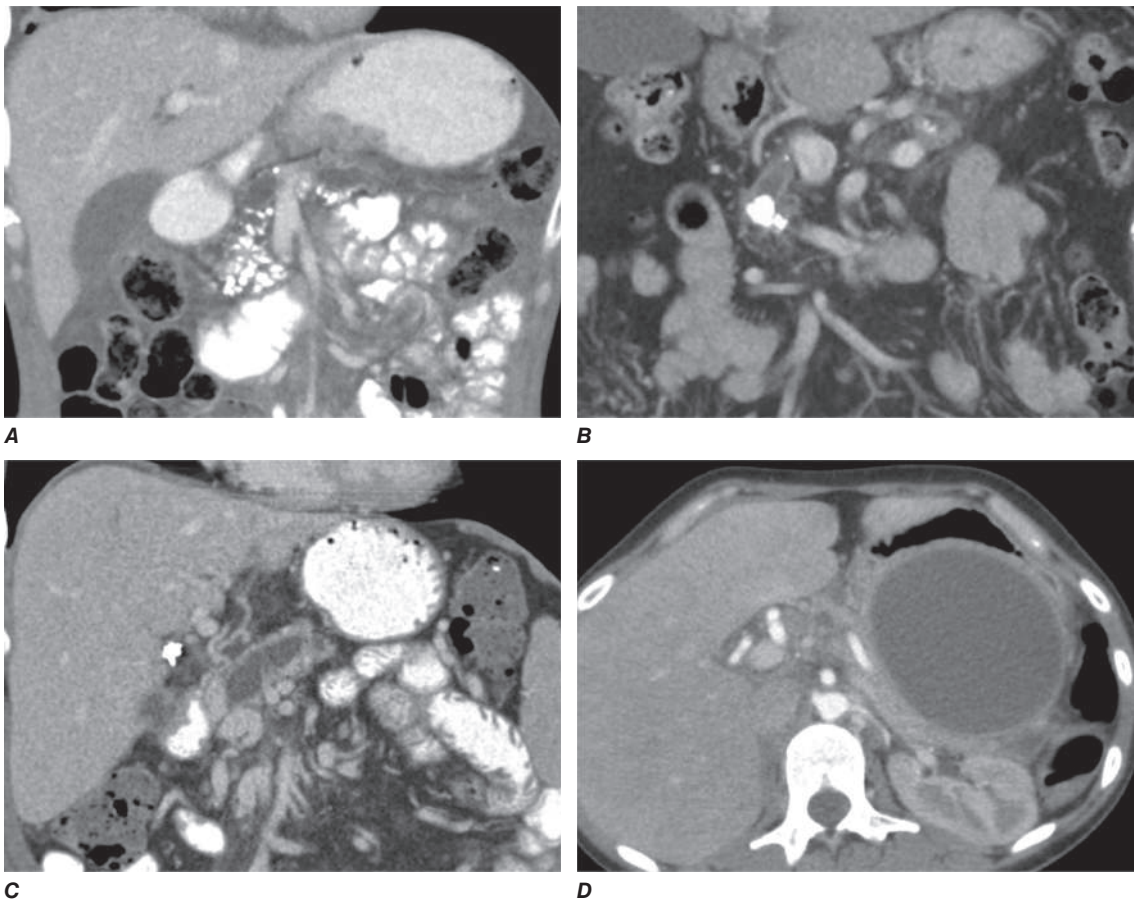

FIGURE 359-4 Distribution of imaging features of chronic pancreatitis on computed tomography (CT). Distinct features of chronic pancreatitis are seen on selected images from contrast-enhanced CT scans of the abdomen from four unique patients, including the following. ***A.*** Numerous punctate calcifications involving the pancreatic parenchyma in the head and body. ***B.*** A moderate-sized calculus visualized in the pancreatic duct with associated ductal dilation. ***C.*** Significant pancreatic duct dilation and adjacent parenchymal atrophy secondary to a pancreatic duct stricture (which is not well seen on this scan). ***D.*** A large unilocular, encapsulated cyst in the tail of the pancreas consistent with a pseudocyst from prior pancreatitis. Note adjacent pancreatic parenchymal atrophy.

eroding into the duodenum, arterial bleeding into the pancreatic duct (hemosuccus pancreaticus), or ruptured varices secondary to splenic vein thrombosis. Jaundice, cholestasis, and biliary cirrhosis may occur from the chronic inflammatory reaction around the intrapancreatic portion of the common bile duct. Twenty years after the diagnosis of chronic calcific pancreatitis, the cumulative risk of pancreatic cancer is 4%. Patients with hereditary *PRSS1* or tropical pancreatitis have an increased risk for pancreatic cancer compared to other forms of chronic pancreatitis.

TREATMENT

Chronic Pancreatitis

There are currently no therapies to reverse or delay the disease progression of chronic pancreatitis, so management is primarily focused on screening for and management of disease-related complications.

STEATORRHEA

The treatment of steatorrhea with pancreatic enzyme replacement therapy is conceptually straightforward, yet complete correction of steatorrhea is uncommon. Enzyme therapy usually brings diarrhea under control and restores absorption of fat to an acceptable level and affects weight gain. Thus, pancreatic enzyme replacement is the cornerstone of therapy. In treating steatorrhea, it is important to use a potent pancreatic formulation that will deliver sufficient lipase into the duodenum to correct maldigestion and decrease steatorrhea. For adult patients with exocrine pancreatic insufficiency, it is generally recommended to start at a dosage of 25,000–50,000 units of lipase taken during each meal; however, the dose may need to be increased up to 100,000 units of lipase depending on the response in symptoms, nutritional parameters, and/or pancreas function test results (although rarely used for this purpose). Additionally, some may require acid suppression with proton pump inhibitors to optimize the response to pancreatic enzymes. Monitoring nutritional parameters such as fat-soluble vitamins, zinc levels, body weight, and periodic bone mineral density measurement should be considered.

TABLE 359-7 Complications of Chronic Pancreatitis

Chronic abdominal pain	Biliary stricture and/or biliary cirrhosis
Exocrine pancreatic insufficiency	Pancreatic duct stricture
Diabetes mellitus	Pseudocyst
Splanchnic venous thrombosis	Pancreatic cancer
Metabolic bone disease (osteoporosis)	Malnutrition, micronutrient deficiencies

ABDOMINAL PAIN

The management of pain in patients with chronic pancreatitis is challenging due to the complex mechanisms of pancreatitis-related pain. Recent meta-analyses have shown no consistent benefit of enzyme therapy at reducing pain in chronic pancreatitis. Pain relief experienced by patients treated with pancreatic enzymes may be due to improvements in dyspepsia from maldigestion. One short-term randomized trial showed that pregabalin could decrease pain in chronic pancreatitis and lower pain medication requirement. Other studies using antioxidants have yielded mixed results.

Endoscopic treatment of chronic pancreatitis pain may involve sphincterotomy, pancreatic duct stenting, stone extraction, and drainage of a pancreatic pseudocyst. Therapy directed to the pancreatic duct would seem to be most appropriate in the setting of a dominant stricture, especially if there is an obstructing intraductal stone. The use of endoscopic stenting for patients with chronic pain

has not been investigated in controlled trials. It is now appreciated that significant complications can occur from stenting (e.g., stent migration, stent occlusion, and stent-induced pancreatic duct strictures). Recent guidelines recommend considering celiac plexus block for treatment of pain in chronic pancreatitis, but recommendations were conditional with very low quality of evidence. Celiac plexus block has not been rigorously studied for chronic pancreatitis and does not provide durable pain relief. It can provide relief in some selected patients, but the a priori identification of those who will respond is difficult. In patients with pancreatic duct dilation, ductal decompression with *surgical therapy* has been the therapy of choice. Among such patients, 80% seem to obtain immediate relief; however, at the end of 3 years, one-half of the patients have recurrence of pain. Two randomized prospective trials comparing endoscopic to surgical therapy for chronic pancreatitis demonstrated that surgical therapy was superior to endoscopy at decreasing pain and improving quality of life in selected patients with dilated ducts and abdominal pain. This would suggest that chronic pancreatitis patients with dilated ducts and pain should be considered for surgical intervention. A recent randomized controlled trial suggests that early surgical intervention may provide superior pain relief in the short term compared to a conservative, nonoperative approach. The role of preoperative stenting prior to surgery as a predictor of response has yet to be proven.

Total pancreatectomy with or without autologous islet cell transplantation has been used in highly selected patients with chronic pancreatitis and abdominal pain refractory to conventional therapy. However, some patients will continue to have pain postoperatively, illustrating the complex nature of pain in this patient population. Patients who benefit most from total pancreatectomy have a shorter duration of symptoms and lower pain medication requirements. The role of this procedure remains to be fully defined but may be an option in lieu of ductal decompression surgery or partial pancreatic resection in patients with intractable, painful, small-duct disease or hereditary pancreatitis.

HEREDITARY PANCREATITIS

Hereditary pancreatitis (*PRSS1*) is a rare form of pancreatitis with early age of onset that is typically associated with familial aggregation of cases. A genome-wide search using genetic linkage analysis identified the hereditary pancreatitis gene on chromosome 7. Mutations in ion codons 29 (exon 2) and 122 (exon 3) of the cationic trypsinogen gene (*PRSS1*) cause an autosomal dominant form of pancreatitis. The codon 122 mutations lead to a substitution of the corresponding arginine with another amino acid, usually histidine. This substitution, when it occurs, eliminates a fail-safe trypsin self-destruction site necessary to eliminate trypsin that is prematurely activated within the acinar cell. These patients have recurring episodes of acute pancreatitis. Patients frequently develop pancreatic calcification, diabetes mellitus, and steatorrhea; in addition, they have an increased incidence of pancreatic cancer with a cumulative incidence of ~10%. A previous natural history study of hereditary pancreatitis in >200 patients from France reported that abdominal pain started in childhood at age 10 years, steatorrhea developed at age 29 years, diabetes at age 38 years, and pancreatic cancer at age 55 years. Abdominal complaints in relatives of patients with hereditary pancreatitis should raise the question of pancreatic disease.

PANCREATIC ENDOCRINE TUMORS

Pancreatic endocrine tumors are discussed in Chap. 89.

OTHER CONDITIONS

ANNULAR PANCREAS

When the ventral pancreatic anlage fails to migrate correctly to make contact with the dorsal anlage, the result may be a ring of pancreatic tissue encircling the duodenum. Such an annular pancreas may cause intestinal obstruction in the neonate or adult. Symptoms of postprandial fullness, epigastric pain, nausea, and vomiting may be present for years before the diagnosis is entertained. The radiographic findings are symmetric dilation of the proximal duodenum with bulging of the recesses on either side of the annular band, effacement but not destruction of the duodenal mucosa, accentuation of the findings in the right anterior oblique position, and lack of change on repeated examinations. The differential diagnosis should include duodenal webs, tumors of the pancreas or duodenum, duodenal ulcer, regional enteritis, and adhesions. Patients with annular pancreas have an increased incidence of pancreatitis and peptic ulcer. Because of these and other potential complications, the treatment for refractory symptoms is surgical. Retrocolic duodenojejunostomy is the procedure of choice, although some surgeons advocate Billroth II gastrectomy, gastroenterostomy, and vagotomy.

PANCREAS DIVISUM

Pancreas divisum is present in 7–10% of the population and occurs when the embryologic ventral and dorsal pancreatic anlagen fail to fuse, so that pancreatic drainage is accomplished mainly through the accessory minor papilla. Pancreas divisum is the most common congenital anatomic variant of the human pancreas. Current evidence indicates that this anomaly does not predispose to the development of pancreatitis in the majority of patients. However, the combination of pancreas divisum and a small accessory orifice can result in dorsal duct obstruction. The challenge is to identify this subset of patients with dorsal duct pathology. Cannulation of the dorsal duct by ERCP is technically challenging and associated with a very high risk of post-ERCP pancreatitis, so patients with pancreatitis and pancreas divisum should likely be treated with conservative measures. In many of these patients, pancreatitis is idiopathic and unrelated to the pancreas divisum. Endoscopic or surgical intervention is indicated if pancreatitis recurs and no other cause can be found. It should be stressed that the ERCP/MRCP appearance of pancreas divisum (i.e., a small-caliber ventral duct with an arborizing pattern) may be mistaken as representing an obstructed main pancreatic duct secondary to a mass lesion.

MACROAMYLASEMIA

In macroamylasemia, amylase circulates in the blood in a polymer form too large to be easily excreted by the kidney. Patients with this condition demonstrate an elevated serum amylase value and a low urinary amylase value. The presence of macroamylase can be documented by chromatography of the serum. The prevalence of macroamylasemia is 1.5% of the nonalcoholic general adult hospital population. Usually, macroamylasemia is an incidental finding and is not related to disease of the pancreas or other organs. Macrolipasemia has now been documented in patients with cirrhosis or non-Hodgkin's lymphoma. In these patients, the pancreas appeared normal on ultrasound and CT examination. Lipase was shown to be complexed with immunoglobulin A. Thus, the possibility of *both* macroamylasemia and macrolipasemia should be considered in patients with elevated blood levels of these enzymes.

Acknowledgment

This chapter represents a revised version of chapters by Drs. Norton J. Greenberger (deceased), Phillip P. Toskes (deceased), Peter A. Banks, and Bechien Wu that were in previous editions of Harrison's.

Section 1 The Immune System in Health and Disease

360 Introduction to the Immune System

Barton F. Haynes, Kelly A. Cuttle, Anthony S. Fauci

DEFINITIONS

- *Adaptive immune system*—recently evolved system of immune responses mediated by T and B lymphocytes. Immune responses by these cells are based on specific antigen recognition by clonotypic receptors that are products of genes that rearrange during development and throughout the life of the organism. Additional cells of the adaptive immune system include various types of antigen-presenting cells (APCs).
- *Antibody*—B cell–produced molecules encoded by genes that rearrange during B-cell development consisting of immunoglobulin heavy and light chains that together form the central component of the B-cell receptor (BCR) for antigen. Antibody can exist as B cell–surface antigen-recognition molecules or as secreted molecules in plasma and other body fluids.
- *Antigens*—foreign or self-molecules that are recognized by the adaptive and innate immune systems resulting in immune cell triggering, T-cell activation, and/or B-cell antibody production.
- *Antigen-presenting cells (APCs)*—a group of immune cells that process antigens to mediate both adaptive immune responses and the maintenance of peripheral tolerance. Classical APCs include dendritic cells, macrophages, and B cells.
- *Apoptosis*—the process of *programmed cell death* whereby signaling through "death receptors" on the surface of cells (e.g., tumor necrosis factor [TNF] receptors, CD95) leads to signaling cascades that involve activation of the caspase family of molecules and leads to DNA cleavage and cell death. Apoptosis, which does not lead to induction of inordinate inflammation, is to be contrasted with *cell necrosis*, which does lead to induction of inflammatory responses.
- *Autoimmune diseases*—diseases such as systemic lupus erythematosus and rheumatoid arthritis in which cells of the adaptive immune system such as autoreactive T and B cells become overreactive and produce pathogenic T-cell and antibody responses.
- *Autoinflammatory diseases*—hereditary disorders such as hereditary periodic fevers (HPFs) characterized by recurrent episodes of severe inflammation and fever due to mutations in controls of the innate inflammatory response, i.e., the inflammasome (see below and Table 360-5). Patients with HPFs also have rashes and serosal and joint inflammation, and some can have neurologic symptoms. Autoinflammatory diseases are different from autoimmune diseases in that evidence for activation of adaptive immune cells such as autoreactive B cells is not present.
- *Autophagy*—lysosomal degradation pathway mechanism of cells to dispose of intracellular debris and damaged organelles. Autophagy by cells of the innate immune system is used to control intracellular infectious agents such as mycobacteria, in part by initiation of phagosome maturation and enhancing major histocompatibility complex (MHC) class II antigen presentation to CD4 T cells.
- *B-cell receptor (BCR) for antigen*—complex of surface molecules that rearrange during postnatal B-cell development, made up of surface immunoglobulin (Ig) and associated Ig αβ chain molecules that recognize nominal antigen via Ig heavy- and light-chain variable regions, and signal the B cell to terminally differentiate to make antigen-specific antibody.
- *B lymphocytes*—bone marrow–derived lymphocytes that express surface immunoglobulin (the BCR for antigen) and secrete specific antibody after interaction with antigen.
- *B regulatory cells*—a population of suppressive B cells that aid in the inhibition of inflammation through the release of cytokines such as interleukin-(IL) 10.
- *CD classification of human lymphocyte differentiation antigens*—the development of monoclonal antibody technology led to the discovery of a large number of new leukocyte surface molecules. From a series of International Workshop on Leukocyte Differentiation Antigens has come the *cluster of differentiation* (CD) classification of leukocyte antigens.
- *CD4 T cell*—T lymphocyte subset that participates in adaptive immunity and helps B cells make antibody.
- *CD8 T cell*—cytotoxic T lymphocyte subset that kills tumor cells and cells infected with pathogens.
- *Chemokines*—soluble molecules that direct and determine immune cell movement and circulation pathways.
- *Complement*—cascading series of plasma enzymes and effector proteins that function to lyse pathogens and/or target them to be phagocytized by neutrophils and monocyte/macrophage lineage cells of the reticuloendothelial system.
- *Co-stimulatory molecules*—molecules of APCs (such as B7-1, B7-2, or CD40) that lead to T-cell activation when bound by ligands on activated T cells (such as CD28 or CD40 ligand).
- *Crystallopathies*—nanoparticle- or microparticle-sized deposits of crystals, misfolded proteins, or airborne particulate matter that can stimulate the inflammasome and initiate inflammation and tissue damage.
- *Cytokines*—soluble proteins that interact with specific cellular receptors that are involved in the regulation of the growth and activation of immune cells and mediate normal or pathologic inflammatory and immune responses.
- *Dendritic cells*—myeloid and/or lymphoid lineage APCs of the adaptive immune system. Immature dendritic cells (DCs), or DC precursors, are key components of the innate immune system by responding to infections with production of high levels of cytokines. DCs are key initiators of innate immune responses via cytokine production and mediators of adaptive immune responses via presentation of antigen to T lymphocytes.
- *Ig fragment crystallizable (Fc) receptors (Rs)*—receptors found on the surface of certain cells including B cells, natural killer (NK) cells, macrophages, neutrophils, and mast cells. Fc receptors bind to the Fc domains of antibodies that have attached to invading pathogen-infected cells. FcRs stimulate cytotoxic cells to destroy microbe-infected cells through antibody-dependent cell-mediated cytotoxicity (ADCC). Examples of important FcRs include CD16 (FcγRIIIa), CD23 (FcεR), CD32 (FcγRII), CD64 (FcγRI), and CD89 (FcαR).
- *Inflammasome*—large cytoplasmic complexes of intracellular proteins that link the sensing of microbial products and cellular stress to the proteolytic activation of IL-1β and IL-18 inflammatory cytokines. Activation of molecules in the inflammasome is a key step in the response of the innate immune system for intracellular recognition of microbial and other danger signals in both health and pathologic states.
- *Innate immune system*—ancient immune recognition system of host cells bearing germline-encoded pattern recognition receptors (PRRs) that recognize pathogens and trigger a variety of mechanisms of pathogen elimination. Cells of the innate immune system include NK cell lymphocytes, monocytes/macrophages, DCs, neutrophils, basophils, eosinophils, tissue mast cells, and epithelial cells.
- *Innate lymphoid cells (ILCs)*—lymphocytes that do not express the type of diversified antigen receptors on T cell and B cells. ILC1s,

ILC2s, and ILC3s are tissue resident cells and functionally may be analogous to CD4 T_H1, T_H2, and T_H17 cells, respectively.

- *Natural killer (NK) cells*—a type of ILC that kills target cells expressing few or no human leukocyte antigen (HLA) class I molecules, such as malignantly transformed cells and virally infected cells. NK cells express receptors that inhibit killer cell function when self-MHC class I is present. Innate NK cells mirror the cytolytic functions of CD8 cytotoxic T cells of the adaptive immune system.
- *NK T cells*—innate-like lymphocytes that use an invariant T-cell receptor (TCR)-α chain combined with a limited set of TCR-β chains and coexpress receptors commonly found on NK cells. NK T cells recognize lipid antigens of bacterial, viral, fungal, and protozoal infectious agents.
- *Pathogen-associated molecular patterns (PAMPs)*—invariant molecular structures expressed by large groups of microorganisms that are recognized by host cellular PRRs in the mediation of innate immunity.
- *Pattern recognition receptors (PRR)*—germline-encoded receptors expressed by cells of the innate immune system that recognize PAMPs.
- *T lymphocytes*—thymus-derived lymphocytes that mediate adaptive cellular immune responses including T helper, T regulatory, and cytotoxic T lymphocyte effector cell functions.
- *T-cell exhaustion*—state of T cells when the persistence of antigen disrupts memory T-cell function, resulting in defects in memory T-cell responses. Most frequently occurs in malignancies and in chronic viral infections such as HIV-1 and hepatitis C.
- *TCR for antigen*—complex of surface molecules that rearrange during postnatal T-cell development made up of clonotypic TCR-α and -β chains that are associated with the CD3 complex composed of invariant γ, δ, ε, ζ, and η chains. TCR-α and -β chains recognize peptide fragments of protein antigen physically bound in APC MHC class I or II molecules, leading to signaling via the CD3 complex to mediate effector functions.
- *T follicular helper T cells (TFH)*—CD4 T cells regulated by bcl-6 in B-cell follicle germinal centers that produce IL-4 and IL-21 and drive B-cell differentiation and affinity maturation in peripheral lymphoid tissues such as lymph node and spleen.
- *T_H1 T cells*—CD4 helper T-cell subset regulated by transcription factor T-bet that produces interferon (IFN)-γ, IL-2, and TNF-β and participates in cell-mediated immunity.
- *T_H2 T cells*—CD4 helper T-cell subset regulated by transcription factors STAT6 and GATA3 that produces IL-4, IL-5, IL-6, IL-9, IL-10, and IL-13 and regulates antibody and eosinophil responses.
- *T regulatory cells (Treg)*—CD4 or CD8 T cells regulated by the transcription factor forkhead box P3 (FOXP3) that play roles in modulating immune responses to prevent harmful immune activation. Treg cells that prevent autoimmunity can arise in the thymus (thymic Tregs) after exposure to self-antigens on thymic epithelial cells or can arise outside the thymus and are called peripheral Tregs. Intestinal Tregs are essential to preventing pathogenic immune responses to the gut microbiome, thus preventing intestinal inflammation.
- *T_H9 T cells*—CD4 T cells regulated by the transcription factor PU.1 that secrete IL-9 and enhance inflammation in atopic disease and inflammatory bowel disease as well as mediate antitumor immunity.
- *T_H13 T cells*—T follicular helper cells (TFH) regulated by the GATA3 transcription factor that produce IL-4, IL-5, and IL-13. T_H13 TFH induce high-affinity IgE antibody responses that cause anaphylactic reactions to allergens.
- *T_H17 T cells*—CD4 T cells regulated by the transcription factor RORγt that secrete IL-17, IL-22, and IL-26 and play roles in autoimmune inflammatory disorders as well as defend against bacterial and fungal pathogens.
- *Tolerance*—B- and T-cell nonresponsiveness to antigens that results from encounter with foreign or self-antigens by B and T lymphocytes in the absence of expression of APC co-stimulatory molecules. Tolerance to antigens may be induced and maintained by multiple mechanisms either centrally (B-cell deletion in the thymus for T cells or bone marrow for B cells) or peripherally (by cell deletion or anergy at sites throughout the peripheral immune system).
- *Trained immunity*—the epigenetic, transcriptional, and functional reprogramming of innate immune cells to adapt to previous encounters with pathogens and respond to a second challenge in an altered manner.

INTRODUCTION

The human immune system has evolved over millions of years from both invertebrate and vertebrate organisms to develop sophisticated defense mechanisms that protect the host from microbes and their virulence factors. The normal immune system has three key properties: a highly diverse repertoire of antigen receptors that enables recognition of a nearly infinite range of pathogens; immune memory, to mount rapid recall immune responses; and immunologic tolerance, to avoid immune damage to self-tissues.

From invertebrates, humans have inherited the *innate immune system*, an ancient defense system that uses germline-encoded proteins to recognize pathogens. Cells of the innate immune system, such as macrophages, DCs, and NK lymphocytes, recognize PAMPs that are highly conserved among many microbes and use a diverse set of PRR molecules. Important components of the recognition of microbes by the innate immune system include recognition by germline-encoded host molecules, recognition of key microbe virulence factors but not recognition of self-molecules, and nonrecognition of benign foreign molecules or microbes such as are found in mucosal or other barrier microbiomes. Upon contact with pathogens, cells of the innate immune system may kill pathogens directly or, in concert with DCs, activate a series of events that both slow the infection and recruit the more recently evolved arm of the human immune system, the *adaptive immune system*. In addition, innate immune cells undergo epigenetic, transcriptional, and functional changes that allow adapted (either enhanced or reduced) innate cell responses to repeat encounters with pathogens, called *trained immunity*.

Adaptive immunity is found only in vertebrates and is based on the generation of antigen receptors on T and B lymphocytes by gene rearrangements, such that individual T or B cells express unique antigen receptors on their surface capable of specifically recognizing diverse antigens of infectious agents in the environment. Coupled with specific recognition mechanisms that maintain tolerance (nonreactivity) to self-antigens or nonpathogenic microbes **(Chap. 361)**, T and B lymphocytes bring both *specificity* and *immune memory* to vertebrate host defenses.

This chapter describes the cellular components, key molecules **(Table 360-1)**, and mechanisms that make up the innate and adaptive immune systems and describes how adaptive immunity is recruited to the defense of the host by innate immune responses. An appreciation of the cellular and molecular bases of innate and adaptive immune responses is critical to understanding the pathogenesis of inflammatory, autoimmune, infectious, and immunodeficiency diseases, as well as a wide range of diseases associated with inflammation such as atherosclerotic cardiovascular disease and neurodegenerative diseases.

THE INNATE IMMUNE SYSTEM

All multicellular organisms, including humans, have developed the use of surface and intracellular germline-encoded molecules that recognize pathogens. Because of the myriad of human pathogens, host molecules of the human innate immune system sense "danger signals" and either recognize PAMPs, the common molecular structures shared by many pathogens, or recognize host cell molecules produced in response to infection such as heat shock proteins and fragments of the extracellular matrix. PAMPs must be conserved structures vital to pathogen virulence and survival, such as bacterial endotoxin, so that pathogens cannot mutate molecules of PAMPs to evade human innate immune responses. PRRs are host proteins of the innate immune system that recognize PAMPs as host danger signal molecules **(Tables 360-2 and 360-3)**. Thus, recognition of pathogen molecules by hematopoietic and nonhematopoietic cell types leads to activation/production of the complement cascade, cytokines, or antimicrobial peptides as effector molecules. In addition, pathogen PAMPs as host danger signal molecules activate DCs to mature and to express molecules on the DC surface that optimize antigen presentation to respond to foreign antigens.

TABLE 360-1 Human Leukocyte Surface Antigens—The CD Classification of Leukocyte Differentiation Antigens

SURFACE ANTIGEN (OTHER NAMES)	FAMILY	MOLECULAR MASS, kDa	DISTRIBUTION	LIGAND(S)	FUNCTION
CD1a (T6, HTA-1)	Ig	49	CD, cortical thymocytes, Langerhans type of DCs	TCRγδ T cells, NK T cells	CD1 molecules present lipid antigens of intracellular bacteria such as *Mycobacterium leprae* and *M. tuberculosis* to TCRγδT cells or NK T cells
CD1b	Ig	45	CD, cortical thymocytes, Langerhans type of DCs	TCRγδ T cells, NK T cells	
CD1c	Ig	43	DC, cortical thymocytes, subset of B cells, Langerhans type of DCs	TCRγδ T cells, NK T cells	
CD1d	Ig	37	Cortical thymocytes, intestinal epithelium, Langerhans type of DCs	TCRγδ T cells, NK T cells	
CD2 (T12, LFA-2)	Ig	50	T, NK	CD58, CD48, CD59, CD15	Alternative T-cell activation, T-cell anergy, T-cell cytokine production, T- or NK-mediated cytolysis, T-cell apoptosis, cell adhesion
CD3 (T3, Leu-4)	Ig	γ:25–28, δ:21–28, ε:20–25, η:21–22, ζ:16	T, NK T	Associates with the TCR	T-cell activation and function; ζ is the signal transduction component of the CD3 complex
CD4 (T4, Leu-3)	Ig	55	T, myeloid	MHC-II, HIV gp120, IL-16, SABP	T-cell selection, T-cell activation, signal transduction with p56*lck*, primary receptor for HIV-1
CD7 (3A1, Leu-9)	Ig	40	T, NK	K-12 (CD7L)	T- and NK-cell signal transduction and regulation of IFN-γ, TNF-α production
CD8 (T8, Leu-2)	Ig	34	T, subset of NK	MHC-I	T-cell selection, T-cell activation, signal transduction with p56*lck*
CD14 (LPS-receptor)	LRG	53–55	M, G (weak), not by myeloid progenitors	Endotoxin (lipopolysaccharide), lipoteichoic acid, PI	TLR4 mediates with LPS and other PAMP activation of innate immunity
CD16a (FcγRIIIa)	Ig	50–80	NK, macrophages, neutrophils	Fc portion of IgG	Mediates phagocytosis and ADCC
CD19 B4	Ig	95	B (except plasma cells), FDC	Not known	Associates with CD21 and CD81 to form a complex involved in signal transduction in B-cell development, activation, and differentiation
CD20 (B1)	Unassigned	33–37	B (except plasma cells)	Not known	Cell signaling, may be important for B-cell activation and proliferation
CD21 (B2, CR2, EBV-R, C3dR)	RCA	145	Mature B, FDC, subset of thymocytes	C3d, C3dg, iC3b, CD23, EBV	Associates with CD19 and CD81 to form a complex involved in signal transduction in B-cell development, activation, and differentiation; Epstein-Barr virus receptor
CD22 (BL-CAM)	Ig	130–140	Mature B	CDw75	Cell adhesion, signaling through association with p72*sky*, p53/56*lyn*, PI3 kinase, SHP1, fLCγ
CD23 (FcεRII, B6, Leu-20, BLAST-2)	C-type lectin	45	B, M, FDC	IgE, CD21, CD11b, CD11c	Regulates IgE synthesis, cytokine release by monocytes
CD28	Ig	44	T, plasma cells	CD80, CD86	Co-stimulatory for T-cell activation; involved in the decision between T-cell activation and anergy
CD32a (FcγRIIa)	Ig	40	NK, macrophages, neutrophils	Fc portion of IgG	Mediates phagocytosis and ADCC
CD40	TNFR	48–50	B, DC, EC, thymic epithelium, MP, cancers	CD154 (CD40L)	B-cell activation, proliferation, and differentiation; formation of GCs; isotype switching; rescue from apoptosis
CD45 (LCA, T200, B220)	PTP	180, 200, 210, 220	All leukocytes	Galectin-1, CD2, CD3, CD4	T and B activation, thymocyte development, signal transduction, apoptosis
CD45RA	PTP	210, 220	Subset T, medullary thymocytes, "naive" T	Galectin-1, CD2, CD3, CD4	Isoforms of CD45 containing exon 4 (A), restricted to a subset of T cells
CD45RB	PTP	200, 210, 220	All leukocytes	Galectin-1, CD2, CD3, CD4	Isoforms of CD45 containing exon 5 (B)
CD45RC	PTP	210, 220	Subset T, medullary thymocytes, "naive" T	Galectin-1, CD2, CD3, CD4	Isoforms of CD45 containing exon 6 (C), restricted to a subset of T cells
CD45RO	PTP	180	Subset T, cortical thymocytes, "memory" T	Galectin-1, CD2, CD3, CD4	Isoforms of CD45 containing no differentially spliced exons, restricted to a subset of T cells
CD64 (FcγRI)	Ig	45–55	Macrophages and monocytes	Fc portion of IgG	Mediates phagocytosis and ADCC
CD80 (B7-1, BB1)	Ig	60	Activated B and T, MP, DC	CD28, CD152 (CTLA-4)	Co-regulator of T-cell activation; signaling through CD28 stimulates and through CD152 inhibits T-cell activation
CD86 (B7-2, B70)	Ig	80	Subset B, DC, EC, activated T, thymic epithelium	CD28, CD152 (CTLA-4)	Co-regulator of T-cell activation; signaling through CD28 stimulates and through CD152 inhibits T-cell activation
CD89 (FCαR)	Ig	55–100	Neutrophils, eosinophils, monocytes, and MP	Fc portion of IgG	Mediates phagocytosis and ADCC of IgA-coated pathogens

(*Continued*)

TABLE 360-1 Human Leukocyte Surface Antigens—The CD Classification of Leukocyte Differentiation Antigens (Continued)

SURFACE ANTIGEN (OTHER NAMES)	FAMILY	MOLECULAR MASS, kDa	DISTRIBUTION	LIGAND(S)	FUNCTION
CD95 (APO-1, Fas)	TNFR	43	Activated T and B	Fas ligand	Mediates apoptosis
CD112 (nekton-2, PVRL2)	Ig	62	Epithelial cells, endothelial cells, other tissues	DNAM-1 (CD226), TIGIT	T-cell activation (DNAM-1), T-cell inhibition (TIGIT)
CD134 (OX40)	TNFR	48	Activated T	OX40L (CD252)	T-cell survival, cytokine stimulation
CD137 (4-1BB)	TNFR	19	Activated T, DCs, B, NK	CD137L (41BBL)	T-cell co-stimulation
CD155 (PVR)	Ig	50–65	DCs, NK, epithelial cells	TIGIT, CD96, DNAM-1	T-cell inhibition (TIGIT, CD96), T-cell activation (DNAM-1)
CD223 (LAG-3)	Ig	57	NK, B, activated T	MHC class II	T-cell inhibition
CD226 (DNAM-1)	Ig	65	NK, monocytes, T	CD112, CD155	T-cell activation (CD112), T-cell activation (CD155)
CD252 (OX40L)	TNFR	16–25	Antigen-presenting cells, endothelial cells	OX40	T-cell survival, cytokine stimulation
CD272 (BTLA)	Ig	16	Activated T	HVEM	T-cell inhibition
CD274 (PD-L1)	Ig	40	T, NK, myeloid, B, tumor cells	PD-1 (CD279)	Inhibit TCR activation
CD278 (ICOS)	Ig	55–60	Activated T	ICOSL	T-cell activation
CD357 (GTTR)	TNFR	41	Activated T, Tregs	GITRL	T-cell activation
CD152 (CTLA-4)	Ig	30–33	Activated T	CD80, CD86	Inhibits T-cell proliferation
CD154 (CD40L)	TNF	33	Activated CD4+ T, subset CD8+ T, NK, M, basophil	CD40	Co-stimulatory for T-cell activation, B-cell proliferation and differentiation
CD279 (PD-1)	Ig	50–55	B, T, TFH	PD-L1 (CD274), PD-L2 (CD273)	Inhibits T-cell proliferation

Abbreviations: ADCC, antibody-dependent cell-mediated cytotoxicity; BTLA, band T lymphocyte attenuators; CTLA, cytotoxic T lymphocyte–associated protein; DC, dendritic cells; DNAM-1, DNAX accessory molecule-1; EBV, Epstein-Barr virus; EC, endothelial cells; ECM, extracellular matrix; Fcγ RIII, low-affinity IgG receptor isoform A; FDC, follicular dendritic cells; G, granulocytes; GC, germinal center; GITR, glucocorticoid-induced TNFR-related protein; GPI, glycosyl phosphatidylinositol; HTA, human thymocyte antigen; HVEM, herpesvirus entry mediator; ICOS, inducible T-cell co-stimulator; Ig, immunoglobulin; IgG, immunoglobulin G; LAG-3, lymphocyte-activation gene 3; LCA, leukocyte common antigen; LPS, lipopolysaccharide; MHC-I, major histocompatibility complex class I; MP, macrophages; Mr, relative molecular mass; NK, natural killer cells; P, platelets; PBT, peripheral blood T cells; PD-1, programmed cell death-1; PI, phosphatidylinositol; PI3K, phosphatidylinositol 3-kinase; PLC, phospholipase C; PTP, protein tyrosine phosphatase; PVR, polio virus receptor; PVRL2, polio virus receptor-related 2; RCA, regulators of complement activation; SABP, seminal actin binding protein; TCR, T-cell receptor; TFH, T follicular helper cells; TIGIT, T-cell immunoreceptor with Ig and ITIM domains; TNF, tumor necrosis factor; TNFR, tumor necrosis factor receptor.

Note: For an expanded list of cluster of differentiation (CD) human antigens, see Harrison's Online at *accessmedicine.com*; and for a full list of CD human antigens from the most recent Human Workshop on Leukocyte Differentiation Antigens (VII), D Mason, P Andre, A Bensussan, et al (eds): *Leucocyte Typing VII*. Oxford: Oxford University Press, 2002.

PATTERN RECOGNITION

Major PRR families of proteins include transmembrane proteins, such as the Toll-like receptors (TLRs) and C-type lectin receptors (CLRs), and cytoplasmic proteins, such as the retinoic acid–inducible gene (RIG)-1-like receptors (RLRs) and NOD-like receptors (NLRs) (Table 360-4). A major group of PRR collagenous glycoproteins with C-type lectin domains are termed *collectins* and include the serum protein mannose-binding lectin (MBL). MBL and other collectins, as well as two other protein families—the pentraxins (such as C-reactive protein and serum amyloid P) and macrophage scavenger receptors—all have the property of opsonizing (coating) bacteria for phagocytosis by macrophages and can also activate the complement cascade to lyse bacteria. Integrins are cell-surface adhesion molecules that affect attachment between cells and the extracellular matrix and mediate signal transduction that reflects the chemical composition of the cell environment. For example, integrins signal after cells bind bacterial lipopolysaccharide (LPS) and activate phagocytic cells to ingest pathogens.

TABLE 360-2 Major Components of the Innate Immune System

Pattern recognition receptors (PRRs)	Toll-like receptors (TLRs), C-type lectin receptors (CLRs), retinoic acid–inducible gene (RIG)-1-like receptors (RLRs), and NOD-like receptors (NLRs)
Antimicrobial peptides	α-Defensins, β-defensins, cathelin, protegrin, granulysin, histatin, secretory leukoprotease inhibitor, and probiotics
Cells	Macrophages, dendritic cells, innate lymphoid cells (ILC1, ILC2, ILC3, NK cells, lymphoid tissue inducer [LTi] cells), mucosal-associated invariant T (MAIT) cells, NK-T cells, neutrophils, eosinophils, mast cells, basophils, and epithelial cells
Complement components	Classic and alternative complement pathway, and proteins that bind complement components
Cytokines	Autocrine, paracrine, endocrine cytokines that mediate host defense and inflammation, as well as recruit, direct, and regulate adaptive immune responses

Abbreviation: NK, natural killer.

There are multiple connections between the innate and adaptive immune systems; these include (1) a plasma protein, LPS-binding protein, that binds and transfers LPS to the macrophage LPS receptor, CD14; (2) the human family of proteins called *Toll-like receptor proteins* (TLRs), some of which are associated with CD14, bind LPS, and signal epithelial cells, DCs, and macrophages to produce cytokines and upregulate cell-surface molecules that signal the initiation of adaptive immune responses (**Fig. 360-1**, Table 360-3); and (3) families of intracellular microbial sensors called NLRs and RLRs. Proteins in the Toll family can be expressed on macrophages, DCs, and B cells as well as on a variety of nonhematopoietic cell types, including respiratory epithelial cells. Eleven TLRs have been identified in humans (Table 360-3). Upon ligation, TLRs activate a series of intracellular events that lead to the killing of bacteria- and viral-infected cells as well as to the recruitment and ultimate activation of antigen-specific T and B lymphocytes (Fig. 360-1). Importantly, signaling by massive amounts of LPS through TLR4 leads to the release of high levels of cytokines that mediate LPS-induced shock. Mutations in TLR4 proteins in mice protect from LPS shock, and TLR mutations in humans can protect from LPS-induced inflammatory diseases such as LPS-induced asthma. **Table 360-4** lists diseases caused by gene variants in nucleic acid–sensing Toll family and related receptors.

Two other families of cytoplasmic PRRs are the NLRs and the RLRs. These families, unlike the TLRs, are composed primarily of soluble

TABLE 360-3 Pattern Recognition Receptors (PRRs) and Their Ligands

PRR	LOCALIZATION	LIGAND	ORIGIN OF THE LIGAND
TLR			
TLR1	Plasma membrane	Triacyl lipoprotein	Bacteria
TLR2	Plasma membrane	Lipoprotein	Bacteria, viruses, parasite, self
TLR3	Endolysosome	dsRNA	Virus
TLR4	Plasma membrane	LPS	Bacteria, viruses, self
TLR5	Plasma membrane	Flagellin	Bacteria
TLR6	Plasma membrane	Diacyl lipoprotein	Bacteria, viruses
TLR7 (human TLR8)	Endolysosome	ssRNA	Virus, bacteria, self
TLR9	Endolysosome	CpG-DNA	Virus, bacteria, protozoa, self
TLR10	Endolysosome	Unknown	Unknown
TLR11	Plasma membrane	Profilin-like molecule	Protozoa
RLR			
RIG-I	Cytoplasm	Short dsRNA, triphosphate dsRNA	RNA viruses, DNA virus
MDA5	Cytoplasm	Long dsRNA	RNA viruses (Picornaviridae)
LGP2	Cytoplasm	Unknown	RNA viruses
NLR			
NOD1	Cytoplasm	iE-DAP	Bacteria
NOD2	Cytoplasm	MDP	Bacteria
CLR			
Dectin-1	Plasma membrane	β^2-Glucan	Fungi
Dectin-2	Plasma membrane	β^2-Glucan	Fungi
MINCLE	Plasma membrane	SAP130	Self, fungi

Abbreviations: CLR, C-type lectin receptors; dsRNA, double-strand RNA; iE-DAP, D-glutamyl-meso-diaminopimelic acid moiety; LGP2, Laboratory of Genetics and Physiology 2 protein encoded by the gene *DHX58*; MDA5, melanoma differentiation-associated protein 5; MDP, MurNAc-L-Ala-D-isoGln, also known as muramyl dipeptide; MINCLE, macrophage-inducible C-type lectin; NLR, NOD-like receptor; NOD, NOTCH protein domain; RIG, retinoic acid–inducible gene; RLR, RIG-like receptors; SAP130, Sin-3 associated protein 130; TLR, Toll-like receptor.

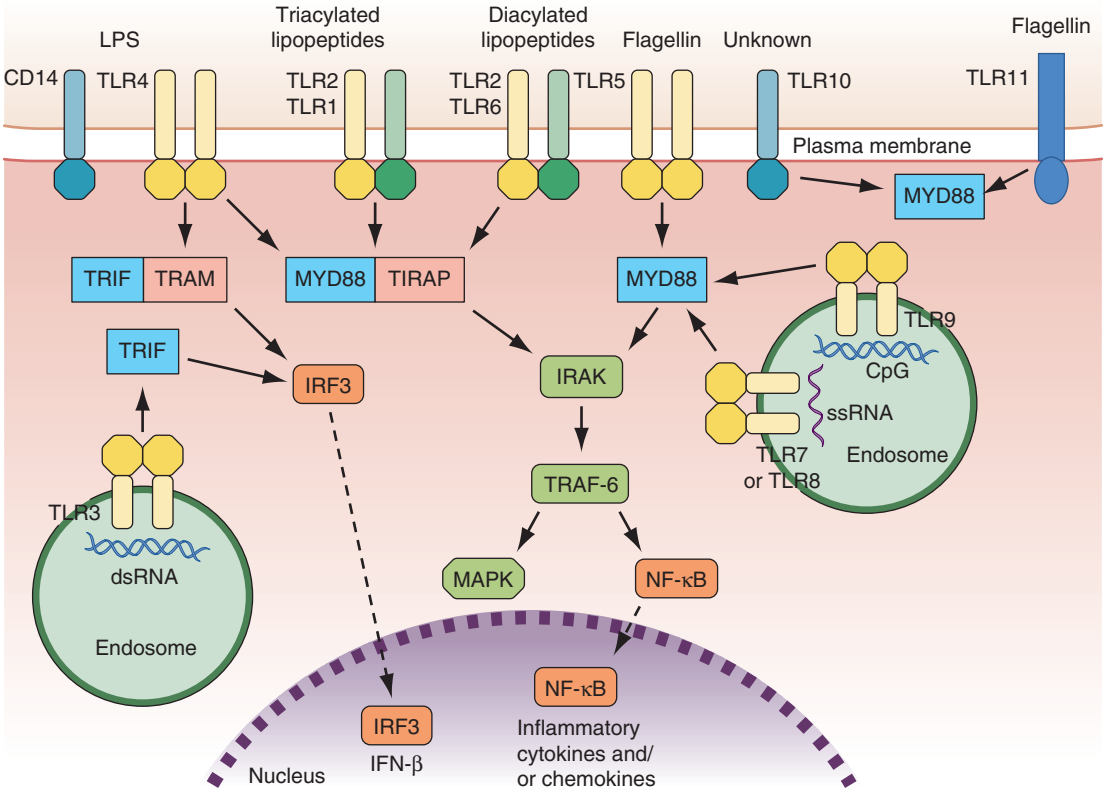

FIGURE 360-1 Overview of major TLR signaling pathways. All TLRs signal through MYD88, with the exception of TLR3. TLR4 and the TLR2 subfamily (TLR1, TLR2, TLR6) also engage TIRAP (Toll-interleukin 1 receptor domain-containing adapter protein). TLR3 signals through TRIF (Toll-interleukin 1 receptor domain-containing adapter-inducing interferon-β). TRIF is also used in conjunction with TRAM (TRIF-related adaptor molecule) in the TLR4-MYD88-independent pathway. *Dashed arrows* indicate translocation into the nucleus. dsRNA, double-strand RNA; IFN, interferon; IRF3, interferon regulatory factor 3; LPS, lipopolysaccharide; MAPK, mitogen-activated protein kinases; NF-κB, nuclear factor-κB; ssRNA, single-strand RNA; TLR, Toll-like receptor. *(Reproduced with permission from D Van Duin et al: Triggering TLR signaling in vaccination. Trends Immunol 27:49, 2006.)*

intracellular proteins that scan host cell cytoplasm for intracellular pathogens (Tables 360-2 and 360-3).

The intracellular microbial sensors, NLRs, after triggering, form large cytoplasmic complexes termed *inflammasomes*, which are aggregates of molecules including NOD-like receptor pyrin (NLRP) proteins (Table 360-5). Inflammasomes activate inflammatory caspases and IL-1β in the presence of nonbacterial danger signals (cell stress) and bacterial PAMPs. Mutations in inflammasome proteins can lead to chronic inflammation in a group of periodic febrile diseases called *autoinflammatory syndromes*. Polymorphisms in inflammasome components can either protect or enhance risk of infections or autoimmune/autoinflammatory diseases (Table 60-4). Inflammasomes are activated upon sensing of PAMPs. Crystallopathies are diseases caused by tissue crystal deposition such as monosodium urate that can activate the inflammasome and, in the case of urate deposition, can lead to gout with arthritis or renal disease.

EFFECTOR CELLS OF INNATE IMMUNITY

Cells of the innate immune system and their roles in the first line of host defense are listed in Table 360-6. Equally important as their roles in the mediation of innate immune responses are the roles that each cell type plays in recruiting T and B lymphocytes of the adaptive immune system to engage in specific pathogen responses.

Monocytes-Macrophages Monocytes arise from precursor cells within bone marrow (Fig. 360-2) and circulate with a half-life ranging from 1 to 3 days. Monocytes leave the peripheral circulation via capillaries and migration into a vast extravascular cellular pool. Tissue macrophages arise from monocytes that have migrated out of the circulation and by in situ proliferation of macrophage precursors in tissue. Common locations where tissue macrophages (and certain of their specialized forms) are found are lymph node, spleen, bone marrow, perivascular connective tissue, serous cavities such as the peritoneum, pleura, skin connective tissue, lung (alveolar macrophages), liver (Kupffer cells), bone (osteoclasts), central nervous system (microglia cells), and synovium (type A lining cells).

In general, monocytes-macrophages are on the first line of defense associated with innate immunity and ingest and destroy microorganisms through the release of toxic products such as hydrogen peroxide (H_2O_2) and nitric oxide (NO). Inflammatory mediators produced by macrophages attract additional effector cells such as neutrophils to the site of infection. Macrophage mediators include prostaglandins; leukotrienes; platelet activating factor; cytokines such as IL-1, TNF-α, IL-6, and IL-12; and chemokines (Tables 360-7 and 360-8).

Although monocytes-macrophages were originally thought to be the major APCs of the immune system, it is now clear that cell types called *dendritic cells* are the most potent and effective classical APCs in the body (see below). Monocytes-macrophages mediate innate immune effector functions such as destruction of antibody-coated bacteria, tumor cells, or even normal hematopoietic cells in certain types of autoimmune cytopenias. Monocytes-macrophages ingest bacteria

TABLE 360-5 Mutations in Innate Inflammasome Molecules Associated with Clinical Disease

Inherited Inflammasomopathies

MUTATED GENE	DISEASE	INHERITED PATTERN AND EFFECT	PHENOTYPE	PREDOMINANT EFFECTOR CELLS
NLRP1	NLRP1-associated autoinflammation with arthritis and dyskeratosis	Autosomal dominant GoF	Hyperkeratotic ulcerative skin lesions, fever, arthritis, ANA	Keratinocytes
NLRP3	Cryopyrin-associated periodic syndromes (CAPS)	Autosomal dominant GoF	Spectrum from cold-induced urticaria and fever to CNS inflammation and bone overgrowth	Monocytes, granulocytes (neutrophils), chondrocytes
NLRC4	Autoinflammatory infantile fever with enterocolitis (AIFEC)	Autosomal dominant GoF	Recurrent MAS, enterocolitis, cold-induced fever and urticaria, CNS inflammation	Monocytes/macrophages
MEFV	Familial Mediterranean fever (FMF)	Autosomal recessive LoF or gene-dosage-dependent autosomal dominant GoF	Fever, serositis, rash, SAA amyloidosis	Neutrophils, monocytes, serosal and synovial fibroblasts

Genetic Polymorphisms in Inflammasome Components and Human Infectious Diseases

Note: Mutated gene and respective syndrome name are reported for inflammasomopathies, as well as inheritance pattern and effect of mutations, clinical phenotype, and predominant disease effector cells. Inflammasome variants previously associated with infectious agents and/or diseases are briefly resumed from literature (*https://www.ncbi.nlm.nih.gov/pubmed*). Significantly associated polymorphisms were grouped according to the infectious agent/disease. Infectious agent or disease (in alphabetical order), gene name (gene), identification number of polymorphism (ID), resulting effect on inflammasome activation ("increased," "decreased," or "unknown"), cohort origin (cohort) and eventually specifications (severity, etc.), sample size (n), and type (case/control or cases only), association result ("risk" or "protection"), and respective reference are reported.

Abbreviations: ANA, antinuclear antibodies; CNS, central nervous system; GoF, gain-of-function; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HPV, human papillomavirus; HS, Henoch-Schönlein; HSV, herpes simplex virus; HTLV, human T-lymphotropic virus; IBD, inflammatory bowel disease; JIA, juvenile idiopathic arthritis; LoF, loss-of-function; MAS, macrophage activation syndrome; PFAPA, periodic fever with aphthous stomatitis, pharyngitis, and cervical adenitis; SAA, serum amyloid A; SLE, systemic lupus erythematosus.

or are infected by viruses, and in doing so, they frequently undergo programmed cell death or *apoptosis*. Macrophages that are infected by intracellular infectious agents are recognized by DCs as infected and apoptotic cells and are phagocytosed by DCs. In this manner, DCs "cross-present" infectious agent antigens of macrophages to T cells. Activated macrophages can also mediate antigen-nonspecific lytic activity and eliminate cell types such as tumor cells in the absence of antibody. This activity is largely mediated by cytokines (i.e., TNF-α and IL-1). Monocytes-macrophages express lineage-specific molecules (e.g., the cell-surface LPS receptor, CD14) as well as surface receptors for a number of molecules, including the Fc region of IgG, activated complement components, and various cytokines (Table 360-7).

Dendritic Cells Human DCs contain several subsets, including myeloid DCs and plasmacytoid DCs. Myeloid DCs can differentiate into either macrophages-monocytes or tissue-specific DCs. In contrast to myeloid DCs, plasmacytoid DCs are potent producers of TLR-7 dependent type I IFN (e.g., IFN-α) in response to free virus and virus-infected cells. The maturation of DCs is regulated through cell-to-cell contact and soluble factors, and DCs attract immune effectors through secretion of chemokines. When DCs come in contact with bacterial products, viral proteins, or host proteins released as danger signals from distressed host cells (Fig. 360-2), infectious agent molecules bind to various TLRs and activate DCs to release cytokines and chemokines that drive cells of the innate immune system to become activated to

TABLE 360-6 Cells of the Innate Immune System and Their Major Roles in Triggering Adaptive Immunity

CELL TYPE	MAJOR ROLE IN INNATE IMMUNITY	MAJOR ROLE IN ADAPTIVE IMMUNITY
Macrophages	Phagocytose and kill bacteria; produce antimicrobial peptides; bind LPS; produce inflammatory cytokines	Produce IL-1 and TNF-α to upregulate lymphocyte adhesion molecules and chemokines to attract antigen-specific lymphocyte. Produce IL-12 to recruit T_H1 T helper cell responses; upregulate co-stimulatory and MHC molecules to facilitate T and B lymphocyte recognition and activation. Macrophages and dendritic cells, after LPS signaling, upregulate co-stimulatory molecules B7-1 (CD80) and B7-2 (CD86) that are required for activation of pathogen-specific T cells. There are also Toll-like proteins on B cells and dendritic cells that, after LPS ligation, induce CD80 and CD86 on these cells for T-cell antigen presentation.
Plasmacytoid dendritic cells (DCs) of lymphoid lineage	Produce large amounts of interferon-α (IFN-α), which has antitumor and antiviral activity, and are found in T-cell zones of lymphoid organs; they circulate in blood	IFN-α is a potent activator of macrophage and mature DCs to phagocytose invading pathogens and present pathogen antigens to T and B cells.
Myeloid DCs are of two types: interstitial and Langerhans-derived	Interstitial DCs are strong producers of IL-12 and IL-10 and are located in T-cell zones of lymphoid organs, circulate in blood, and are present in the interstices of the lung, heart, and kidney; Langerhans DCs are strong producers of IL-12; are located in T-cell zones of lymph nodes, skin epithelia, and the thymic medulla; and circulate in blood	Interstitial DCs are potent activators of macrophage and mature DCs to phagocytose invading pathogens and present pathogen antigens to T and B cells.
ILC1 cells	Weakly cytotoxic, dependent on T-bet transcription factor, first line of defense against viruses and bacteria	Produce IFN-γ to recruit CD4 T_H1 T cells
ILC2 cells	Mediate innate responses to parasites/helminths, repair damaged tissues by producing amphiregulin	Produce IL-4, IL-5, IL-13; recruit CD4 T_H2 T cells
ILC3 cells	Innate immune response to extracellular bacteria and gut microbiome	Produce IL-22, IL-17, GM-CSF, lymphotoxin; recruit CD4 T_H17 T cells
Lymphoid tissue inducer (LTi) cells	Critical for formation of secondary lymphoid tissue during embryogenesis	Produce lymphotoxin for lymph node and Peyer's patch development in which adaptive immune responses occur
Natural killer (NK) cells	Kill foreign and host cells that have low levels of MHC+ self-peptides. Express NK receptors that inhibit NK function in the presence of high expression of self-MHC.	Produce TNF-α and IFN-γ, which recruit T_H1 helper T-cell responses
NK-T cells	Lymphocytes with both T-cell and NK surface markers that recognize lipid antigens of intracellular bacteria such as *Mycobacterium tuberculosis* by CD1 molecules and kill host cells infected with intracellular bacteria	Produce IL-4 to recruit T_H2 helper T-cell responses, IgG1 and IgE production
Neutrophils	Phagocytose and kill bacteria, produce antimicrobial peptides	Produce nitric oxide synthase and nitric oxide, which inhibit apoptosis in lymphocytes and can prolong adaptive immune responses
Eosinophils	Kill invading parasites	Produce IL-5, which recruits Ig-specific antibody responses
Mast cells and basophils	Release TNF-α, IL-6, and IFN-γ in response to a variety of bacterial PAMPs	Produce IL-4, which recruits T_H2 helper T cell responses, and recruit IgG1- and IgE-specific antibody responses
Epithelial cells	Produce antimicrobial peptides; tissue-specific epithelia produce mediator of local innate immunity; e.g., lung epithelial cells produce surfactant proteins (proteins within the collectin family) that bind and promote clearance of lung-invading microbes	Produces TGF-β, which triggers IgA-specific antibody responses

Abbreviations: GM-CSF, granulocyte-macrophage colony-stimulating factor; IL-4, IL-5, IL-6, IL-10, and IL-12, interleukin 4, 5, 6, 10, and 12, respectively; ILC, innate lymphoid cell; MHC, major histocompatibility complex: LPS, lipopolysaccharide; PAMP, pathogen-associated molecular patterns; TGF, transforming growth factor; T_H, helper T cell; TNF-α, tumor necrosis factor-alpha.

Source: Reproduced with permission from R Medzhitov, CA Janeway: Curr Opinion Immunol 9:4-9; 1997.

respond to invading organisms, and recruit T and B cells of the adaptive immune system to respond. Plasmacytoid DCs produce antiviral IFN-α that activates NK cell killing of pathogen-infected cells; IFN-α also activates CD8 T cells to mature into antipathogen cytotoxic (killer) T cells. Following contact with pathogens, both plasmacytoid and myeloid DCs produce chemokines that attract helper and cytotoxic T cells, B cells, polymorphonuclear cells, and naïve and memory T cells as well as regulatory T cells to ultimately dampen the immune response once the pathogen is controlled. TLR engagement on DCs upregulates MHC class II, B7-1 (CD80), and B7-2 (CD86), which enhance DC-specific antigen presentation and induce cytokine production. Thus, DCs are important bridges between early (innate) and later (adaptive) immunity. DCs also modulate and determine the types of immune responses induced by pathogens via the TLRs expressed on DCs (TLR7–9 in plasmacytoid DCs, TLR4 on monocytoid DCs) and via the TLR adapter proteins that are induced to associate with TLRs (Fig. 360-1, Table 360-1). In addition, other PRRs, such as C-type lectins, NLRs, and mannose receptors, upon ligation by pathogen products, activate cells of the adaptive immune system and, like TLR stimulation, by a variety of factors, determine the type and quality of the adaptive immune response that is triggered.

Innate Lymphoid Cells ILCs are comprised of ILC1, ILC2, ILC3, lymphoid tissue inducer (LTi), and NK cells. ILC1, ILC2, ILC3, and LTi are primarily tissue resident cells. ILCs develop from a common lymphoid precursor in the bone marrow and then differentiate into one of five ILC types—ILC1, ILC2, ILC3, LTi, or NK cells—based on their development **(Fig. 360-3*A*)** and function **(Fig. 360-3*B*)**. NK cells and ILC1s depend on T-bet transcription factor for their development and function and produce IFN-γ. NK cells are innate analogues to CD8 cytotoxic T cells in that they both mediate granzyme and perforin-based cytotoxic cell activity. ILC1s mirror CD4 T_H1 lymphocytes and react to intracellular pathogens such as viruses and to tumors. ILC2s are the analogues of T_H2 CD4 T cells and are dependent on GATA3 and RORα factors and produce type 2 cytokines, such as IL-5 and IL-13. ILC2s respond to extracellular parasites and allergens. ILC3s and LTi cells are dependent on transcription factor retinoic acid receptor-related orphan receptor γt (RORγt) and produce IL-17. ILC3s are analogues of CD4 T_H17 lymphocytes and attack extracellular pathogens such as bacteria and fungi. LTi cells are critical for the formation of lymph nodes and Peyer's patches in gut during fetal development (Fig. 360-3*B*).

In the intestine, a critical function of the immune system is not only to quickly respond to pathogens but also to ignore benign

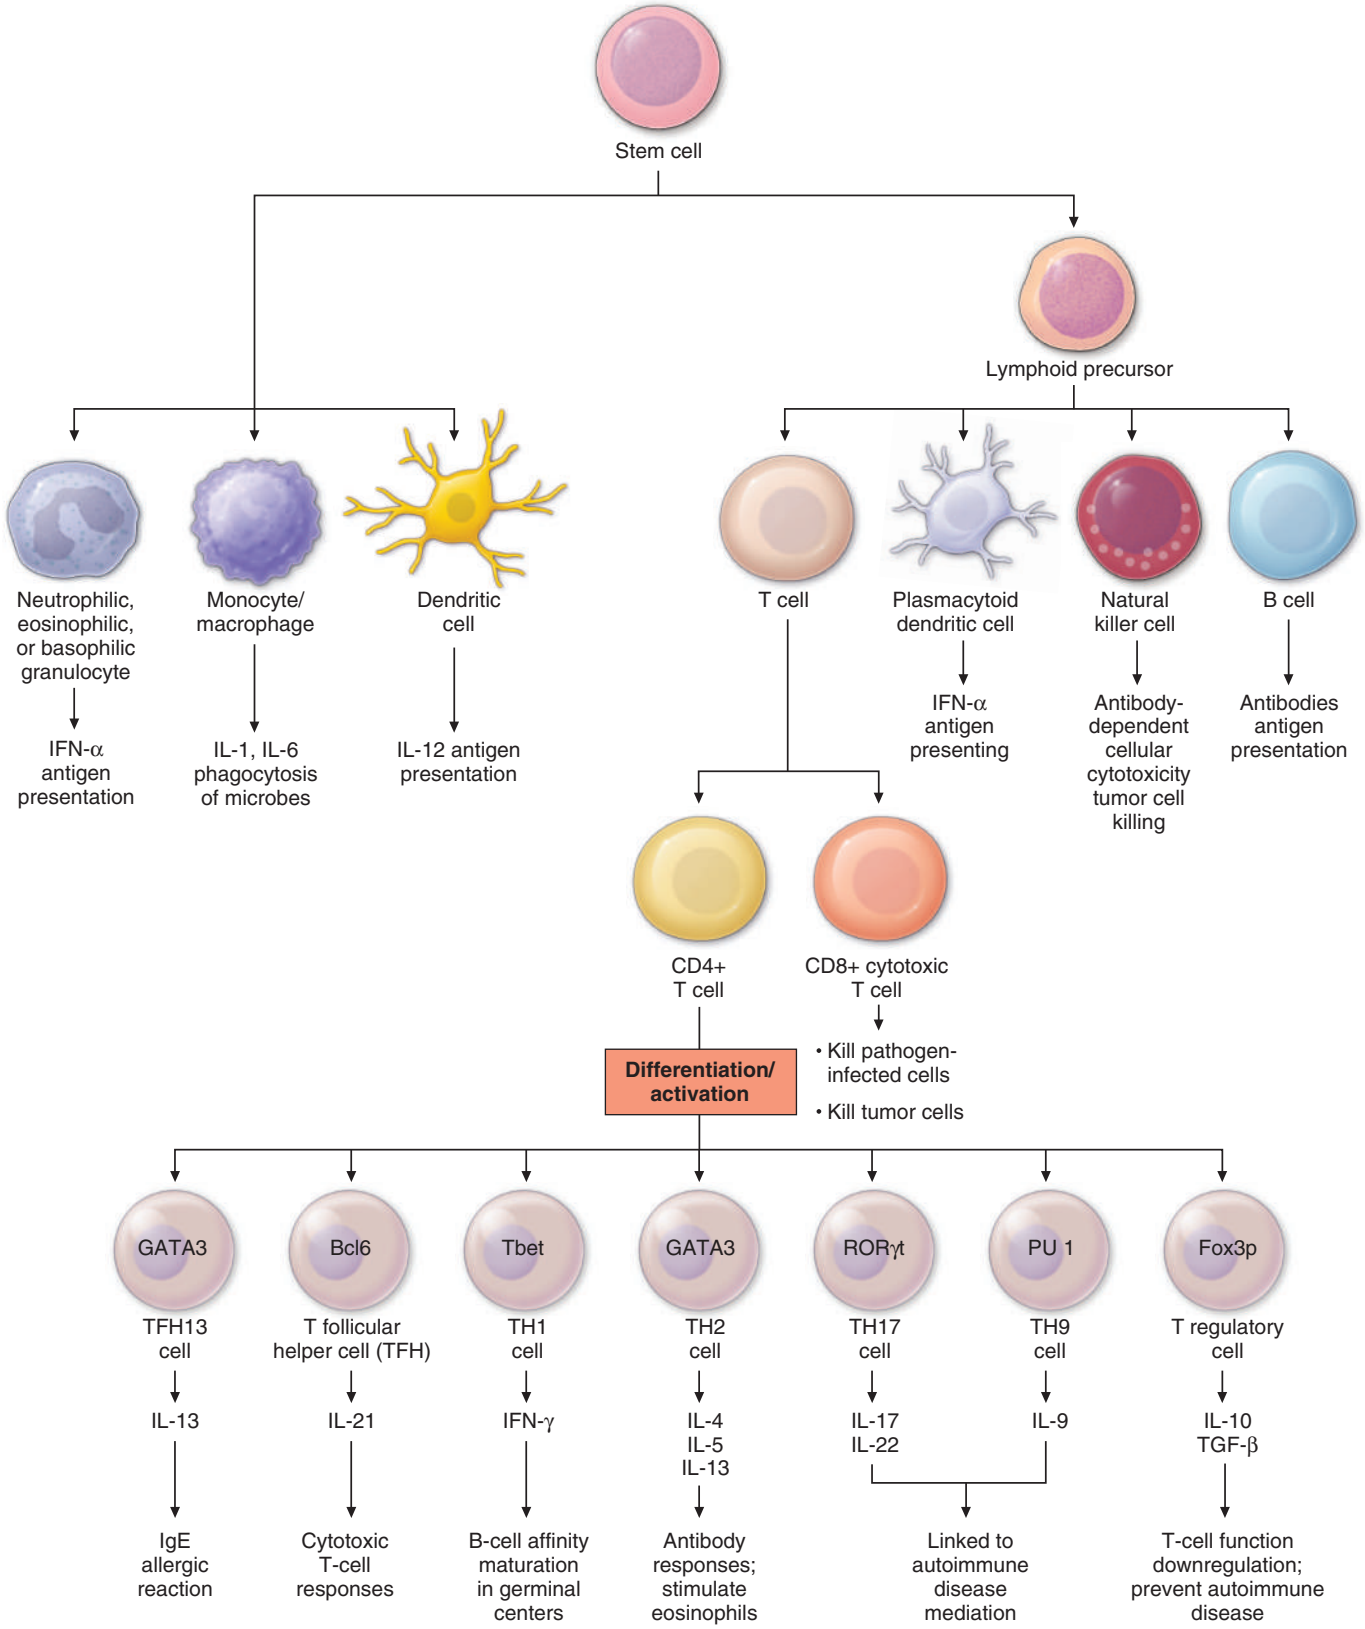

FIGURE 360-2 Model of immune effector cell development. Hematopoietic stem cells differentiate into T cells, antigen-presenting dendritic cells, natural killer cells, macrophages, granulocytes, or B cells. Foreign antigen is processed by dendritic cells, macrophages, and B cells, and peptide fragments of foreign antigen are presented to CD4+ and/or CD8+ T cells. CD8+ T-cell activation leads to induction of cytotoxic T lymphocyte (CTL) or killer T-cell generation, as well as induction of cytokine-producing CD8+ cytotoxic T cells. Granulocytes (neutrophils, eosinophils, or basophils) are effector cells of the innate immune system and mediate anti-infectious agent activity by cytokine production, infectious agent killing, or both. T_H1 CD4+ T cells play an important role in defense against intracellular microbes and help in the generation of CD8+ cytotoxic T cells. T_H2 CD4+ T cells producing interferon (IFN) γ or interleukin (IL) 4, IL-5, or IL-13 regulate Ig class switching and determine the type of antibody produced. T_H17 cells secrete IL-17 and IL-22, T_H9 cells secrete IL-9, and TFH13 cells secrete IL-4, IL-5, and IL-13. T_H17 and T_H9 CD4 T cells are linked to mediation of autoimmune disease, and TFH13 cells are linked to IgE-mediated anaphylaxis. CD4+ T regulatory cells produce IL-10 and transforming growth factor (TGF)-β and downregulate T- and B-cell responses once the microbe has been eliminated. Each of the types of CD4+ T cells are regulated by different transcription factors, and the key transcription factors are shown in the circles above each CD4+ T-cell type.

TABLE 360-7 Cytokines and Cytokine Receptors

CYTOKINE	RECEPTOR	CELL SOURCE	CELL TARGET	BIOLOGIC ACTIVITY
IL-1α, β	Type I IL-1r, type II IL-1r	Monocytes/macrophages, B cells, fibroblasts, most epithelial cells including thymic epithelium, endothelial cells	All cells	Upregulates adhesion molecule expression, neutrophil and macrophage emigration, mimics shock, fever, upregulates hepatic acute-phase protein production, facilitates hematopoiesis
IL-2	IL-2r α, β, common γ	T cells	T cells, B cells, NK cells, monocytes-macrophages	Promotes T-cell activation and proliferation, B-cell growth, NK-cell proliferation and activation, enhanced monocyte/macrophage cytolytic activity
IL-3	IL-3r, common β	T cells, NK cells, mast cells	Monocytes-macrophages, mast cells, eosinophils, bone marrow progenitors	Stimulates hematopoietic progenitors
IL-4	IL-4r α, common γ	T cells, mast cells, basophils	T cells, B cells, NK cells, monocytes-macrophages, neutrophils, eosinophils, endothelial cells, fibroblasts	Stimulates T_H2 helper T-cell differentiation and proliferation; stimulates B-cell Ig class switch to IgG1 and IgE anti-inflammatory action on T cells, monocytes; produced by T follicular helper cells in B-cell germinal centers that stimulate B-cell maturation
IL-5	IL-5r α, common γ	T cells, mast cells, eosinophils	Eosinophils, basophils, murine B cells	Regulates eosinophil migration and activation
IL-6	IL-6r, gp130	Monocytes-macrophages, B cells, fibroblasts, most epithelium including thymic epithelium, endothelial cells	T cells, B cells, epithelial cells, hepatocytes, monocytes-macrophages	Induces acute-phase protein production, T- and B-cell differentiation and growth, myeloma cell growth, and osteoclast growth and activation
IL-7	IL-7r α, common γ	Bone marrow, thymic epithelial cells	T cells, B cells, bone marrow cells	Differentiates B-, T-, and NK-cell precursors, activates T and NK cells
IL-8	CXCR1, CXCR2	Monocytes-macrophages, T cells, neutrophils, fibroblasts, endothelial cells, epithelial cells	Neutrophils, T cells, monocytes-macrophages, endothelial cells, basophils	Induces neutrophil, monocyte, and T-cell migration, induces neutrophil adherence to endothelial cells and histamine release from basophils, and stimulates angiogenesis; suppresses proliferation of hepatic precursors
IL-9	IL-9r α, common γ	T cells	Bone marrow progenitors, B cells, T cells, mast cells	Induces mast cell proliferation and function, synergizes with IL-4 in IgG and IgE production and T-cell growth, activation, and differentiation
IL-10	IL-10r	Monocytes-macrophages, T cells, B cells, keratinocytes, mast cells	Monocytes-macrophages, T cells, B cells, NK cells, mast cells	Inhibits macrophage proinflammatory cytokine production, downregulates cytokine class II antigen and B7-1 and B7-2 expression, inhibits differentiation of T_H1 helper T cells, inhibits NK cell function, stimulates mast cell proliferation and function, B-cell activation, and differentiation
IL-11	IL-11r α, gp130	Bone marrow stromal cells	Megakaryocytes, B cells, hepatocytes	Induces megakaryocyte colony formation and maturation, enhances antibody responses, stimulates acute-phase protein production
IL-12 (35-kDa and 40-kDa subunits)	IL-12r	Activated macrophages, dendritic cells, neutrophils	T cells, NK cells	Induces T_H1 T helper cell formation and lymphokine-activated killer cell formation; increases CD8+ CTL cytolytic activity; ↓IL-17, ↑IFN-γ
IL-13	IL-13r/IL-4r α	T cells (T_H2)	Monocytes-macrophages, B cells, endothelial cells, keratinocytes	Upregulates VCAM-1 and C-C chemokine expression on endothelial cells and B-cell activation and differentiation, and inhibits macrophage proinflammatory cytokine production
IL-14	Unknown	T cells	Normal and malignant B cells	Induces B-cell proliferation, inhibits antibody secretion, and expands selected B-cell subgroups
IL-15	IL-15r α, common γ, IL2r β	Monocytes-macrophages, epithelial cells, fibroblasts	T cells, NK cells	Promotes T-cell activation and proliferation, angiogenesis, and NK cells
IL-16	CD4	Mast cells, eosinophils, CD8+ T cells, respiratory epithelium	CD4+ T cells, monocytes-macrophages, eosinophils	Promotes chemoattraction of CD4+ T cells, monocytes, and eosinophils; inhibits HIV-1 replication; inhibits T-cell activation through CD3/T-cell receptor
IL-17	IL-17r	CD4+ T cells	Fibroblasts, endothelium, epithelium, macrophages	Enhances cytokine/chemokine secretion; promotes delayed-type reactions
IL-18	IL-18r (IL-1R-related protein)	Keratinocytes, macrophages	T cells, B cells, NK cells	Upregulates IFN-γ production, enhances NK cell cytotoxicity
IL-21	IL-δγ chain/IL-21R	CD4 T cells	NK cells	Downregulates NK cell–activating molecules, NKG2D/DAP10; produced by T follicular helper cells in B-cell germinal centers that stimulate B-cell maturation
IL-22	IL-22 R1/IL-10R2	DC, T cells	Epithelial cells	Innate responses against bacterial pathogens; promotes hepatocyte survival
IL-23	IL-12Rb1/IL23R	Macrophages, other cell types	T cells	Opposite effects of IL-12 (↑IL-17, ↑IFN-γ)
IL-24	IL-20R1/IL-20R2 IL-22R1/IL-20R2	Macrophages, T_H2 cells	Nonhematopoietic cells such as fibroblasts	Promotes wound healing

(*Continued*)

TABLE 360-7 Cytokines and Cytokine Receptors (Continued)

CYTOKINE	RECEPTOR	CELL SOURCE	CELL TARGET	BIOLOGIC ACTIVITY
IL-25 (also called IL-17E)	IL-17RB	CD4 T cells, mast cells	Fibroblasts, endothelium, epithelium, macrophages	Proinflammatory; induces cytokine production
IL-26	IL-20R1/IL-10R2	T_H1, T_H17 T cells, synovial cells	Epithelial cells	Proinflammatory; induces cytokine production
IL-27	gp130t wsx-1	Myeloid cells such as macrophages and DCs	T cells	Collaborates with other cytokines to activate T-cell differentiation
IL-28A (IFN-λ2)	IFN-λ receptor 1, IL-28Rα, IL-10Rβ	Myeloid lineage cells; epithelial cells	Epithelial cells	Enhanced clearance of viral infections
IL-28B (IFN-λ3)	IFN-λ receptor 1, IL-28Rα, IL-10Rβ	Myeloid lineage cells; epithelial cells	Epithelial cells	Enhanced clearance of viral infections
IL-29 (IFN-λ1)	IFN-λ receptor 1, IL-28Rα, IL-10Rβ	Myeloid lineage cells; epithelial cells	Epithelial cells	Enhanced clearance of viral infections
IL-30 (p28 of IL-27)	IL-27Rα; gp130+wsx-1	Activated macrophages and DCs; epithelial malignancies	Monocytes	Anti-inflammatory cytokines; upregulation of breast and prostate cancer metastasis
IL-31	IL-31RA/ oncostatin MRβ	Eosinophils, CD4 T cells	Epithelial cells, monocytes	Pruritis, proinflammatory
IL-32 (NK4)	?	Monocytes, T cells, NK cells, epithelial cells	Monocytes, macrophages, bone marrow stroma	Angiogenesis, IL-2 production in bone marrow, proinflammatory
IL-33 (NF-HEV; IL-1 F11)	ST-2	Endothelial cells, epithelial cells, fibroblasts, mucosal epithelium	T cells, mast cells eosinophils, basophils, ILC2s	Alarmin cytokine, proinflammatory
IL-34 (C16of77)	CSF-1R, PTP-E, CD138	Neurons, Treg, myeloid cells		Anti-inflammatory myeloid cell proliferation
IL-35	IL-12Rβ2/ IL-12Rβ2, gp130/ gp130, IL-12Rb2/ gp130	Tregs, Bregs	Macrophages, T cells	Prevents T_H1 and T_H17 proliferation; induced Treg/Breg proliferation/anti-inflammatory
IL-36α IL36β IL36γ IL36RA (IL-1 F5)	IL-36R	Keratocytes Mucosal epithelial cells Monocytes-macrophages Langerhans cells CD4 T cells	Epithelial cells, macrophages, DCs, T cells, B cells, plasma cells	T_H responses, proinflammatory
IL-38 IL-10 F10	IL-1R, IL-36R, IL-1RA PL1	Epithelial cells, B cells	Epithelial cells, macrophages, DCs, T cells, B cells, plasma cells	Blocks IL-36; anti-inflammatory
IL-39	?	Macrophages, DCs, B cells	Neutrophils	Proinflammatory
IL-40	?	B cells, bone marrow/stroma	B cells	Involved in IgA production, B-cell homeostasis and development
IFN-α	Type I interferon receptor	All cells	All cells	Promotes antiviral activity; stimulates T-cell, macrophage, and NK-cell activity; direct antitumor effects; upregulates MHC class I antigen expression; used therapeutically in viral and autoimmune conditions
IFN-β	Type I interferon receptor	All cells	All cells	Antiviral activity; stimulates T-cell, macrophage, and NK-cell activity; direct antitumor effects; upregulates MHC class I antigen expression; used therapeutically in viral and autoimmune conditions
IFN-γ	Type II interferon receptor	T cells, NK cells	All cells	Regulates macrophage and NK-cell activations; stimulates immunoglobulin secretion by B cells; induction of class II histocompatibility antigens; T_H1 T-cell differentiation
TNF-α	TNFrI, TNFrII	Monocytes-macrophages, mast cells, basophils, eosinophils, NK cells, B cells, T cells, keratinocytes, fibroblasts, thymic epithelial cells	All cells except erythrocytes	Fever, anorexia, shock, capillary leak syndrome, enhanced leukocyte cytotoxicity, enhanced NK-cell function, acute phase protein synthesis, proinflammatory cytokine induction
TNF-β	TNFrI, TNFrII	T cells, B cells	All cells except erythrocytes	Cell cytotoxicity, lymph node and spleen development
LT-β	LTβR	T cells	All cells except erythrocytes	Cell cytotoxicity, normal lymph node development
G-CSF	G-CSFr; gp130	Monocytes-macrophages, fibroblasts, endothelial cells, thymic epithelial cells, stromal cells	Myeloid cells, endothelial cells	Regulates myelopoiesis; enhances survival and function of neutrophils; clinical use in reversing neutropenia after cytotoxic chemotherapy
GM-CSF	GM-CSFr, common β	T cells, monocytes-macrophages, fibroblasts, endothelial cells, thymic epithelial cells	Monocytes-macrophages, neutrophils, eosinophils, fibroblasts, endothelial cells	Regulates myelopoiesis; enhances macrophage bactericidal and tumoricidal activity; mediator of dendritic cell maturation and function; upregulates NK-cell function; clinical use in reversing neutropenia after cytotoxic chemotherapy

(*Continued*)

TABLE 360-7 Cytokines and Cytokine Receptors (Continued)

CYTOKINE	RECEPTOR	CELL SOURCE	CELL TARGET	BIOLOGIC ACTIVITY
M-CSF	M-CSFr (*c-fms* protooncogene)	Fibroblasts, endothelial cells, monocytes-macrophages, T cells, B cells, epithelial cells including thymic epithelium	Monocytes-macrophages	Regulates monocyte-macrophage production and function
LIF	LIFr-α; gp130	Activated T cells, bone marrow stromal cells, thymic epithelium	Megakaryocytes, monocytes, hepatocytes, possibly lymphocyte subpopulations	Induces hepatic acute-phase protein production; stimulates macrophage differentiation; promotes growth of myeloma cells and hematopoietic progenitors; stimulates thrombopoiesis
OSM	OSMr; LIFr; gp130	Activated monocytes-macrophages and T cells, bone marrow stromal cells, some breast carcinoma cell lines, myeloma cells	Neurons, hepatocytes, monocytes-macrophages, adipocytes, alveolar epithelial cells, embryonic stem cells, melanocytes, endothelial cells, fibroblasts, myeloma cells	Induces hepatic acute-phase protein production; stimulates macrophage differentiation; promotes growth of myeloma cells and hematopoietic progenitors; stimulates thrombopoiesis; stimulates growth of Kaposi's sarcoma cells
SCF	SCFr (*c-kit* protooncogene)	Bone marrow stromal cells and fibroblasts	Embryonic stem cells, myeloid and lymphoid precursors, mast cells	Stimulates hematopoietic progenitor cell growth, mast cell growth; promotes embryonic stem cell migration
TGF-β (3 isoforms)	Type I, II, III TGF-β receptor	Most cell types	Most cell types	Downregulates T-cell, macrophage, and granulocyte responses; stimulates synthesis of matrix proteins; stimulates angiogenesis
Lymphotactin/ SCM-1	XCR1	NK cells, mast cells, double-negative thymocytes, activated CD8+ T cells	T cells, NK cells	Chemoattractant for lymphocytes; only known chemokine of C class
MCP-1	CCR2	Fibroblasts, smooth-muscle cells, activated PBMCs	Monocytes-macrophages, NK cells, memory T cells, basophils	Chemoattractant for monocytes, activated memory T cells, and NK cells; induces granule release from CD8+ T cells and NK cells; potent histamine-releasing factor for basophils; suppresses proliferation of hematopoietic precursors; regulates monocyte protease production
MCP-2	CCR1, CCR2	Fibroblasts, activated PBMCs	Monocytes-macrophages, T cells, eosinophils, basophils, NK cells	Chemoattractant for monocytes, memory and naïve T cells, eosinophils,? NK cells; activates basophils and eosinophils; regulates monocyte protease production
MCP-3	CCR1, CCR2	Fibroblasts, activated PBMCs	Monocytes-macrophages, T cells, eosinophils, basophils, NK cells, dendritic cells	Chemoattractant for monocytes, memory and naïve T cells, dendritic cells, eosinophils,? NK cells; activates basophils and eosinophils; regulates monocyte protease production
MCP-4	CCR2, CCR3	Lung, colon, small intestinal epithelial cells, activated endothelial cells	Monocytes-macrophages, T cells, eosinophils, basophils	Chemoattractant for monocytes, T cells, eosinophils, and basophils
Eotaxin	CCR3	Pulmonary epithelial cells, heart	Eosinophils, basophils	Potent chemoattractant for eosinophils and basophils; induces allergic airways disease; acts in concert with IL-5 to activate eosinophils; antibodies to eotaxin inhibit airway inflammation
TARC	CCR4	Thymus, dendritic cells, activated T cells	T cells, NK cells	Chemoattractant for T and NK cells
MDC	CCR4	Monocytes-macrophages, dendritic cells, thymus	Activated T cells	Chemoattractant for activated T cells; inhibits infection with T-cell tropic HIV-1
MIP-1α	CCR1, CCR5	Monocytes-macrophages, T cells	Monocytes-macrophages, T cells, dendritic cells, NK cells, eosinophils, basophils	Chemoattractant for monocytes, T cells, dendritic cells, and NK cells, and weak chemoattractant for eosinophils and basophils; activates NK-cell function; suppresses proliferation of hematopoietic precursors; necessary for myocarditis associated with coxsackievirus infection; inhibits infection with monocytotropic HIV-1
MIP-1β	CCR5	Monocytes-macrophages, T cells	Monocytes-macrophages, T cells, NK cells, dendritic cells	Chemoattractant for monocytes, T cells, and NK cells; activates NK-cell function; inhibits infection with monocytotropic HIV-1
RANTES	CCR1, CCR2, CCR5	Monocytes-macrophages, T cells, fibroblasts, eosinophils	Monocytes-macrophages, T cells, NK cells, dendritic cells, eosinophils, basophils	Chemoattractant for monocytes-macrophages, CD4+, CD45Ro+ T cells, CD8+ T cells, NK cells, eosinophils, and basophils; induces histamine release from basophils; inhibits infections with monocytotropic HIV-1
LARC/MIP-3α/ Exodus-1	CCR6	Dendritic cells, fetal liver cells, activated T cells	T cells, B cells	Chemoattractant for lymphocytes
ELC/MIP-3β	CCR7	Thymus, lymph node, appendix	Activated T cells and B cells	Chemoattractant for B and T cells; receptor upregulated on EBV-infected B cells and HSV-infected T cells
I-309/TCA-3	CCR8	Activated T cells	Monocytes-macrophages, T cells	Chemoattractant for monocytes; prevents glucocorticoid-induced apoptosis in some T-cell lines
SLC/TCA-4/ Exodus-2	CCR7	Thymic epithelial cells, lymph node, appendix, and spleen	T cells	Chemoattractant for T lymphocytes; inhibits hematopoiesis
DC-CK1/PARC	Unknown	Dendritic cells in secondary lymphoid tissues	Naïve T cells	May have a role in induction of immune responses

(*Continued*)

TABLE 360-7 Cytokines and Cytokine Receptors (Continued)

CYTOKINE	RECEPTOR	CELL SOURCE	CELL TARGET	BIOLOGIC ACTIVITY
TECK	CCR9	Dendritic cells, thymus, liver, small intestine	T cells, monocytes-macrophages, dendritic cells	Thymic dendritic cell–derived cytokine, possibly involved in T-cell development
GRO-α/MGSA	CXCR2	Activated granulocytes, monocyte-macrophages, and epithelial cells	Neutrophils, epithelial cells,? endothelial cells	Neutrophil chemoattractant and activator; mitogenic for some melanoma cell lines; suppresses proliferation of hematopoietic precursors; angiogenic activity
GRO-β/MIP-2α	CXCR2	Activated granulocytes and monocyte-macrophages	Neutrophils and? endothelial cells	Neutrophil chemoattractant and activator; angiogenic activity
NAP-2	CXCR2	Platelets	Neutrophils, basophils	Derived from platelet basic protein; neutrophil chemoattractant and activator
IP-10	CXCR3	Monocytes-macrophages, T cells, fibroblasts, endothelial cells, epithelial cells	Activated T cells, tumor-infiltrating lymphocytes,? endothelial cells,? NK cells	IFN-γ-inducible protein that is a chemoattractant for T cells; suppresses proliferation of hematopoietic precursors
MIG	CXCR3	Monocytes-macrophages, T cells, fibroblasts	Activated T cells, tumor-infiltrating lymphocytes	IFN-γ-inducible protein that is a chemoattractant for T cells; suppresses proliferation of hematopoietic precursors
SDF-1	CXCR4	Fibroblasts	T cells, dendritic cells,? basophils,? endothelial cells	Low-potency, high-efficacy T-cell chemoattractant; required for B lymphocyte development; prevents infection of CD4+, CXCR4+ cells by T-cell tropic HIV-1
Fractalkine	CX3CR1	Activated endothelial cells	NK cells, T cells, monocytes-macrophages	Cell-surface chemokine/mucin hybrid molecule that functions as a chemoattractant, leukocyte activator, and cell adhesion molecule
PF-4	Unknown	Platelets, megakaryocytes	Fibroblasts, endothelial cells	Chemoattractant for fibroblasts; suppresses proliferation of hematopoietic precursors; inhibits endothelial cell proliferation and angiogenesis

Abbreviations: B7-1, CD80; B7-2, CD86; Breg, regulatory B cells; CCR, CC-type chemokine receptor; CXCR, CXC-type chemokine receptor; DC, dendritic cell; DC-CK, dendritic cell chemokine; EBV, Epstein-Barr virus; ELC, EB11 ligand chemokine (MIP-1b); G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; GRP, growth-related peptide; HSV, herpes simplex virus; IFN, interferon; Ig, immunoglobulin; IL, interleukin; IP-10, IFN-γ-inducible protein-10; LARC, liver- and activation-regulated chemokine; LIF, leukemia inhibitory factor; MCP, monocyte chemotactic protein; M-CSF, macrophage colony-stimulating factor; MDC, macrophage-derived chemokine; MGSA, melanoma growth-stimulating activity; MHC, major histocompatibility complex; MIG, monokine induced by IFN-γ; MIP, macrophage inflammatory protein; NAP, neutrophil-activating protein; NK, natural killer; OSM, oncostatin M; PARC, pulmonary- and activation-regulated chemokine; PBMC, peripheral blood mononuclear cells; PF, platelet factor; RANTES, regulated on activation, normally T cell–expressed and –secreted; SCF, stem cell factor; SDF, stromal cell–derived factor; SLC, secondary lymphoid tissue chemokine; TARC, thymus- and activation-regulated chemokine; TCA, T-cell activation protein; TECK, thymus-expressed chemokine; TGF, transforming growth factor; T_H1 and T_H2, helper T cell subsets; TNF, tumor necrosis factor; Treg, regulatory T cells; VCAM, vascular cell adhesion molecule.

microorganisms or environmental antigens. Inability to prevent immune responses to the gut microbiome can be a factor in the cause of inflammatory bowel diseases **(Chap. 337)**. In healthy individuals, a subset of RORγt+ ILCs, possibly ILC3s, stimulate naïve CD4 T cells to differentiate into peripheral Tregs that suppress immune responses to microbiome organisms.

NK cells express surface receptors for the Fc portion of IgG (FcR) (CD16) and for NCAM-I (CD56), and many NK cells express T lineage markers, particularly CD2, CD7, and CD8, and proliferate in response to IL-2. NK cells arise in both bone marrow and thymic microenvironments. In addition to mediating cytotoxicity to foreign or malignant cells, NK cells also mediate ADCC. ADCC is the binding of an opsonized (antibody-coated) target cell to an Fc receptor-bearing effector cell via the Fc region of antibody, resulting in target cell lysis. NK cell cytotoxicity is the MHC-unrestricted, non-antibody-mediated killing of target cells, which are usually malignant cell types, transplanted foreign cells, or virus-infected cells. Thus, NK cell cytotoxicity may play an important role in immune surveillance and destruction of malignant and virus-infected host cells. NK cell hyporesponsiveness is also observed in patients with *Chédiak-Higashi syndrome*, an autosomal recessive disease associated with fusion of cytoplasmic granules and defective degranulation of neutrophil lysosomes.

NK cells have a variety of surface receptors that have inhibitory or activating functions **(Table 360-9)**. NK immunoglobulin superfamily receptors include the killer cell immunoglobulin-like activating or inhibitory receptors (KIRs), many of which have been shown to have HLA class I ligands. The KIRs are made up proteins with either two (KIR2D) or three (KIR3D) extracellular immunoglobulin domains (D). Moreover, their nomenclature designates their function as either inhibitory KIRs with a long (L) cytoplasmic tail and immunoreceptor tyrosine-based inhibitory motif (ITIM) (KIRDL) or activating KIRs with a short (S) cytoplasmic tail (KIRDS). NK cell inactivation by KIRs is a central mechanism to prevent damage to normal host cells. Genetic studies have demonstrated the association of KIRs with viral infection outcome, or to outcomes in autoimmune or malignant diseases **(Table 360-10)**.

In addition to the KIRs, a second set of immunoglobulin superfamily receptors includes the natural cytotoxicity receptors (NCRs), which include NKp46, NKp30, and NKp44. These receptors help to mediate NK cell activation against target cells. The ligands to which NCRs bind on target cells have been recently recognized to be comprised of molecules of pathogens such as influenza, cytomegalovirus, and malaria, as well as host molecules expressed on tumor cells. Signaling lymphocytic activating molecule (SLAM) family receptors are expressed on hematopoietic cells, with SLAMF2 (CD48), SLAMF4 (2B4), and SLAMF7/CD2-like receptor activating cytotoxic cells (CRACCs) the most prominent on NK cells (Table 360-9).

NK cell signaling is, therefore, a highly coordinated series of inhibiting and activating signals that prevent NK cells from responding to uninfected, nonmalignant self-cells; however, they are activated to attack malignant and virally infected cells **(Fig. 360-4)**. Recent evidence suggests that NK cells, although not possessing rearranging immune recognition genes, may be able to mediate recall for NK cell responses to viruses and for immune responses such as contact hypersensitivity.

Some NK cells express CD3 and invariant TCR-α chains and are termed *NK T cells*. TCRs of NK T cells recognize lipid molecules of intracellular bacteria when presented in the context of CD1 molecules on APCs. Upon activation, NK T cells secrete effector cytokines such as IL-4 and IFN-γ. This mode of recognition of intracellular bacteria such as *Listeria monocytogenes* and *Mycobacterium tuberculosis* by NK T cells leads to induction of activation of DCs and is thought to be an important innate defense mechanism against these organisms.

TABLE 360-8 CC, CXC_1, CX_3, C_1, and XC Families of Chemokines and Chemokine Receptors

CHEMOKINE RECEPTOR	CHEMOKINE LIGANDS	CELL TYPES	DISEASE CONNECTION
CCR1	CCL3 (MIP-1α), CCL5 (RANTES), CCL7 (MCP-3), CCL14 (HCC1)	T cells, monocytes, eosinophils, basophils	Rheumatoid arthritis, multiple sclerosis
CCR2	CCL2 (MCP-1), CCL8 (MCP-2), CCL7 (MCP-3), CCL13 (MCP-4), CCL16 (HCC4)	Monocytes, dendritic cells (immature), memory T cells	Atherosclerosis, rheumatoid arthritis, multiple sclerosis, resistance to intracellular pathogens, type 2 diabetes mellitus
CCR3	CCL11 (eotaxin), CCL13 (eotaxin-2), CCL7 (MCP-3), CCL5 (RANTES), CCL8 (MCP-2), CCL13 (MCP-4)	Eosinophils, basophils, mast cells, T_H2, platelets	Allergic asthma and rhinitis
CCR4	CCL17 (TARC), CCL22 (MDC)	T cells (T_H2), dendritic cells (mature), basophils, macrophages, platelets	Parasitic infection, graft rejection, T-cell homing to skin
CCR5	CCL3 (MIP-1α), CCL4 (MIP-1α), CCL5 (RANTES), CCL11 (eotaxin), CCL14 (HCC1), CCL16 (HCC4)	T cells, monocytes	HIV-1 co-receptor (T cell–tropic strains), transplant rejection
CCR6	CCL20 (MIP-3α, LARC)	T cells (T regulatory and memory), B cells, dendritic cells	Mucosal humoral immunity, allergic asthma, intestinal T-cell homing
CCR7	CCL19 (ELC), CCL21 (SLC)	T cells, dendritic cells (mature)	Transport of T cells and dendritic cells to lymph nodes, antigen presentation, and cellular immunity
CCR8	CCL1 (1309)	T cells (T_H2), monocytes, dendritic cells	Dendritic cell migration to lymph node, type 2 cellular immunity, granuloma formation
CCR9	CCL25 (TECK)	T cells, IgA+ plasma cells	Homing of T cells and IgA+ plasma cells to the intestine, inflammatory bowel disease
CCR10	CCL27 (CTACK), CCL28 (MEC)	T cells	T-cell homing to intestine and skin
CXCR1	CXCL8 (interleukin-8), CXCL6 (GCP2)	Neutrophils, monocytes	Inflammatory lung disease, COPD
CXCR2	CXCL8, CXCL1 (GROα), CXCL2 (GROα), CXCL3 (GROα), CXCL5 (ENA-78), CXCL6	Neutrophils, monocytes, microvascular endothelial cells	Inflammatory lung disease, COPD, angiogenic for tumor growth
CXCR3-A	CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC)	Type 1 helper cells, mast cells, mesangial cells	Inflammatory skin disease, multiple sclerosis, transplant rejection
CXCR3-B	CXCL4 (PF4), CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC)	Microvascular endothelial cells, neoplastic cells	Angiostatic for tumor growth
CXCR4	CXCL12 (SDF-1)	Widely expressed	HIV-1 co-receptor (T cell–tropic), tumor metastases, hematopoiesis
CXCR5	CXCL13 (BCA-1)	B cells, follicular helper T cells	Formation of B-cell follicles
CXCR6	CXCL16 (SR-PSOX)	CD8+ T cells, natural killer cells, and memory CD4+ T cells	Inflammatory liver disease, atherosclerosis (CXCL16)
CX_3CR1	CX3CL1 (fractalkine)	Macrophages, endothelial cells, smooth-muscle cells	Atherosclerosis
XCR1	XCL1 (lymphotactin), XCL2	T cells, natural killer cells	Rheumatoid arthritis, IgA nephropathy, tumor response

Abbreviations: BCA-1, B-cell chemoattractant 1; COPD, chronic obstructive pulmonary disease; CTACK, cutaneous T cell–attracting chemokine; ELC, Epstein-Barr I1-ligand chemokine; ENA, epithelial cell–derived neutrophil-activating peptide; GCP, granulocyte chemotactic protein; GRO, growth-regulated oncogene; HCC, hemofiltrate chemokine; IP-10, interferon inducible 10; I-TAC, interferon-inducible T-cell alpha chemoattractant; LARC, liver- and activation-regulated chemokine; MCP, monocyte chemoattractant protein; MDC, macrophage-derived chemokine; MEC, mammary-enriched chemokine; MIG, monokine induced by interferon-γ; MIP, macrophage inflammatory protein; PF, platelet factor; SDF, stromal cell–derived factor; SLC, secondary lymphoid-tissue chemokine; SR-PSOX, scavenger receptor for phosphatidylserine-containing oxidized lipids; TARC, thymus- and activation-regulated chemokine; TECK, thymus-expressed chemokine; T_H2, type 2 helper T cells.

The receptors for the Fc portion of IgG (FcγRs) are present on NK cells, B cells, macrophages, neutrophils, and mast cells and mediate interactions of IgG with antibody-coated target cells, such as virally infected cells. Antibody-NK interaction via antibody Fc and NK cell FcR links the adaptive and innate immune systems and regulates the mediation of IgG antibody effector functions such as ADCC. There are both activation and inhibitory FcγRs. Activation FcRs, such as FcγRI (CD64), FcγRIIa (CD32a), and FcγRIIIa (CD16a), are characterized by the presence of an immunoreceptor tyrosine-based activating motif (ITAM) sequence, whereas inhibitory FcRs, such as FcγRIIb (CD32b), contain an ITIM sequence. There is evidence that dysregulation in IgG-FcγR interactions plays roles in arthritis, multiple sclerosis, and systemic lupus erythematosus.

Neutrophils, Eosinophils, and Basophils Granulocytes are present in nearly all forms of inflammation and are amplifiers and effectors of innate immune responses (Fig. 360-2). Unchecked accumulation and activation of granulocytes can lead to host tissue damage, as seen in neutrophil- and eosinophil-mediated *systemic necrotizing vasculitis*. Granulocytes are derived from stem cells in bone marrow. Each type of granulocyte (neutrophil, eosinophil, or basophil) is derived from a different subclass of progenitor cell that is stimulated to proliferate by colony-stimulating factors (Table 360-6). During terminal maturation of granulocytes, class-specific nuclear morphology and cytoplasmic granules appear that allow for histologic identification of granulocyte type.

Neutrophils express Fc receptor IIIa for IgG (CD16a) as well as receptors for activated complement components (C3b or CD35). Upon interaction of neutrophils with antibody-coated (opsonized) bacteria or immune complexes, azurophilic granules (containing myeloperoxidase, lysozyme, elastase, and other enzymes) and specific granules (containing lactoferrin, lysozyme, collagenase, and other enzymes) are released, and microbicidal superoxide radicals (O_2^-) are generated at the neutrophil surface. The generation of superoxide leads to inflammation by direct injury to tissue and by alteration of macromolecules such as collagen and DNA.

Eosinophils are potent cytotoxic effector cells for various parasitic organisms. In *Nippostrongylus brasiliensis* helminth infection, eosinophils are important cytotoxic effector cells for removal of these parasites. Key to regulation of eosinophil cytotoxicity to *N. brasiliensis*

worms are antigen-specific T helper cells that produce IL-4, thus providing an example of regulation of innate immune responses by adaptive immunity antigen-specific T cells. Intracytoplasmic contents of eosinophils, such as major basic protein, eosinophil cationic protein, and eosinophil-derived neurotoxin, are capable of directly damaging tissues and may be responsible in part for the organ system dysfunction in the *hypereosinophilic syndromes* (Chap. 67). Because the eosinophil granule contains anti-inflammatory types of enzymes (histaminase, arylsulfatase, phospholipase D), eosinophils may also downregulate or terminate ongoing inflammatory responses.

Basophils and tissue mast cells are potent reservoirs of cytokines such as IL-4 and can respond to bacteria and viruses with cytokine production through multiple TLRs expressed on their surface. Mast cells and basophils can also mediate antipathogen immunity through the binding of antibodies. This is a particularly important host defense mechanism against parasitic diseases. Basophils express high-affinity surface receptors for IgE (FcεRII) (CD23) and, upon cross-linking of basophil-bound IgE by antigen, can release histamine, eosinophil chemotactic factor of anaphylaxis, and neutral proteases—all mediators of allergic immediate (anaphylaxis) hypersensitivity responses.

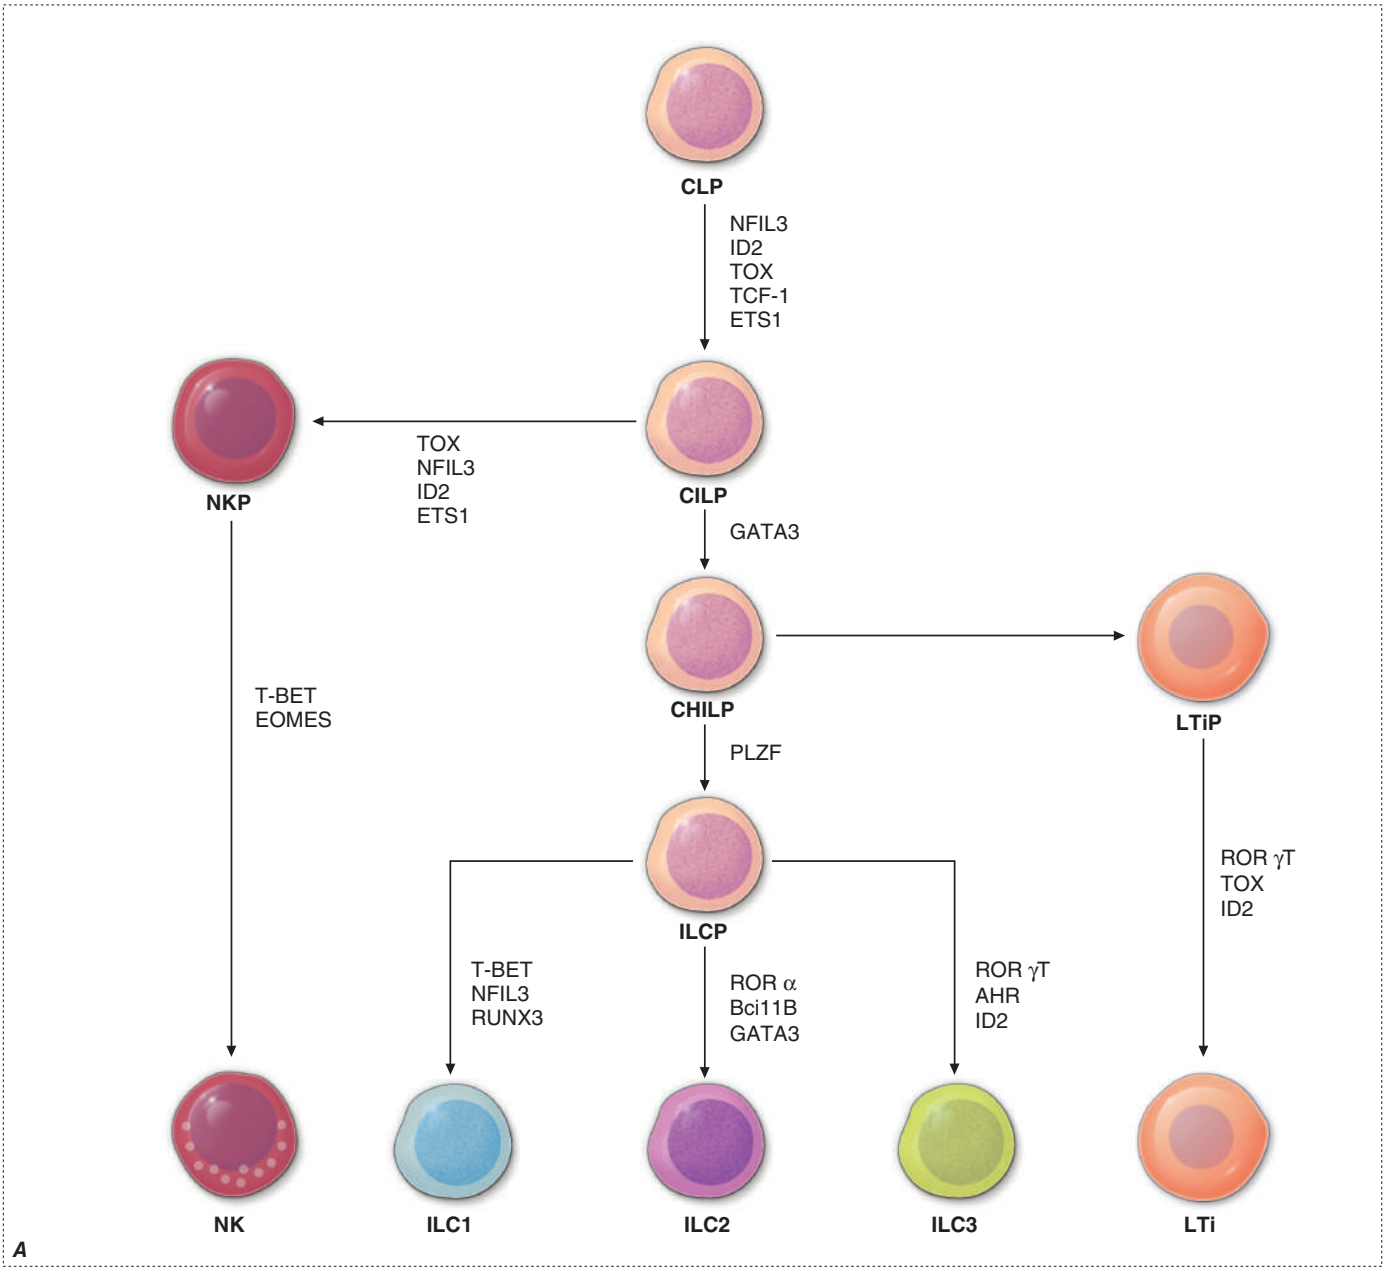

FIGURE 360-3 Development and function of innate lymphoid cells (ILCs). ***A.*** ILC development, mainly based on mouse ILC differentiation paths, is schematized. ILCs develop from common innate lymphoid progenitors (CILPs), which themselves differentiate from common lymphoid progenitors (CLPs). CILPs can differentiate into natural killer (NK) cell precursor (NKP) cells or into common helper innate lymphoid progenitors (CHILPs), which themselves give rise to lymphoid tissue inducer progenitors (LTiPs) and innate lymphoid cell precursors (ILCPs). LTiPs differentiate into lymphoid tissue inducers (LTis) and ILCPs into ILC1, ILC2, or ILC3. Each stage of differentiation is dependent on the expression of the indicated transcription factors: NFIL3 (nuclear factor IL-3 induced), Id2 (inhibitor of DNA binding 2), TOX (thymocyte selection-associated high mobility group box protein), TCF-1 (T-cell factor 1), ETS1 (avian erythroblastosis virus E26 homolog-1), GATA3 (GATA binding protein 3), PLZF (promyelocytic leukemia zinc finger), T-bet (T-box transcription factor), Eomes (eomesodermin), RUNX3 (runt-related transcription factor 3), RORα (RAR-related orphan receptor α), Bcl11b (B cell lymphoma/leukemia 11B), RORγt (RAR-related orphan receptor γt), and AHR (Aryl hydrocarbon receptor). It has been shown in humans that ILC1 subsets may originate from precursors other than ILCPs, but the identity of these precursors remains unknown at this time. ***B.*** Some of the most well-known immune functions of each ILC subset are shown: NK cells and ILC1s react to intracellular pathogens, such as viruses, and to tumors; ILC2s respond to large extracellular parasites and allergens; ILC3s combat extracellular microbes, such as bacteria and fungi; and Lutes are involved in the formation of secondary lymphoid structures. For each ILC subset, effector molecules that can be produced upon activation are indicated AREG, amphiregulin; RANK, receptor activation of nuclear factor κB; RANK-L, RANK-ligand. *(Reproduced with permission from E Vivier et al: Innate lymphoid cells: 10 years on. Cell 174:1054, 2018.)*

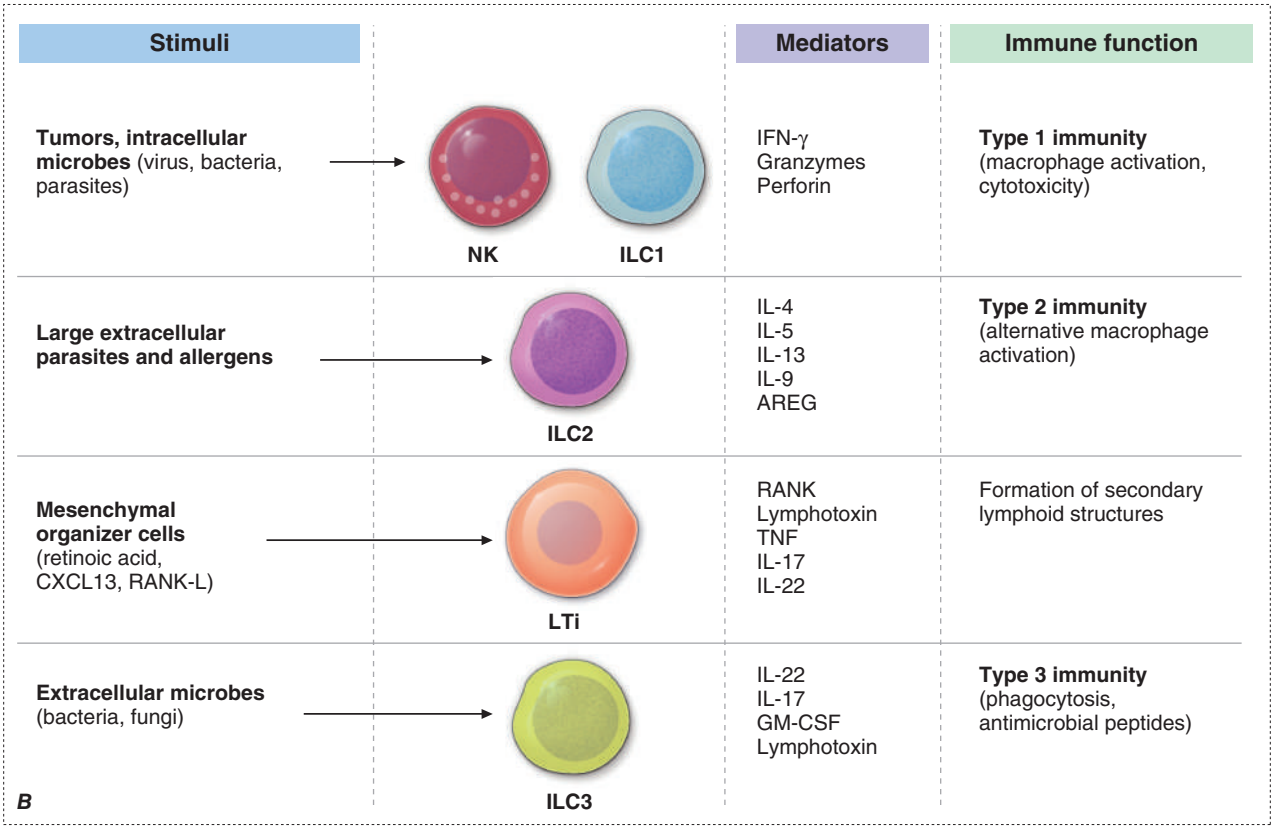

FIGURE 360-3 (*Continued*)

In addition, basophils express surface receptors for activated complement components (C3a, C5a), through which mediator release can be directly effected. Thus, basophils, like most cells of the immune system, can be activated in the service of host defense against pathogens, or they can be activated for mediator release and cause pathogenic responses in allergic and inflammatory diseases. **For further discussion of tissue mast cells, see Chap. 366.**

The Complement System The complement system, an important soluble component of the innate immune system, is a series of plasma enzymes, regulatory proteins, and proteins that are activated in a cascading fashion, resulting in cell lysis. There are four pathways of the complement system: the classic activation pathway activated by antigen/antibody immune complexes, the MBL (a serum collectin) activation pathway activated by microbes with terminal mannose groups, the alternative activation pathway activated by microbes or tumor cells, and the terminal pathway that is common to the first three pathways and leads to the membrane attack complex that lyses cells **(Fig. 360-5)**. The series of enzymes of the complement system are serine proteases.

Activation of the classic complement pathway via immune complex binding to C1q links the innate and adaptive immune systems via specific antibody in the immune complex. The alternative complement activation pathway is antibody-independent and is activated by binding of C3 directly to pathogens and "altered self" such as tumor cells. In the renal glomerular inflammatory disease *IgA nephropathy*, IgA activates the alternative complement pathway and causes glomerular damage and decreased renal function. Activation of the classic complement pathway via C1, C4, and C2 and activation of the alternative pathway via factor D, C3, and factor B both lead to cleavage and activation of C3. C3 activation fragments, when bound to target surfaces such as bacteria and other foreign antigens, are critical for opsonization (coating by antibody and complement) in preparation for phagocytosis. The MBL pathway substitutes MBL-associated serine proteases (MASPs) 1 and 2 for C1q, C1r, and C1s to activate C4. The MBL activation pathway is activated by mannose on the surface of bacteria and viruses.

The three pathways of complement activation all converge on the final common terminal pathway. C3 cleavage by each pathway results in activation of C5, C6, C7, C8, and C9, resulting in the membrane attack complex that physically inserts into the membranes of target cells or bacteria and lyses them.

Thus, complement activation is a critical component of innate immunity for responding to microbial infection. The functional consequences of complement activation by the three initiating pathways and the terminal pathway are shown in Fig. 360-5. In general, the cleavage products of complement components facilitate microbe or damaged cell clearance (C1q, C4, C3), promote activation and enhancement of inflammation (anaphylatoxins, C3a, C5a), and promote microbe or opsonized cell lysis (membrane attack complex).

CYTOKINES

Cytokines are soluble proteins produced by a wide variety of cell types (Tables 360-7 and 360-8). They are critical for both normal innate and adaptive immune responses, and their expression may be perturbed in most immune, inflammatory, and infectious disease states.

Cytokines are involved in the regulation of the growth, development, and activation of immune system cells and in the mediation of the inflammatory response. In general, cytokines are characterized by considerable redundancy in that different cytokines have similar functions. In addition, many cytokines are pleiotropic in that they are capable of acting on many different cell types. This pleiotropism results from the expression on multiple cell types of receptors for the same cytokine (see below), leading to the formation of "cytokine networks." The action of cytokines may be (1) *autocrine* when the target cell is the same cell that secretes the cytokine, (2) *paracrine* when the target cell is nearby, and (3) *endocrine* when the cytokine is secreted into the circulation and acts distal to the source.

Cytokines have been named based on presumed targets or based on presumed functions. Those cytokines that are thought to primarily target leukocytes have been named IL-1, -2, -3, etc. Many cytokines that were originally described as having a certain function have retained those names (e.g., granulocyte colony-stimulating factor [G-CSF]). Cytokines

TABLE 360-9 NK-Cell Receptors, Cognate Ligands, and Their Known Signaling Domains/Proximal Adapters

RECEPTOR	GENE	LIGAND	SIGNALING DOMAINS AND PROXIMAL ADAPTERS
Inhibitory KIR		Conserved epitopes on HLA I ("KIR ligands")	ITIM, Src phosphatases
KIR2DL1	*KIR2DL1*	HLA-C2 alleles (Lys80)

TABLE 360-10 Association of KIRS with Disease

DISEASE	KIR ASSOCIATION	OBSERVATION
Psoriatic arthritis	KIR2DS1/KIR2DS2; HLA-Cw group homozygosity	Susceptibility
Spondylarthritides	Increased KIR3DL2 expression Interaction of HLA-B27 homodimers with KIR3DL1/KIR3DL2; independent of peptide	May contribute to disease pathology May contribute to disease pathogenesis
Ankylosing spondylitis	KIR3DL1/3DS1; HLA-B27 genotypes	Susceptibility
Rheumatoid vasculitis	KIR2DS2; HLA-Cw*03 Increased KIR2L2/2DS2 in patients with extraarticular manifestations	Susceptibility Clinical manifestations may have different genetic backgrounds with respect to KIR genotype
Rheumatoid arthritis	Decreased KIR2DS1/3DS1 in patients without bone erosions KIR2DS4; HLA-Cw4	Susceptibility Susceptibility
Scleroderma	KIR2DS2+/KIR2DL2–	Susceptibility
Behçet's disease	Altered KIR3DL1 expression	Associated with severe eye disease
Psoriasis vulgaris	2DS1; HLA-Cw*06 2DS1; 2DL5; haplotype B	Susceptibility Susceptibility
IDDM	KIR2DS2; HLA-C1	Susceptibility
Type 1 diabetes	KIR2DS2; HLA-C1 and no HLA-C2, no HLA-Bw4	Increased disease progression
Preeclampsia	KIR2DL1 with fewer KIR2DS (mother); HLA-C2 (fetus)	Increased disease progression
AIDS	KIR3DS1; HLA-Bw4Ile80 KIR3DS1 homozygous; no HLA-Bw4Ile80	Decreased disease progression Increased disease progression
HCV infection	KIR2DL3 homozygous; HLA-C1 homozygous	Decreased disease progression
Cervical neoplasia (HPV induced)	KIR3DS1; HLA-C1 homozygous and no HLA-Bw4	Increased disease progression
Malignant melanoma	KIR2DL2 and/or KIR2DL3; HLA-C1	Increased disease progression

Abbreviations: HCV, hepatitis C virus; HLA, human leukocyte antigen; HPV, human papillomavirus; IDDM, insulin-dependent diabetes mellitus; KIR, killer cell immunoglobulin-like receptor.

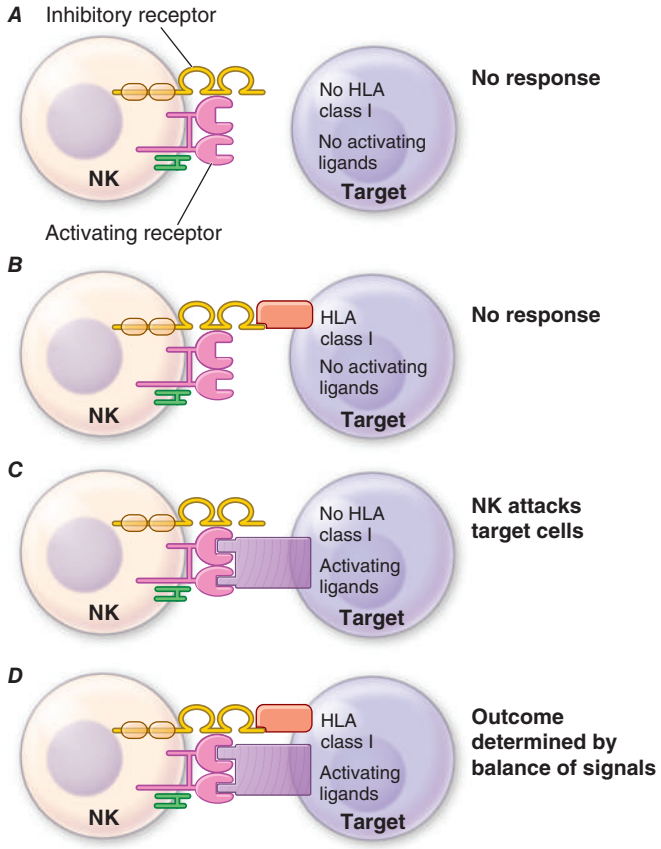

FIGURE 360-4 Encounters between natural killer (NK) cells: Potential targets and possible outcomes. The amount of activating and inhibitory receptors on the NK cells and the amount of ligands on the target cell, as well as the qualitative differences in the signals transduced, determine the extent of the NK response. ***A.*** When target cells have no HLA class I or activating ligands, NK cells cannot kill target cells. ***B.*** When target cells bear self-HLA, NK cells cannot kill targets. ***C.*** When target cells are pathogen-infected and have downregulated HLA and express activating ligands, NK cells kill target cells. ***D.*** When NK cells encounter targets with both self-HLA and activating receptors, then the level of target killing is determined by the balance of inhibitory and activating signals to the NK cell. HLA, human leukocyte antigen. *(Republished with permission of Annual Review of Immunology, from NK Cell Recognition, L Lanier 23:225,2005: permission conveyed through Copyright Clearance Center, Inc.)*

belong in general to three major structural families: the hematopoietin family; the TNF, IL-1, platelet-derived growth factor (PDGF), and transforming growth factor (TGF) β families; and the CXC and C-C chemokine families. Chemokines are cytokines that regulate cell movement and trafficking; they act through G protein–coupled receptors and have a distinctive three-dimensional structure (Table 360-7).

In general, cytokines exert their effects by influencing gene activation that results in cellular activation, growth, differentiation, functional cell-surface molecule expression, and cellular effector function. In this regard, cytokines can have dramatic effects on the regulation of immune responses and the pathogenesis of a variety of diseases. Indeed, T cells have been categorized on the basis of the pattern of cytokines that they secrete, which results in either humoral immune response (T_H2) or cell-mediated immune response (T_H1). A third type of T helper cell is the T_H17 cell that contributes to host defense against extracellular bacteria and fungi, particularly at mucosal sites (Fig. 360-2).

Cytokine receptors can be grouped into five general families based on similarities in their extracellular amino acid sequences and conserved structural domains. The *immunoglobulin (Ig) superfamily* represents a large number of cell-surface and secreted proteins. The IL-1 receptors (type 1, type 2) are examples of cytokine receptors with extracellular Ig domains.

The hallmark of the *hematopoietic growth factor (type 1) receptor* family is that the extracellular regions of each receptor contain two conserved motifs. One motif, located at the N terminus, is rich in cysteine residues. The other motif is located at the C terminus proximal to the transmembrane region and comprises five amino acid residues, tryptophan-serine-X-tryptophan-serine (WSXWS). This family can be grouped on the basis of the number of receptor subunits they have and on the utilization of shared subunits. A number of cytokine receptors, i.e., IL-6, IL-11, IL-12, and leukemia inhibitory factor, are paired with gp130. There is also a common 150-kDa subunit shared by IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF) receptors. The gamma chain (γ_c) of the IL-2 receptor is common to the IL-2, IL-4, IL-7, IL-9, and IL-15 receptors. Thus, the specific cytokine receptor is responsible for ligand-specific binding, whereas the subunits such as gp130, the 150-kDa subunit, and γ_c are important in signal transduction. The γ_c gene is on the X chromosome, and mutations in the γ_c protein result in the *X-linked form of severe combined immune deficiency syndrome (X-SCID)* **(Chap. 362)**.

The members of the *interferon (type II) receptor* family include the receptors for IFN-γ and -β, which share a similar 210-amino-acid binding domain with conserved cysteine pairs at both the amino and carboxy termini. The members of the *TNF (type III) receptor family* share a common binding domain composed of repeated cysteine-rich regions. Members of this family include the p55 and p75 receptors for TNF (TNF-R1 and TNF-R2, respectively); CD40 antigen, which is an important B-cell surface marker involved in immunoglobulin isotype switching; fas/Apo-1, whose triggering induces apoptosis; CD27 and CD30, which are found on activated T cells and B cells; and nerve growth factor receptor.

The common motif for the *seven transmembrane helix family* was originally found in receptors linked to GTP-binding proteins. This family includes receptors for chemokines (Table 360-8), β-adrenergic receptors, and retinal rhodopsin. It is important to note that two members of the chemokine receptor family, CXC chemokine receptor type 4 (CXCR4) and β chemokine receptor type 5 (CCR5), have been found to serve as the two major co-receptors for binding and entry of HIV-1 into CD4-expressing host cells **(Chap. 208)**.

Significant advances have been made in defining the signaling pathways through which cytokines exert their intracellular effects. The Janus family of protein tyrosine kinases (JAK) is a critical element involved in signaling via the hematopoietin receptors. Four JAK

kinases, JAK1, JAK2, JAK3, and Tyk2, preferentially bind different cytokine receptor subunits. Cytokine binding to its receptor brings the cytokine receptor subunits into apposition and allows a pair of JAKs to transphosphorylate and activate one another. The JAKs then phosphorylate the receptor on the tyrosine residues and allow signaling molecules to bind to the receptor, whereby the signaling molecules become phosphorylated. Signaling molecules bind the receptor because they have domains (SH2, or src homology 2 domains) that can bind phosphorylated tyrosine residues. There are a number of these important signaling molecules that bind the receptor, such as the adapter molecule SHC, which can couple the receptor to the activation of the mitogen-activated protein kinase pathway. In addition, an important class of substrate of the JAKs is the signal transducers and activators of transcription (STAT) family of transcription factors. STATs have SH2 domains that enable them to bind to phosphorylated receptors, where they are then phosphorylated by the JAKs. It appears that different STATs have specificity for different receptor subunits. The STATs then dissociate from the receptor and translocate to the nucleus, bind to DNA motifs that they recognize, and regulate gene expression. The STATs preferentially bind DNA motifs that are slightly different from one another and thereby control transcription of specific genes. The importance of this pathway is particularly relevant to lymphoid development. Mutations of JAK3 itself also result in a disorder identical to X-SCID; however, because JAK3 is found on chromosome 19 and not on the X chromosome, JAK3 deficiency occurs in boys and girls **(Chap. 362)**. A new class of immunosuppressive drugs of JAK inhibitors has been developed that are approved to treat chronic inflammatory diseases such as rheumatoid arthritis **(Chap. 370)**, psoriatic arthritis **(Chap. 374)**, ulcerative colitis **(Chap. 337)**, atopic dermatitis **(Chap. 59)**, and alopecia areata **(Chap. 61)**.

THE ADAPTIVE IMMUNE SYSTEM

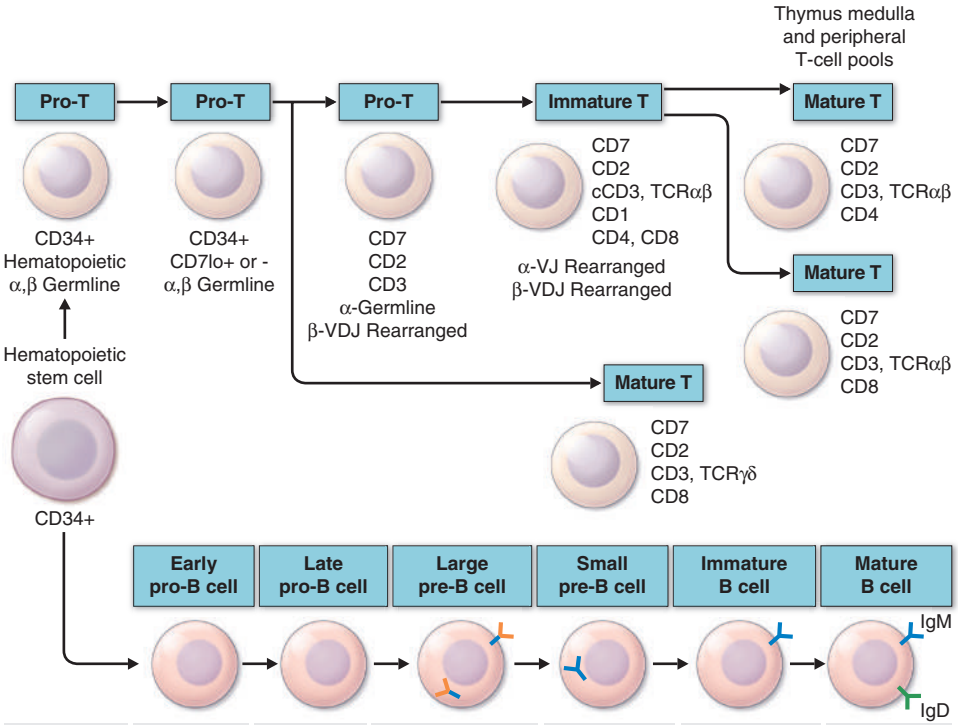
Adaptive immunity is characterized by antigen-specific responses to a foreign antigen or pathogen. A key feature of adaptive immunity is that following the initial contact with antigen (*immunologic priming*), subsequent antigen exposure leads to more rapid and vigorous immune responses (*immunologic memory*). The adaptive immune system consists of dual limbs of cellular and humoral immunity. The principal effectors of cellular immunity are T lymphocytes, whereas the principal effectors of humoral immunity are B lymphocytes. Both B and T lymphocytes derive from a common stem cell **(Fig. 360-6)**.

The proportion and distribution of immunocompetent cells in various tissues reflect cell traffic, homing patterns, and functional capabilities. Bone marrow is the major site of maturation of B cells, monocytes-macrophages, DCs, and granulocytes and contains pluripotent stem cells that, under the influence of various colony-stimulating factors, can give rise to all hematopoietic cell types. T-cell precursors also arise from hematopoietic stem cells and home to the thymus for maturation. Mature T lymphocytes, B lymphocytes, monocytes, and DCs enter the circulation and home to peripheral lymphoid organs (lymph nodes, spleen) and mucosal surface-associated lymphoid tissue (gut, genitourinary, and respiratory tracts) as well as the skin and mucous membranes and await activation by foreign antigen.

T Cells The pool of effector T cells is established in the thymus early in life and is maintained throughout life both by new T-cell production in the thymus and by antigen-driven expansion of virgin peripheral T cells into "memory" T cells that reside in peripheral lymphoid organs. The thymus exports ~2% of the total number of thymocytes per day throughout life, with the total number of daily thymic emigrants decreasing by ~3% per year during the first four decades of life.

Mature T lymphocytes constitute 70–80% of normal peripheral blood lymphocytes (only 2% of the total-body lymphocytes are contained in peripheral blood), 90% of thoracic duct lymphocytes, 30–40% of lymph node cells, and 20–30% of spleen lymphoid cells. In lymph nodes, T cells occupy deep paracortical areas around B-cell germinal centers, and in the spleen, they are located in periarteriolar areas of white pulp **(Chap. 70)**. T cells are the primary effectors of cell-mediated immunity, with subsets of T cells maturing into CD8+ cytotoxic T cells capable of lysis of virus-infected or foreign cells (short-lived effector T cells) and CD4+ T cells capable of T-cell help for CD8+ T-cell and B-cell development. Two populations of long-lived memory T cells are triggered by infections: effector memory and central memory T cells. Effector memory T cells reside in nonlymphoid organs and respond rapidly to repeated pathogenic infections with cytokine production and cytotoxic functions to kill virus-infected cells. Central memory T cells home to lymphoid organs where they replenish long- and short-lived and effector memory T cells as needed.

In general, CD4+ T cells are the primary regulatory cells of T and B lymphocyte and monocyte function by the production of cytokines and by direct cell contact (Fig. 360-2). In addition, T cells regulate erythroid cell maturation in bone marrow and, through cell contact (CD40 ligand), have an important role in activation of B cells and induction of Ig isotype switching. Considerable evidence now exists that colonization of the gut by commensal bacteria (the gut microbiome) is responsible for expansion of the peripheral CD4+ T-cell compartment in normal children and adults.



Human T cells express cell-surface proteins that mark stages of intrathymic T-cell maturation or identify specific functional subpopulations of mature T cells. Many of these molecules mediate or participate in important T-cell functions (Table 360-1, Fig. 360-6, **Chap. 361**).

The earliest identifiable T-cell precursors in bone marrow are CD34+ pro-T cells (i.e., cells in which TCR genes are neither rearranged nor expressed). In the thymus, CD34+ T-cell precursors begin cytoplasmic (c) synthesis of components of the CD3 complex of TCR-associated molecules (Fig. 360-6). Within T-cell precursors, TCR for antigen gene rearrangement yields two T-cell lineages, expressing either TCR-αβ chains or TCR-γδ chains. T cells expressing the TCR-αβ chains constitute the majority of peripheral T cells in blood, lymph node, and spleen and terminally differentiate into either CD4+ or CD8+ cells. Cells expressing TCR-γδ chains circulate as a minor population in blood; their functions have been postulated to be those of immune surveillance at epithelial surfaces and cellular defenses against mycobacterial organisms and other intracellular bacteria through recognition of bacterial lipids.

In the thymus, the recognition of self-peptides on thymic epithelial cells, thymic macrophages, and DCs plays an important role in shaping T-cell repertoire. As immature cortical thymocytes begin to express surface TCR for antigen, thymocytes with TCRs capable of interacting with self-peptides in the context of self-MHC antigens with low affinity are activated and survive (positive selection). Thymocytes with TCRs that are incapable of binding to self-MHC antigens or bind with high affinity die of attrition (no selection) or by apoptosis (negative selection). Thymocytes that are positively selected undergo maturation into CD4 or CD8 single positive T cells, and then migrate to the thymus medulla where they interact with self-peptide–self-MHC molecules, where they can again undergo selection. The purpose of negative and positive thymocyte selection is to eliminate potential pathogenic autoreactive T cells, and at the same time, select a repertoire of mature T cells capable of recognizing foreign antigens.

Mature TCRαβ thymocytes that are positively selected are functional MHC class II–restricted CD4+ T cells (Fig. 360-2), or they are CD8+ T cells destined to become CD8+ MHC class I–restricted cytotoxic T cells. *MHC class I* or *class II restriction* means that T cells recognize antigen peptide fragments only when they are presented in the antigen-recognition site of a class I or class II MHC molecule, respectively. After thymocyte maturation and selection, CD4 and CD8 thymocytes leave the thymus and migrate to the peripheral immune system. The thymus can continue to be a contributor to the peripheral immune system well into adult life, both normally and when the peripheral T-cell pool is damaged, such as occurs in AIDS and cancer chemotherapy.

MOLECULAR BASIS OF T-CELL RECOGNITION OF ANTIGEN The TCR for antigen is a complex of molecules consisting of an antigen-binding heterodimer of either αβ or γδ chains noncovalently linked with five CD3 subunits (γ, δ, ε, ζ, and η) **(Fig. 360-7)**. The CD3 ζ chains are either disulfide-linked homodimers (CD3-ζ_2) or disulfide-linked

Heavy-chain genes	D-J rearranging	VDJ rearranging	VDJ rearranged	VDJ rearranged	VDJ rearranged	VDJ rearranged
Light-chain genes	Germline	Germline	Germline	VJ rearranging	VJ rearranged	VJ rearranged

Surface marker proteins	CD34 CD10 CD38	CD10 CD19 CD38 CD40	CD19 CD20 CD38	CD19 CD20 CD38	CD19 CD20	CD19 CD20 CD21

FIGURE 360-6 Development stages of T and B cells. Elements of the developing T- and B-cell receptor for antigen are shown schematically. The classification into the various stages of B-cell development is primarily defined by rearrangement of the immunoglobulin (Ig) heavy (H) and light (L) chain genes and by the absence or presence of specific surface markers. The classification of stages of T-cell development is primarily defined by cell-surface marker protein expression (sCD3, surface CD3 expression; cCD3, cytoplasmic CD3 expression; TCR, T-cell receptor). For B-cell development, the pre-B-cell receptor is shown as a blue-orange B-cell receptor. *(Adapted from Janeway's Immunobiology, 9th ed by Kenneth Murphy and Casey Weaver. heterodimers composed of one ζ chain and one η chain. TCR-αβ or TCR-γδ molecules must be associated with CD3 molecules to be inserted into the T-cell surface membrane, TCR-α being paired with TCR-β and TCR-γ being paired with TCR-δ. Molecules of the CD3 complex mediate transduction of T-cell activation signals via TCRs, whereas TCR-α and -β or -γ and -δ molecules combine to form the TCR antigen-binding site.

The α, β, γ, and δ TCR for antigen molecules have amino acid sequence homology and structural similarities to immunoglobulin heavy and light chains and are members of the *immunoglobulin gene superfamily* of molecules. The genes encoding TCR molecules are encoded as clusters of gene segments that rearrange during T-cell maturation. This creates an efficient and compact mechanism for housing the diversity requirements of antigen receptor molecules. The TCR-α chain is on chromosome 14 and consists of a series of V (variable), J (joining), and C (constant) regions. The TCR-β chain is on chromosome 7 and consists of multiple V, D (diversity), J, and C TCR-β loci. The TCR-γ chain is on chromosome 7, and the TCR-δ chain is in the middle of the TCR-α locus on chromosome 14. Thus, molecules of the TCR for antigen have constant (framework) and variable regions, and the gene segments encoding the α, β, γ, and δ chains of these molecules are recombined and selected in the thymus, culminating in synthesis of the completed molecule. In both T- and B-cell precursors (see below), DNA rearrangements of antigen receptor genes involve the same enzymes, recombinase activating gene RAG1 and RAG2, both DNA-dependent protein kinases.

TCR diversity is created by the different V, D, and J segments that are possible for each receptor chain by the many permutations of V, D, and J segment combinations, by "N-region diversification" due to the addition of nucleotides at the junction of rearranged gene segments, and by the pairing of individual chains to form a TCR dimer. As T cells mature in the thymus, the repertoire of antigen-reactive T cells is modified by selection processes that eliminate many autoreactive T cells, enhance the proliferation of cells that function appropriately with self-MHC molecules and antigen, and allow T cells with nonproductive TCR rearrangements to die.

TCR-αβ cells do not recognize native protein or carbohydrate antigens. Instead, T cells recognize only short (~9–13 amino acids) peptide fragments derived from protein antigens taken up or produced in APCs. Foreign antigens may be taken up by endocytosis into acidified

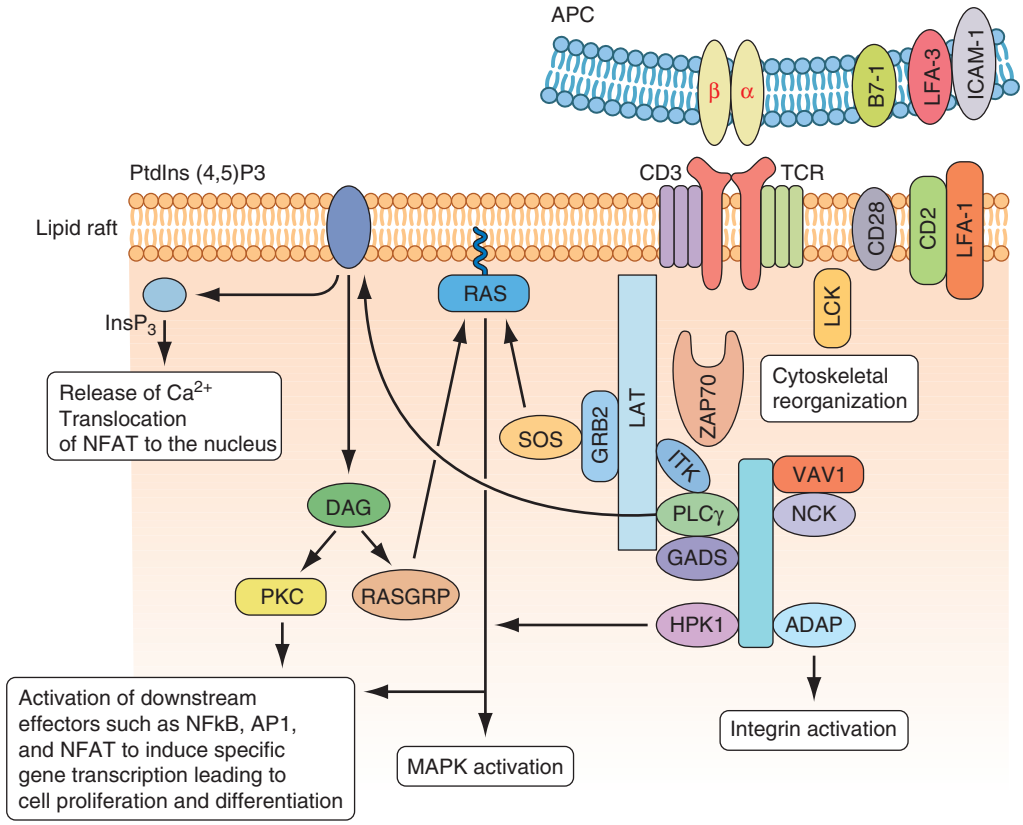

FIGURE 360-7 Signaling through the T-cell receptor. Activation signals are mediated via immunoreceptor tyrosine-based activation (ITAM) sequences in LAT and CD3 chains (*blue bars*) that bind to enzymes and transduce activation signals to the nucleus via the indicated intracellular activation pathways. Ligation of the T-cell receptor (TCR) by MHC complexed with antigen results in sequential activation of LCK and γ-chain-associated protein kinase of 70 kDa (ZAP70). ZAP70 phosphorylates several downstream targets, including LAT (linker for activation of T cells) and SLP76 (SCR homology 2 [SH2] domain-containing leukocyte protein of 76 kDa). SLP76 is recruited to membrane-bound LAT through its constitutive interaction with GADS (GRB2-related adaptor protein). Together, SLP76 and LAT nucleate a multimolecular signaling complex, which induces a host of downstream responses, including calcium flux, mitogen-activated protein kinase (MAPK) activation, integrin activation, and cytoskeletal reorganization. APC, antigen-presenting cell; NFAT, nuclear factor of activated T cells. *(Reproduced with permission from GA Koretzky, F Abtahian, MA Silverman. SLP76 and SLP65: Complex regulation of signalling in lymphocytes and beyond. Nat Rev Immunol 6:67, 2006.)*

intracellular vesicles or by phagocytosis and degraded into small peptides that associate with MHC class II molecules (exogenous antigen-presentation pathway). Other foreign antigens arise endogenously in the cytosol (such as from replicating viruses) and are broken down into small peptides that associate with MHC class I molecules (endogenous antigen-presenting pathway). Thus, APCs proteolytically degrade foreign proteins and display peptide fragments embedded in the MHC class I or II antigen-recognition site on the MHC molecule surface, where foreign peptide fragments are available to bind to TCR-αβ or TCR-γδ chains of reactive T cells. CD4 molecules act as adhesives and, by direct binding to MHC class II (DR, DQ, or DP) molecules, stabilize the interaction of TCR with peptide antigen (Fig. 360-7). Similarly, CD8 molecules also act as adhesives to stabilize the TCR-antigen interaction by direct CD8 molecule binding to MHC class Ia (HLA A, B, or C) molecules or to MHC class Ib (HLA E).

Antigens that arise in the cytosol and are processed via the endogenous antigen-presentation pathway are cleaved into small peptides by a complex of proteases called the *proteasome*. From the proteasome, antigen peptide fragments are transported from the cytosol into the lumen of the endoplasmic reticulum by a heterodimeric complex termed *transporters associated with antigen processing* or TAP proteins. There, MHC class I molecules in the endoplasmic reticulum membrane physically associate with processed cytosolic peptides. Following peptide association with class I molecules, peptide–class I complexes are exported to the Golgi apparatus, and then to the cell surface, for recognition by CD8+ T cells.

Antigens taken up from the extracellular space via endocytosis into intracellular acidified vesicles are degraded by vesicle proteases into peptide fragments. Intracellular vesicles containing MHC class II molecules fuse with peptide-containing vesicles, thus allowing peptide fragments to physically bind to MHC class II molecules. Peptide–MHC class II complexes are then transported to the cell surface for recognition by CD4+ T cells.

Whereas it is generally agreed that the TCR-αβ receptor recognizes peptide antigens in the context of MHC class I or class II molecules, lipids in the cell wall of intracellular bacteria such as *M. tuberculosis* can also be presented to a wide variety of T cells, including subsets of TCR-γδ T cells, and a subset of CD8+ TCR-αβ T cells. Importantly, bacterial lipid antigens are not presented in the context of MHC class I or II molecules, but rather are presented in the context of MHC-related CD1 molecules. Some γδ T cells that recognize lipid antigens via CD1 molecules have very restricted TCR usage, do not need antigen priming to respond to bacterial lipids, and may be a form of innate rather than acquired immunity to intracellular bacteria.

Just as foreign antigens are degraded and their peptide fragments presented in the context of MHC class I or class II molecules on APCs, endogenous self-proteins also are degraded, and self-peptide fragments are presented to T cells in the context of MHC class I or class II molecules on APCs. In peripheral lymphoid organs, there are T cells that are capable of recognizing self-protein fragments but normally are *anergic* or *tolerant*, i.e., nonresponsive to self-antigenic stimulation, due to lack of self-antigen upregulating APC *co-stimulatory molecules* such as B7-1 (CD80) and B7-2 (CD86) (see below and **Chap. 361**).

Once engagement of mature T-cell TCR by foreign peptide occurs in the context of self-MHC class Ia (A, B, or C), class 1b (E), or class II molecules, binding of non-antigen-specific adhesion ligand pairs such as CD54-CD11/CD18 and CD58-CD2 stabilizes MHC peptide-TCR binding, and the expression of these adhesion molecules is upregulated. Once antigen ligation of the TCR occurs, the T-cell membrane is partitioned into *lipid membrane microdomains*, or *lipid rafts*, that coalesce the key signaling molecules TCR/CD3 complex, CD28, CD2, LAT (linker for activation of T cells), intracellular activated

(dephosphorylated) src family protein tyrosine kinases (PTKs), and the key CD3ζ-associated protein-70 (ZAP-70) PTK (Fig. 360-7). Importantly, during T-cell activation, the CD45 molecule, with protein tyrosine phosphatase activity, is partitioned away from the TCR complex to allow activating phosphorylation events to occur. The coalescence of signaling molecules of activated T lymphocytes in *microdomains* has suggested that T cell–APC interactions can be considered *immunologic synapses*, analogous in function to neuronal synapses.

After TCR-MHC binding is stabilized, activation signals are transmitted through the cell to the nucleus and lead to the expression of gene products important in mediating the wide diversity of T-cell functions such as the secretion of IL-2. The TCR does not have intrinsic signaling activity but is linked to a variety of signaling pathways via ITAMs expressed on the various CD3 chains that bind to proteins that mediate signal transduction. Each of the pathways results in the activation of particular transcription factors that control the expression of cytokine and cytokine receptor genes. Thus, antigen-MHC binding to the TCR induces the activation of the src family of PTKs, Fyn and Lck (Lck is associated with CD4 or CD8 co-stimulatory molecules); phosphorylation of CD3ζ chain; activation of the related tyrosine kinases ZAP-70 and Syk; and downstream activation of the calcium-dependent calcineurin pathway, the ras pathway, and the protein kinase C pathway. Each of these pathways leads to activation of specific families of transcription factors (including *NF-AT*, *fos* and *jun*, and *rel/NF-κB*) that form heteromultimers capable of inducing expression of IL-2, IL-2 receptor, IL-4, TNF-α, and other T-cell mediators.

In addition to the signals delivered to the T cell from the TCR complex and CD4 and CD8, molecules on the T cell, such as CD28 and inducible co-stimulator (ICOS), and molecules on DCs, such as B7-1 (CD80) and B7-2 (CD86), also deliver important co-stimulatory signals that upregulate T-cell cytokine production and are essential for T-cell activation. If signaling through CD28 or ICOS does not occur, or if CD28 is blocked, the T cell becomes anergic rather than activated (see "Immune Tolerance and Autoimmunity" below and **Chap. 361**). CTLA-4 (CD152) is similar to CD28 in its ability to bind CD80 and CD86. Unlike CD28, CTLA-4 transmits an inhibitory signal to T cells, acting as an off switch.

T-CELL EXHAUSTION IN VIRAL INFECTIONS AND CANCER In chronic viral infections such as HIV-1, hepatitis C virus, and hepatitis B virus and in chronic malignancies, the persistence of antigen disrupts memory T-cell function, resulting in defects in memory T-cell responses. This has been defined as *T-cell exhaustion* and is associated with T-cell programmed cell death protein 1 (PD-1) (CD279) expression. Exhausted T cells have compromised proliferation and lose the ability to produce effector molecules, like IL-2, TNF-α, and IFN-γ. PD-1 and CTLA-4 activation downregulates T-cell responses and is associated with T-cell exhaustion and tumor progression. Inhibition of T-cell PD-1 or CTLA-4 activity to enhance effector T-cell killing of tumor cells has become a critical component of therapy for certain malignancies **(Chap. 361)**.

T-CELL SUPERANTIGENS Conventional antigens bind to MHC class I or II molecules in the groove of the αβ heterodimer and bind to T cells via the V regions of the TCR-α and -β chains. In contrast, superantigens bind directly to the lateral portion of the TCR-β chain and MHC class II β chain and stimulate T cells based solely on the Vβ gene segment used independent of the D, J, and Vα sequences present. *Superantigens* are protein molecules capable of activating up to 20% of the peripheral T-cell pool, whereas conventional antigens activate <1 in 10,000 T cells. T-cell superantigens include staphylococcal enterotoxins and other bacterial products. Superantigen stimulation of human peripheral T cells occurs in the clinical setting of *staphylococcal toxic shock syndrome*, leading to massive overproduction of T-cell cytokines that leads to hypotension and shock **(Chap. 152)**.

B CELLS Mature B cells constitute 5–10% of human peripheral blood lymphocytes, 20–30% of lymph node cells, 50% of splenic lymphocytes, and ~10% of bone marrow lymphocytes. B cells express on their surface intramembrane immunoglobulin (Ig) molecules that function as BCRs for antigen in a complex of Ig-associated α and β signaling molecules with properties similar to those described in T cells **(Fig. 360-8)**. Unlike T cells, which recognize only processed peptide fragments of conventional antigens embedded in the notches of MHC class I and class II antigens of APCs, B cells are capable of recognizing and proliferating to whole unprocessed native antigens via antigen binding to B-cell surface Ig (sIg) receptors. B cells also express surface receptors for the Fc region of IgG molecules (CD32) as well as receptors for activated complement components (C3d or CD21, C3b or CD35). The primary function of B cells is to produce antibodies. B cells also serve as APCs and are highly efficient at antigen processing. Their antigen-presenting function is enhanced by a variety of cytokines. Mature B cells are derived from bone marrow precursor cells that arise continuously throughout life (Fig. 360-6).

B lymphocyte development can be separated into antigen-independent and antigen-dependent phases. Antigen-independent B-cell development occurs in primary lymphoid organs and includes all stages of B-cell maturation up to the sIg+ mature B cell. Antigen-dependent B-cell maturation is driven by the interaction of antigen with the mature B-cell sIg, leading to memory B-cell induction, Ig class switching, and plasma cell formation. Antigen-dependent stages of B-cell maturation occur in secondary lymphoid organs, including lymph node, spleen, and gut Peyer's patches. In contrast to the T-cell repertoire that is generated intrathymically before contact with foreign antigen, the repertoire of B cells expressing diverse antigen-reactive sites is modified by further alteration of Ig genes by the enzyme activation-induced cytidine deaminase after stimulation by antigen—a process called *somatic hypermutation*—that occurs in lymph node germinal centers.

During B-cell development, diversity of the antigen-binding variable region of Ig is generated by an ordered set of Ig gene rearrangements that are similar to the rearrangements undergone by TCR α, β, γ, and δ genes. For the heavy chain, there is first a rearrangement of D segments to J segments, followed by a second rearrangement between a V gene segment and the newly formed D-J sequence; the C segment is aligned to the V-D-J complex to yield a functional Ig heavy chain gene (V-D-J-C). During later stages, a functional κ or γ light chain gene is generated by rearrangement of a V segment to a J segment, ultimately yielding an intact Ig molecule composed of heavy and light chains.

The process of Ig gene rearrangement is regulated and results in a single antibody specificity produced by each B cell, with each Ig molecule comprising one type of heavy chain and one type of light chain. Although each B cell contains two copies of Ig light and heavy chain genes, only one gene of each type is productively rearranged and expressed in each B cell, a process termed *allelic exclusion*.

There are ~300 V_κ genes and 5 J_κ genes, resulting in the pairing of V_κ and J_κ genes to create >1500 different kappa light chain combinations. There are ~70 V_λ genes and 4 J_λ genes for >280 different lambda light chain combinations. The number of distinct light chains that can be generated is increased by somatic mutations within the V and J genes, thus creating large numbers of possible specificities from a limited amount of germline genetic information. As noted above, in heavy chain Ig gene rearrangement, the VH domain is created by the joining of three types of germline genes called V_H, D_H, and J_H, thus allowing for even greater diversity in the variable region of heavy chains than of light chains.

The most immature B-cell precursors (early pro-B cells) lack cytoplasmic Ig (cIg) and sIg (Fig. 360-6). The large pre-B cell is marked by the acquisition of the surface pre-BCR composed of μ heavy (H) chains and a pre-B light chain, termed *V pre-B*. V pre-B is a surrogate light chain receptor encoded by the non-rearranged V pre-B and the γ5 light chain locus (the pre-BCR). Pro- and pre-B cells are driven to proliferate and mature by signals from bone marrow stroma—in particular, IL-7. Light chain rearrangement occurs in the small pre-B-cell stage such that the full BCR is expressed at the immature B-cell stage. Immature B cells have rearranged Ig light chain genes and express sIgM. As immature B cells develop into mature B cells, sIgD is expressed as well as sIgM. At this point, B lineage development in bone marrow is complete, and B cells exit into the peripheral circulation and migrate to secondary lymphoid organs to encounter specific antigens.

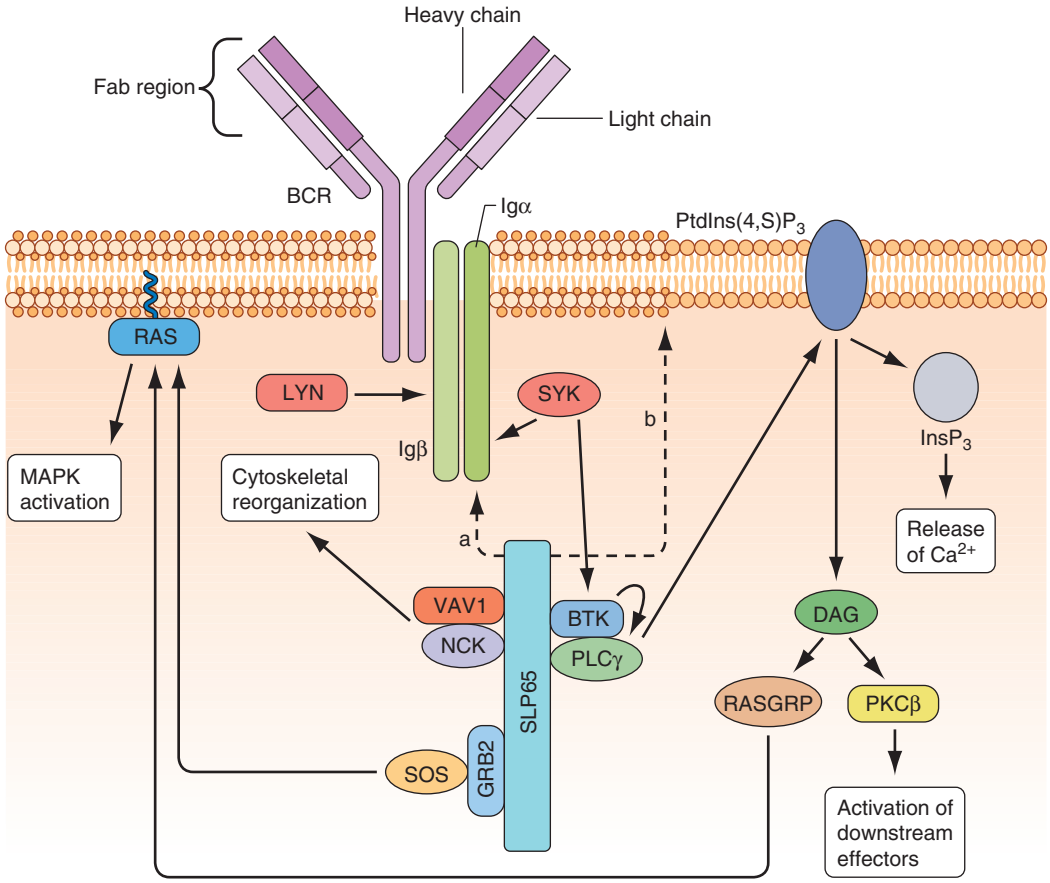

FIGURE 360-8 B-cell receptor (BCR) activation results in the sequential activation of protein tyrosine kinases, which results in the formation of a signaling complex and activation of downstream pathways as shown. Whereas SLP76 is recruited to the membrane through GADS and LAT, the mechanism of SLP65 recruitment is unclear. Studies have indicated two mechanisms: (a) direct binding by the SH2 domain of SLP65 to immunoglobulin (Ig) of the BCR complex or (b) membrane recruitment through a leucine zipper in the amino terminus of SLP65 and an unknown binding partner. ADAP, adhesion- and degranulation-promoting adaptor protein; AP1, activator protein 1; BTK, Bruton's tyrosine kinase; DAG, diacylglycerol; GRB2, growth factor receptor-bound protein 2; HPK1, hematopoietic progenitor kinase 1; $InsP_3$, inositol-1,4,5-trisphosphate; ITK, interleukin-2-inducible T-cell kinase; NCK, noncatalytic region of tyrosine kinase; NF-B, nuclear factor B; PKC, protein kinase C; PLC, phospholipase C; $PtdIns(4,5)P_2$, phosphatidylinositol-4,5-bisphosphate; RASGRP, RAS guanyl-releasing protein; SOS, son of sevenless homologue; SYK, spleen tyrosine kinase. *(Reproduced with permission from GA Koretzky et al: SLP76 and SLP65: Complex regulation of signalling in lymphocytes and beyond. Nat Rev Immunol 6:67, 2006.)*

Random rearrangements of Ig genes occasionally generate self-reactive antibodies, and mechanisms must be in place to correct these mistakes. One such mechanism is BCR editing, whereby autoreactive BCRs are mutated to not react with self-antigens. If receptor editing is unsuccessful in eliminating autoreactive B cells, then autoreactive B cells may undergo negative selection in the bone marrow through induction of apoptosis after BCR engagement of self-antigen.

After leaving the bone marrow, B cells populate peripheral B-cell sites, such as lymph node and spleen, and await contact with foreign antigens that react with each BCR. Antigen-driven B-cell activation occurs through the BCR, and *somatic hypermutation* takes place whereby point mutations in rearranged H- and L-genes give rise to mutant sIg molecules, some of which bind antigen better than the original sIg molecules. Somatic hypermutation, therefore, is a process whereby memory B cells in peripheral lymph organs have the best binding or the highest-affinity antibodies. This overall process of generating the best antibodies is called *affinity maturation of antibody*.

Lymphocytes that synthesize IgG, IgA, and IgE are derived from sIgM+, sIgD+ mature B cells. Ig class switching occurs in lymph node and other peripheral lymphoid tissue germinal centers. CD40 on B cells and CD40 ligand on T cells constitute a critical co-stimulatory receptor-ligand pair of immune-stimulatory molecules. Pairs of CD40+ B cells and CD40 ligand+ T cells bind and drive B-cell Ig class switching via T cell–produced cytokines such as IL-4 and TGF-β. IL-1, -2, -4, -5, and -6 synergize to drive mature B cells to proliferate and differentiate into Ig-secreting cells.

Humoral Mediators of Adaptive Immunity: Immunoglobulins

Immunoglobulins are the products of differentiated B cells and mediate the humoral arm of the immune response. The primary functions of antibodies are to bind specifically to antigen and bring about the inactivation or removal of the offending toxin, microbe, parasite, or other foreign substance from the body. The structural basis of Ig molecule function and Ig gene organization has provided insight into the role of antibodies in normal protective immunity, pathologic immune-mediated damage by immune complexes, and autoantibody formation against host determinants.

All immunoglobulins have the basic structure of two heavy and two light chains (Fig. 360-8). Immunoglobulin isotype (i.e., G, M, A, D, E) is determined by the type of Ig heavy chain present. IgG and IgA isotypes can be divided further into subclasses (G1, G2, G3, G4, and A1, A2) based on specific antigenic determinants on Ig heavy chains. The characteristics of human immunoglobulins are outlined in **Table 360-11**. The four chains are covalently linked by disulfide bonds. Each chain is made up of a V region and C regions (also called *domains*), themselves made up of units of ~110 amino acids. Light chains have one variable (V_L) and one constant (C_L) unit; heavy chains have one variable unit (V_H) and three or four constant (C_H) units, depending on isotype. As the name suggests, the constant, or C, regions of Ig molecules are made up of homologous sequences and share the same primary structure as all other Ig chains of the same isotype and subclass. Constant regions are involved in biologic functions of Ig molecules. The C_H2 domain of IgG and the C_H4 units of IgM are involved with the binding of the C1q portion of C1 during complement activation. The C_H region at the carboxy-terminal end of the IgG molecule, the Fc region, binds to surface Fc receptors (CD16, CD32, CD64) of macrophages, DCs, NK cells, B cells, neutrophils, and eosinophils. The Fc of IgA binds to FcαR (CD89), and the Fc of IgE binds to FcεR (CD23).

TABLE 360-11 Physical, Chemical, and Biologic Properties of Human Immunoglobulins

PROPERTY	IgG	IgA	IgM	IgD	IgE
Usual molecular form	Monomer	Monomer, dimer	Pentamer, hexamer	Monomer	Monomer
Other chains	None	J chain, SC	J chain	None	None
Subclasses	G1, G2, G3, G4	A1, A2	None	None	None
Heavy chain allotypes	Gm (=30)	No A1, A2m (2)	None	None	None
Molecular mass, kDa	150	160, 400	950, 1150	175	190
Serum level in average adult, mg/mL	9.5–12.5	1.5–2.6	0.7–1.7	0.04	0.0003
Percentage of total serum Ig	75–85	7–15	5–10	0.3	0.019
Serum half-life, days	23	6	5	3	2.5
Synthesis rate, mg/kg per day	33	65	7	0.4	0.016
Antibody valence	2	2, 4	10, 12	2	2
Classical complement activation	+(G1, 2?, 3)	–	++	–	–
Alternate complement activation	+(G4)	+	–	+	–
Binding cells via Fc	Macrophages, neutrophils, large granular lymphocytes	Lymphocytes	Lymphocytes	None	Mast cells, basophils, B cells
Biologic properties	Placental transfer, secondary antibody for most antipathogen responses	Secretory immunoglobulin	Primary antibody responses	Marker for mature B cells	Allergy, antiparasite responses

Variable regions (V_L and V_H) constitute the antibody-binding (Fab) region of the molecule. Within the V_L and V_H regions are hypervariable regions (extreme sequence variability) that constitute the antigen-binding site unique to each Ig molecule. The idiotype is defined as the specific region of the Fab portion of the Ig molecule to which antigen binds. Antibodies against the idiotype portion of an antibody molecule are called *anti-idiotype antibodies*. The formation of such antibodies in vivo during a normal B-cell antibody response may generate a negative (or "off") signal to B cells to terminate antibody production.

IgG constitutes ~75–85% of total serum immunoglobulin. The four IgG subclasses are numbered in order of their level in serum, IgG1 being found in greatest amounts and IgG4 the least. IgG subclasses have clinical relevance in their varying ability to bind macrophage and neutrophil Fc receptors and to activate complement (Table 360-11). Moreover, selective deficiencies of certain IgG subclasses give rise to clinical syndromes in which the patient is inordinately susceptible to bacterial infections. IgG antibodies are frequently the predominant antibody made after rechallenge of the host with antigen (secondary antibody response).

IgM antibodies normally circulate as a 950-kDa pentamer with 160-kDa bivalent monomers joined by a molecule called the *J chain*, a 15-kDa nonimmunoglobulin molecule that also effects polymerization of IgA molecules. IgM is the first immunoglobulin to appear in the immune response (primary antibody response) and is the initial type of antibody made by neonates. Membrane IgM in the monomeric form also functions as a major antigen receptor on the surface of mature B cells (Table 360-11). IgM is an important component of immune complexes in autoimmune diseases. For example, IgM antibodies against IgG molecules (rheumatoid factors) are present in high titers in *rheumatoid arthritis*, other collagen diseases, and some infectious diseases (*subacute bacterial endocarditis*).

IgA constitutes only 7–15% of total serum immunoglobulin but is the predominant class of immunoglobulin in secretions. IgA in secretions (tears, saliva, nasal secretions, gastrointestinal tract fluid, and human milk) is in the form of secretory IgA (sIgA), a polymer consisting of two IgA monomers, a joining molecule, again termed the J chain, and a glycoprotein called the *secretory protein*. Of the two IgA subclasses, IgA1 is primarily found in serum, whereas IgA2 is more prevalent in secretions. IgA fixes complement via the alternative complement pathway and has potent antiviral activity in humans by prevention of virus binding to respiratory and gastrointestinal epithelial cells.

IgD is found in minute quantities in serum and, together with IgM, is a major receptor for antigen on the naïve B-cell surface. IgE, which is present in serum in very low concentrations, is the major class of immunoglobulin involved in arming mast cells and basophils by binding to these cells via the Fc region. Antigen cross-linking of IgE molecules on basophil and mast cell surfaces results in release of mediators of the immediate hypersensitivity (allergic) response (Table 360-11).

CELLULAR INTERACTIONS IN REGULATION OF NORMAL IMMUNE RESPONSES

The net result of activation of the humoral (B-cell) and cellular (T-cell) arms of the adaptive immune system by foreign antigen is the elimination of antigen directly by specific effector T cells or in concert with specific antibody.

The expression of adaptive immune cell function is the result of a complex series of immunoregulatory events that occur in phases. Both T and B lymphocytes mediate immune functions, and each of these cell types, when given appropriate signals, passes through stages, from activation and induction through proliferation, differentiation, and ultimately effector functions. The effector function expressed may be at the end point of a response, such as secretion of antibody by a differentiated plasma cell, or it might serve a regulatory function that modulates other functions, such as is seen with CD4 and CD8 T lymphocytes that modulate both differentiation of B cells and activation of CD8 cytotoxic T cells.

T_H1 CD4+ T cells, through elaboration of IFN-γ, have a central role in mediating intracellular killing by a variety of pathogens. T_H1 CD4+ T cells also provide T-cell help for generation of cytotoxic T cells and some types of opsonizing antibody, and they generally respond to antigens that lead to delayed hypersensitivity types of immune responses for many intracellular viruses and bacteria (such as HIV-1 or *M. tuberculosis*). In contrast, T_H2 cells have a primary role in regulatory humoral immunity and isotype switching. T_H2 cells, through production of IL-4 and IL-10, have a regulatory role in limiting proinflammatory responses mediated by T_H1 cells (Fig. 360-2). In addition, T_H2 CD4+ T cells provide help to B cells for specific Ig production and respond to antigens that require high antibody levels for foreign antigen elimination (extracellular encapsulated bacteria such as *Streptococcus pneumoniae* and certain parasite infections). T_H17 cells secrete cytokines IL-17, -22, and -26 and have been shown to play a role in autoimmune inflammatory disorders in addition to defense against extracellular bacteria and fungi, particularly at mucosal surfaces. T_H9 cells are defined by their secretion of IL-9 and have been shown to play a role in atopic disease, inflammatory bowel disease, and antitumor immunity. Moreover, the TFH subset of helper T cells secrete IL-21 and is crucial for providing the necessary signals to B cells in germinal centers to undergo affinity maturation. TFH13 cells secrete IL-4, IL-5, and IL-13 in response to allergens and and have been postulated to

mediate anaphylaxis reactions (Fig. 360-2). In summary, the type of T-cell response generated in an immune response is determined by the microbe PAMPs presented to the DCs, the TLRs on the DCs that become activated, the types of DCs that are activated, and the cytokines that are produced (Table 360-7). Commonly, myeloid DCs produce IL-12 and activate T_H1 T-cell responses that result in IFN-γ and cytotoxic T-cell induction, and plasmacytoid DCs produce IFN-α and lead to T_H2 responses that result in IL-4 production and enhanced antibody responses.

As shown in Fig. 360-2, upon activation by DCs, T-cell subsets that produce IL-2, IL-3, IFN-γ, and/or IL-4, -5, -6, -10, and -13 are generated and exert positive and negative influences on effector T and B cells. For B cells, trophic effects are mediated by a variety of cytokines, particularly T cell–derived IL-3, -4, -5, and -6, that act at sequential stages of B-cell maturation, resulting in B-cell proliferation, differentiation, and ultimately antibody secretion. For cytotoxic T cells, trophic factors include inducer T-cell secretion of IL-2, IFN-γ, and IL-12.

Important types of immunomodulatory T cells that control immune responses are *CD4 and CD8 Treg cells*. These cells express the α chain of the IL-2 receptor (CD25), produce IL-10, and suppress both T- and B-cell responses. T regulatory cells (Tregs) are induced by immature DCs and play key roles in maintaining tolerance to self-antigens. Loss of Treg cells is the cause of organ-specific autoimmune disease in mice such as autoimmune thyroiditis, adrenalitis, and oophoritis and plays a role in inflammatory bowel disease (see "Immune Tolerance and Autoimmunity" below, **Chap. 361**). Tregs also play key roles in controlling the magnitude and duration of immune responses to microbes. Normally, after the initial immune response to a microbe has eliminated the invader, Tregs are activated to suppress the antimicrobe response and prevent host injury. Some microbes have adapted to induce Treg activation at the site of infection to promote parasite infection and survival. In *Leishmania* infection, the parasite induces Treg accumulation at skin infection sites that dampens anti-*Leishmania* T-cell responses and prevents parasite elimination. Although B cells recognize native antigen via B-cell surface Ig receptors, B cells require T-cell help to produce high-affinity antibody of multiple isotypes that are the most effective in eliminating foreign antigen. In B-cell germinal centers, CD4 T cells that promote B-cell maturation and affinity maturation are termed T follicular helper (TFH) cells. T cell–B cell interactions that lead to high-affinity antibody production require (1) processing of native antigen by B cells and expression of peptide fragments on the B-cell surface for presentation to T_H cells, (2) the ligation of B cells by both the TCR complex and the CD40 ligand, (3) induction of the process termed *antibody isotype switching* in antigen-specific B-cell clones, and (4) induction of the process of affinity maturation of antibody in the germinal centers of B-cell follicles of lymph node and spleen.

Naïve B cells express cell-surface IgD and IgM, and initial contact of naïve B cells with antigen is via binding of native antigen to B-cell surface IgM. T-cell cytokines, released following T_H2 cell contact with B cells or by a "bystander" effect, induce changes in Ig gene conformation that promote recombination of Ig genes. These events then result in the switching of expression of heavy chain exons in a triggered B cell, leading to the secretion of IgG, IgA, or, in some cases, IgE antibody with the same V region antigen specificity as the original IgM antibody, for response to a wide variety of extracellular bacteria, protozoa, and helminths. CD40 ligand expression by activated T cells is critical for induction of B-cell antibody isotype switching and for B-cell responsiveness to cytokines. Patients with mutations in T-cell CD40 ligand have B cells that are unable to undergo isotype switching, resulting in lack of memory B-cell generation and the immunodeficiency syndrome of *X-linked hyper-IgM syndrome* **(Chaps. 361 and 362)**.

IMMUNE TOLERANCE AND AUTOIMMUNITY

Immune tolerance is defined as the absence of activation of pathogenic autoreactivity to self-antigens. Mechanisms of immune tolerance can be classified as *cell intrinsic* or *cell extrinsic*. Cell intrinsic mechanisms of tolerance include apoptosis and induction of cell unresponsiveness (anergy). Mechanisms of cell extrinsic tolerance include suppression of immune responses by immunomodulatory cells such as Tregs. *Autoimmune diseases* are syndromes caused by the activation of T or B cells or both, with no evidence of other causes such as infections or malignancies **(Chaps. 361 and 367)**. Low levels of autoreactivity of T and B cells with self-antigens in the periphery are critical to T- and B-cell survival. Similarly, low levels of autoreactivity and thymocyte recognition of self-antigens in the thymus are the mechanisms whereby normal T cells are positively selected to survive and leave the thymus to respond to foreign microbes in the periphery and T cells highly reactive to self-antigens are negatively selected and die to prevent overly self-reactive T cells from migrating to the periphery (central tolerance). Unlike the presentation of microbial antigens by mature DCs, the presentation of self-antigens by immature DCs neither activates nor matures the DCs to express high levels of co-stimulatory molecules such as B7-1 (CD80) or B7-2 (CD86). When peripheral T cells are stimulated by DCs expressing self-antigens in the context of HLA molecules, sufficient stimulation of T cells occurs to keep them alive, but otherwise, they remain anergic, or nonresponsive, until T cells contact a DC with high levels of co-stimulatory molecules expressing microbial antigens and become activated to respond to the microbe. If B cells have high self-reactive BCRs, they normally undergo either deletion in the bone marrow or receptor editing to express a less autoreactive receptor. Although many autoimmune diseases are characterized by abnormal or pathogenic autoantibody production (**see Chap. 361**, Table 361-4), most autoimmune diseases are caused by a combination of excess T- and B-cell reactivity.

Multiple factors contribute to the genesis of autoimmune disease syndromes, including genetic susceptibility (e.g., HLA-B27 with ankylosing spondylitis), environmental immune stimulants such as drugs (e.g., procainamide and phenytoin [Dilantin] with drug-induced systemic lupus erythematosus), infectious agent triggers (e.g., Epstein-Barr virus and autoantibody production against red blood cells and platelets), and loss of Treg cells (leading to thyroiditis, adrenalitis, and oophoritis).

Immunity at Mucosal Surfaces Mucosa covering the respiratory, digestive, and urogenital tracts; the eye conjunctiva; the inner ear; and the ducts of all exocrine glands contain cells of the innate and adaptive mucosal immune system that protect these surfaces against pathogens. In the healthy adult, mucosa-associated lymphoid tissue (MALT) contains 80% of all immune cells within the body and constitutes the largest mammalian lymphoid organ system.

MALT has three main functions: (1) to protect the mucous membranes from invasive pathogens; (2) to prevent uptake of foreign antigens from food, commensal organisms, and airborne pathogens and particulate matter; and (3) to prevent pathologic immune responses from foreign antigens if they do cross the mucosal barriers of the body.

MALT is a compartmentalized system of immune cells that functions independently from systemic immune organs. Whereas the systemic immune organs are essentially sterile under normal conditions and respond vigorously to pathogens, MALT immune cells are continuously bathed in foreign proteins and commensal bacteria, and they must select those pathogenic antigens that must be eliminated. MALT contains anatomically defined foci of immune cells in the intestine, tonsil, appendix, and peribronchial areas that are inductive sites for mucosal immune responses. From these sites, immune T and B cells migrate to effector sites in mucosal parenchyma and exocrine glands where mucosal immune cells eliminate pathogen-infected cells. In addition to mucosal immune responses, all mucosal sites have strong mechanical and chemical barriers and cleansing functions to repel pathogens.

Key components of MALT include specialized epithelial cells called "membrane" or "M" cells that take up antigens and deliver them to DCs or other APCs. Regulatory cells that maintain gut homeostasis include ILC APCs, likely ILC3, that drive the development of CD4 Tregs that suppress pathogenic immune responses to benign commensal microbiota. Effector cells in MALT include B cells producing antipathogen neutralizing antibodies of secretory IgA as well as IgG isotype, T cells producing similar cytokines as in systemic immune responses, and T helper and cytotoxic T cells that respond to pathogen-infected cells.

Secretory IgA is produced in amounts of >50 mg/kg of body weight per 24 h and functions to inhibit bacterial adhesion, inhibit macromolecule absorption in the gut, neutralize viruses, and enhance antigen elimination in tissue through binding to IgA and receptor-mediated transport of immune complexes through epithelial cells.

Recent studies have demonstrated the importance of commensal gut and other mucosal bacteria to the health of the human immune system. Normal commensal flora induces anti-inflammatory events in the gut and protects epithelial cells from pathogens through TLRs and other PRR signaling. When the gut is depleted of normal commensal flora, the immune system becomes abnormal, with loss of T_H1 T-cell function. Restoration of the normal gut flora can reestablish the balance in Treg and T helper cell ratios characteristic of the normal immune system. Diet also has an impact on the gut microbiome. Altered microbiome composition has been etiologically related to obesity, insulin resistance, inflammatory bowel disease, and diabetes. When the gut barrier is intact, either antigens do not transverse the gut epithelium or, when pathogens are present, a self-limited, protective MALT immune response eliminates the pathogen. However, when the gut barrier breaks down, immune responses to commensal flora antigens can contribute to *Crohn's disease* and, perhaps, *ulcerative colitis* **(Chap. 337)**. Uncontrolled MALT immune responses to food antigens, such as gluten, can cause *celiac disease* **(Chap. 337)**.

THE CELLULAR AND MOLECULAR CONTROL OF PROGRAMMED CELL DEATH

The process of apoptosis (programmed cell death) plays a crucial role in regulating normal immune responses to antigen. In general, a wide variety of stimuli trigger one of several apoptotic pathways to eliminate microbe-infected cells, eliminate cells with damaged DNA, or eliminate activated immune cells that are no longer needed. The largest known family of "death receptors" is the TNF receptor (TNF-R) family (TNF-R1, TNF-R2, Fas [CD95], death receptor 3 [DR3], death receptor 4 [DR4; TNF-related apoptosis-including ligand receptor 1, or TRAIL-R1], and death receptor 5 [DR5, TRAIL-R2]); their ligands are all in the TNF-α family. Binding of ligands to these death receptors leads to a signaling cascade that involves activation of the *caspase* family of molecules that leads to DNA cleavage and cell death. Two other pathways of programmed cell death involve nuclear *p53* in the elimination of cells with abnormal DNA and *mitochondrial cytochrome c* to induce cell death in damaged cells. A number of human diseases have now been described that result from, or are associated with, mutated apoptosis genes. These include mutations in the Fas and Fas ligand genes in autoimmune and lymphoproliferation syndromes, and multiple associations of mutations in genes in the apoptotic pathway with malignant syndromes **(Chap. 361)**.

MECHANISMS OF IMMUNE-MEDIATED DAMAGE TO MICROBES OR HOST TISSUES

Several responses by the host innate and adaptive immune systems to foreign microbes culminate in rapid and efficient elimination of microbes. In these scenarios, the classic weapons of the adaptive immune system (T cells, B cells) interface with cells (macrophages, DCs, NK cells, neutrophils, eosinophils, basophils) and soluble products (microbial peptides, pentraxins, complement and coagulation systems) of the innate immune system **(Chaps. 67 and 363)**.

There are five general phases of host defenses: (1) migration of leukocytes to sites of antigen localization; (2) antigen-nonspecific recognition of pathogens by macrophages and other cells and systems of the innate immune system; (3) specific recognition of foreign antigens mediated by T and B lymphocytes; (4) amplification of the inflammatory response with recruitment of specific and nonspecific effector cells by complement components, cytokines, kinins, arachidonic acid metabolites, and mast cell–basophil products; and (5) macrophage, neutrophil, and lymphocyte participation in destruction of antigen with ultimate removal of antigen particles by phagocytosis (by macrophages or neutrophils) or by direct cytotoxic mechanisms (involving macrophages, neutrophils, DCs, or lymphocytes). Under normal circumstances, orderly progression of host defenses through these phases results in a well-controlled immune and inflammatory response that protects the host from the offending antigen. However, dysfunction of any of the host defense systems can damage host tissue and produce clinical disease. Furthermore, for certain pathogens or antigens, the normal immune response itself might contribute substantially to the tissue damage. For example, the immune and inflammatory response in the brain to certain pathogens such as *M. tuberculosis* may be responsible for much of the morbidity rate of this disease in that organ system **(Chap. 183)**. In addition, the morbidity rate associated with certain pneumonias such as that caused by *Pneumocystis jirovecii* may be associated more with inflammatory infiltrates than with the tissue-destructive effects of the microorganism itself **(Chap. 227)**.

Molecular Basis of Lymphocyte–Endothelial Cell Interactions The control of lymphocyte circulatory patterns between the bloodstream and peripheral lymphoid organs operates at the level of lymphocyte–endothelial cell interactions to control the specificity of lymphocyte subset entry into organs. Similarly, lymphocyte–endothelial cell interactions regulate the entry of lymphocytes into inflamed tissue. Adhesion molecule expression on lymphocytes and endothelial cells regulates the retention and subsequent egress of lymphocytes within tissue sites of antigenic stimulation, delaying cell exit from tissue and preventing reentry into the circulating lymphocyte pool **(Fig. 360-9)**. All types of lymphocyte migration begin with lymphocyte attachment to specialized regions of vessels, termed *high endothelial venules* (HEVs). An important concept is that adhesion molecules do not generally bind their ligand until a conformational change (ligand activation) occurs in the adhesion molecule that allows ligand binding. Induction of a conformation-dependent determinant on an adhesion molecule can be accomplished by cytokines or via ligation of other adhesion molecules on the cell.

The first stage of lymphocyte–endothelial cell interactions, *attachment and rolling*, occurs when lymphocytes leave the stream of flowing blood cells in a postcapillary venule and roll along venule endothelial cells (Fig. 360-9). Lymphocyte rolling is mediated by the L-selectin molecule (LECAM-1, LAM-1, CD62L) and slows cell transit time through venules, allowing time for activation of adherent cells.

The second stage of lymphocyte–endothelial cell interactions, *firm adhesion with activation-dependent stable arrest*, requires stimulation of lymphocytes by chemoattractants or by endothelial cell–derived cytokines. Cytokines thought to participate in adherent cell activation include members of the IL-8 family, platelet-activation factor, leukotriene B_4, and C5a. In addition, HEVs express chemokines, SLC (CCL21) and ELC (CCL19), which participate in this process. Following activation by chemoattractants, lymphocytes shed L-selectin from the cell surface and upregulate cell CD11b/18 (MAC-1) or CD11a/18 (LFA-1) molecules, resulting in firm attachment of lymphocytes to HEVs.

Lymphocyte homing to peripheral lymph nodes involves adhesion of L-selectin to glycoprotein HEV ligands collectively referred to as *peripheral node addressin* (*PNAd*), whereas homing of lymphocytes to intestine Peyer's patches primarily involves adhesion of the α4β7 integrin to mucosal addressin cell adhesion molecule-1 (MAdCAM-1) on the Peyer's patch HEVs. However, for migration to mucosal Peyer's patch lymphoid aggregates, naïve lymphocytes primarily use L-selectin, whereas memory lymphocytes use α4β7 integrin. α4β1 integrin (CD49d/CD29, VLA-4)–VCAM-1 interactions are important in the initial interaction of memory lymphocytes with HEVs of multiple organs in sites of inflammation.

The third stage of leukocyte emigration in HEVs is *sticking and arrest*. Sticking of the lymphocyte to endothelial cells and arrest at the site of sticking are mediated predominantly by ligation of a1β2 integrin LFA-1 to the integrin ligand ICAM-1 on HEVs. Whereas the first three stages of lymphocyte attachment to HEVs take only a few seconds, the fourth stage of lymphocyte emigration, *transendothelial migration*, takes ~10 min. Although the molecular mechanisms that control lymphocyte transendothelial migration are not fully characterized, the HEV CD44 molecule and molecules of the HEV glycocalyx (extracellular matrix) are thought to play important regulatory roles in

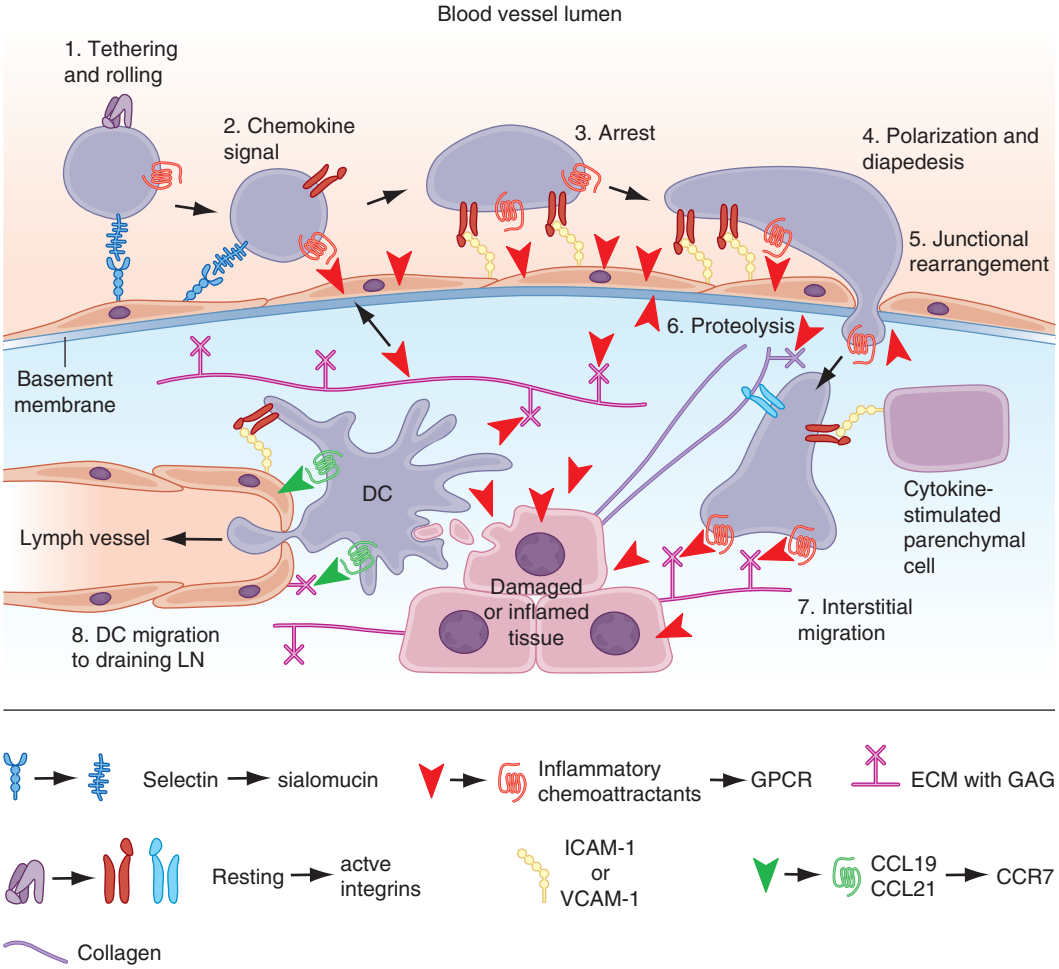

FIGURE 360-9 Key migration steps of immune cells at sites of inflammation. Inflammation due to tissue damage or infection induces the release of cytokines (not shown) and inflammatory chemoattractants (*red arrowheads*) from distressed stromal cells and "professional" sentinels, such as mast cells and macrophages (not shown). The inflammatory signals induce upregulation of endothelial selectins and immunoglobulin "superfamily" members, particularly ICAM-1 and/or VCAM-1. Chemoattractants, particularly chemokines, are produced by or translocated across venular endothelial cells (*red arrow*) and are displayed in the lumen to rolling leukocytes. Those leukocytes that express the appropriate set of trafficking molecules undergo a multistep adhesion cascade (steps 1–3) and then polarize and move by diapedesis across the venular wall (steps 4 and 5). Diapedesis involves transient disassembly of endothelial junctions and penetration through the underlying basement membrane (step 6). Once in the extravascular (interstitial) space, the migrating cell uses different integrins to gain "footholds" on collagen fibers and other ECM molecules, such as laminin and fibronectin, and on inflammation-induced ICAM-1 on the surface of parenchymal cells (step 7). The migrating cell receives guidance cues from distinct sets of chemoattractants, particularly chemokines, which may be immobilized on glycosaminoglycans (GAG) that "decorate" many ECM molecules and stromal cells. Inflammatory signals also induce tissue dendritic cells (DCs) to undergo maturation. Once DCs process material from damaged tissues and invading pathogens, they upregulate CCR7, which allows them to enter draining lymph vessels that express the CCR7 ligand CCL21 (and CCL19). In lymph nodes (LNs), these antigen-loaded mature DCs activate naïve T cells and expand pools of effector lymphocytes, which enter the blood and migrate back to the site of inflammation. T cells in tissue also use this CCR7-dependent route to migrate from peripheral sites to draining lymph nodes through afferent lymphatics. *(Reproduced with permission from AD Luster et al: Immune cell migration in inflammation: present and future therapeutic targets. Nat Immunol 6:1182, 2005.)*

this process (Fig. 360-10). Finally, expression of matrix metalloproteases capable of digesting the subendothelial basement membrane, rich in nonfibrillar collagen, appears to be required for the penetration of lymphoid cells into the extravascular sites.

Abnormal induction of HEV formation and use of the molecules discussed above have been implicated in the induction and maintenance of inflammation in a number of chronic inflammatory diseases. In animal models of type 1 diabetes mellitus, MAdCAM-1 and GlyCAM-1 have been shown to be highly expressed on HEVs in inflamed pancreatic islets, and treatment of these animals with inhibitors of L-selectin and a4 integrin function blocked the development of type 1 diabetes mellitus (Chap. 415). A similar role for abnormal induction of the adhesion molecules of lymphocyte emigration has been suggested in *rheumatoid arthritis* (Chap. 370), *Hashimoto's thyroiditis* (Chap. 394), *Graves' disease* (Chap. 394), *multiple sclerosis* (Chap. 455), *Crohn's disease* (Chap. 337), and *ulcerative colitis* (Chap. 337).

Immune-Complex Formation Clearance of antigen by immune-complex formation between antigen, complement, and antibody is a highly effective mechanism of host defense. However, depending on the level of immune complexes formed and their physicochemical properties, immune complexes may or may not result in host and foreign cell damage. After antigen exposure, certain types of soluble antigen-antibody complexes freely circulate and, if not cleared by the reticuloendothelial system, can be deposited in blood vessel walls and in other tissues such as renal glomeruli and cause *vasculitis* or *glomerulonephritis* syndromes (Chaps. 326 and 375). Deficiencies of early complement components are associated with inefficient clearance of immune complexes and immune complex–mediated autoimmune syndromes or encapsulated bacterial infections such as *S. pneumoniae*, whereas deficiencies of the later complement components are associated with susceptibility to recurrent *Neisseria* infections (Table 360-12).

Immediate-Type Hypersensitivity Helper T cells that drive antiallergen IgE responses are usually T_H2-type inducer T cells that secrete IL-4, IL-5, IL-6, and IL-10. A subset of TFH, TFH13, cells have been identified that produce IL-4, IL-5, and IL-13, which play a key role in responses to allergens that induce IgE and mediate anaphylaxis. Mast cells and basophils have high-affinity receptors for the Fc portion of IgE (FcRI), and cell-bound antiallergen IgE effectively

TABLE 360-12 Complement Deficiencies and Associated Diseases	
COMPONENT	**ASSOCIATED DISEASES**
Classic Pathway	
Clq, Clr, Cls, C4	Immune-complex syndromes,[a] pyogenic infections
C2	Immune-complex syndromes,[a] few with pyogenic infections
C1 inhibitor	Rare immune-complex disease, few with pyogenic infections
C3 and Alternative Pathway C3	
C3	Immune-complex syndromes,[a] pyogenic infections
D	Pyogenic infections
Properdin	*Neisseria* infections
I	Pyogenic infections
H	Hemolytic-uremic syndrome
Membrane Attack Complex	
C5, C6, C7, C8	Recurrent *Neisseria* infections, immune-complex disease
C9	Rare *Neisseria* infections

[a]Immune-complex syndromes include systemic lupus erythematosus (SLE) and SLE-like syndromes, glomerulonephritis, and vasculitis syndromes.

"arms" basophils and mast cells. Mediator release is triggered by antigen (allergen) interaction with Fc receptor-bound IgE, and the mediators released are responsible for the pathophysiologic changes of *allergic diseases*. Mediators released from mast cells and basophils can be divided into three broad functional types: (1) those that increase vascular permeability and contract smooth muscle (histamine, platelet-activating factor, SRS-A, BK-A), (2) those that are chemotactic for or activate other inflammatory cells (ECF-A, NCF, leukotriene B_4), and (3) those that modulate the release of other mediators (BK-A, platelet-activating factor) **(Chap. 363)**.

Cytotoxic Reactions of Antibody In this type of immunologic injury, complement-fixing (C1-binding) antibodies against normal or foreign cells or tissues (IgM, IgG1, IgG2, IgG3) bind complement via the classic pathway and initiate a sequence of events similar to that initiated by immune-complex deposition, resulting in cell lysis or tissue injury. Examples of antibody-mediated cytotoxic reactions include red cell lysis in *transfusion reactions*, *Goodpasture's syndrome* with anti–glomerular basement membrane antibody formation, and *pemphigus vulgaris* with anti-epidermal antibodies inducing blistering skin disease.

Delayed-Type Hypersensitivity Reactions Inflammatory reactions initiated by mononuclear leukocytes and not by antibody alone have been termed *delayed-type hypersensitivity reactions*. The term *delayed* has been used to contrast a secondary cellular response that appears 48–72 h after antigen exposure with an *immediate* hypersensitivity response generally seen within 12 h of antigen challenge and initiated by basophil mediator release or preformed antibody. For example, in an individual previously infected with *M. tuberculosis* organisms, intradermal placement of tuberculin purified protein derivative as a skin test challenge results in an indurated area of skin at 48–72 h, indicating previous exposure to tuberculosis.

The cellular events that result in classic delayed-type hypersensitivity responses are centered on T cells (predominantly, although not exclusively, IFN-γ, IL-2, and TNF-α-secreting T_H1-type helper T cells) and macrophages. Recently, NK cells have been suggested to play a major role in the form of delayed hypersensitivity that occurs following skin contact with immunogens. First, local immune and inflammatory responses at the site of foreign antigen upregulate endothelial cell adhesion molecule expression, promoting the accumulation of lymphocytes at the tissue site. In the scheme outlined in Fig. 360-2, antigen is processed by DCs and presented to small numbers of CD4+ T cells expressing a TCR specific for the antigen. IL-12 produced by APCs induces T cells to produce IFN-γ (T_H1 response). Macrophages frequently undergo epithelioid cell transformation and fuse to form multinucleated giant cells in response to IFN-γ. This type of mononuclear cell infiltrate is termed *granulomatous inflammation*. Examples of diseases in which delayed-type hypersensitivity plays a major role are fungal infections (*histoplasmosis*; **Chap. 218**), mycobacterial infections (*tuberculosis*, *leprosy*; **Chaps. 183** and **184**), chlamydial infections (*lymphogranuloma venereum*; **Chap. 194**), helminth infections (*schistosomiasis*; **Chap. 241**), reactions to toxins (*berylliosis*; **Chap. 300**), and hypersensitivity reactions to organic dusts (*hypersensitivity pneumonitis*; **Chap. 299**). In addition, delayed-type hypersensitivity responses play important roles in tissue damage in autoimmune diseases such as *rheumatoid arthritis*, *temporal arteritis*, and granulomatosis with polyangiitis **(Chaps. 370 and 375)**.

Autophagy Autophagy is a process that involves a lysosomal degradation pathway mechanism of cells to dispose of intracellular debris and damaged organelles. Autophagy by cells of the innate immune system is used to control intracellular infectious agents such as *M. tuberculosis*, in part by initiation of phagosome maturation and enhancing MHC class II antigen presentation to CD4 T cells.

CLINICAL EVALUATION OF IMMUNE FUNCTION

Clinical assessment of immunity requires investigation of the four major components of the immune system that participate in host defense and in the pathogenesis of autoimmune diseases: (1) humoral immunity (B cells); (2) cell-mediated immunity (T cells, monocytes); (3) phagocytic cells of the reticuloendothelial system (macrophages), as well as polymorphonuclear leukocytes; and (4) complement. Clinical problems that require an evaluation of immunity include chronic infections, recurrent infections, unusual infecting agents, and certain autoimmune syndromes. The type of clinical syndrome under evaluation can provide information regarding possible immune defects **(Chap. 362)**. Defects in cellular immunity generally result in viral, mycobacterial, and fungal infections. An extreme example of deficiency in cellular immunity is AIDS **(Chap. 208)**. Antibody deficiencies result in recurrent bacterial infections, frequently with organisms such as *S. pneumoniae* and *Haemophilus influenzae* **(Chap. 362)**. Disorders of phagocyte function are frequently manifested by recurrent skin infections, often due to *Staphylococcus aureus* **(Chap. 67)**. Finally, deficiencies of early and late complement components are associated with autoimmune phenomena and recurrent *Neisseria* infections (Table 360-12). Artificial intelligence/machine learning algorithms are now being tested for improving the diagnosis of infectious, immune deficiency, and autoimmune diseases. **For further discussion of useful initial screening tests of immune function, see Chap. 362.**

IMMUNOTHERAPY

Many therapies for autoimmune and inflammatory diseases involve the use of nonspecific immune-modulating or immunosuppressive agents such as glucocorticoids or cytotoxic drugs. The goal of development of new treatments for immune-mediated diseases is to design ways to specifically interrupt pathologic immune responses, leaving nonpathologic immune responses intact **(Chap. 361)**. Novel ways to interrupt pathologic immune responses that are under investigation include the use of anti-inflammatory cytokines or specific cytokine inhibitors as anti-inflammatory agents, the use of monoclonal antibodies against T or B lymphocytes as therapeutic agents, the use of intravenous Ig for certain infections and immune complex–mediated diseases, the use of specific cytokines to reconstitute components of the immune system, and bone marrow transplantation to replace the pathogenic immune system with a more normal immune system **(Chaps. 67, 208, 361, and 362)**. CTLA-4 inhibitors such as ipilimumab and tremelimumab and anti-PD-1 antibodies such as nivolumab are *termed checkpoint inhibitors* and have been shown to reverse CD8 T-cell exhaustion in melanoma and other solid tumors and induce immune cell control of tumor growth **(Chap. 361)**. A technique that engineers autologous T cells to express antibody receptors that target leukemic cells, termed *chimeric antigen receptor T cells* (CAR T cells), has been approved by the U.S. Food and Drug Administration (FDA) for the treatment of certain types of leukemias and lymphomas **(Chap. 361)**.

Cell-based therapies have been studied for many years, including ex vivo activation of NK cells for reinfusion into patients with

malignancies and DC therapy of ex vivo priming of DCs for enhanced presentation of cancer antigens, with reinfusion of primed DCs into the patient. One such strategy for DC therapy has been approved by the FDA for treatment of advanced prostate cancer.

Cytokines and Cytokine Inhibitors Several TNF inhibitors are used as biological therapies in the treatment of rheumatoid arthritis; these include monoclonal antibodies, TNF-R Fc fusion proteins, and Fab fragments. Use of anti-TNF-α antibody therapies such as adalimumab, infliximab, and golimumab has resulted in clinical improvement in patients with these diseases and has opened the way for targeting TNF-α to treat other severe forms of autoimmune and/or inflammatory disease **(Chap. 361)**. Blockage of TNF-α has been effective in *rheumatoid arthritis*, *psoriasis*, *Crohn's disease*, and *ankylosing spondylitis*. Other cytokine inhibitors are recombinant soluble TNF-α receptor (R) fused to human Ig and anakinra (soluble *IL-1 receptor antagonist*, or IL-1ra).

TNF-αR-Fc fusion protein (etanercept) and IL-1ra act to inhibit the activity of pathogenic cytokines in rheumatoid arthritis, i.e., TNF-α and IL-1, respectively. Similarly, anti-IL-6, IFN-β, and IL-11 act to inhibit pathogenic proinflammatory cytokines. Anti-IL-6 (tocilizumab) inhibits IL-6 activity, whereas IFN-β and IL-11 decrease IL-1 and TNF-α production **(Chap. 361)**. Of particular note has been the successful use of IFN-γ in the treatment of the phagocytic cell defect in *chronic granulomatous disease* **(Chap. 67)**.

T_H17 CD4 T cells have been implicated in the pathogenesis of psoriasis, ulcerative colitis, and other autoimmune diseases. Monoclonal antibodies have now been developed that target cytokines (IL-12, IL-23) that induce T_H17 T-cell differentiation and are licensed by the FDA for treatment of psoriasis and inflammatory bowel disease. Monoclonal antibodies that directly target IL-17 have also recently been licensed for psoriasis and psoriatic arthritis treatment. Monoclonal antibodies against cytokines and immunoregulatory molecules are now mainstays of cancer and autoimmune disease therapy **(Chap. 361)**.

Intravenous Immunoglobulin (IVIg) IVIg has been used successfully to block reticuloendothelial cell function and immune complex clearance in various immune cytopenias such as immune thrombocytopenia **(Chap. 120)**. In addition, IVIg is useful for prevention of tissue damage in certain inflammatory syndromes such as Kawasaki disease **(Chap. 375)** and as Ig replacement therapy for certain types of immunoglobulin deficiencies **(Chap. 362)**. In addition, controlled clinical trials support the use of IVIg in selected patients with graft-versus-host disease, multiple sclerosis, myasthenia gravis, Guillain-Barré syndrome, and chronic demyelinating polyneuropathy.

Stem Cell Transplantation Hematopoietic stem cell transplantation (SCT) is now being studied to treat several autoimmune diseases including systemic lupus erythematosus, multiple sclerosis, and scleroderma. The goal of immune reconstitution in autoimmune disease syndromes is to replace a dysfunctional immune system with a normally reactive immune cell repertoire. Controlled clinical trials in these three diseases are now being launched in the United States and Europe to compare the toxicity and efficacy of conventional immunosuppression therapy with that of myeloablative autologous SCT. Recently, SCT was used in the setting of HIV-1 infection. HIV-1 infection of CD4+ T cells requires the presence of surface CD4 receptor and the chemokine receptor 5 (CCR5) co-receptor. Studies have demonstrated that patients who are homozygous for a 32-bp deletion in the CCR5 allele do not express CD4+ T-cell CCR5 and thus are resistant to HIV-1 infection with HIV-1 strains that use this co-receptor. Stem cells from a homozygous CCR5 delta32 donor were transplanted to an HIV-1-infected individual following standard conditioning for such transplants and resulted in long-term control of the virus without antiretrovirals. Thus, a number of recent insights into immune system function have spawned a new field of interventional immunotherapy and have enhanced the prospect for development of more specific and nontoxic therapies for immune and inflammatory diseases **(Chap. 361)**.

361 Mechanisms of Regulation and Dysregulation of the Immune System

Barton F. Haynes, Kelly A. Cuttle, Anthony S. Fauci

DEFINITIONS

Anergy—A reversible tolerance mechanism in which the T or B cell is in an unresponsive state following an antigen encounter but remains alive.

Chimeric antigen receptor T cells (CAR T)—Synthetic hybrid receptors created by recombinant techniques that combine an extracellular domain, usually derived from an antibody single-chain variable fragment (scFv), with intracellular signaling domains from activating co-stimulatory molecules (from endogenous T-cell receptors [TCRs], CD28, or 4-1BB) that allow for retargeting of T cells to antigens on malignant cells.

Checkpoint inhibition therapy—A form of cancer immunotherapy whereby antibodies against T-cell or antigen-presenting cell regulators of immune cell inhibition are used to activate cytotoxic T cells to kill tumor cells.

Co-stimulation of T cells—A secondary signal that T cells require for activation following presentation of peptide antigen by major histocompatibility complex (MHC) molecules to TCRs on either CD4 or CD8 T cells. A prime mediator of co-stimulation is the T cell CD28 molecule binding to B7-1 (CD80, CD86) on antigen-presenting cells.

Cytokines—Soluble proteins that interact with specific cellular receptors that are involved in the regulation of the growth and activation of immune cells and mediate normal and pathologic inflammatory and immune responses.

Immune homeostasis—Balanced protective immunity that does not overreact to pathogens and harm the host, and immunity that is not deficient and does not predispose the host to harmful infections or malignancies.

Immunoediting—Process of immunity selecting clones of cancer cells with reduced immunogenicities resulting in tumor escape.

Natural killer cells—Lymphocytes with cytotoxic potential for host cells with non-self-antigens, such as cells infected with pathogens or tumor cells expressing tumor-specific neoantigens.

T-cell exhaustion—State of T cells when the persistence of antigen disrupts memory T-cell function, resulting in defects in memory T-cell responses. Most frequently occurs in malignancies and in chronic viral infections such as HIV-1 and hepatitis C.

T regulatory cells (Tregs)—CD4 or CD8 T cells regulated by the transcription factor FOXP3 that play roles in downmodulating B- and T-cell responses in peripheral lymphoid tissues to prevent deleterious immune activation that can lead to autoimmune diseases.

Tumor-infiltrating lymphocytes—Lymphocytes that infiltrate tumors that may be in the exhausted state and upon which checkpoint inhibition therapy works.

Tumor neoantigens—Molecules in malignant cells that develop mutations that create non-self-antigens that are recognized by host T cells as non-self and against which tumor-infiltrating CD4 and CD8 T cells respond to reject the tumor.

INTRODUCTION

Immune homeostasis is the maintenance of balanced immunity that protects the host and prevents dysregulated immunity that predisposes the host to immunodeficiency, autoimmunity, malignancy, or harmful immune responses to infectious agents. Overactivity of innate and adaptive immunity leads to autoimmunity and/or inflammatory diseases. Underactivity of immune responses can lead to both immune deficiency and autoimmunity. Disruption of immune homeostasis contributes either directly or indirectly to many forms of disease. Thus, a major goal of immunotherapy is to either maintain immune homeostasis or reestablish immune balance in diseases of immune dysregulation.

This is an important time in the study of the biology of the immune system. The development of high-throughput genome sequencing, full genome transcriptome analysis, proteomics, metabolomics, and the realization of the importance of the human microbiome to immune system homeostasis have provided remarkable opportunities for development of new treatments for immune-mediated and malignant diseases. The emerging concept is that the immune system itself can be manipulated to be used as a therapeutic intervention for cancer and also can be safely manipulated for control of autoimmune disease. Moreover, new data are emerging that immune dysregulation is involved in the pathogenesis of diseases not traditionally thought of as immune-related, such as neurodegenerative diseases and atherosclerotic cardiovascular disease, and that the normal process of aging is associated with inflammatory processes.

Thus, a new frontier of medicine is to understand basic regulatory mechanisms of the innate and adaptive immune system with the goal of learning specific rules of immune system regulation, such that eventually the immune system can be "tuned" to safely stay in the zone of immune homeostasis and, at the same time, effectively protect against emerging and reemerging infectious diseases or eliminate malignancies as they arise. Moreover, when inflammatory or autoimmune diseases arise, effective strategies of immune regulation can be developed to safely treat them.

Thus, this chapter builds on **Chap. 360**, Introduction to the Immune System, to discuss T- and B-cell immunoregulation, to highlight recent successes in translating basic immunologic research into treatments of various hematopoietic and solid tumors, and to discuss mechanisms of immune dysregulation in autoimmunity and aging.

MECHANISMS OF REGULATION OF T-CELL ACTIVATION

Key roles of T cells are to respond to and eliminate cells bearing foreign antigens and to ignore cells expressing self-antigens. To respond to foreign antigens, stimulating cells must deliver an activating co-stimulating signal in addition to TCR ligation. To avoid responding to cells bearing self-antigens, T cells must also maintain immune tolerance. Central T-cell tolerance is maintained by autoreactive T-cell deletion in the thymus, while peripheral tolerance is either by cell apoptosis or anergy (cell intrinsic mechanisms), or maintained by extrinsic mechanism suppression by immune modulating cells such as regulatory T cells (Treg) (see section below, "Mechanisms of Immune Dysregulation in Autoimmune Disease"). Thus, T-cell activation is an integral component of the adaptive immune response to pathogens as well as to tumor neoantigens.

Two stimulatory signals are required for T-cell activation. One T-cell signal is delivered by antigen peptide presented in the context of MHC **(Chap. 360)**. However, in the absence of a co-stimulating signal, the T cell will not be activated by peptide MHC alone but rather will become anergic or unresponsive. A second co-stimulatory signal is needed for T-cell activation, resulting in cytoskeletal remodeling, production of cytokines, and cell survival and differentiation. In addition to the TCR/CD3 complex **(Chap. 360)**, T cells express a complex array of co-stimulatory as well as inhibitory molecules that bind to their respective receptors on the surface of antigen-presenting cells (APCs) and orchestrate both initiation and control of T-cell activation to maintain immune homeostasis **(Fig. 361-1, and see Chap. 360, Table 360-1)**. Of these, CD28, cytotoxic T lymphocyte antigen 4 (CTLA-4), and programmed cell death protein 1 (PD-1) and their ligands were among the first to be recognized to be central to control of T-cell activation.

The CD28 molecule is a member of the immunoglobulin (Ig) superfamily and is the original member of a subfamily of co-stimulatory or inhibitory molecules on the surface of T cells that includes CTLA-4, inducible T-cell costimulator (ICOS), PD-1, T-cell immunoreceptor with Ig and ITIM domains (TIGIT), and B- and T-cell attenuator (BTLA) (Fig. 361-1). CD28 stimulates intracellular signaling through AKT and PI3 kinase, resulting in induction of NF-κB, AP-1, and NFAT, which are all critical for T-cell activation and differentiation **(Chap. 360, Fig. 360-7)**. CTLA-4 and PD-1 are CD28 subfamily members that control T-cell activation by inhibiting the stimulating activity of CD28 and other T-cell co-stimulatory molecules.

CTLA-4 is a key negative regulator of T-cell activation that downmodulates the T-cell response to antigen by interaction with its ligands, B7-1 and B7-2, to control unchecked T-cell proliferation. CTLA-4 is upregulated following TCR engagement with MHC/peptide, thus

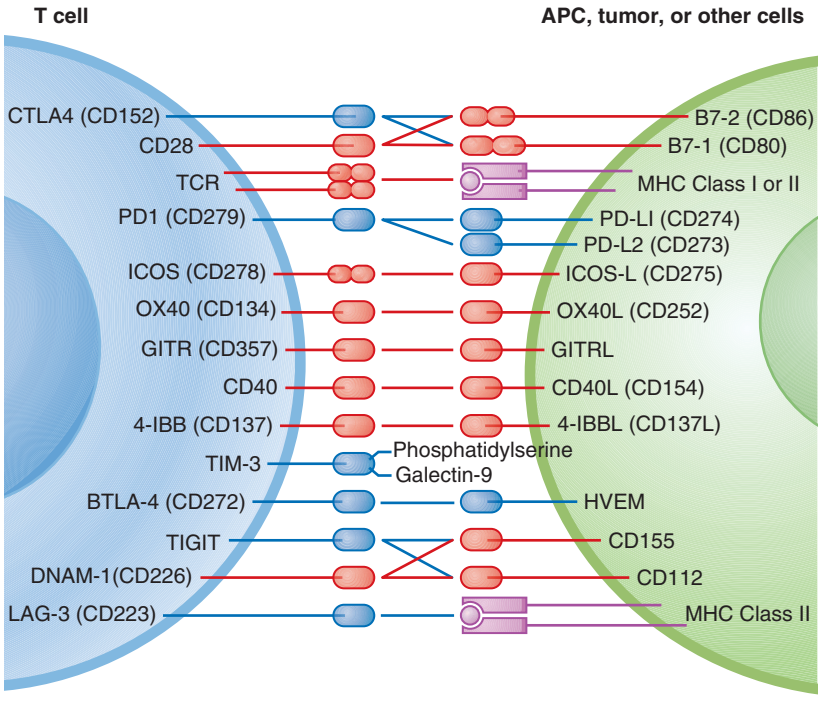

FIGURE 361-1 Regulatory stimulating or inhibiting molecules on T cells or antigen-presenting cells (APCs), tumor cells, or other cells.

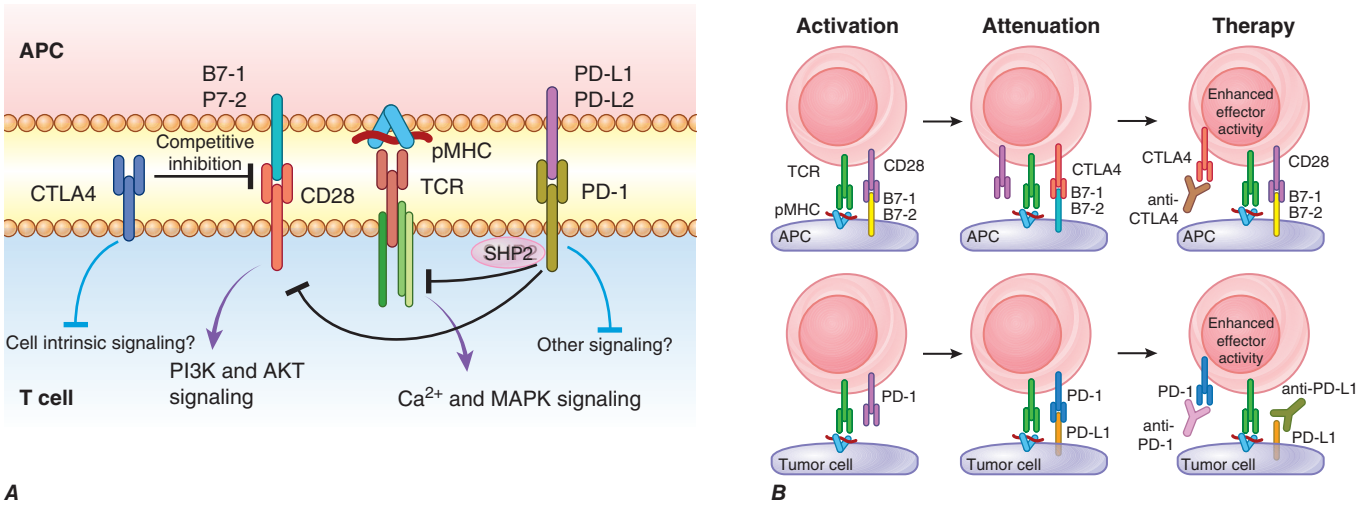

FIGURE 361-2 Molecular mechanisms of CTLA-4 and PD-1 attenuation of T-cell activation and schematic of the molecular mechanisms of action of CTLA-4 and PD-1 blockade. ***A.*** Schematic of the molecular interactions and downstream signaling induced by ligation of CTLA-4 and PD-1 by their respective ligands. The possibility of additional downstream cell-intrinsic signaling mechanisms is highlighted for both CTLA-4 and PD-1. ***B.*** The stepwise progression of T-cell activation, attenuation by normal regulatory mechanisms, and release of such negative regulation by therapeutic intervention using anti-CTLA-4 or anti-PD-1 antibodies is outlined. *(Reprinted from Cancer Discovery, 2018,8/9, 1069–1086, SC Wei et al: Fundamental Mechanisms of Immune Checkpoint Blockade Therapy, with permission from AACR.)*

dampening TCR signaling by competing with CD28 binding to B7 ligands (B7-1 [CD80] and B7-2 [CD86]) on APCs by virtue of higher affinity of CTLA-4 for B7 ligands. In this manner, T cells respond to foreign antigen but are prevented from damaging host tissues due to overexuberant responses (Fig. 361-2*A*). CTLA-4 thus mediates its dampening effect on T-cell activation by competing with T-cell CD28 binding to B7 receptors, as well as through the suppressive effect of CTLA-4-positive Tregs. The human *CTLA4* gene is just one of several genes in which monogenetic mutations are associated with decreased Treg function and autoimmune syndromes (Table 361-1).

PD-1 is also a major inhibitory molecule of T-cell activation by interaction with its ligands PD-L1 and PD-L2 on APCs (Fig. 361-1). While initially thought to be a cell death receptor, PD-1 is expressed upon activation of T and B cells and is also a marker of T follicular helper CD4+ T cells in B-cell germinal centers. PD-1 acts to dampen T-cell activation by dephosphorylation of CD28 via the Src homology region 2–containing protein tyrosine phosphatase 2 (SHP2).

Although a marker of immune cell activation, PD-1 is also a marker for exhausted T cells. T-cell exhaustion is an important mechanism of maintaining immune homeostasis and preventing host tissue T-cell

TABLE 361-1 Monogenetic Mutations That Lead to Immune Dysregulation and Autoimmunity

MUTATIONS AND FUNCTIONAL DEFICITS	DISEASES OR SYNDROME
RAG1, RAG2; lymphopenia with recombinase deficiency	Severe combined immune deficiency (Omenn's syndrome) with autoreactive T cells
Fas, FasL, CASP10; apoptosis defects	Autoimmune lymphoproliferative disease
AIRE, deletion chromosome 22q11.2; decrease in central tolerance	**Ch. 22q11.2:** DiGeorge's syndrome with autoimmune T cells **AIRE:** autoimmunity, polyneuropathy, candidiasis, ectodermal dysplasia (APECED syndrome)
FOXP3, CD25, CTLA-4, LRBA; decrease in peripheral immune tolerance with decrease in Treg function	**FOXP3:** IPEX syndrome (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) **CD25:** enteropathy, dermatitis, autoimmunity, susceptibility to infections **CTLA-4:** associated with multiple autoimmune syndromes **LRBA:** infant with enteritis; hypogammaglobulinemia, autoimmune cytopenias
STAT-1, STAT-3; modulation of type 1 interferons	**STAT-1 deficiency:** decreased IFN-γ, susceptible to TB **STAT-1 gain of function:** chronic mucocutaneous candidiasis with autoimmune diseases **STAT-3 deficiency:** hyper-IgE syndrome (Job's syndrome) **STAT-3 gain of function:** lymphopenia, autoimmune cytopenias, diabetes, enteropathy
C1q, C1r/s, C2, C4; complement deficiencies	Systemic lupus erythematosus (SLE)
FcγRII, FcγRIII, C-reactive protein, complement receptor for C3bi (ITGAM or compliment receptor 3), COPA, tripeptidyl peptidase; lack of removal of cell debris	**FcγII, FcγIII, CRP, complement receptor for C3bi:** systemic lupus erythematosus **COPA:** autoimmune lung, renal, joint disease **Tripeptidyl peptidase II:** susceptibility to bacterial, viral, and fungal pathogens
Phosphoinositide-3-kinase delta (PI3Kδ), phospho-lipase Cγ2, protein kinase Cδ (PKCδ) deficiency, protein kinase Cδ (PKCδ) deficiency; hyperactivation of lymphocytes	**PI3Kδ:** lymphoproliferation, respiratory infections, hypogammaglobulinemia **Phospholipase Cγ2:** cold urticaria, antibody deficiency, autoimmunity **PKCδ:** early-onset SLE with decreased B-cell apoptosis, autoantibody-mediated renal disease and lymphoproliferation
Activation-induced cytidine deaminase (AID); class-impaired B-cell development	Hyper IgM syndrome type 2, low IgA, IgG, recurrent bacterial switch recombination; infections, autoimmune cytopenias, SLE

Abbreviations: APECED, autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy; AIRE, autoimmune regulator; COPA, gene encodes the non-clathrin-coated vesicular coat protein, COP-alpha; CTLA-4, cytotoxic T lymphocyte associated protein-4; FcγR, Fcγ receptor; FOXP3, forkhead box P3; IFN, interferon; ITGAM, integrin alpha M; LRBA, lipopolysaccharide (LPS)-responsive and beige-like anchor protein; RAG, recombinase activating gene; STAT, signal transducer and activator of transcription; TB, tuberculosis; Treg, T regulatory cell.

damage, but also leads to immune dysfunction in the setting of chronic antigenic stimulation such as occurs in chronic viral diseases (HIV-1, hepatitis C) and in cancer. Chronic viral diseases and tumors lead to transcriptional and metabolic signatures that define the exhausted T-cell state. T-cell exhaustion has been a major roadblock to overcome for successful cancer immunotherapy.

CHECKPOINT INHIBITION THERAPY FOR CANCER

The field of immune checkpoint therapy has joined surgery, radiation, chemotherapy, and targeted therapy as a mainstay for cancer therapy. There are now an extensive number of therapeutic monoclonal antibodies approved by the U.S. Food and Drug Administration (FDA), initially starting with melanoma in 2011–2014 and now available for a wide range of malignancies including kidney, lung, liver, head and neck, and gastric tumors **(Table 361-2)**. Both CTLA-4 and PD-1 blockade have proved remarkably successful in treating a number of tumors, but only in a fraction of patients. Because each receptor ligand pair regulates distinct T-cell inhibitory pathways, combination therapy using anti-PD-1 and anti-CTLA-4 antibodies has been especially useful and has induced significant tumor regression in ~50% of melanoma patients. What is different in the use of checkpoint inhibitor antibodies is that the therapy is not targeted to the tumor per se, but rather is targeted to immunoregulatory molecules on host T cells. Moreover, therapy is not targeted to specific molecules on tumors, but rather is targeted to release exhausted tumor-infiltrating T cells (TILs) to be activated to kill tumor cells by removing immune regulatory inhibition.

CTLA-4 induces tumor rejection by a number of mechanisms. First, anti-CTLA-4 antibody mediates direct blockade of CTLA-4 competition with CD28 for B7-1 and B7-2 co-stimulatory ligands, thus allowing CD28-mediated T-cell activation **(Fig. 361-2*B*)**. Tumor cells do not express B7 molecules; thus, CTLA-4 blockade likely occurs in tumor-draining lymph nodes where exhausted T cells interact with APCs presenting tumor neoantigens to T cells. A second mechanism of CTLA-4 blockade–induced tumor rejection is depletion or reduction in suppressive effects of Tregs. Suppressive effect of Tregs include secretion of immunosuppressive cytokines such as transforming growth factor (TGF)-β or interleukin- (IL) 10 or by direct inhibition of T-cell

TABLE 361-2 Summary of the Tumor Types for Which Immune Checkpoint Blockade Therapies Are Approved by the U.S. Food and Drug Administration (FDA)

TUMOR TYPE	THERAPEUTIC AGENT	TARGET	FDA APPROVAL YEAR
Melanoma	Ipilimumab	CTLA-4	2011
Melanoma	Nivolumab	PD-1	2014
Melanoma	Pembrolizumab	PD-1	2014
Non-small-cell lung cancer	Nivolumab	PD-1	2015
Non-small-cell lung cancer	Pembrolizumab	PD-1	2015
Melanoma (*BRAF* wild-type)	Ipilimumab + nivolumab	CTLA-4 + PD-1	2015
Melanoma (adjuvant)	Ipilimumab	CTLA-4	2015
Renal cell carcinoma	Nivolumab	PD-1	2015
Hodgkin's lymphoma	Nivolumab	PD-1	2016
Urothelial carcinoma	Atezolizumab	PD-L1	2016
Head and neck squamous cell carcinoma	Nivolumab	PD-1	2016
Head and neck squamous cell carcinoma	Pembrolizumab	PD-1	2016
Melanoma (any *BRAF* status)	Ipilimumab + nivolumab	CTLA-4 + PD-1	2016
Non-small-cell lung cancer	Atezolizumab	PD-L1	2016
Hodgkin's lymphoma	Pembrolizumab	PD-1	2017
Merkel cell carcinoma	Avelumab	PD-L1	2017
Urothelial carcinoma	Avelumab	PD-L1	2017
Urothelial carcinoma	Durvalumab	PD-L1	2017
Urothelial carcinoma	Nivolumab	PD-1	2017
Urothelial carcinoma	Pembrolizumab	PD-1	2017
MSI-high or MMR-deficient solid tumors of any histology	Pembrolizumab	PD-1	2017
MSI-high, MMR-deficient metastatic colorectal cancer	Nivolumab	PD-1	2017
Pediatric melanoma	Ipilimumab	CTLA-4	2017
Hepatocellular carcinoma	Nivolumab	PD-1	2017
Gastric and gastroesophageal carcinoma	Pembrolizumab	PD-1	2017
Non-small-cell lung cancer	Durvalumab	PD-L1	2018
Renal cell carcinoma	Ipilimumab + nivolumab	CTLA-4 + PD-1	2018
Endometrial cancer	Dostarlimab	PD-1	2021
Melanoma	Relatlimab + nivolumab	LAG-3 + PD-1	2022
Liver cancer	Tremelimumab	CTLA-4	2022
Merkle cell cancer	Retifanlimab	PD-1	2023
Nasopharyngeal carcinoma, esophageal squamous cell carcinoma	Toripalimab	PD-1	2023

Note: A summary of the tumor indications, therapeutic agents, and year of FDA approval for immune checkpoint blockade therapies. FDA approval includes regular approval and accelerated approval granted as of December 2023. Ipilimumab is an anti-CTLA-4 antibody. Nivolumab and pembrolizumab are anti-PD-1 antibodies. Atezolizumab, avelumab, and durvalumab are anti-PD-L1 antibodies. Tumor type reflects the indications for which treatment has been approved. Only the first FDA approval granted for each broad tissue type or indication for each therapeutic agent is noted. In cases where multiple therapies received approval for the same tumor type in the same year, agents are listed alphabetically.

Abbreviations: BRAF, v-raf murine sarcoma viral oncogene, homolog B1; MMR, mismatch repair; MSI, microsatellite instability.

Source: Reprinted from Cancer Discovery, 2018,8/9, 1069–1086, WC Spencer et al: Fundamental mechanisms of immune checkpoint blockade therapy, with permission from AACR.

proliferation and/or cytolytic activity. A third potential mechanism of anti-CTLA-4 blockade is remodeling and broadening of the peripheral TCR repertoire for tumor antigens. Evidence suggests that the effects of anti-CTLA-4 antibody are restricted primarily to tumor neoantigen-specific CD8 T cells within the tumor microenvironment and not to T cells in lymph nodes or spleen.

PD-1 blockade by PD-1 antibody also induces tumor regression by reversing T-cell exhaustion, leading to enhanced T-cell killing of tumor cells. Optimal PD-1 antibody-mediated checkpoint inhibition is seen when infiltrating CD8 T cells are present in the tumor microenvironment and reversal of the exhausted T-cell state can occur in situ. PD-1 blockade can also act by reversal of metabolic reprogramming of exhausted T cells, leading to enhanced cytolytic T-cell effector function. Antibodies to the primary PD-1 receptor, PD-L1, are also sufficient to induce reversal of T-cell exhaustion and induce tumor killing and are approved by the FDA for treatment of non-small-cell lung cancer (Table 361-2). PD-L1 is induced on tumor cells by T_H1 cytokines, which may explain anti-PD-L1 efficacy since T_H1 cytokines drive cytotoxic T-cell responses **(Chap. 360)**. Efficacy of anti-PD-L1 may also be due in part to mediation of antibody-dependent cellular cytotoxicity (ADCC) killing of tumor cells **(Chap. 360)**.

Tumor cells express neoantigens that are targets for T-cell recognition in the tumor microenvironment. Immune pressure within the tumor microenvironment can select for tumor cells that present few or mutated neoantigens and thus escape ongoing antitumor immunity. Moreover, a low number of tumor-infiltrating lymphocytes, tumor microenvironment production of immunosuppressive indoleamine 2,3-dioxygenase (IDO), and tumor infiltration with either myeloid-derived suppressor cells or Tregs can also limit checkpoint blockade therapy.

Other strategies for improving the immunoregulation of antitumor responses include combinations of anti-PD-1, anti-CTLA-4, or anti-PD-L1 antibodies with other checkpoint inhibitors (**see Chap. 360, Table 360-1,** and Fig. 361-1). For example, engagement of the ICOS pathway enhances the efficacy of CTLA-4 blockade in animal models of cancer immunotherapy. T-cell immunoglobulin and mucin-domain containing-3 (TIM-3), TIGIT, or lymphocyte-activation gene 3 (LAG-3) inhibition has been suggested to enhance checkpoint inhibition and augment CD8 tumor cell killing. A new transcription factor, thymocyte-selection-associated high mobility box (TOX), has been defined as a key controller of CD8 T-cell exhaustion. Thus, TOX inhibition could synergize with checkpoint inhibition therapy to reverse the T-cell exhaustion state. The combination of checkpoint inhibition with other cancer treatments including chemotherapy, radiation, tumor signaling pathway inhibitors, and epigenetic modulators is being tested.

Modified mRNAs have revolutionized the field of infectious disease vaccine development, and this technology is now being applied to cancer vaccine development. Tumor neoantigens are being sequenced from individual patients, and mRNAs that encode them are being studied for their ability to boost antitumor CD8 T-cell responses. Messenger RNAs that encode individualized tumor antigens are being tested with checkpoint inhibitors such as pembrolizumab (anti-PD-1) or with traditional chemotherapy.

Anti-PD-L1 antibodies also mediate antitumor effects by ADCC, which utilizes natural killer (NK) effector cells **(Chap. 360)**. Indeed, a number of checkpoint inhibitor molecules have been found to be expressed on NK cells including CTLA-4, PD-1, LAG-3, TIGIT, and TIM-3 (Fig. 361-1; **see also Chap. 360, Table 360-1**). A new field of work is to target NK cells with existing checkpoint inhibitors and with antibodies against an NK-specific inhibitory molecule, NKG2A, that are designed release NK cells to kill tumor cells. One such anti-NKG2A antibody, monalizumab, has entered human clinical trials. NK cells also express natural cytotoxicity-activating receptors including NKp30, NKp44, and NKp46 receptors **(Chap. 360)**. Engagement of natural cytotoxicity-activating receptors in concert with the NK FcγRIII (CD16) and antibody against a tumor antigen also can enhance NK cell targeting of tumor antigens and is in preclinical development.

An important consequence of checkpoint blockade for cancer treatment is the frequent occurrence of immune-related adverse events (irAEs). Clinically, irAEs occur most often at skin, lungs, and the gastrointestinal (GI) tract—barrier sites to invading antigens. Colitis is among the most common irAE. Endocrinopathies with organ-specific autoantibodies such as antithyroid or antipituitary antibodies have also been reported. While the pathophysiology of irAEs is not fully known, it is likely that both checkpoint inhibitor–released autoimmunity with decreased inhibition of Treg cell function and bystander activation of immune cells with nonspecific inflammation contribute to checkpoint inhibitor side effects. The makeup of the gut microbiome can affect the efficacy of checkpoint inhibition therapy, and in addition, certain microbiome bacterial strains are associated with the occurrence of irAEs.

CHIMERIC ANTIGEN RECEPTOR T CELLS

Chimeric antigen receptor (CAR) T cells are synthetic hybrid receptors created by recombinant techniques that combine an extracellular domain, usually derived from an antibody single-chain variable fragment (scFv), with intracellular signaling domains from activating co-stimulatory molecules (from endogenous TCRs, CD28, or 4-1BB) that allow for retargeting of T cells to antigens on malignant cells **(Fig. 361-3)**. A CAR T cell targeting the CD19 molecule on malignant B cells provided the first and most promising therapeutic results in the treatment of B-cell malignancies, with complete response rates of 70–90%. CAR T cells targeting the NY-ESO antigen on sarcoma cells have induced remissions in patients with synovial cell sarcoma. CAR T cells targeting B-cell maturation antigen (BCMA) on myeloma cells have also induced clinical responses. The CAR T-cell strategy is being developed for targeting solid tumors and modified as universal CAR T cells to overcome the need for MHC matching with T CAR recipients. One such strategy is to modify T cells to release cytokine, express co-stimulatory ligands, or secrete checkpoint-blocking single-chain variable fragment (scFvs). The next generation of CAR T cells are known as T cells redirected for universal cytokine-mediated killing (TRUCKs). Cytokine-secreting tumor-specific T cells could harness the adjuvant effect of recombinant cytokines by local delivery to the tumor to decrease cytokine side effects of excess inflammation, termed *cytokine release syndrome*, that can be seen with CAR T-cell therapy. Messenger RNAs that encode for tumor antigens are now being combined with CAR T cells with specificity for the same tumor antigens to expand tumor-specific CAR T cells and amplify their therapeutic effect.

Cell 168:724, 2017.)*

TABLE 361-3 Immune Tolerance Checkpoints in T- and B-Cell Immunity

CENTRAL TOLERANCE	PERIPHERAL TOLERANCE
THYMUS	**PERIPHERAL LYMPHOID TISSUES**
– TCR editing by V(D)J	– B- and T-cell anergy and inhibitory signaling (CTLA-4, PD-1, and other checkpoint molecules)
– Thymic negative selection	– TCR or BCR induction of BIM
– T-cell anergy and inhibitory signaling	– T-cell competition for IL-2, IL-7, IL-15, and peptide-MHC
– T regulatory cell differentiation	– B-cell competition for survival cytokine BAFF
	– T-cell growth dependence on CD28 ligands and other co-stimulatory molecules
	– Elimination of antigen-bearing dendritic cells by activated T cells producing perforin or FasL
	– Suppression of T- and B-cell responses by T regulatory cells and TGF-β, IL-10
	– T-cell death by FasL
	– Regulation of T follicular helper cell differentiation and function
BONE MARROW	– B-cell growth dependence on BCR ligands
– Immature B cell maturation arrest	– B-cell growth dependence on TCR ligands
– BCR editing by V(D)J recombination	– B-cell death by FasL on T cells
– Immature B cell deletion	– BCR modulation of plasma cell differentiation
	– BCR-induced death of germinal center B cells
	– Germinal center B-cell dependence on T follicular helper cells (CD40L, IL-21)

Abbreviations: BAFF, B cell activating factor; BCR, B-cell receptor; BIM, Bcl-2-like protein 11; FasL, Fas ligand that binds to the death receptor; IL, interleukin; MHC, major histocompatibility complex; TCR, T cell receptor; TGF-β, transforming growth factor beta; V(D)J, variable, diversity, joining regions of antibody V region.

MECHANISMS OF IMMUNE DYSREGULATION IN AUTOIMMUNE DISEASE

Autoimmune diseases occur in ~5% of people and are caused by immune dysregulation from breakdowns in immune tolerance. A complex array of immune checkpoints is involved in the maintenance of immune homeostasis and, when mutated, can result in autoimmune syndromes (Table 361-1 and **Table 361-3**). Central tolerance for deletion of autoreactive T cells or modification of their TCRs occurs in the thymus, and for B cells with self-reactive B-cell receptors, central deletion occurs in bone marrow. Peripheral tolerance occurs in lymph nodes, spleen, and tissue-associated lymphoid tissue such as gastrointestinal tract Peyer's patches. The sites and modes of peripheral tolerance are varied and reflect the complex cellular and cytokine interactions that occur in mediation of T- and B-cell adaptive immunity **(Chap. 360)**. While B- and T-cell deletion by immune cell apoptosis can occur in the periphery, peripheral tolerance can also occur with cell inactivation termed *anergy*, a state of immune unresponsiveness following contact with antigen. T- and B-cell responses are also dampened in the periphery by Tregs producing TGF-β and IL-10. The result of immune dysregulation in autoimmune disease is the production of a myriad of antibodies against self-antigens (autoantibodies), many of which are pathogenic for the clinical manifestations of the autoimmune disease **(Table 361-4)**.

Tregs are CD4 or CD8 T cells that downmodulate B- and T-cell responses in peripheral lymphoid tissues to prevent autoimmune diseases, and the transcriptional regulator FOXP3 is centrally involved in the establishment of the Treg phenotype. Mutations in genes that lead to loss of Tregs or their function result in autoimmune and inflammatory syndromes (Table 361-1). Mutations in FOXP3 lead to an X-linked syndrome characterized by immune dysregulation, polyendocrinopathy, and enteropathy (IPEX). Similarly, mutations in the CD25 (IL-2 receptor α) molecule expressed on Tregs lead to enteropathy, dermatitis, other manifestations of autoimmunity, and susceptibility to infections. Mutations in the checkpoint inhibitor T-cell molecule CTLA-4—also expressed on Tregs—lead to loss of Treg function and result in multiple autoimmune syndromes in humans depending on the CTLA-4 mutation. In mice, knockout of the *ctla4* gene leads to massive uncontrolled lymphoproliferation and early death. Finally, mutations in the lipopolysaccharide (lipopolysaccharide-responsive and beige-like anchor [LRBA]) protein cause a syndrome in infants characterized by enteritis, hypogammaglobulinemia, and autoimmune cytopenias.

Chronic viral infections can perturb Treg number and function. In HIV-1 infection, chronic antigenic stimulation leads to shifts in the B-cell repertoire toward an autoimmune permissive state, with increased numbers of autoreactive B cells and decreased CD4+ Tregs leading to serum autoantibodies or clinical manifestations of autoimmune disease in ~50% of untreated HIV-1-infected individuals.

In addition to checkpoint inhibition for cancer immunotherapy, monoclonal antibodies can be used for immune modulation to correct dysregulated immunity in autoimmune diseases to restore normal levels of immunoregulatory tolerance control. Monoclonal therapies have been developed and successfully used for the treatment of autoimmune and inflammatory diseases **(Table 361-5)**. Some of the monoclonal antibodies such as anti-CD20 (rituximab) have also been used for the treatment of B-cell malignancies. CTLA-4-Fc has been developed to prevent CD28-induced T-cell activation, resulting in immune suppression for rheumatoid arthritis (RA) and transplantation. TNF-α has been shown to play a central role in RA pathogenesis, and anti-TNF-α antibodies have been successful in treatment of RA and are approved for other autoimmune syndromes including other forms of arthritis, inflammatory bowel disease, and psoriasis. Antibodies against α4 integrin block the migration of α4β7+ T cells to the gastrointestinal tract and are used to treat inflammatory bowel disease (IBD). The T_H17 cytokine IL-17 has been found to be overproduced in psoriasis, and monoclonal anti-IL-17 antibody therapy for psoriasis is now approved by the FDA **(Chap. 60)**.

Tregs are therapeutic candidates for restoring immune tolerance in autoimmune and autoinflammatory diseases, with the prospect of reducing or replacing immunosuppressive drugs. Like CAR T cells, Treg therapy involves expanding autologous Treg cells in vitro and reinfusing them into individuals with autoimmune or inflammatory diseases. To make Treg therapy more targeted for suppression of antigen-specific immune responses, CAR T technology is being used to redirect Tregs to pathogenic T and B cells. Treg cellular therapy is in human clinical trials for the treatment of graft-versus-host disease in the setting of transplantation and for prevention of progression of type 1 diabetes mellitus **(Chap. 416)**.

IMMUNE DYSREGULATION IN AGING

Aging of the immune system in humans is characterized by decline in both innate and adaptive immunity. Aging is also paradoxically associated with a state of chronic inflammation, termed "inflammaging,"

TABLE 361-4 Recombinant or Purified Autoantigens Recognized by Autoantibodies Associated with Human Autoimmune Disorders

AUTOANTIGEN	AUTOIMMUNE DISEASES
Cell- or Organ-Specific Autoimmunity	
Acetylcholine receptor	Myasthenia gravis
Actin	Chronic active hepatitis, primary biliary cirrhosis
Adenine nucleotide translator (ANT)	Dilated cardiomyopathy, myocarditis
β-Adrenoreceptor	Dilated cardiomyopathy
Aromatic L-amino acid decarboxylase	Autoimmune polyendocrine syndrome type 1 (APS-1)
Asialoglycoprotein receptor	Autoimmune hepatitis
Bactericidal/permeability-increasing protein (Bpi)	Cystic fibrosis vasculitides
Calcium-sensing receptor	Acquired hypoparathyroidism
Cholesterol side-chain cleavage enzyme (CYP11a)	Autoimmune polyglandular syndrome 1
Citrullinated proteins	Rheumatoid arthritis
Collagen type IV-α3-chain	Goodpasture's syndrome
Cytochrome P450 2D6 (CYP2D6)	Autoimmune hepatitis
Desmin	Crohn's disease, coronary artery disease
Desmoglein 1	Pemphigus foliaceus
Desmoglein 3	Pemphigus vulgaris
F-actin	Autoimmune hepatitis
GM gangliosides	Guillain-Barré syndrome
Glutamate decarboxylase (GAD65)	Type 1 diabetes, stiff-person syndrome
Glutamate receptor (GLUR)	Rasmussen encephalitis
H/K ATPase	Autoimmune gastritis
17-α-Hydroxylase (CYP17)	Autoimmune polyglandular syndrome 1
21-Hydroxylase (CYP21)	Addison's disease
IA-2 (ICA512)	Type 1 diabetes
Insulin	Type 1 diabetes, insulin hypoglycemic syndrome (Hirata's disease)
Insulin receptor	Type B insulin resistance, acanthosis, systemic lupus erythematosus
Intrinsic factor type 1	Pernicious anemia
Leukocyte function-associated antigen (LFA-1)	Treatment-resistant Lyme arthritis
Myelin-associated glycoprotein (MAG)	Polyneuropathy
Myelin-basic protein	Multiple sclerosis, demyelinating diseases
Myelin oligodendrocyte glycoprotein (MOG)	Multiple sclerosis
Myosin	Rheumatic fever
p-80-Collin	Atopic dermatitis
Pyruvate dehydrogenase complex-E2 (PDC-E2)	Primary biliary cirrhosis
Sodium iodide symporter (NIS)	Graves' disease, autoimmune hypothyroidism
SOX-10	Vitiligo
Thyroid and eye muscle shared protein	Thyroid-associated ophthalmopathy
Thyroglobulin	Autoimmune thyroiditis
Thyroid peroxidase	Autoimmune Hashimoto's thyroiditis
Thyrotropin receptor	Graves' disease
Tissue transglutaminase	Celiac disease
Transcription coactivator p75	Atopic dermatitis
Tryptophan hydroxylase	Autoimmune polyglandular syndrome 1
Tyrosinase	Vitiligo, metastatic melanoma
Tyrosine hydroxylase	Autoimmune polyglandular syndrome 1
Systemic Autoimmunity	
Adrenocorticotropic hormone (ACTH)	ACTH deficiency
Aminoacyl-tRNA histidyl synthetase	Myositis, dermatomyositis
Aminoacyl-tRNA synthetase (several)	Polymyositis, dermatomyositis
Cardiolipin	Systemic lupus erythematosus, antiphospholipid syndrome
Carbonic anhydrase II	Systemic lupus erythematosus, Sjögren's syndrome, systemic sclerosis
Collagen (multiple types)	Rheumatoid arthritis, systemic lupus erythematosus, progressive systemic sclerosis
Centromere-associated proteins	Systemic sclerosis
DNA-dependent nucleoside-stimulated ATPase	Dermatomyositis
Fibrillarin	Scleroderma
Fibronectin	Systemic lupus erythematosus, rheumatoid arthritis, morphea
Glucose-6-phosphate isomerase	Rheumatoid arthritis
β2-Glycoprotein I (B2-GPI)	Primary antiphospholipid syndrome
Golgin (95, 97, 160, 180) heat shock protein	Sjögren's syndrome, systemic lupus erythematosus, rheumatoid arthritis, various immune-related disorders
Hemidesmosomal protein 180	Bullous pemphigoid, herpes gestationis, cicatricial pemphigoid
Histone H2A-H2B-DNA	Systemic lupus erythematosus
IgE receptor	Chronic idiopathic urticaria
Keratin-8	Rheumatoid arthritis
Ku-DNA-protein kinase	Systemic lupus erythematosus
Ku-nucleoprotein La phosphoprotein (La 55-B)	Connective tissue syndrome Sjögren's syndrome
Myeloperoxidase	Necrotizing and crescentic glomerulonephritis, systemic vasculitis
Proteinase 3 (PR3)	Granulomatosis with polyangiitis (Wegener's), Churg-Strauss syndrome
RNA polymerase I–III (RNP)	Systemic sclerosis, systemic lupus erythematosus
Signal recognition protein (SRP54)	Polymyositis
Topoisomerase-1 (Scl-70)	Scleroderma, Raynaud's syndrome
Tublin	Chronic liver disease, visceral leishmaniasis
Vimentin	Systemic autoimmune disease
Plasma Protein and Cytokine Autoimmunity	
C1 inhibitor	Autoimmune C1 deficiency
C1q	Systemic lupus erythematosus, membrane proliferative glomerulonephritis
Cytokines (IL-1α, IL-1β, IL-6, TNF-α, IFN-γ IL17A, IL-17F, GM-CSF)	IL-1α, IL-1β: rheumatoid arthritis, systemic sclerosis, systemic lupus erythematosus; IL-6: bacterial infections; IFN-γ: bacterial infections, varicella-zoster virus reactivation; IL-17A, IL-17F: chronic mucocutaneous candidiasis; GM-CSF: pulmonary alveolar proteinosis, fungal infections
Factor II, factor V, factor VII, factor VIII, factor IX, factor X, factor XI, thrombin vWF	Prolonged coagulation time
Glycoprotein IIb/IIIg and Ib/IX	Autoimmune thrombocytopenia purpura
IgA	Immunodeficiency associated with systemic lupus erythematosus, pernicious anemia, thyroiditis, Sjögren's syndrome, and chronic active hepatitis
Oxidized LDL (OxLDL)	Atherosclerosis
Cancer and Paraneoplastic Autoimmunity	
Amphiphysin	Neuropathy, small-cell lung cancer
Cyclin B1	Hepatocellular carcinoma
DNA topoisomerase II	Liver cancer

(*Continued*)

TABLE 361-4 Recombinant or Purified Autoantigens Recognized by Autoantibodies Associated with Human Autoimmune Disorders (Continued)

AUTOANTIGEN	AUTOIMMUNE DISEASES
Desmoplakin	Paraneoplastic pemphigus
Gephyrin	Paraneoplastic stiff-person syndrome
Hu proteins	Paraneoplastic encephalomyelitis
Neuronal nicotinic acetylcholine receptor	Subacute autonomic neuropathy, cancer
p53	Cancer, systemic lupus erythematosus
p62 (IGF-II mRNA-binding protein)	Hepatocellular carcinoma (China)
Recoverin	Cancer-associated retinopathy
Ri protein	Paraneoplastic opsoclonus myoclonus ataxia
βIV spectrin	Lower motor neuron syndrome
Synaptotagmin	Lambert-Eaton myasthenic syndrome
Voltage-gated calcium channels	Lambert-Eaton myasthenic syndrome
Yo protein	Paraneoplastic cerebellar degeneration

Abbreviations: ATPase, enzymes that catalyze hydrolysis of adenosine; Histone 2A and 2B, core histone proteins at the periphery of the nucleosome; Hu proteins, neuronal molecules; IGF-II, insulin-like growth factor-2; Ku, protein complex for DNA repair; La, Sjogren's syndrome antigen B (SSB) involved in RNA processing; RI, ribonuclease inhibitor; SOX-10, SRY-related HMG-box-10 transcription factor; Yo antigen, cellular degeneration-related antigen.

TABLE 361-5 Monoclonal Antibodies Approved for Clinical Use in Autoimmune Disease, Some of Which Are Also Used in Malignancies[a]

TARGET MOLECULE	FUNCTION	FDA-APPROVED mAbs, TRAPS, AND BISPECIFIC mAbs	AUTOIMMUNE/ INFLAMMATORY	MALIGNANCY	OTHER/COMMENTS
CD52	Marker of T and B lymphocyte subsets	Alemtuzumab (Lemtrada)	Multiple sclerosis	Chronic lymphocytic leukemia	Trade name changed from Campath-1H (cancer) to Lemtrada (multiple sclerosis) Humanized IgG1k
CD25	Alpha-chain of the IL-2 receptor	Basiliximab (Simulect) Daclizumab (Zenapax)	Multiple sclerosis Transplant rejection		Basiliximab: chimeric mouse/human IgG1k Daclizumab: humanized IgG1
CD20	Participates in B-cell differentiation	Obinutuzumab (Gazyva) Ibritumomab tiuxetan (Zevalin) Tositumomab (Bexxar)[a] Ofatumumab (Arzerra) Rituximab (Rituxan)	Rheumatoid arthritis	B-cell malignancies	Obinutuzumab is the first approved glycoengineered IgG1 mAb with enhanced ADCC Rituximab is chimeric mouse/human IgG1k Ibritumomab tiuxetan and tositumomab are radio-conjugates that can be used when tumors stop responding to the anti-CD20 mAbs Ibritumomab and tositumomab are mouse IgG2a
α4 β7 integrin (LPAM)	Block immune cell migration	Vedolizumab (Entyvio)	Ulcerative colitis, Crohn's disease		Humanized IgG1
CD80/CD86	Provide co-stimulatory signals necessary for T-cell activation and survival; ligand trap prevents activation of CD28 immune checkpoint resulting in immune suppression	Belatacept (Nulojix) Abatacept (Orencia) (both CTLA-4-Fc fusion proteins)	Rheumatoid arthritis Transplant rejection		
IGF-IR	Human IgG1; binds insulin-like growth factor-1 receptor on orbital fibroblasts and decreases inflammatory cytokine production	Teprotumumab (Tepezza)	Thyroid eye disease		
TNF-α	Inflammatory cytokine that drives multiple autoimmune diseases[a]	Adalimumab (Humira) Certolizumab pegol (Cimzia) Golimumab (Simponi) Infliximab (Remicade) Etanercept (Enbrel) There are more than 20 anti-TNF biosimilars in various stages of development. Already approved are infliximab biosimilars (Remsima, Inflectra, Flixabi), etanercept biosimilars (Erelzi, Benepali), and adalimumab biosimilars (Amjevita). This field will change very rapidly as many dossiers are now under regulatory scrutiny. Biosimilars are given a suffix, e.g., etanercept-szzs (Erelzi)	Crohn's disease, ulcerative colitis, RA, juvenile idiopathic arthritis, psoriatic arthritis, ankylosing spondylitis, plaque psoriasis, hidradenitis suppurativa, uveitis		Not all TNF blockers are approved for all indications Drugs in italics are biosimilars: adalimumab, infliximab, infliximab, *Inflectra*, *adalimumab-atto* are IgG1k mAbs; *certolizumab pegol* is a pegylated Fab fragment; etanercept is a soluble Fc:TNF receptor trap that binds TNF (there is one biosimilar). At least four biosimilar TNF blockers have been approved in the EU (two each for infliximab and etanercept)

TARGET MOLECULE	FUNCTION	FDA-APPROVED mAbs, TRAPS, AND BISPECIFIC mAbs	AUTOIMMUNE/ INFLAMMATORY	MALIGNANCY	OTHER/COMMENTS
VEGF	Cytokine that stimulates vasculogenesis and angiogenesis. Overproduced in some inflammatory disorders and tumors to induce increased blood supply.	Bevacizumab (Avastin) Ramucirumab (Cyramza) Aflibercept (Eylea/Zaltrap) Ranibizumab (Lucentis)	Age-related macular degeneration, macular edema, diabetic macular edema, diabetic retinopathy	Colorectal cancer, nonsquamous NSCLC, breast cancer, glioblastoma, renal cell carcinoma, gastric cancer or gastroesophageal junction adenocarcinoma	Bevacizumab and ramucirumab are IgG1 mAbs for cancer therapy (ramucirumab was derived from phage display); ranibizumab is a Fab fragment (single arm binder). It has a short half-life if administered intravenously, but it is stable when locally injected into the eye. Aflibercept is a ligand trap with optical (Eylea) and cancer (Zaltrap) applications.
IL-4 receptor alpha subunit	Receptor that mediates IL-4 and IL-13-induced inflammation	Dupilumab (Dupixent)	Atopic dermatitis (eczema), steroid-dependent asthma		
IgE	Binds to mast cells, basophils, and other cells that express Fc-epsilon receptor and induces release of inflammatory cytokines	Omalizumab (Xolair)	Asthma		IgG1k mAb also used off-label to treat IgE-related conditions (allergic rhinitis, drug allergies, other)
Alpha-4 integrin	Alpha-4 integrin facilitates exit of inflammatory cells from blood into intestine or across the blood-brain barrier	Vedolizumab (Entyvio) Natalizumab (Tysabri)	Multiple sclerosis, Crohn's disease, and ulcerative colitis		IgG4 natalizumab therapy has been associated with PML caused by John Cunningham virus in immunocompromised patients. IgG1k vedolizumab may not be associated with PML.
Complement C5	Inhibits complement cascade	Eculizumab (Solaris) Pozelimab (Vepoz)	Prevents destruction of red blood cells by activated complement (paroxysmal nocturnal hemoglobinuria) Treats complement hyperactivation, angiopathic thrombosis, and protein-losing enteropathy (CHAPLE)		IgG2/4 mAb Pozelimab, IgG4
FcRn	Delivers IgG antibodies to tissues	Rozanolixizumab (Rustiggo)	Myasthenia gravis		IgG4. Rozanolixizumab binds to human neonatal Fc receptor (FcRn), thus reducing the concentration of pathogenic IgG autoantibodies.
IL-1	Mutations in cryopyrin lead to overproduction of IL-1 and inflammatory disease; IL-1 also drives other inflammatory diseases	Canakinumab (Ilaris) Rilonacept (Arcalyst)[a]	Rare inflammatory syndromes, active juvenile arthritis, gouty arthritis		Canakinumab is an IgG1k mAb; rilonacept is an IL-1 trap designed from the IL-1R fused with human mAb Fc region.
IL-6	Overexpression of IL-6 is associated with multiple malignancies	Siltuximab (Sylvant)		Pseudo-malignancy: Castleman's disease (similar to lymphoma)	Murine/human chimeric IgG1κ
IL-6R (IL-6 receptor)	Current approvals based on role of IL-6 in promoting inflammatory autoimmune disease	Tocilizumab (Actemra)	Rheumatoid arthritis, polyarticular juvenile arthritis, juvenile idiopathic arthritis		Human/mouse chimeric mAb with initial approval for efficacy in RA after failure of TNF blocker
BAFF (tumor necrosis factor superfamily member 13b)	Role in proliferation and differentiation of B cells	Belimumab (Benlysta)	Systemic lupus erythematosus		IgG1-γ/λ
SLAMF7/CD319	SLAMF7 triggers the activation and differentiation of a wide variety of immune cells (innate and adaptive immune response) perhaps primarily mediated by natural killer cells and myeloma cells	Elotuzumab (Empliciti)		Multiple myeloma	This IgG1k mAb is thought to activate SLAMF7 receptor and to have a secondary mechanism of mediating ADCC vs multiple myeloma cells

TARGET MOLECULE	FUNCTION	FDA-APPROVED mAbs, TRAPS, AND BISPECIFIC mAbs	AUTOIMMUNE/ INFLAMMATORY	MALIGNANCY	OTHER/COMMENTS
IL-5	Induces differentiation and survival of eosinophils	Reslizumab (Cinqair) Mepolizumab (Nucala)	Asthma		Both IgG1k mAbs
IL-13	Inflammatory cytokine	Lebrikizumab (Ebglyss) Tralokinumab (Adtralza; Adbry)	Atopic dermatitis		IgG4
IL-17A	Inflammatory cytokine	Ixekizumab (Taltz) Secukinumab (Cosentyx)	Plaque psoriasis, ankylosing spondylitis		Ixekizumab is an IgG4; secukinumab is an IgG1k
IL-23p19		Mirikizumab (Omvoh) Risankizumab (Skyrizi) Guselkumab (Tremfya)	Ulcerative colitis Plaque psoriasis Plaque psoriasis		Mirikizumab humanized IgG4 Risankizumab humanized IgG4 Guselkumab humanized IgG4

[a]Approved for use in United States only.

Note: An actively updated summary of MAb approvals can be found at *www.antibodysociety.org*. mAbs can be murine, chimeric (human Fc region), humanized, or human; traps are derived from receptors and compete with natural receptor for binding target; bispecific mAbs are engineered to bind to two different targets simultaneously (usually to bring immune cell into contact with target cell, thereby triggering target cell killing). Antibody-drug conjugate (X): toxin or radioisotope attached to mAb to increase efficacy. Agents approved for use in the United States only are noted; others are approved in both United States and United Kingdom.

Abbreviations: ADCC, antibody-dependent cell-mediated cytotoxicity; BAFF, B-cell activating factor; CTLA-4, cytotoxic T-cell lymphocyte-associated protein-4; EU, European Union; Ig, immunoglobulin; FDA, U.S. Food and Drug Administration; IL, interleukin; mAb, monoclonal antibody; NSCLC, non-small-cell lung cancer; PML, progressive multifocal leukoencephalopathy; RA, rheumatoid arthritis; SLAMF7, signaling lymphocyte activation molecule family member 7; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

with an increased risk of autoimmune disease. Aging is associated with reduced NK cell function, reduced monocyte/macrophage immune cell expression of toll-like receptors, reduced chemotaxis and phagocytosis, and reduced MHC expression and signaling. Other phagocytic cells such as polymorphonuclear cells are similarly dysfunctional. Dendritic cells in aged individuals are present in reduced numbers with impaired antigen-presenting function and signaling. Adaptive immunity is similarly impaired with decreased antibody repertoire breadth, decrease in number of B cells, and decrease in B-cell responses to specific antigens. Similarly, T-cell responses to antigen are decreased, such as to seasonal influenza vaccination.

Aging is characterized by accumulation of senescent cells in many tissues that secrete inflammatory cytokines, chemokines, and other inflammatory mediators. The best example of the role of enhanced cytokine production in the "inflammaging" syndrome is in thymic atrophy, which is a major event contributing to age-associated immune system decline. During life, the thymus decreases in size and naïve T-cell output decreases; beginning with puberty, thymocytes progressively decrease in number, such that after ~50 years of age, ~90% of thymocytes have been replaced by adipocytes in the thymus perivascular space. Thymic adipocytes produce leukemia inhibitory factor, oncostatin M, IL-6, and stem cell factor (SCF). Administration of these cytokines to young mice induces thymic atrophy, demonstrating that these thymosuppressive cytokines actively induce thymocyte loss. Adipocytes in other sites also produce inflammatory cytokines, contributing to tissue senescence. Finally, respiratory failure due to SARS-CoV-1, Middle Eastern respiratory syndrome, or SARS-CoV-2 infection is associated with a cytokine release syndrome with IL-6 overproduction, which occurs most frequently in older individuals.

362 Primary Immune Deficiency Diseases

Alain Fischer

Immunity is intrinsic to life and an important tool in the fight for survival against pathogenic microorganisms. The human immune system can be divided into two major components: the innate immune system and the adaptive immune system **(Chap. 360)**. The innate immune system provides the rapid triggering of inflammatory responses based on the recognition (at the cell surface or within cells) of either molecules expressed by microorganisms or molecules that serve as "danger signals" released by cells under attack. These receptor/ligand interactions trigger signaling events that ultimately lead to inflammation. Virtually all cell lineages (not just immune cells) are involved in innate immune responses; however, myeloid cells (i.e., neutrophils and macrophages) play a major role because of their phagocytic capacity. The adaptive immune system operates by clonal recognition of antigens followed by a dramatic expansion of antigen-reactive cells and execution of an immune effector program. Most of the effector cells die off rapidly, whereas memory cells persist. Although both T and B lymphocytes recognize distinct chemical moieties and execute distinct adaptive immune responses, the latter is largely dependent on the former in

generating long-lived humoral immunity. Adaptive responses utilize components of the innate immune system; for example, the antigen-presentation capabilities of dendritic cells help to determine the type of effector response. Not surprisingly, immune responses are controlled by a series of regulatory mechanisms.

Hundreds of gene products have been characterized as effectors or mediators of the immune system **(Chap. 360)**. Whenever the expression or function of one of these products is genetically impaired (provided the function is nonredundant), a primary immunodeficiency (PID) occurs.

PIDs are genetic diseases with primarily Mendelian inheritance. More than 550 conditions have now been described, and deleterious mutations in ~500 genes have been identified. The overall prevalence of PIDs has been estimated in various countries at 5–10 per 100,000 individuals; however, given the difficulty in diagnosing these rare and complex diseases, this figure is probably an underestimate. PIDs can involve all possible aspects of immune responses, from innate through adaptive, cell differentiation, and effector function and regulation. For the sake of clarity, PIDs should be classified according to (1) the arm of the immune system that is defective and (2) the mechanism of the defect (when known). **Table 362-1** classifies the most prevalent PIDs according to this manner of classification; however, one should bear in mind that the classification of PIDs sometimes involves arbitrary decisions because of overlap and, in some cases, lack of data.

TABLE 362-1 Classification of Primary Immune Deficiency Diseases

Deficiencies of the Innate Immune System	
• Phagocytic cells:	
• Impaired production: severe congenital neutropenia (SCN)	
• Asplenia	
• Impaired adhesion: leukocyte adhesion deficiency (LAD)	
• Impaired killing: chronic granulomatous disease (CGD)	
• Innate immunity receptors and signal transduction:	
• Defects in Toll-like receptor signaling	
• Mendelian susceptibility to mycobacterial disease	
• Complement deficiencies:	
• Classical, alternative, and lectin pathways	
• Lytic phase	
Deficiencies of the Adaptive Immune System	
• T lymphocytes:	
• Impaired development	Severe combined immune deficiencies (SCIDs)
• Impaired survival, migration, function	DiGeorge's syndrome
	Combined immunodeficiencies
	Hyper-IgE syndrome (autosomal dominant)
	DOCK8 deficiency
	CD40 ligand deficiency
	Wiskott-Aldrich syndrome
	Ataxia-telangiectasia and other DNA repair deficiencies
• B lymphocytes:	
• Impaired development	XL and AR agammaglobulinemia
• Impaired function	Hyper-IgM syndrome
	Common variable immunodeficiency (CVID)
	IgA deficiency
Regulatory Defects	
• Innate immunity	Autoinflammatory syndromes (outside the scope of this chapter)
	Severe colitis
	Hemophagocytic lymphohistiocytosis (HLH)
• Adaptive immunity	Autoimmune lymphoproliferation syndrome (ALPS)
	Autoimmunity and inflammatory diseases (IPEX, APECED)

Abbreviations: APECED, autoimmune polyendocrinopathy candidiasis ectodermal dysplasia; AR, autosomal recessive; IPEX, immunodysregulation polyendocrinopathy enteropathy X-linked syndrome; XL, X-linked.

Today, PIDs tend to be integrated in a larger group of inborn errors of immunity that also include autoinflammatory syndromes.

The consequences of PIDs vary widely as a function of the molecules that are defective. This concept translates into multiple levels of vulnerability to infection by pathogenic and opportunistic microorganisms, ranging from extremely broad (as in severe combined immunodeficiency [SCID]) to narrowly restricted to a single microorganism (as in Mendelian susceptibility to mycobacterial disease [MSMD]). The locations of the sites of infection and the causal microorganisms involved will thus help physicians arrive at proper diagnoses. PIDs can also lead to immunopathologic responses such as allergy (as in Wiskott-Aldrich syndrome [WAS]), lymphoproliferation, and autoimmunity. A combination of recurrent infections, inflammation, and autoimmunity can be observed in a number of PIDs, thus creating obvious therapeutic challenges. Finally, some PIDs increase the risk of cancer, notably but not exclusively lymphocytic cancers, for example, lymphoma.

DIAGNOSIS OF PRIMARY IMMUNODEFICIENCIES

The most frequent symptom prompting the diagnosis of a PID is the presence of recurrent or unusually severe infections. As mentioned above, recurrent allergic or autoimmune manifestations may also alert the physician to a possible diagnosis of PID. In such cases, a detailed account of the subject's personal and family medical history should be obtained. It is of the utmost importance to gather as much medical information as possible on relatives and up to several generations of ancestors. In addition to the obvious focus on primary symptoms, the clinical examination should evaluate the size of lymphoid organs and, when appropriate, look for the characteristic signs of a number of complex syndromes that may be associated with a PID.

The performance of laboratory tests should be guided to some extent by the clinical findings. Infections of the respiratory tract (bronchi, sinuses) mostly suggest a defective antibody response. In general, invasive bacterial infections can result from complement deficiencies, signaling defects of innate immune responses, asplenia, or defective antibody responses. Viral infections, recurrent *Candida* infections, and opportunistic infections are generally suggestive of impaired T-cell immunity. Skin infections and deep-seated abscesses primarily reflect innate immune defects (such as chronic granulomatous disease); however, they may also appear in the autosomal dominant hyper-IgE syndrome. **Table 362-2** summarizes the laboratory tests that are most frequently used to diagnose a PID. More specific tests (notably genetic tests) are then used to make a definitive diagnosis. Genomic tools now allow us to more efficiently track genetic defects through usage of gene panel resequencing and/or whole exome/genome sequencing.

The PIDs discussed below have been grouped together according to the affected cells and the mechanisms involved (Table 362-1, **Fig. 362-1**).

PRIMARY IMMUNODEFICIENCIES OF THE INNATE IMMUNE SYSTEM

PIDs of the innate immune system are relatively rare and account for ~10% of all PIDs.

SEVERE CONGENITAL NEUTROPENIA

Severe congenital neutropenia (SCN) consists of a group of inherited diseases that are characterized by severely impaired neutrophil counts (<500 polymorphonuclear leukocytes [PMN]/μL of blood). The condition is usually manifested from birth. SCN may also be cyclic (with a 3-week periodicity), and other neutropenia syndromes can also be intermittent. Although the most frequent inheritance pattern for SCN is autosomal dominant, autosomal recessive and X-linked recessive conditions also exist. Bacterial infections at the interface between the body and the external milieu (e.g., the orifices, wounds, and the respiratory tract) are common manifestations. Bacterial infections can rapidly progress through soft tissue and are followed by dissemination in the bloodstream. Severe visceral fungal infections can also ensue. The absence of pus is a hallmark of this condition.

Diagnosis of SCN requires examination of the bone marrow. Most SCNs are associated with a block in granulopoiesis at the promyelocytic

TABLE 362-2 Tests Most Frequently Used to Diagnose a Primary Immunodeficiency (PID)

TEST	INFORMATION	PID DISEASE
Blood cell counts and cell morphology	Neutrophil counts[a] Lymphocyte counts[a] Eosinophilia Howell-Jolly bodies	↓ Severe congenital neutropenia, ↑↑ LAD T-cell ID WAS, hyper-IgE syndrome Asplenia
Chest x-ray	Thymic shadow Costochondral junctions	SCID, DiGeorge's syndrome Adenosine deaminase deficiency
Bone x-ray	Metaphyseal ends	Cartilage hair hypoplasia
Immunoglobulin serum levels	IgG, IgA, IgM IgE	B-cell ID Hyper-IgE syndrome, WAS, T-cell ID
Lymphocyte phenotype	T, B lymphocyte counts	T-cell ID, agammaglobulinemia
Dihydrorhodamine fluorescence (DHR) assay Nitroblue tetrazolium (NBT) assay	Reactive oxygen species production by PMNs	Chronic granulomatous disease
CH50, AP50	Classic and alternative complement pathways	Complement deficiencies
Ultrasonography of the abdomen	Spleen size	Asplenia

[a]Normal counts vary with age. For example, the lymphocyte count is between 3000 and 9000/μL of blood below the age of 3 months and between 1500 and 2500/μL in adults.

Abbreviations: ID, immunodeficiency; LAD, leukocyte adhesion deficiency; PMNs, polymorphonuclear leukocytes; SCID, severe combined immunodeficiency; WAS, Wiskott-Aldrich syndrome.

stage (Fig. 362-1). SCN has multiple etiologies, and to date, mutations in 21 different genes have been identified. Most of these mutations result in isolated SCN, whereas others are syndromic (**Chap. 67**). The most frequent forms of SCN are caused by the premature cell death of granulocyte precursors, as observed in deficiencies of GFI1, HAX1, and elastase 2 (*ELANE*), with the latter accounting for 50% of SCN sufferers. Certain *ELANE* mutations cause cyclic neutropenia syndrome. A gain-of-function mutation in the *WASP* gene (see the section "Wiskott-Aldrich Syndrome" below) causes X-linked SCN, which is also associated with monocytopenia.

As mentioned above, SCN exposes the patient to life-threatening, disseminated bacterial and fungal infections. Treatment requires careful hygiene measures, notably in infants. Later in life, special oral and dental care is essential, along with the prevention of bacterial infection by prophylactic administration of trimethoprim/sulfamethoxazole. Subcutaneous injection of the cytokine granulocyte colony-stimulating factor (G-CSF) usually improves neutrophil development and thus prevents infection in most SCN diseases. However, there are two caveats: (1) a few cases of SCN with *ELANE* mutation are refractory to G-CSF and may require curative treatment via allogeneic hematopoietic stem cell transplantation (HSCT); and (2) a subset of G-CSF-treated patients carrying *ELANE* mutations are at a greater risk of developing acute myelogenous leukemia associated (in most cases) with somatic gain-of-function mutations of the G-CSF receptor gene.

A few SCN conditions are associated with additional immune defects involving leukocyte migration as observed in the warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) syndrome (gain-of-function mutation of the chemokine *CXCR4*) or in moesin deficiency.

ASPLENIA

Primary failure of the development of a spleen is an extremely rare disease that can be either syndromic (in Ivemark syndrome) or isolated

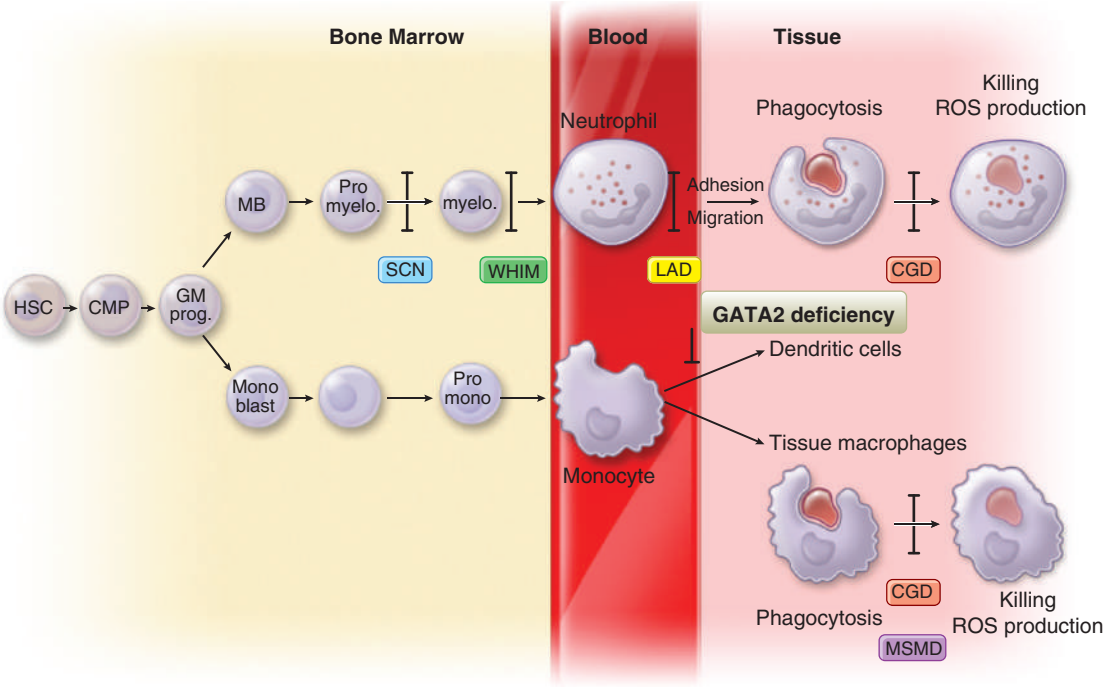

FIGURE 362-1 Differentiation of phagocytic cells and related primary immunodeficiencies (PIDs). Hematopoietic stem cells (HSCs) differentiate into common myeloid progenitors (CMPs) and then granulocyte-monocyte progenitors (GM prog.), which, in turn, differentiate into neutrophils (MB: myeloblasts; Promyelo: promyelocytes; myelo: myelocytes) or monocytes (monoblasts and promonocytes). Upon activation, neutrophils adhere to the vascular endothelium, transmigrate, and phagocytose the targets. Reactive oxygen species (ROS) are delivered to the microorganism-containing phagosomes. Macrophages in tissues kill using the same mechanism. Following activation by interferon γ (not shown here), macrophages can be armed to kill intracellular pathogens such as mycobacteria. For sake of simplicity, not all cell differentiation stages are shown. The abbreviations for PIDs are contained in boxes placed at corresponding stages of the pathway. CGD, chronic granulomatous diseases; GATA2, zinc finger transcription factor; LAD, leukocyte adhesion deficiencies; MSMD, Mendelian susceptibility to mycobacterial disease; SCN, severe congenital neutropenia; WHIM, warts, hypogammaglobulinemia, infections, and myelokathexis.

with an autosomal dominant expression; in the latter case, mutations in the ribosomal protein SA were recently found. Due to the absence of natural filtration of microbes in the blood, asplenia predisposes affected individuals to fulminant infections by encapsulated bacteria. Although most infections occur in the first years of life, cases may also arise in adulthood. The diagnosis is confirmed by abdominal ultrasonography and the detection of Howell-Jolly bodies in red blood cells. Effective prophylactic measures (twice-daily oral penicillin and appropriate vaccination programs) usually prevent fatal outcomes.

GATA2 DEFICIENCY

Recently, an immunodeficiency combining monocytopenia and dendritic and lymphoid (B and natural killer [NK]) cell deficiency (DCML), also called monocytopenia with nontuberculous mycobacterial infections (mono-MAC), has been described as a consequence of a dominant mutation in the gene *GATA2*, a transcription factor involved in hematopoiesis. This condition also predisposes to lymphedema, myelodysplasia, and acute myeloid leukemia. Infections (bacterial and viral) are life-threatening, thus indicating, together with the malignant risk, HSCT.

LEUKOCYTE ADHESION DEFICIENCY

Leukocyte adhesion deficiency (LAD) consists of three autosomal recessive conditions (LAD I, II, and III) **(Chap. 67)**. The most frequent condition (LAD I) is caused by mutations in the β2 integrin gene; following leukocyte activation, β2 integrins mediate adhesion to inflamed endothelium expressing cognate ligands. LAD III results from a defect in a regulatory protein (kindlin, also known as Fermt 3) involved in activating the ligand affinity of β2 integrins. The extremely rare LAD II condition is the end result of a defect in selectin-mediated leukocyte rolling that occurs prior to β2 integrin binding. There is a primary defect in fucose transporter such that oligosaccharide selectin ligands are missing in this syndromic condition.

Given that neutrophils are not able to reach infected tissues, LAD renders the individual susceptible to bacterial and fungal infections in a way that is similar to that of patients with SCN. LAD also causes impaired wound healing and delayed loss of the umbilical cord. A diagnosis can be suspected in cases of pus-free skin/tissue infections and massive hyperleukocytosis (>30,000/μL) in the blood (mostly granulocytes). Patients with LAD III also develop bleeding because the β2 integrin in platelets is not functional. Use of immunofluorescence and functional assays to detect β2 integrin can help form a diagnosis. Severe forms of LAD may require HSCT, although gene therapy is also now being considered. Inflammatory consequences of LAD can be mitigated by anti-interleukin (IL)-17A antibody therapy. Neutrophil-specific granule deficiency (a very rare condition caused by a mutation in the gene for transcription factor C/EBPα) results in a condition that is clinically similar to LAD. Infrequent additional leukocyte motility defects have also been reported.

CHRONIC GRANULOMATOUS DISEASES

Chronic granulomatous diseases (CGDs) are characterized by impaired phagocytic killing of microorganisms by neutrophils and macrophages **(Chap. 67)**. The incidence is ~1 per 200,000 live births. About 70% of cases are associated with X-linked recessive inheritance versus autosomal inheritance in the remaining 30%. CGD causes deep-tissue bacterial and fungal abscesses in macrophage-rich organs such as the lymph nodes, liver, and lungs. Recurrent skin infections (such as folliculitis) are common and can prompt an early diagnosis of CGD. The infectious agents are typically catalase-positive bacteria (such as *Staphylococcus aureus* and *Serratia marcescens*) but also include *Burkholderia cepacia*, pathogenic mycobacteria (in certain regions of the world), and fungi (mainly filamentous molds, such as *Aspergillus*).

CGD is caused by defective production of reactive oxygen species (ROS) in the phagolysosome membrane following phagocytosis of microorganisms. It results from the lack of a component of NADPH oxidase (gp91phox or p22phox) of the associated adapter/activating proteins (p47phox, p67phox, or p40phox) or a regulator of NADPH oxidase expression (CYBC1) that mediates the transport of electrons into the phagolysosome for creating ROS by interaction with O_2. Under normal circumstances, these ROS either directly kill engulfed microorganisms or enable the rise in pH needed to activate the phagosomal proteases that contribute to microbial killing. Diagnosis of CGD is based on assays of ROS production in neutrophils and monocytes (Table 362-2). As its name suggests, CGD is also a granulomatous disease. Macrophage-rich granulomas can often arise in the liver, spleen, and other organs. These are sterile granulomas that cause disease by obstruction (bladder, pylorus, etc.) or protracted inflammation (colitis, restrictive lung disease).

The management of infections in patients with CGD can be a complex process. The treatment of bacterial infections is generally based on combination therapy with antibiotics that are able to penetrate into cells. The treatment of fungal infections requires aggressive, long-term use of antifungals. Inflammatory/granulomatous lesions are usually steroid-sensitive, but often become glucocorticoid-dependent; liver abscesses are best managed by administering antibiotics together with glucocorticoids.

The treatment of CGD mostly relies on preventing infections. It has been unambiguously demonstrated that prophylactic usage of trimethoprim/sulfamethoxazole is both well tolerated and highly effective in reducing the risk of bacterial infection. Daily administration of azole derivatives (notably itraconazole) also reduces the frequency of fungal complications. It has long been suggested that interferon γ administration is helpful, although medical experts continue to disagree over this controversial issue. Patients may do reasonably well for some time with prophylaxis and careful management. However, patients are at high risk lifelong of severe and persistent fungal infections and/or chronic inflammatory complications, leading to consideration of performing HSCT. Due to an increase in reported successes, HSCT is now an established curative approach for CGD; however, the risk-versus-benefit ratio must be carefully assessed on a case-by-case basis. Gene therapy approaches are also being evaluated.

MENDELIAN SUSCEPTIBILITY TO MYCOBACTERIAL DISEASE

This group of diseases is characterized by a defect in the IL-12–interferon (IFN) γ axis (including IL-12p40, IL-12 receptor [R] β_1 and β_2, IFN-γ R_1 and R_2, TYK2, STAT1, IRF8, and ISG515 deficiencies), which ultimately leads to impaired IFN-γ-dependent macrophage activation. Both recessive and dominant inheritance modes have been observed. The hallmark of this PID is a specific and relatively narrow vulnerability to tuberculous and nontuberculous mycobacteria. The most severe phenotype (as observed in complete IFN-γ receptor deficiency) is characterized by disseminated infection that can be fatal even when aggressive and appropriate antimycobacterial therapy is applied. In addition to mycobacterial infections, MSMD patients (and particularly those with an IL-12/IL-12R deficiency) are prone to developing *Salmonella* infections. Although MSMDs are very rare, they should be considered in any patient with persistent mycobacterial infection. Treatment with IFN-γ may efficiently bypass an IL-12/IL-12R deficiency. HSCT is a therapeutic option for the most severe cases.

TOLL-LIKE RECEPTOR (TLR) PATHWAY DEFICIENCIES

In a certain group of patients with early-onset, invasive *Streptococcus pneumoniae* infections or (less frequently) *Staphylococcus aureus* or other pyogenic infections, conventional screening for PIDs does not identify the cause of the defect in host defense. It has been established that these patients carry recessive mutations in genes that encode essential adaptor molecules (IRAK4 and MYD88) involved in the signaling pathways of the majority of known TLRs **(Chap. 360)**. Remarkably, susceptibility to infection appears to decrease after the first few years of life—perhaps an indication that adaptive immunity (once triggered by an initial microbial challenge) is then able to prevent recurrent infections.

Certain TLRs (TLR-3, -7, -8, and -9) are involved in the recognition of RNA and DNA and usually become engaged during viral infections. Very specific susceptibility to herpes simplex encephalitis has

been described in patients with a deficiency in Unc93b (a molecule associated with TLR-3, -7, -8, and -9 required for correct subcellular localization), TLR-3, or associated signaling molecules TRIF, TBK1, and TRAF3, resulting in defective type I IFN production. The fact that no other TLR deficiencies have been found—despite extensive screening of patients with unexplained, recurrent infections—strongly suggests that these receptors are functionally redundant. Hypomorphic mutations in NEMO/IKK-γ (a member of the NF-κB complex, which is activated downstream of TLR receptors) lead to a complex, variable immunodeficiency and a number of associated features. Susceptibility to both invasive, pyogenic infections and mycobacteria may be observed in this particular setting.

Rare cases of predisposition to severe viral infections (influenza, live measles vaccine) have been found in patients with genetic defects in IFN type I receptor and signaling pathways (STAT1, STAT2, KRF9, IRF7, MDA5). TLR7 deficiency has been shown to be a vulnerability factor of severe COVID-19. Autoantibodies to IFN-α or β, as observed in some PIDs (AIRE, NF-κB deficiencies), are also associated with severe COVID-19 disease.

COMPLEMENT DEFICIENCY

The complement system is composed of a complex cascade of plasma proteins (Chap. 360) that leads to the deposition of C3b fragments on the surface of particles and the formation of immune complexes that can culminate in the activation of a lytic complex at the bacterial surface. C3 cleavage can be mediated via three pathways: the classic, alternate, and lectin pathways. C3b coats particles as part of the opsonization process that facilitates phagocytosis following binding to cognate receptors. A deficiency in any component of the classic pathway (C1q, C1r, C1s, C4, and C2) can predispose an individual to bacterial infections that are tissue-invasive or that occur in the respiratory tract. Likewise, a C3 deficiency or a deficiency in factor I (a protein that regulates C3 consumption, thus leading to a C3 deficiency due to its absence) also results in the same type of vulnerability to infection. It has recently been reported that a very rare deficiency in ficolin-3 predisposes affected individuals to bacterial infections. Deficiencies in the alternative pathway (factors D and properdin) are associated with the occurrence of invasive *Neisseria* infections.

Lastly, deficiencies of any complement component involved in the lytic phase (C5, C6, C7, C8, and, to a lesser extent, C9) predispose affected individuals to systemic infection by *Neisseria*. This is explained by the critical role of complement in the lysis of the thick cell wall possessed by this class of bacteria.

Diagnosis of a complement deficiency relies primarily on testing the status of the classic and alternate pathway via functional assays, that is, the CH50 and AP50 tests, respectively. When either pathway is profoundly impaired, determination of the status of the relevant components in that pathway enables a precise diagnosis. Appropriate vaccinations and daily administration of oral penicillin are efficient means of preventing recurrent infections. It is noteworthy that several complement deficiencies (in the classic pathway and the lytic phase) may also predispose affected individuals to autoimmune diseases (notably systemic lupus erythematosus; Chap. 368).

PRIMARY IMMUNODEFICIENCIES OF THE ADAPTIVE IMMUNE SYSTEM

T LYMPHOCYTE DEFICIENCIES (TABLE 362-1, FIGS. 362-2 AND 362-3)

Given the central role of T lymphocytes in adaptive immune responses (Chap. 360), PIDs involving T cells generally have severe pathologic consequences; this explains the poor overall prognosis and the need for early diagnosis and the early intervention with appropriate therapy. Several differentiation pathways of T-cell effectors have been described,

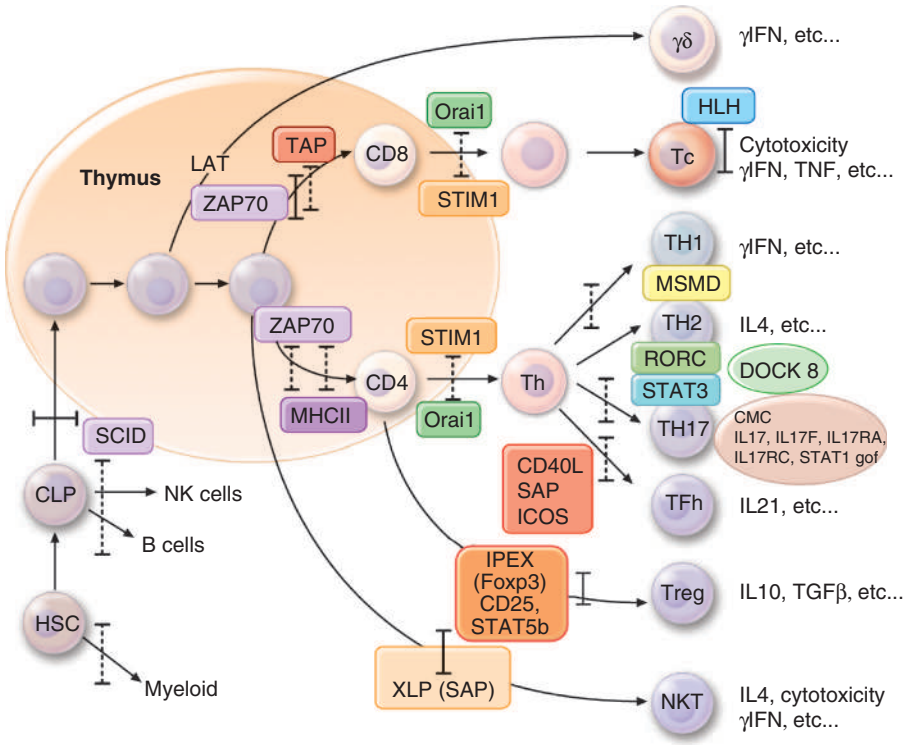

FIGURE 362-2 T-cell differentiation, effector pathways, and related primary immunodeficiencies (PIDs). Hematopoietic stem cells (HSCs) differentiate into common lymphoid progenitors (CLPs), which, in turn, give rise to the T-cell precursors that migrate to the thymus. The development of CD4+ and CD8+ T cells is shown. Known T-cell effector pathways are indicated, that is, γδ cells, cytotoxic T cells (Tc), T_H1, T_H2, T_H17, TFh (follicular helper) CD4 effector T cells, regulatory T cells (Treg), and natural killer T cells (NKTs); abbreviations for PIDs are contained in boxes. Vertical bars indicate a complete deficiency; broken bars a partial deficiency. DOCK8, autosomal recessive form of hyper-IgE syndrome; HLH, hematopoietic lymphohistiocytosis; IL17F, IL17RA, STAT1 (gof: gain of function), CMC (chronic mucocutaneous candidiasis), CD40L, ICOS, SAP deficiencies; IPEX, immunodysregulation polyendocrinopathy enteropathy X-linked syndrome; LAT, linker for activation of T cells; MHCII, major histocompatibility complex class II deficiency; MSMD, Mendelian susceptibility to mycobacterial disease; Orai1, STIM1 deficiencies; RORC, RAR related orphan receptor C; SCID, severe combined immunodeficiency; STAT3, autosomal dominant form of hyper-IgE syndrome; TAP, TAP1 and TAP2 deficiencies; XLP, X-linked proliferative syndromes; ZAP70, zeta-associated protein deficiency.

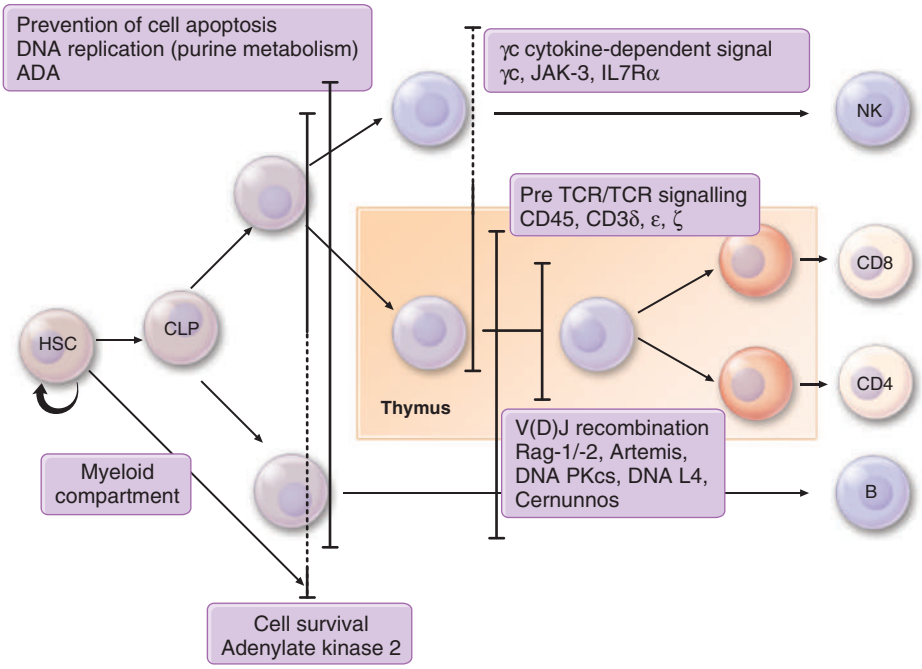

FIGURE 362-3 T-cell differentiation and severe combined immunodeficiencies (SCIDs). The vertical bars indicate the five mechanisms currently known to lead to SCID. The names of deficient proteins are indicated in the boxes adjacent to the vertical bars. A broken line means that deficiency is partial or involves only some of the indicated immunodeficiencies. ADA, adenosine deaminase deficiency; CLPs, common lymphoid progenitors; DNAL4, DNA ligase 4; HSCs, hematopoietic stem cells; NKs, natural killer cells; TCR, T-cell receptor.

one or all of which may be affected by a given PID (Fig. 362-2). Follicular helper CD4+ T cells in germinal centers are required for T-dependent antibody production, including the generation of Ig class-switched, high-affinity antibodies. CD4+ T_H1 cells provide cytokine-dependent (mostly IFN-γ-dependent) help to macrophages for intracellular killing of various microorganisms, including mycobacteria and *Salmonella*. CD4+ T_H2 cells produce IL-4, IL-5, and IL-13 and thus recruit and activate eosinophils and other cells required to fight helminth infections. CD4+ T_H17 cells produce IL-17 and IL-22 cytokines that recruit neutrophils to the skin and lungs to fight bacterial and fungal infections. Cytotoxic CD8+ T cells can kill infected cells, notably in the context of viral infections. In addition, certain T-cell deficiencies predispose affected individuals to *Pneumocystis jirovecii* lung infections early in life and to chronic gut/biliary duct/liver infections by *Cryptosporidium* and related genera later on in life. Lastly, naturally occurring or induced regulatory T cells are essential for controlling inflammation (notably reactivity to commensal bacteria in the gut) and autoimmunity. The role of other T-cell subsets with limited T-cell receptor (TCR) diversity (such as γδTCR T cells or natural killer T [NKT] cells) in PIDs is less well known; however, these subsets can be defective in certain PIDs, and this finding can sometimes contribute to the diagnosis (e.g., NKT-cell deficiency in X-linked proliferative syndrome [XLP]). T-cell deficiencies account for ~20% of all cases of PID.

Severe Combined Immunodeficiencies SCIDs constitute a group of rare PIDs characterized by a profound block in T-cell development and thus the complete absence of these cells. The developmental block is always the consequence of an intrinsic deficiency. The incidence of SCID is estimated to be 1 in 50,000 live births. Given the severity of the T-cell deficiency, clinical consequences occur early in life (usually within 3–6 months of birth). The most frequent clinical manifestations are recurrent oral candidiasis, failure to thrive, and protracted diarrhea and/or acute interstitial pneumonitis caused by *P. jirovecii* (although the latter can also be observed in the first year of life in children with B-cell deficiencies). Severe viral infections or invasive bacterial infections can also occur. Patients may also experience complications related to infections caused by live vaccines (notably Rotavirus causing protracted diarrhea or bacille Calmette-Guérin [BCG]) that may lead not only to local and regional infection but also to disseminated infection manifested by fever, splenomegaly, and skin and lytic bone lesions. A scaly skin eruption can be observed in a context of maternal T-cell engraftment (see below). A diagnosis of SCID can be suspected based on the patient's clinical history and, possibly, a family history of deaths in very young children (suggestive of either X-linked or recessive inheritance). Lymphocytopenia is strongly suggestive of SCID in >90% of cases (Table 362-2). The absence of a thymic shadow on a chest x-ray can also be suggestive of SCID. An accurate diagnosis relies on precise determination of the number of circulating T, B, and NK lymphocytes and their subsets. T-cell lymphopenia may be masked in some patients by the presence of maternal T cells (derived from maternal-fetal blood transfers) that cannot be eliminated. Although counts are usually low (<500/μL of blood), higher maternal T-cell counts may, under some circumstances, initially mask the presence of SCID. Thus, screening for maternal cells by using adequate genetic markers should be performed whenever necessary. Inheritance pattern analysis and lymphocyte phenotyping can discriminate between various forms of SCID and provide guidance in the choice of accurate molecular diagnostic tests (see below). To date, five distinct causative mechanisms for SCID (Fig. 362-3) have been identified. T-cell quantification of receptor excision circles (TREC) by using the Guthrie card is a reliable diagnostic test for newborn screening. It is now operational in the United States and several other countries worldwide. Its more widespread use will lead to the provision of therapy (see below) to uninfected patients resulting in a maximal chance of cure.

SEVERE COMBINED IMMUNODEFICIENCY CAUSED BY A CYTOKINE-SIGNALING DEFICIENCY The most frequent SCID phenotype (accounting for 30–40% of all cases) is the absence of both T and NK cells. This outcome results from a deficiency in either the common γ chain (γc) receptor that is shared by several cytokine receptors (the IL-2, -4, -7, -9, -15, and -21 receptors) or Jak-associated kinase (JAK) 3 that binds to the cytoplasmic portion of the γc chain receptor and induces signal transduction following cytokine binding. The former form of SCID (γc deficiency) has an X-linked inheritance mode, while the second is autosomal recessive. A lack of the IL-7Rα chain (which, together with γc, forms the IL-7 receptor) induces a selective T-cell deficiency.

PURINE METABOLISM DEFICIENCY Ten to 20% of SCID patients exhibit a deficiency in adenosine deaminase (ADA), an enzyme of purine metabolism that deaminates adenosine (ado) and deoxyadenosine (dAdo). An ADA deficiency results in the accumulation of

ado and dAdo metabolites that induce premature cell death of lymphocyte progenitors. The condition results in the absence of B and NK lymphocytes as well as T cells. The clinical expression of complete ADA deficiency typically occurs very early in life. Since ADA is a ubiquitous enzyme, its deficiency can also cause bone dysplasia with abnormal costochondral junctions and metaphyses (found in 50% of cases) and neurologic defects. The very rare purine nucleoside phosphorylase (PNP) deficiency causes a profound although incomplete T-cell deficiency that is often associated with severe neurologic impairments.

DEFECTIVE REARRANGEMENTS OF T- AND B-CELL RECEPTORS A series of SCID conditions are characterized by a selective deficiency in T and B lymphocytes with autosomal recessive inheritance. These conditions account for 20–30% of SCID cases and result from mutations in genes encoding proteins that mediate the recombination of V(D)J gene elements in T- and B-cell antigen receptor genes (required for the generation of diversity in antigen recognition). The main deficiencies involve RAG1, RAG2, DNA-dependent protein kinase, and Artemis. A less severe (albeit variable) immunologic phenotype can result from other deficiencies in the same pathway, that is, DNA ligase 4 and Cernunnos deficiencies. Given that these latter factors are involved in DNA repair, these deficiencies may also cause developmental defects.

DEFECTIVE (PRE-)T-CELL RECEPTOR SIGNALING IN THE THYMUS A selective T-cell defect can be caused by a series of rare deficiencies in molecules involved in signaling via the pre-TCR or the TCR. These include deficiencies in CD3 subunits associated with the (pre-)TCR (i.e., CD3δ, ε, and ζ) and CD45.

RETICULAR DYSGENESIS Reticular dysgenesis is an extremely rare form of SCID that causes T and NK deficiencies with severe neutropenia and sensorineural deafness. It results from an adenylate kinase 2 deficiency. RAC-2 gain of function can cause the same immunologic phenotype.

Patients with SCID require appropriate care with aggressive anti-infective therapies, immunoglobulin replacement, and (when necessary) parenteral nutrition support. In most cases, curative treatment relies on HSCT. Today, HSCT provides a very high curative potential for SCID patients who are otherwise in reasonably good condition. Gene therapy has been found to be successful for cases of X-linked SCID (γc deficiency), SCID caused by an ADA deficiency, and SCID caused by Artemis deficiency. Lastly, a third option for the treatment of ADA deficiency consists of enzyme substitution with a pegylated enzyme.

Thymic Defects A profound T-cell defect can also result from faulty development of the thymus, as is most often observed in rare cases of DiGeorge's syndrome—a relatively common condition leading to a constellation of developmental defects. In ~1% of such cases, the thymus is completely absent, leading to virtually no mature T cells. However, expansion of oligoclonal T cells can occur and is associated with skin lesions. Diagnosis (using immunofluorescence in situ hybridization) is based on the identification of a hemizygous deletion in the long arm of chromosome 22. To recover the capability for T-cell differentiation, these cases require a thymic graft. CHARGE (*c*oloboma of the eye, *h*eart anomaly, choanal *a*tresia, *r*etardation, *g*enital, and *e*ar anomalies) syndrome (CHD7 deficiency) is a less frequent cause of impaired thymus development. Lastly, the very rare "nude" defect is characterized by the absence of both hair and the thymus.

Omenn Syndrome *Omenn syndrome* consists of a subset of T-cell deficiencies that present with a unique phenotype, including early-onset erythroderma, alopecia, hepatosplenomegaly, and failure to thrive. These patients usually display T-cell lymphocytosis, eosinophilia, and low B-cell counts. It has been found that the T cells of these patients exhibit a low TCR heterogeneity. This peculiar syndrome is the consequence of hypomorphic mutations in genes usually associated with SCID, that is, *RAG1*, *RAG2*, or (less frequently) *ARTEMIS* or *IL-7Rα*. The impaired homeostasis of differentiating T cells thus causes this immune system–associated disease. These patients are very fragile, requiring simultaneous anti-infective therapy, nutritional support, and immunosuppression. HSCT provides a curative approach.

Functional T-Cell Defects (Fig. 362-2) A subset of T-cell PIDs with autosomal inheritance is characterized by partially preserved T-cell differentiation but defective activation resulting in abnormal effector function. There are many causes of these defects, but all lead to susceptibility to viral and opportunistic infections, chronic diarrhea, and failure to thrive, with onset during childhood often associated with autoimmune manifestations. Careful phenotyping and in vitro functional assays are required to identify these diseases, the best characterized of which are the following.

ZETA-ASSOCIATED PROTEIN 70 (ZAP70) DEFICIENCY Zeta-associated protein 70 (ZAP70) is recruited to the TCR following antigen recognition. A ZAP70 deficiency leads typically to an almost complete absence of CD8+ T cells; CD4+ T cells are present but cannot be activated in vitro by TCR stimulation.

CALCIUM SIGNALING DEFECTS A small number of patients have been reported who exhibit a profound defect in in vitro T- and B-cell activation as a result of defective antigen receptor-mediated Ca^{2+} influx. This defect is caused by a mutation in the calcium channel gene (*ORAI1*) or its activator (*STIM-1*). It is noteworthy that these patients are also prone to autoimmune manifestations (blood cytopenias) and exhibit a nonprogressive muscle disease.

HUMAN LEUKOCYTE ANTIGEN (HLA) CLASS II DEFICIENCY Defective expression of HLA class II molecules is the hallmark of a group of four recessive genetic defects, all of which affect molecules (RFX5, RFXAP, RFXANK, and CIITA) involved in the transactivation of the genes coding for HLA class II. As a result, low but variable CD4+ T-cell counts are observed in addition to defective antigen-specific T- and B-cell responses. These patients are particularly susceptible to herpesvirus, adenovirus, and enterovirus infections and chronic gut/liver *Cryptosporidium* infections.

HLA CLASS I DEFICIENCY Defective expression of molecules involved in antigen presentation by HLA class I molecules (i.e., TAP-1, TAP-2, and tapasin) leads to reduced CD8+ T-cell counts, loss of HLA class I antigen expression, and a particular phenotype consisting of chronic obstructive pulmonary disease and severe vasculitis.

OTHER DEFECTS A variety of other T-cell PIDs have been described, some of which are associated with a precise molecular defect (e.g., IL-2-inducible T-cell kinase [ITK] deficiency; CD27, CD70, IL-21, and IL-21 receptor deficiencies; CARD11 deficiency; MALT1 deficiency; BCL10 deficiency; DOCK8 deficiency, DOCK2 deficiency; RORC deficiency; RLTPR deficiency, IKAROS deficiency). These conditions are also characterized by profound vulnerability to infections, such as severe Epstein-Barr virus (EBV)–induced B-cell proliferation and autoimmune disorders. Milder phenotypes are associated with CD8 and CD3γ deficiencies. Combined immunodeficiency associated with anhidrotic ectodermic dysplasia is the consequence of defects in the NF-κB signaling pathway (X-linked IKKγ deficiency and gain-of-function IKbα). Other deficiencies of the NF-κB complex component also lead to combined immunodeficiency.

HSCT is indicated for most of these diseases, although the prognosis is worse than in SCID because many patients are chronically infected at the time of diagnosis. Fairly aggressive immunosuppression and myeloablation may be necessary to achieve engraftment of allogeneic stem cells.

T-Cell Primary Immunodeficiencies with DNA Repair Defects This is a group of PIDs characterized by a combination of T- and B-cell defects of variable intensity, together with a number of nonimmunologic features resulting from DNA fragility. The autosomal recessive disorder *ataxia-telangiectasia* (AT) is the most frequently encountered condition in this group. It has an incidence of 1:40,000 live births and causes B-cell defects (low IgA, IgG2 deficiency, and low antibody production), which often require immunoglobulin replacement. AT is associated with a progressive T-cell immunodeficiency. As the name suggests, the hallmark features of AT are telangiectasia and cerebellar ataxia. The latter manifestations may not be detectable before the age of 3–4 years, so that AT should be considered in young

children with IgA deficiency and recurrent and problematic infections. Diagnosis is based on a cytogenetic analysis showing excessive chromosomal rearrangements (mostly affecting chromosomes 7 and 14) in lymphocytes. AT is caused by a mutation in the gene encoding the ATM protein—a kinase that plays an important role in the detection and repair of DNA lesions (or cell death if the lesions are too numerous) by triggering several different pathways. Overall, AT is a progressive disease that carries a very high risk of lymphoma, leukemia, and (during adulthood) carcinomas. A variant of AT ("AT-like disease") is caused by mutation in the *MRE11* gene.

Nijmegen breakage syndrome (NBS) is a less common condition that also results from chromosome instability (with the same cytogenetic abnormalities as in AT). NBS is characterized by a severe T- and B-cell combined immune deficiency with autosomal recessive inheritance. Individuals with NBS exhibit microcephaly and a bird-like face but have neither ataxia nor telangiectasia. The risk of malignancies is very high. NBS results from a deficiency in nibrin (NBSI, a protein associated with MRE11 and Rad50 that is involved in checking DNA lesions) caused by hypomorphic mutations.

Severe forms of *dyskeratosis congenita* (also known as Hoyeraal-Hreidarsson syndrome) combine a progressive immunodeficiency that can also include an absence of B and NK lymphocytes, progressive bone marrow failure, microcephaly, in utero growth retardation, and gastrointestinal disease. The disease can be X-linked or, more rarely, autosomal recessive. It is caused by the mutation of genes encoding telomere maintenance proteins, including dyskerin (DKC1).

Finally, *immunodeficiency with centromeric and facial anomalies* (ICF) is a complex syndrome of autosomal recessive inheritance that variably combines a mild T-cell immune deficiency with a more severe B-cell immune deficiency, coarse face, digestive disease, and mild intellectual disability. A diagnostic feature is the detection by cytogenetic analysis of multiradial aspects in multiple chromosomes (most frequently 1, 9, and 16) corresponding to an abnormal DNA structure secondary to defective DNA methylation. It is the consequence of a deficiency in most cases in the DNA methyltransferase DNMT3B, ZBTB24, CDCA7, or HELLS.

T-Cell Primary Immunodeficiencies with Hyper-IgE Several T-cell PIDs are associated with elevated serum IgE levels (as in Omenn syndrome). A condition sometimes referred to as *autosomal recessive hyper-IgE syndrome* is notably characterized by recurrent bacterial infections in the skin and respiratory tract and severe skin and mucosal infections by pox viruses and human papillomaviruses, together with severe allergic manifestations. T and B lymphocyte counts are low. Mutations in the *DOCK8* gene have been found in many of these patients. This condition is an indication for HSCT.

A very rare, related condition with autosomal recessive inheritance that causes a similar susceptibility to infection with various microbes (see above), including mycobacteria, reportedly results from a deficiency in Tyk-2, a JAK family kinase involved in the signaling of many different cytokine receptors.

Autosomal Dominant Hyper-IgE Syndrome This unique condition, the *autosomal dominant hyper-IgE syndrome*, is usually diagnosed by the combination of recurrent skin and lung infections that can be complicated by pneumatoceles. Infections are caused by pyogenic bacteria and fungi. Several other manifestations characterize hyper-IgE syndrome, including facial dysmorphy, defective loss of primary teeth, hyperextensibility, scoliosis, and osteoporosis. Elevated serum IgE levels are typical of this syndrome. Defective T_H17 effector responses have been shown to account at least in part for the specific patterns of susceptibility to particular microbes. This condition is caused by a heterozygous (dominant) mutation in the gene encoding the transcription factor STAT3 that is required in a number of signaling pathways following binding of cytokine to cytokine receptors (such as that of IL-6 and the IL-6 receptor). It also results in partially defective antibody production because of defective IL-21 receptor signaling. Hence, immunoglobulin substitution can be considered as prophylaxis of bacterial infections.

Most recently, a recessive condition that mimics immunologic aspects of hyper-IgE syndrome has been ascribed to ZNF341 deficiency.

Cartilage Hair Hypoplasia The autosomal recessive *cartilage hair hypoplasia* (CHH) disease is characterized by short-limb dwarfism, metaphyseal dysostosis, and sparse hair, together with a combined T- and B-cell PID of extremely variable intensity (ranging from quasi-SCID to no clinically significant immune defects). The condition can predispose to erythroblastopenia, autoimmunity, and tumors. It is caused by mutations in the *RMRP* gene for a noncoding ribosome-associated RNA. Schimke immuno-osseous dysplasia is another autosomal recessive condition variably associating combined immunodeficiency, bone disease, and more importantly severe nephropathy. Other extremely rare immuno-osseous dysplasias with combined immunodeficiency have been reported, notably the MOPD1 deficiency.

CD40 Ligand and CD40 Deficiencies *Hyper-IgM syndrome* (HIGM) is a well-known PID that was previously classified as a B-cell immune deficiency (see **Fig. 362-4** and below). It results from defective immunoglobulin class switch recombination (CSR) in germinal centers and leads to profound deficiency in production of IgG, IgA, and IgE (although IgM production is maintained). Approximately half of HIGM sufferers are also prone to opportunistic infections, for example, interstitial pneumonitis caused by *P. jirovecii* (in young children), protracted diarrhea and cholangitis caused by *Cryptosporidium*, and infection of the brain with *Toxoplasma gondii*.

In the majority of cases, this condition has an X-linked inheritance and is caused by a deficiency in CD40 ligand (L). CD40L induces signaling events in B cells that are necessary for both CSR and adequate activation of other CD40-expressing cells that are involved in innate immune responses against the above-mentioned microorganisms. More rarely, the condition is caused by a deficiency in CD40 itself. The poorer prognosis of CD40L and CD40 deficiencies (relative to most other HIGM conditions) implies that (1) thorough investigations have to be performed in all cases of HIGM and (2) potentially curative HSCT should be discussed on a case-by-case basis for this group of patients.

Wiskott-Aldrich Syndrome WAS is a complex, recessive, X-linked disease with an incidence of ~1 in 200,000 live births. It is caused by mutations in the *WASP* gene that affect not only T lymphocytes but also the other lymphocyte subsets, dendritic cells, and platelets. WAS is typically characterized by the following clinical manifestations: recurrent bacterial infections, eczema, and bleeding caused by thrombocytopenia. However, these manifestations are highly variable—mostly as a consequence of the many different *WASP* mutations that have been observed. Null mutations predispose affected individuals to invasive and bronchopulmonary infections, viral infections, severe eczema, and autoimmune manifestations. The latter include autoantibody-mediated blood cytopenia, glomerulonephritis, skin and visceral vasculitis (including brain vasculitis), erythema nodosum, and arthritis. Another possible consequence of WAS is lymphoma, which may be virally induced (e.g., by EBV or Kaposi's sarcoma–associated herpesvirus). Thrombocytopenia can be severe and compounded by the peripheral destruction of platelets associated with autoimmune disorders. Hypomorphic mutations usually lead to milder outcomes that are generally limited to thrombocytopenia. It is noteworthy that even patients with "isolated" X-linked thrombocytopenia can develop severe autoimmune disease and/or lymphoma later in life. The immunologic workup is not very informative; there can be a relative CD8+ T-cell deficiency, frequently accompanied by low serum IgM levels and decreased antigen-specific antibody responses. A typical feature is reduced-sized platelets on a blood smear. Diagnosis is based on intracellular immunofluorescence analysis of WAS protein (WASp) expression in blood cells. WASp regulates the actin cytoskeleton and thus plays an important role in many lymphocyte functions, including cell adhesion and migration and the formation of synapses between antigen-presenting and target cells. Predisposition to autoimmune disorders is in part related to defective regulatory T cells. The treatment

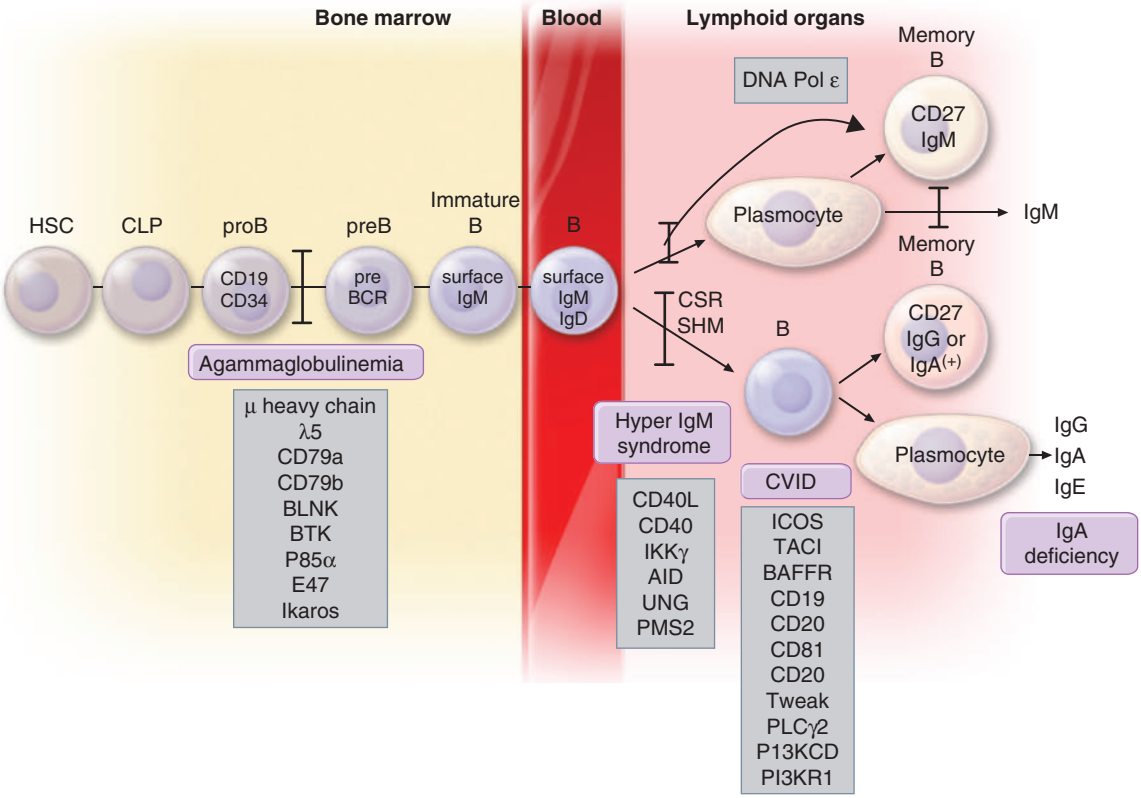

FIGURE 362-4 B-cell differentiation and related primary immunodeficiencies (PIDs). Hematopoietic stem cells (HSCs) differentiate into common lymphoid progenitors (CLPs), which give rise to pre-B cells. The B-cell differentiation pathway goes through the pre–B-cell stage (expression of the μ heavy chain and surrogate light chain), the immature B-cell stage (expression of surface IgM), and the mature B-cell stage (expression of surface IgM and IgD). The main phenotypic characteristics of these cells are indicated. In lymphoid organs, B cells can differentiate into plasma cells and produce IgM or undergo (in germinal centers) Ig class switch recombination (CSR) and somatic mutation of the variable region of V genes (SHM) that enable selection of high-affinity antibodies. These B cells produce antibodies of various isotypes and generate memory B cells. PIDs are indicated in the purple boxes. CVID, common variable immunodeficiency.

of WAS should match the severity of disease expression. Prophylactic antibiotics, immunoglobulin G (IgG) supplementation, and careful topical treatment of eczema are indicated. Although splenectomy improves platelet count in a majority of cases, this intervention is associated with a significant risk of infection and is thus contraindicated (both before and after HSCT). Allogeneic HSCT is curative, with excellent results overall. Gene therapy trials have been performed with success. A similar condition has been reported in a few cases with a deficiency in the Wiskott-Aldrich interacting protein (WIP) with autosomal recessive inheritance.

A few other complex PIDs are worth mentioning. *Sp110 deficiency* causes a T-cell PID with liver venoocclusive disease and hypogammaglobulinemia. *Chronic mucocutaneous candidiasis* (CMC) is a heterogeneous disease, considering the different inheritance patterns that have been observed. In some cases, chronic candidiasis is associated with late-onset bronchopulmonary infections, bronchiectasis, and brain aneurysms. Moderate forms of CMC are related to autoimmunity and AIRE deficiency (see below). In this setting, predisposition to *Candida* infection is associated with the detection of autoantibodies to T_H17 cytokines. Recently, deficiencies in IL-17A, IL-17F, and IL-17 receptor A and C and in the associated protein Act1, and above all, gain-of-function mutations in *STAT1* have been found to be associated with CMC. In all cases, CMC is related to defective T_H17 function. Innate immunodeficiency in CARD9 also predisposes to chronic invasive fungal infection.

B LYMPHOCYTE DEFICIENCIES (TABLE 362-1, FIG. 362-4)

Deficiencies that predominantly affect B lymphocytes are the most frequent PIDs and account for 60–70% of all cases. B lymphocytes make antibodies. Pentameric IgMs are found in the vascular compartment and are also secreted at mucosal surfaces. IgG antibodies diffuse freely into extravascular spaces, whereas IgA antibodies are produced and secreted predominantly from mucosa-associated lymphoid tissues. Although Ig isotypes have distinct effector functions, including Fc receptor–mediated and (indirectly) C_3 receptor–dependent phagocytosis of microorganisms, they share the ability to recognize and neutralize a given pathogen. Defective antibody production therefore allows the establishment of invasive, pyogenic bacterial infections as well as recurrent sinus and pulmonary infections (mostly caused by *S. pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and, less frequently, gram-negative bacteria). If left untreated, recurrent bronchial infections lead to bronchiectasis and, ultimately, cor pulmonale and death. Parasitic infections such as caused by *Giardia lamblia* and bacterial infections caused by *Helicobacter* and *Campylobacter* of the gut are also observed. A complete lack of antibody production (namely agammaglobulinemia) can also predispose affected individuals to severe, chronic, disseminated enteroviral or astrovirus infections causing meningoencephalitis, hepatitis, and a dermatomyositis-like disease. Other enteric viruses can also cause persistent hepatitis.

Even with the most profound of B-cell deficiencies, infections rarely occur before the age of 6 months; this is because of transient protection provided by the transplacental passage of immunoglobulins during the last trimester of pregnancy. Conversely, a genetically nonimmunodeficient child born to a mother with hypogammaglobulinemia is, in the absence of maternal Ig substitution, usually prone to severe bacterial infections in utero and for several months after birth.

Diagnosis of B-cell PIDs relies on the determination of serum Ig levels (Table 362-2). Determination of antibody production following immunization with tetanus toxoid vaccine or nonconjugated pneumococcal polysaccharide antigens can also help diagnose more subtle deficiencies. Another useful test is B-cell phenotype determination in switched μ–δ– CD27+ and nonswitched memory B cells (μ+δ+ CD27+). In agammaglobulinemic patients, examination of bone marrow B-cell precursors (Fig. 362-4) can help obtain a precise diagnosis and guide the choice of genetic tests.

Agammaglobulinemia Agammaglobulinemia is characterized by a profound defect in B-cell development (<1% of the normal B-cell blood count). In most patients, very low residual Ig isotypes can be detected in the serum. In 85% of cases, agammaglobulinemia is caused by a mutation in the *BTK* gene that is located on the X chromosome. The *BTK* gene product is a kinase that participates in (pre) B-cell receptor signaling. When the kinase is defective, there is a block (albeit a leaky one) at the pre-B to B-cell stage (Fig. 362-4). Detection of *BTK* by intracellular immunofluorescence of monocytes, and lack thereof in patients with X-linked agammaglobulinemia (XLA), is a useful diagnostic test. Not all of the mutations in *BTK* result in agammaglobulinemia, since some patients have a milder form of hypogammaglobulinemia and low but detectable B-cell counts. These cases should not be confused with common variable immunodeficiency (CVID; see below). About 10% of agammaglobulinemia cases are caused by alterations in genes encoding elements of the pre-B-cell receptor, i.e., the μ heavy chain, the λ5 surrogate light chain, Igα or Igβ, the scaffold protein BLNK, the p85 α subunit of phosphatidylinositol 3 phosphate kinase (P13K), the E47, and the Ikaros transcription factors. In 5% of cases, the defect is unknown. It is noteworthy that agammaglobulinemia can be observed in patients with ICF syndrome, despite the presence of normal peripheral B-cell counts. Lastly, agammaglobulinemia can be a manifestation of a myelodysplastic syndrome (associated or not with neutropenia). Treatment of agammaglobulinemic patients is based on immunoglobulin replacement (see below). HSCT is considered in special cases. Profound hypogammaglobulinemia is also observed in adults, in association with thymoma.

Hyper-IgM (HIGM) Syndromes *HIGM* is a rare B-cell PID characterized by defective Ig CSR. It results in very low serum levels of IgG and IgA and elevated or normal serum IgM levels. The clinical severity is similar to that seen in agammaglobulinemia, although chronic lung disease and sinusitis are less frequent and enteroviral infections are uncommon. As discussed above, a diagnosis of HIGM involves screening for an X-linked CD40L deficiency and an autosomal recessive CD40 deficiency, which affect both B and T cells. In 50% of cases affecting only B cells, these isolated HIGM syndromes result from mutations in the gene encoding activation-induced deaminase, the protein that induces CSR in B-cell germinal centers. These patients usually have enlarged lymphoid organs. In the other 50% of cases, the etiology is unknown (except for rare UNG and PMS2 deficiencies). Furthermore, IgM-mediated autoimmunity and lymphomas can occur in HIGM syndrome. It is noteworthy that HIGM can result from fetal rubella syndrome or can be a predominant immunologic feature of other PIDs, such as the immunodeficiency associated with ectodermic anhydrotic hypoplasia X-linked NEMO deficiency and the combined T- and B-cell PIDs caused by DNA repair defects such as AT and Cernunnos deficiency.

Common Variable Immunodeficiency CVID is an ill-defined condition characterized by low serum levels of one or more Ig isotypes. Its prevalence is estimated to be 1 in 20,000. The condition is recognized predominantly in adults, although clinical manifestations can occur earlier in life. Hypogammaglobulinemia is associated with at least partially defective antibody production in response to vaccine antigens. B lymphocyte counts are often normal but can be low. Besides infections, CVID patients may develop lymphoproliferation (splenomegaly), granulomatous lesions, colitis, antibody-mediated autoimmune disease, and lymphomas that define disease prognosis. A family history is found in 10% of cases. A clear-cut dominant inheritance pattern is found in some families, whereas recessive inheritance is observed more rarely. In most cases, no molecular cause can be identified. A small number of patients in Germany were found to carry mutations in the *ICOS* gene encoding a T-cell membrane protein that contributes to B-cell activation and survival. In 10% of patients with CVID, monoallelic or biallelic mutations of the gene encoding TACI (a member of the tumor necrosis factor [TNF] receptor family that is expressed on B cells) have been found. In fact, heterozygous TACI mutations correspond to a genetic susceptibility factor, since similar heterozygous mutations are found in 1% of controls. NFkB1 transcription factor mutations have been found in a small fraction of patients with CVID. The B-cell activating factor (BAFF) receptor was found to be defective in a kindred with CVID, although not all individuals carrying the mutation have CVID. A group of patients with hypogammaglobulinemia and lymphoproliferation was shown to exhibit dominant gain-of-function mutations in the *PIK3CD* gene encoding the p110δ form of P13 kinase or in the *PI3KR1* gene encoding the regulatory p85α subunit of PI3 kinase. Rare cases of hypogammaglobulinemia were found to be associated with CD19, CD20, CD21, and CD81 deficiencies. These patients have B cells that can be identified by typing for other B-cell markers.

A diagnosis of CVID should be made after excluding the presence of hypomorphic mutations associated with agammaglobulinemia or more subtle T-cell defects; this is particularly the case in children. It is possible that many cases of CVID result from a constellation of factors, rather than a single genetic defect. Hypogammaglobulinemia can be associated with neutropenia and lymphopenia in the WHIM syndrome caused by a dominant gain-of-function mutation of *CXCR4*, resulting in cell retention in the bone marrow.

Selective Ig Isotype Deficiencies *IgA deficiency* and CVID represent polar ends of a clinical spectrum due to the same underlying gene defect(s) in a large subset of these patients. IgA deficiency is the most common PID; it can be found in 1 in every 600 individuals. It is asymptomatic in most cases; however, individuals may present with increased numbers of acute and chronic respiratory infections that may lead to bronchiectasis. In addition, over their lifetime, these patients experience an increased susceptibility to drug allergies, atopic disorders, and autoimmune diseases. Symptomatic IgA deficiency is probably related to CVID, since it can be found in relatives of patients with CVID. Furthermore, IgA deficiency may progress to CVID. It is thus important to assess serum Ig levels in IgA-deficient patients (especially when infections occur frequently) in order to detect changes that should prompt the initiation of immunoglobulin replacement. Selective IgG2 (+G4) deficiency (which in some cases may be associated with IgA deficiency) can also result in recurrent sinopulmonary infections and should thus be specifically sought in this clinical setting. These conditions are ill-defined and often transient during childhood. A pathophysiologic explanation has not been found.

Selective Antibody Deficiency to Polysaccharide Antigens Some patients with normal serum Ig levels are prone to *S. pneumoniae* and *H. influenzae* infections of the respiratory tract. Defective production of antibodies against polysaccharide antigens (such as those in the *S. pneumoniae* cell wall) can be observed and is probably causative. This condition may correspond to a defect in marginal zone B cells, a B-cell subpopulation involved in T-independent antibody responses.

Immunoglobulin Replacement IgG antibodies have a half-life of 21–28 days. Thus, injection of plasma-derived polyclonal IgG containing a myriad of high-affinity antibodies can provide protection against disease-causing microorganisms in patients with defective IgG antibody production. This form of therapy should not be based on laboratory data alone (i.e., IgG and/or antibody deficiency) but should be guided by the occurrence or not of infections; otherwise, patients might be subjected to unjustified IgG infusions. Immunoglobulin replacement can be performed by IV or subcutaneous routes. In the former case, injections have to be repeated every 3–4 weeks, with a residual target level above 800 mg/mL in patients who had very low IgG levels prior to therapy. Subcutaneous injections are typically performed once a week, although the frequency can be adjusted on a case-by-case basis. New preparations containing hyaluronidase allow reduced frequency of injection by increasing volume injected. A trough level above 800 mg/mL is desirable. Whatever the mode of administration, the main goal is to reduce the frequency of the respiratory tract infections and prevent chronic lung and sinus disease. The two routes appear to be equally safe and efficacious, and so the choice should be left to the preference of the patient.

In patients with chronic lung disease, chest physical therapy with good pulmonary toilet and the use of antibiotics, notably azithromycin,

are also needed. Immunoglobulin replacement is well tolerated by most patients, although the selection of the best-tolerated Ig preparation may be necessary in certain cases. Since IgG preparations contain a small proportion of IgAs, caution should be taken in patients with residual antibody production capacity and a complete IgA deficiency, as these subjects may develop anti-IgA antibodies that can trigger anaphylactic shock. These patients should be treated with IgA-free IgG preparations. Immunoglobulin replacement is a lifelong therapy; its rationale and procedures have to be fully understood and mastered by the patient and their family in order to guarantee the strict observance required for efficacy.

PRIMARY IMMUNODEFICIENCIES AFFECTING REGULATORY PATHWAYS (TABLE 362-1)

An increasing number of PIDs have been found to cause homeostatic dysregulation of the immune system, either alone or in association with increased vulnerability to infections. Defects of this type affecting the innate immune system and autoinflammatory syndromes will not be covered in this chapter. However, three specific entities (hemophagocytic lymphohistiocytosis [HLH], lymphoproliferation, and autoimmunity) will be described below.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

HLH is characterized by an unremitting activation of CD8+ T lymphocytes and macrophages that leads to organ damage (notably in the liver, bone marrow, and central nervous system). This syndrome results from a broad set of inherited diseases, most of which impair T and NK lymphocyte cytotoxicity. The manifestations of HLH are often induced by a viral infection. EBV is the most frequent trigger. In severe forms of HLH, disease onset may start during the first year of life or even (in rare cases) at birth.

Diagnosis relies on the identification of the characteristic symptoms of HLH (fever, hepatosplenomegaly, edema, neurologic diseases, blood cytopenia, increased liver enzymes, hypofibrinogenemia, high triglyceride [hyperferritinemia] levels, elevated markers of T-cell activation, and hemophagocytic features in the bone marrow or cerebrospinal fluid). Functional assays of postactivation cytotoxic granule exocytosis (CD107 fluorescence at the cell membrane) can suggest genetically determined HLH. The conditions can be classified into three subsets:

1. Familial HLH with autosomal recessive inheritance, including perforin deficiency (30% of cases) that can be recognized by assessing intracellular perforin expression; Munc13-4 deficiency (30% of cases); syntaxin 11 deficiency (10% of cases); Munc18-2 deficiency (20% of cases); rare deficiencies in FAAP24 and RHOG; and a few residual cases that lack a known molecular defect.
2. HLH with partial albinism. Three conditions combine HLH and abnormal pigmentation, where hair examination can help in the diagnosis: Chédiak-Higashi syndrome, Griscelli syndrome, and Hermansky-Pudlak syndrome type II. Chédiak-Higashi syndrome is also characterized by the presence of giant lysosomes within leukocytes **(Chap. 67)**, in addition to a primary neurologic disorder with slow progression of symptoms over time.
3. XLP is characterized in most patients by the induction of HLH following EBV infection, while other patients develop progressive hypogammaglobulinemia similar to what is observed in CVID and/or certain lymphomas. XLP is caused by a mutation in the *SH2DIA* gene that encodes the adaptor protein SAP (associated with a SLAM family receptor). Several immunologic abnormalities have been described, including low 2B4-mediated NK cell cytotoxicity, impaired differentiation of NKT cells, defective antigen-induced T-cell death, and defective T-cell helper activity for B cells. A related disorder (XLP2) has recently been described. It is also X-linked and induces HLH (frequently after EBV infection), although the clinical manifestation may be less pronounced. The condition is associated with a deficiency of the antiapoptotic molecule XIAP. The pathophysiology of XLP2 remains unclear; however, it may be related to control of inflammation in macrophages as there is a functional link between XIAP and NLRC4, an inflammasome component, in which gain of function can also induce HLH. XLP2 is also frequently associated with colitis.

HLH is a life-threatening complication. The treatment of this condition requires aggressive immunosuppression with either the cytotoxic agent etoposide or anti–T-cell antibodies; specific therapy targeting the IFN-γ pathway (JAK1), which is critical in causing HLH, is an additional option to consider. Once remission has been achieved, HSCT should be performed, since it provides the only curative form of therapy. Of note, acquired forms of HLH are more commonly observed in adults as a complication of infection, malignancies, or autoimmune diseases or sometimes on its own.

AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME

Autoimmune lymphoproliferative syndrome (ALPS) is characterized by nonmalignant T and B lymphoproliferation causing splenomegaly and enlarged lymph nodes; 70% of patients also display autoimmune manifestations such as autoimmune cytopenias, Guillain-Barré syndrome, uveitis, and hepatitis **(Chaps. 70 and 360)**. A hallmark of ALPS is the presence of CD4–CD8– TCRαβ+ T cells (2–50%) in the blood of affected individuals. Hypergammaglobulinemia involving IgG and IgA is also frequently observed. The syndrome is caused by a defect in Fas-mediated apoptosis of lymphocytes, which can thus accumulate and mediate autoimmunity. Furthermore, ALPS can lead to malignancies.

Most patients carry a heterozygous mutation in the gene encoding Fas that is characterized by dominant inheritance and variable penetrance, depending on the nature of the mutation. A rare and severe form of the disease with early onset can be observed in patients carrying a biallelic mutation of Fas, which profoundly impairs the protein's expression and/or function. Fas-ligand, caspase 10, caspase 8, and somatic neuroblastoma RAS viral oncogene homologue (NRAS) and KRAS mutations have also been reported in a few cases of ALPS. Many cases of ALPS have not been precisely delineated at the molecular level. A B cell–predominant ALPS has recently been found associated with a protein kinase Cδ gene mutation. Treatment of ALPS is essentially based on the use of proapoptotic drugs, which need to be carefully administered in order to avoid toxicity.

COLITIS, AUTOIMMUNITY, AND PRIMARY IMMUNODEFICIENCIES

Several PIDs (most of which are T cell–related) can cause severe gut inflammation. The prototypic example is *immunodysregulation polyendocrinopathy enteropathy X-linked syndrome* (IPEX), characterized by a widespread inflammatory enteropathy, food intolerance, skin rashes, autoimmune cytopenias, and diabetes. The syndrome is caused by loss-of-function mutations in the gene encoding the transcription factor FOXP3, which is required for the acquisition of effector function by regulatory T cells. In most cases of IPEX, CD4+CD25+ regulatory T cells are absent from the blood. This condition has a poor prognosis and requires aggressive immunosuppression. The only possible curative approach is allogeneic HSCT. IPEX-like syndromes that lack a *FOXP3* mutation have also been described. In some cases, CD25 (IL-2 receptor α subunit) and CD122 (IL-2 receptor β subunit) deficiencies have been found. Defective IL-2 receptor expression also impairs regulatory cell expansion/function. This functional T-cell deficiency means that IL-2 receptor–deficient patients are also at increased risk of opportunistic infections. It is noteworthy that abnormalities in regulatory T cells have been described in other PID settings, such as in Omenn syndrome, STAT5b deficiency, STIM1 (Ca flux) deficiency, and WAS; these abnormalities may account (at least in part) for the occurrence of inflammation and autoimmunity. The autoimmune features observed in a small fraction of patients with DiGeorge's syndrome may have the same cause. Severe, early-onset inflammatory gut disease has been described in patients with a deficiency in the IL-10 receptor or IL-10.

Dominant mutations in genes encoding the regulatory molecule CTLA-4, recessive mutations in the gene encoding LRBA (a molecule involved in recycling of CTLA-4), as well as dominant gain-of-function

mutation of STAT3 cause a multifaceted lymphoproliferative and autoimmune syndrome, frequently involving inflammatory bowel disease that can be associated with hypogammaglobulinemia. Molecular diagnosis is required before adapted targeted therapies are undertaken. Gain-of-function mutation of *IK2F1* (Ikaros) or BACH2 deficiency can also cause colitis with multiple autoimmune features.

A distinct autoimmune entity is observed in *autoimmune polyendocrinopathy candidiasis ectodermal dysplasia* (APECED) syndrome, which is characterized by autosomal recessive inheritance. It consists of multiple autoimmune manifestations that can affect solid organs in general and endocrine glands in particular. Mild, chronic *Candida* infection is often associated with this syndrome. The condition is due to mutations in the autoimmune regulator (*AIRE*) gene and results in impaired thymic expression of self-antigens by medullary epithelial cells and impaired negative selection of self-reactive T cells that leads to autoimmune manifestations.

A combination of hypogammaglobulinemia, autoantibody production, cold-induced urticaria or skin granulomas, or autoinflammation has been reported and has been termed *PLCγ2-associated antibody deficiency and immune dysregulation* (PLAID or APLAID).

CONCLUSION

The variety and complexity of the clinical manifestations of the many different PIDs strongly indicate that it is important to raise awareness of these diseases. Indeed, early diagnosis is essential for establishing an appropriate therapeutic regimen. Hence, patients with suspected PIDs must always be referred to experienced clinical centers that are able to perform appropriate molecular and genetic tests. A precise molecular diagnosis is not only necessary for initiating the most suitable treatment but also important for genetic counseling and prenatal diagnosis.

One pitfall that may hamper diagnosis is the high variability that is associated with many PIDs. Variable disease expression can result from the differing consequences of various mutations associated with a given condition, as exemplified by WAS and, to a lesser extent, XLA or CTLA4 deficiency. There can also be effects of modifier genes (as also suspected in XLA) and environmental factors such as EBV infection that can be the main trigger of disease in XLP conditions. Furthermore, it has recently been established that somatic mutations in an affected gene can attenuate the phenotype of a number of T-cell PIDs. This has been described for ADA deficiency, X-linked SCID, RAG deficiencies, NF-κB essential modulator (NEMO) deficiency, and, most frequently, WAS. In contrast, somatic mutations can create disease states analogous to PID, as reported for ALPS. The VEXAS syndrome characterized by late-onset inflammation, severe and treatment-resistant vasculitis, and cytopenias is caused by somatic mutation in the X-linked gene *UBA-1*. Lastly, cytokine-neutralizing autoantibodies can mimic a PID, as shown for IFN-γ, IL-6, IL-7, and type I interferon.

Many aspects of the pathophysiology of PIDs are still unknown, and the disease-causing gene mutations have not been identified in all cases (as illustrated by CVID and IgA deficiency). However, our medical understanding of PIDs has now reached the stage where scientifically based approaches to the diagnosis and treatment of these diseases can be implemented. A genetic diagnosis has become a milestone step in the care of PID patients.

Section 2 Disorders of Immune-Mediated Injury

363 Urticaria, Angioedema, and Allergic Rhinitis

Dinah Foer, Joshua A. Boyce

INTRODUCTION

The term *atopy* implies a tendency to manifest asthma, rhinitis, urticaria, food allergy, and atopic dermatitis alone or in combination, in association with the presence of allergen-specific IgE. However, individuals without an atopic background may also develop hypersensitivity reactions, particularly urticaria and anaphylaxis, associated with the presence of allergen-specific IgE. Since mast cells are key effector cells in allergic rhinitis and asthma, and the dominant effector in urticaria, anaphylaxis, and systemic mastocytosis, mast cell development, activation, product profile, and target tissues will be considered in the introduction to these clinical disorders. Dysregulation of mast cell development seen in mastocytosis will be covered in a separate chapter.

The binding of IgE to human mast cells and basophils, a process termed *sensitization*, prepares these cells for subsequent antigen-specific activation. The high-affinity Fc receptor for IgE, designated FcεRI, is composed of one α, one β, and two disulfide-linked γ chains, which together cross the plasma membrane seven times. The α chain is responsible for IgE binding, and the β and γ chains provide for signal transduction that follows the aggregation of the sensitized tetrameric receptors by polymeric antigen. The binding of IgE stabilizes the α chain at the plasma membrane, thus increasing the density of FcεRI receptors at the cell surface while sensitizing the cell for effector responses. This accounts for the correlation between serum IgE levels and the numbers of FcεRI receptors detected on circulating basophils. Signal transduction is initiated through the action of a Src family–related tyrosine kinase termed Lyn that is constitutively associated with the β chain. Lyn transphosphorylates the canonical immunoreceptor tyrosine-based activation motifs (ITAMs) of the β and γ chains of the receptor, resulting in recruitment of more active Lyn to the β chain and of Syk tyrosine kinase. The phosphorylated tyrosines in the ITAMs function as binding sites for the tandem *src* homology two (SH2) domains within Syk. Syk activates not only phospholipase Cγ, which associates with the linker of activated T cells at the plasma membrane, but also phosphatidylinositol 3-kinase to provide phosphatidylinositol-3,4,5-trisphosphate, which allows membrane targeting of the Tec family kinase Btk and its activation by Lyn. In addition, the Src family tyrosine kinase Fyn becomes activated after aggregation of IgE receptors and phosphorylates the adapter protein Gab2 that enhances activation of phosphatidylinositol 3-kinase. Indeed, this additional input is essential for mast cell activation, but it can be partially inhibited by

Lyn, indicating that the extent of mast cell activation is in part regulated by the interplay between these Src family kinases. Activated phospholipase Cγ cleaves phospholipid membrane substrates to provide inositol-1,4,5-trisphosphate (IP_3) and 1,2-diacylglycerols (1,2-DAGs) to mobilize intracellular calcium and activate protein kinase C, respectively. The subsequent opening of calcium-regulated activated channels provides the sustained elevations of intracellular calcium required to recruit the mitogen-activated protein kinases ERK, JNK, and p38 (serine/threonine kinases), which phosphorylate substrates that permit arachidonic acid release and to mediate nuclear translocation of transcription factors for various cytokines. The calcium ion–dependent activation of phospholipases cleaves membrane phospholipids to generate lysophospholipids, which, like 1,2-DAG, may facilitate the fusion of the secretory granule perigranular membrane with the cell membrane, a step that releases the membrane-free granules containing the preformed mast cell mediators.

The secretory granule of the human mast cell has a crystalline structure. IgE-dependent cell activation results in solubilization and swelling of the granule contents within the first minute of receptor perturbation; this reaction is followed by the ordering of intermediate filaments about the swollen granule, movement of the granule toward the cell surface, and fusion of the perigranular membrane with that of other granules and with the plasmalemma to form extracellular channels for mediator release while maintaining cell viability.

In addition to exocytosis, aggregation of FcεRI initiates three additional pathways for generation of bioactive products, namely, lipid mediators, chemokines, and cytokines. Cytokines elaborated by mast cells include tumor necrosis factor α (TNF-α), interleukin (IL) 1, IL-6, IL-4, IL-5, IL-13, and granulocyte-macrophage colony-stimulating factor (GM-CSF). Chemokines include CCL3, CCL4, CCL8, and CXCL8. These products likely contribute to the recruitment of bloodborne leukocytes to the tissues following local activation of mast cells.

Lipid mediator generation **(Fig. 363-1)** involves translocation of calcium ion–dependent cytosolic phospholipase A_2 to the outer nuclear membrane, with subsequent release of arachidonic acid for metabolic processing by the distinct prostanoid and leukotriene pathways. The constitutive prostaglandin endoperoxide synthase-1 (PGHS-1/cyclooxygenase-1) and the de novo inducible PGHS-2 (cyclooxygenase-2) convert released arachidonic acid to the sequential intermediates, prostaglandins G_2 and H_2. The glutathione-dependent hematopoietic prostaglandin D_2 (PGD_2) synthase then converts PGH_2 to PGD_2, the predominant mast cell prostanoid. The PGD_2 receptor DP_1 is expressed by platelets, natural killer cells, dendritic cells, and epithelial cells, whereas DP_2 is expressed by T_H2 lymphocytes, innate lymphoid type 2 cells, eosinophils, and basophils. DP_2 signaling can promote tissue recruitment and activation of these effector cells. Mast cells also generate thromboxane A_2 (TXA_2), a short lived but powerful mediator that induces bronchoconstriction and platelet activation through the T prostanoid (TP) receptor.

For leukotriene biosynthesis, the released arachidonic acid is metabolized by 5-lipoxygenase (5-LO) in the presence of an integral nuclear membrane protein, 5-LO activating protein (FLAP). The calcium ion–dependent translocation of 5-LO to the nuclear membrane converts the arachidonic acid to the sequential intermediates, 5-hydroperoxyeicosatetraenoic acid (5-HPETE) and leukotriene (LT) A_4. LTA_4 is conjugated with reduced glutathione by LTC_4 synthase, an integral nuclear membrane protein homologous to FLAP. Intracellular LTC_4 is released by a carrier-specific export step for extracellular metabolism to the additional cysteinyl leukotrienes, LTD_4 and LTE_4, by the sequential removal of glutamic acid and glycine. Alternatively, cytosolic LTA_4 hydrolase converts some LTA_4 to the dihydroxy leukotriene LTB_4, which also undergoes specific export. Two receptors for LTB_4, BLT_1 and BLT_2, mediate chemotaxis of human neutrophils. Two receptors for the cysteinyl leukotrienes, $CysLT_1$ and $CysLT_2$, are present on smooth muscle of the airways and the microvasculature and on hematopoietic cells such as macrophages, eosinophils, Th2 cells, group 2 innate lymphoid cells, and mast cells. Whereas the $CysLT_1$ receptor has a preference for LTD_4 and is blocked by the receptor antagonists in clinical use, the $CysLT_2$ receptor is equally responsive to LTD_4 and LTC_4, is unaffected by these antagonists, and is a negative regulator of the function of the $CysLT_1$ receptor. LTD_4, acting at $CysLT_1$ receptors, is the most potent known bronchoconstrictor, whereas LTE_4 induces a vascular leak and mediates the recruitment of eosinophils to the bronchial mucosa, as well as the expansion of mucosal tuft/brush cells. Additionally, GPR99, initially identified as a receptor for α-ketoglutarate, was identified as an LTE_4 receptor. The lysophospholipid formed during the release of arachidonic acid from 1-*O*-alkyl-2-acyl-*sn*-glyceryl-3-phosphorylcholine can be acetylated in the second position to form platelet-activating factor (PAF). Serum levels of PAF correlated positively with the severity of anaphylaxis to peanut in a recent study, whereas the levels of PAF acetyl hydrolase (a PAF-degrading enzyme) were inversely related to the same outcome.

Human mast cells express receptors for anaphylatoxin, C5a and C3a, toll-like receptors, receptors for epithelial alarmins thymic stromal lymphopoietin (TSLP) and IL-33, and Mas-related G protein–coupled receptor (MRGPX2), all which activate mast cells in an IgE-dependent manner. MRGPX2 is a target of many small-molecule drugs with a central tetrahydroisoquinoline motif, such as ciprofloxacin and rocuronium, which may explain the observed episodes of anaphylaxis to these medications without evidence of IgE-mediated hypersensitivity. It is also activated by neuropeptides and may participate in neural circuits that activate mast cells.

Unlike most other cells of bone marrow origin, mast cells circulate as committed progenitors lacking their characteristic secretory granules. These committed progenitors lack lineage markers and express c-*kit*, the receptor for stem cell factor (SCF), as well as FcεRI and the β_7 integrin. Unlike most other lineages, they retain and increase c-*kit* expression with maturation. The SCF interaction with c-*kit* is an absolute requirement for the development of both constitutive connective tissue and skin mast cells and for the accumulation of mast cells at mucosal surfaces during T_H2-type immune responses. Several T cell–derived cytokines (IL-3, IL-4, IL-5, and IL-9) can potentiate SCF-dependent mast cell proliferation and/or survival in vitro in mice and humans. Indeed, mast cells are absent from the intestinal mucosa in clinical T-cell deficiencies but are present in the submucosa. Historical mast cell classification has been based on the immunodetection of secretory

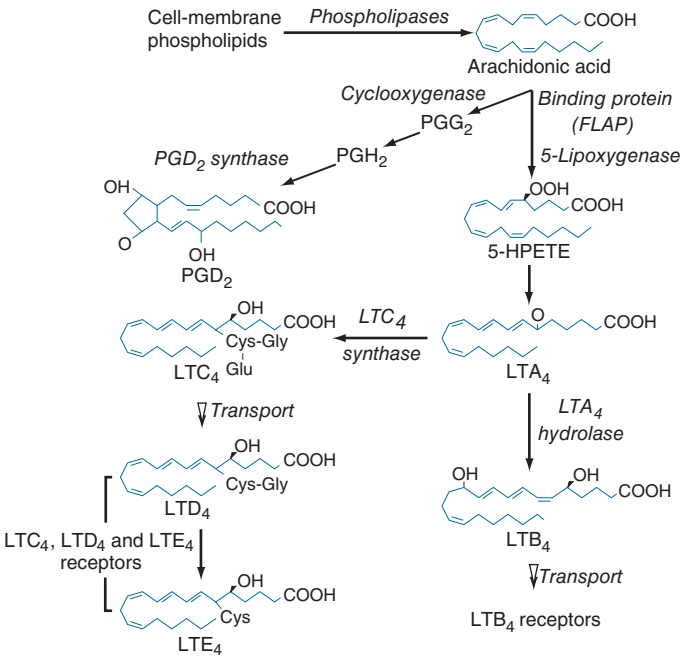

FIGURE 363-1 Pathways for biosynthesis and release of membrane-derived lipid mediators from mast cells. In the 5-lipoxygenase pathway, leukotriene A_4 (LTA_4) is the intermediate from which the terminal-pathway enzymes generate the distinct final products, leukotriene C_4 (LTC_4) and leukotriene B_4 (LTB_4), which leave the cell by separate saturable transport systems. Gamma glutamyl transpeptidase and a dipeptidase then cleave glutamic acid and glycine from LTC_4 to form LTD_4 and LTE_4, respectively. The major mast cell product of the cyclooxygenase system is PGD_2.

granule neutral proteases. Mast cells in the lung parenchyma and intestinal mucosa selectively express tryptase, and those in the intestinal and airway submucosa, perivascular spaces, skin, lymph nodes, and breast parenchyma express tryptase, chymase, and carboxypeptidase A (CPA). Selective environmental cues, such as T_H2 inflammation, can lead to different protease expression; in the mucosal epithelium of severe asthmatics and apical epithelium of nasal polyps, mast cells can express tryptase and CPA without chymase. The secretory granules of mast cells selectively positive for tryptase exhibit closed scrolls with a periodicity suggestive of a crystalline structure by electron microscopy, whereas the secretory granules of mast cells with multiple proteases are scroll-poor, with an amorphous or lattice-like appearance. In addition to immunodetection of proteases, expression profiling through single-cell RNA sequencing methods has further elucidated different mast cell populations, indicating that mast cells are far more functionally heterogeneous than previously thought.

Mast cells are distributed at cutaneous and mucosal surfaces and in submucosal tissues about venules and could influence the entry of foreign substances by their rapid response capability **(Fig. 363-2)**. Upon stimulus-specific activation and secretory granule exocytosis, histamine and acid hydrolases are solubilized, whereas the neutral proteases, which are cationic, remain largely bound to the anionic proteoglycans, heparin and chondroitin sulfate E, with which they function as a complex. Histamine and the various lipid mediators (PGD_2, $LTC_4/D_4/E_4$, PAF) alter venular permeability, thereby allowing influx of plasma proteins such as complement and immunoglobulins, whereas LTB_4 and PGD_2 mediate leukocyte–endothelial cell adhesion and subsequent directed migration (chemotaxis). The accumulation of leukocytes and plasma opsonins facilitates defense of the microenvironment. The inflammatory response can also be detrimental, as in asthma, where the smooth-muscle constrictor activity of the cysteinyl leukotrienes is evident and much more potent than that of histamine.

The cellular component of the mast cell–mediated inflammatory response is augmented and sustained by cytokines and chemokines. IgE-dependent activation of human skin mast cells in situ elicits TNF-α production and release, which in turn induces endothelial cell responses favoring leukocyte adhesion. Similarly, activation of purified human lung mast cells or cord blood–derived cultured mast cells in vitro results in substantial production of proinflammatory (TNF-α) and immunomodulatory cytokines (IL-4, IL-5, IL-13) and chemokines. Bronchial biopsy specimens from patients with asthma reveal that mast cells are immunohistochemically positive for IL-4 and IL-5, but that the predominant localization of IL-4, IL-5, and GM-CSF is to T cells, defined as T_H2 by this profile. IL-4 modulates the T-cell phenotype to the T_H2 subtype, determines the isotype switch to IgE (as does IL-13), and upregulates FcεRI-mediated expression of cytokines by mast cells based on in vitro studies.

An immediate and late cellular phase of allergic inflammation can be induced in the skin, nose, or lung of some allergic humans with local allergen challenge. The immediate phase in the nose involves pruritus and watery discharge; in the lung, it involves bronchospasm and mucus secretion; and in the skin, it involves a wheal-and-flare response with pruritus. Diminished nasal patency, reduced pulmonary function, or erythema with swelling at the skin site in a late-phase response at 6–8 h is associated with biopsy findings of infiltrating and activated T_H2 cells, eosinophils, basophils, and some neutrophils. The progression from early mast cell activation to late cellular infiltration has been used as an experimental surrogate of rhinitis or asthma in allergen-challenged subjects. However, in asthma, there is an intrinsic hyperreactivity of the airways independent of the associated inflammation. Moreover, early- and late-phase responses (at least in the lung) are far more sensitive to blockade of IgE-dependent mast cell activation (or actions of histamine and cysteinyl leukotrienes) than are spontaneous or virally induced asthma exacerbations.

Consideration of the mechanism of immediate-type hypersensitivity diseases in the human has focused largely on the IgE-dependent recognition of otherwise innocuous substances. A region of chromosome 5 (5q23-31) contains genes implicated in the control of IgE levels including IL-4 and IL-13, as well as IL-3 and IL-9, which participate in mucosal mast cell hyperplasia, and IL-5 and GM-CSF, which are central to eosinophil development and their enhanced tissue viability. Genes with linkage to the specific IgE response to particular allergens include those encoding the major histocompatibility complex (MHC) and certain chains of the T-cell receptor (TCR). The complexity of atopy and the associated diseases includes susceptibility, severity, and therapeutic responses, each of which is modulated by both innate and adaptive immune stimuli.

The induction of allergic disease requires sensitization of a predisposed individual to a specific allergen. The greatest propensity for the development of atopic allergy occurs in childhood and early adolescence. The allergen is processed by antigen-presenting cells of the monocytic lineage (particularly dendritic cells) located throughout the body at epithelial surfaces that contact the outside environment, such as the nose, lungs, eyes, skin, and intestine. These antigen-presenting cells present the epitope-bearing peptides via their MHC to T helper cells and their subsets. The T-cell response depends both on cognate recognition and on the cytokine microenvironment provided by the antigen-presenting dendritic cells, with IL-4 directing a T_H2 subset, interferon (IFN) γ a T_H1 profile, and IL-6 with transforming growth factor β (TGF-β) a T_H17 subset. Allergens can induce an epithelial

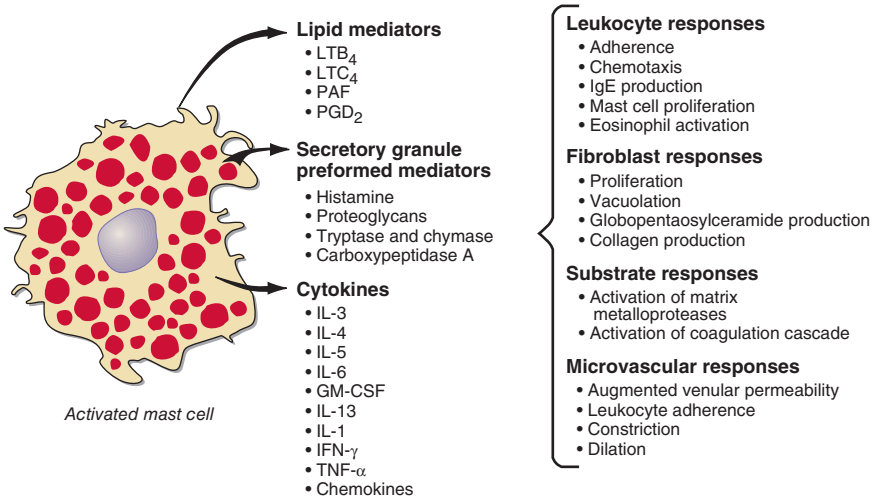

FIGURE 363-2 Bioactive mediators of three categories generated by IgE-dependent activation of murine mast cells can elicit common but sequential target cell effects leading to acute and sustained inflammatory responses. GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; IFN, interferon; LT, leukotriene; PAF, platelet-activating factor; PGD_2, prostaglandin D_2; TNF, tumor necrosis factor.

alarmin response, with expression of IL-25, TSLP, and IL-33, which stimulate group 2 innate lymphoid cells, which can generate large quantities of IL-5 and IL-13. Allergens also contain pattern recognition ligands that facilitate the immune response by direct initiation of cytokine generation from innate cell types such as basophils, mast cells, eosinophils, and others. The T_H2 response is associated with activation of specific B cells that can also present allergens or that transform into plasma cells for antibody production. Synthesis and release into the plasma of allergen-specific IgE results in sensitization of FcεR1-bearing cells such as mast cells and basophils, which become activated on exposure to the specific allergen. In certain diseases, including those associated with atopy, the monocyte and eosinophil populations can express a trimeric FcεR1, which lacks the β chain, and yet respond to its aggregation.

URTICARIA AND ANGIOEDEMA

DEFINITION

Urticaria and angioedema represent similar pathophysiologic processes occurring at different levels of the skin. Urticaria involves dilation of vascular structures in the superficial dermis, while angioedema originates from the deeper dermis and subcutaneous tissues. Not surprisingly, they often appear together, with roughly 40% of patients reporting both, and affect >20% of the population at some time during their life span. Urticaria can occur on any area of the body as well-circumscribed wheals with erythematous raised serpiginous borders and blanched centers that may coalesce to become giant wheals. Urticarial lesions last for <24 h, are intensely pruritic, frequently migrate around the body, and leave no bruising or scarring. Angioedema is marked by dramatic swelling with more pain than pruritus and minimal erythema, which may develop with a pruritic prodrome and takes hours to days to resolve. Acute urticaria and/or angioedema are episodes that occur for <6 weeks' duration, whereas attacks persisting for >6 weeks are designated chronic.

PREDISPOSING FACTORS AND ETIOLOGY

Acute or chronic urticaria and/or angioedema can occur at any point in the life span, with the third to fifth decades the most common for chronic disease. Women are affected more often than men, with a slight predominance for those with a history of atopy. Acute urticaria is most often the result of exposure to a food, environmental, or drug allergen or viral infection, while chronic urticaria is often spontaneous, without an identifiable cause. More than two-thirds of new-onset urticaria cases are ultimately diagnosed as acute.

The classification of urticaria and angioedema, presented in **Table 363-1**, focuses on the different precipitating factors eliciting clinical disease and can be useful for differential diagnosis.

Additional urticaria syndromes include inducible urticarias from physical stimuli such as cold, heat, solar UV radiation, exercise, and mechanical irritation. These urticarias can be distinguished by the precipitating event and other aspects of the clinical presentation. *Dermatographism*, which occurs in 2–5% of the population, is defined by the appearance of a linear wheal with surrounding erythema at the site of a brisk stroke with a firm object **(Fig. 363-3)**. Dermatographism has a prevalence that peaks in the second to third decades, is not influenced by atopy, and has a duration generally of <5 years. *Pressure urticaria*, which often accompanies chronic spontaneous urticaria, presents in response to a sustained stimulus such as a shoulder strap or belt, running (feet), or manual labor (hands). *Cholinergic urticaria* is distinctive in that the pruritic wheals are small (1–2 mm) and surrounded by a large area of erythema; attacks are precipitated by fever, a hot bath or shower, or exercise and are presumptively attributed to a rise in core body temperature. *Exercise-induced anaphylaxis* can be precipitated by exertion alone or can be dependent on food ingestion prior to exercise. Some cases are associated with the presence of IgE specific for α-5 gliadin, a component of wheat. The clinical presentation can be limited to flushing, erythema, and pruritic urticaria but may progress to angioedema of the face, oropharynx, larynx, or intestine and/or to vascular collapse; the wheals are of conventional size and are not induced with passive heating. *Solar urticaria* is subdivided into six groups by the response to specific portions of the light spectrum. *Cold urticaria* is local at body areas exposed to low ambient temperature or cold objects but can progress to vascular collapse with immersion in cold water (swimming). *Vibratory urticaria and angioedema* may occur after years of occupational exposure or can be idiopathic; it may be accompanied by cholinergic urticaria. In rare cases, variants of cold and vibratory urticaria are inherited and syndromic conditions, with mutations in the NLRP3 component of inflammasome leading to familial cold autoinflammatory syndrome, and mutations in the mast cell mechanoreceptor ADGRE2 associated with familial vibratory urticaria. Other rare forms of physical allergy, always defined by stimulus-specific elicitation, include *local heat urticaria*, *aquagenic urticaria* from contact with water of any temperature (sometimes associated with polycythemia vera), and *contact urticaria* from direct interaction with chemical or protein sensitizer (such as latex).

TABLE 363-1 Classification of Urticaria and/or Angioedema

ACUTE	CHRONIC
Drug reactions	Spontaneous/idiopathic—no identifiable trigger
Including (but not limited to): antimicrobials, nonsteroidal anti-inflammatory drugs (NSAIDs), radiocontrast media, opioids, angiotensin-converting enzyme (ACE) inhibitors, dipeptidyl peptidase-4 inhibitors	Autoimmune—autoimmune component
Vaccine reactions	Physical stimuli (inducible urticaria)
Food reactions	Dermatographism
Inhalation or contact with environmental allergens	Cholinergic urticaria
Transfusion reactions	Vibration, cold, pressure, water (aquagenic)
Stinging and biting insects	Sun (solar)
Toxin (scombroid)	Vascular disease—urticarial vasculitis and small vessel vasculitis
Infections—viral, bacterial, parasitic	Mastocytosis (cutaneous or systemic)
	Hereditary
	Hereditary angioedema (HAE)
	C3b inhibitor deficiency
	CIAS1-associated periodic fever syndromes
	(familial cold urticaria, Muckle-Wells syndrome)
	Hypereosinophilic syndrome
	Schnitzler's syndrome
	Gleich's syndrome

Isolated Angioedema Angioedema without urticaria can be idiopathic or due to the generation of bradykinin in the setting of C1 inhibitor (C1INH) deficiency that may be inborn as an autosomal dominant mutation or acquired through the appearance of an autoantibody in the setting of malignancy or autoimmune disease. Angiotensin-converting enzyme (ACE) inhibitors can provoke a similar clinical presentation in 0.2–0.7% of exposed patients due to delayed degradation of bradykinin. Black race, organ transplant, female gender, smoking, and increasing age are known risk factors for ACE inhibitor–related angioedema.

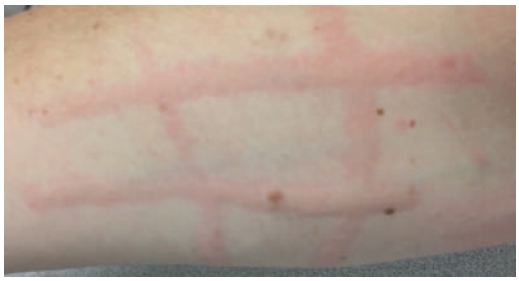

FIGURE 363-3 Dermatographic urticarial lesion induced by stroking the forearm lightly with the edge of a tongue blade. The photograph, taken after 10 min, demonstrates a prominent wheal-and-flare reaction in the shape of a *hashtag*. *(Photograph provided by Katherine N. Cahill, MD, Harvard Medical School.)*

CLINICAL PRESENTATION AND PATHOPHYSIOLOGY

Urticarial eruptions are distinctly pruritic, may involve any area of the body from the scalp to the soles of the feet, and appear in crops of 12- to 36-h duration, with old lesions fading as new ones appear. Most of the inducible urticarias (cold, cholinergic, dermatographism) are an exception, with individual lesions lasting <2 h. Neither urticaria nor angioedema lesions are symmetric or dependent in distribution. The most common sites for angioedema are often periorbital and perioral. Angioedema of the upper respiratory tract may be life-threatening due to transient laryngeal obstruction, whereas gastrointestinal involvement may present with abdominal colic, with or without nausea and vomiting, and can result in unnecessary surgical intervention. No residual scarring occurs with either urticaria or angioedema unless there is an underlying vasculitic process.

The pathology is characterized by edema of the superficial dermis in urticaria and of the subcutaneous tissue and deep dermis in angioedema. Collagen bundles in affected areas are widely separated, and the venules are sometimes dilated. Any perivenular infiltrate consists of lymphocytes, monocytes, eosinophils, and neutrophils that are present in varying combination and numbers.

The best evidence for IgE and mast cell involvement in urticaria and angioedema is *cold urticaria*. Cryoglobulins or cold agglutinins are present in up to 5% of these patients. Ice cube placement on the volar forearm precipitates urticaria or angioedema within minutes of the challenge. Histologic studies reveal marked mast cell degranulation with associated edema of the dermis and subcutaneous tissues. Elevated levels of histamine have been found in the plasma of venous effluent and in the fluid of suction blisters at experimentally induced lesional sites in patients with cold urticaria, dermographism, pressure urticaria, vibratory angioedema, light urticaria, and heat urticaria. By ultrastructural analysis, the pattern of mast cell degranulation in cold urticaria resembles an IgE-mediated response with solubilization of granule contents, fusion of the perigranular and cell membranes, and discharge of granule contents, whereas in a dermatographic lesion, there is additional superimposed zonal (piecemeal) degranulation. Elevations of plasma histamine levels with biopsy-proven mast cell degranulation have also been demonstrated with generalized attacks of *cholinergic urticaria*.

Up to 45% of patients with chronic urticaria have an autoimmune cause for their disease including autoantibodies to IgE or to the α chain of FcεRI. In some patients, autologous serum injected into their own skin can induce a wheal-and-flare reaction involving mast cell activation. The presence of these antibodies can also be recognized by their capacity to release histamine or induce activation markers such as CD63 or CD203 on basophils. An association with antibodies to microsomal peroxidase and/or thyroglobulin has been observed with both clinically significant Hashimoto's thyroiditis as well as a euthyroid state.

The urticaria and angioedema associated with classic serum sickness or with hypocomplementemic cutaneous necrotizing angiitis (urticarial vasculitis) are believed to be immune-complex-mediated diseases.

Isolated Angioedema Hereditary angioedema (HAE) is a fully penetrant, autosomal dominant disease due to a mutation in the *SERPING1* gene leading to a deficiency of C1INH (type 1) in ~85% of patients or to a dysfunctional protein (type 2) in the remainder affecting 1:30,000–80,000 in the general population. Presentation in childhood or adolescence and a family history of angioedema are distinguishing features. C1INH deficiency can also develop in a sporadic acquired form as a result of excessive consumption of C1INH due either to formation of immune complexes or to the generation of an autoantibody directed to C1INH in the setting of lymphoproliferative or autoimmune disease. A third, less common type of HAE has been described in which C1INH function is normal; a causal genetic lesion has been implicated in many of these cases, including a mutant form of factor XII, which leads to generation of excessive bradykinin. C1INH blocks the catalytic function of activated factor XII (Hageman factor) and of kallikrein, as well as the C1r/C1s components of C1, with the common result of degrading bradykinin. During clinical attacks of angioedema, C1INH function or levels fall, patients develop elevated plasma levels of bradykinin leading to angioedema, and excessive activation of C1 lowers C4 and C2 levels.

Bradykinin-mediated angioedema, whether caused by ACE inhibitors or by C1INH deficiency, is noteworthy for the conspicuous absence of concomitant urticaria or pruritus, the frequent involvement of the gastrointestinal tract, and the duration of symptoms >24 h.

DIAGNOSIS

The classification of urticaria and angioedema as presented in Table 363-1 in terms of duration can facilitate identification of possible precipitating factors. History alone of self-limited episodes can be sufficient to make a diagnosis in the setting of acute disease triggered by drug, environmental, or food allergen with history-directed confirmatory skin testing or assay for serum allergen-specific IgE. Provocation and threshold testing for inducible urticaria is particularly valuable because it so often establishes the cause of the lesion. In chronic urticaria with or without angioedema, initial diagnostic testing should be guided by history and physical exam. Practice guidelines provide clinicians two options if history and physical exam are unrevealing: no laboratory testing or limited testing, which includes complete blood count with assessment for eosinophilia, erythrocyte sedimentation rate, or C-reactive protein. Extended testing, such as in thyroid-related tests, varies by guideline. The vast majority of chronic urticaria is associated with no laboratory abnormality. Urticarial lesions that last longer than 36 h, result in scarring, and are reported as painful and not pruritic warrant biopsy to evaluate for cellular infiltration, nuclear debris, and fibrinoid necrosis of the venules consistent with urticarial vasculitis. Isolated angioedema without urticaria additionally warrants assessment of basic chemistries with liver function tests and complement levels. Further testing, including for paraproteinemia, may be guided by patient presentation. Concomitant flushing and hyperpigmented papules that urticate with stroking in the absence of angioedema raise the question of mastocytosis. An appropriate travel history should trigger an evaluation for parasites. Symptom activity and burden can be assessed using validated scoring instruments.

The diagnosis of HAE is suggested not only by family history and age of onset but also by the lack of pruritus and of urticarial lesions, the prominence of recurrent gastrointestinal attacks of colic, episodes of laryngeal edema, and (in contrast to urticaria) a failure to respond to H1 antagonists. Laboratory diagnosis depends on demonstrating a deficiency of C1INH antigen (type 1) or a nonfunctional protein (type 2) by a catalytic inhibition assay. C4 and C2 are chronically depleted and fall further during attacks due to the activation of additional C1. Patients with the acquired forms of C1INH deficiency have the same clinical manifestations but differ in the lack of a familial history. Furthermore, their sera exhibit a reduction of C1 function and C1q protein as well as C1INH, C4, and C2. Lastly, type 3 HAE is associated with normal levels of complement proteins and often an identifiable gene mutation.

TREATMENT

Urticaria and Angioedema

For most forms of urticaria, H_1 antihistamines effectively attenuate both urtication and pruritus; long-acting, nonsedating agents, such as loratadine and fexofenadine, or low-sedating agents, such as cetirizine, generally are used first and can be increased to up to four times daily dosing. Earlier generation antihistamines, such as diphenhydramine, are sedating and induce psychomotor impairment. Their anticholinergic (muscarinic) effects include visual disturbance, urinary retention, and constipation. Some clinical practice guidelines indicate that the addition of an H_2 antagonist such as ranitidine or famotidine in conventional dosages and a $CysLT_1$ receptor antagonist, such as montelukast 10 mg daily, may

add benefit when H_1 antihistamines are inadequate. For chronic urticaria that fails to respond to first-line options, a monoclonal anti-IgE antibody (omalizumab) is the next line of therapy. Older agents with antihistamine properties such as doxepin, cyproheptadine, and hydroxyzine have proven effective when H_1 antihistamines fail but are less effective than omalizumab and are sedating. Cyclosporine is efficacious for patients with chronic spontaneous urticaria that is severe and poorly responsive to other modalities. Phase III trial data of a Btk inhibitor, remibrutinib, showed promise in the treatment of chronic spontaneous urticaria that resisted improvement with H1 antagonists.

Topical glucocorticoids are of no value, and systemic glucocorticoids are generally avoided in idiopathic, allergen-induced, or inducible urticarias due to long-term toxicity. Systemic glucocorticoids are useful in the management of patients with pressure urticaria, vasculitic urticaria (especially with eosinophil prominence), idiopathic angioedema with or without urticaria, or chronic urticaria that responds poorly to conventional treatment and should be considered in any patient with debilitating disease. With persistent vasculitic urticaria, hydroxychloroquine, dapsone, or colchicine may be added to the regimen before or along with systemic glucocorticoids. In certain contexts, refractory chronic spontaneous urticaria may be treated with immunosuppressants (i.e., calcineurin inhibitors) and anti-inflammatory agents (i.e., hydroxychloroquine), though evidence is lacking.

BRADYKININ-MEDIATED ANGIOEDEMA

Infusion of plasma-derived C1INH protein, a monoclonal anti-plasma kallikrein antibody (lanadelumab), and a small-molecule plasma kallikrein inhibitor (berotralstat) are approved for prophylaxis of HAE attacks. Administration of plasma-derived or recombinant C1INH protein, a bradykinin 2 receptor antagonist (icatibant), or a kallikrein inhibitor (ecallantide) may be used for treatment of an acute attack of HAE. Older, less expensive preventative options include attenuated androgens, which stimulate production by the normal gene of an amount of functional C1INH. The antifibrinolytic agent ε-aminocaproic acid may be used for preoperative prophylaxis but is contraindicated in patients with thrombotic tendencies or arterial atherosclerosis. Fresh frozen plasma infusion can be used for acute attacks in a setting where newer modalities are not available. Published studies are conflicting on the efficacy of bradykinin 2 receptor antagonists and C1INH protein in the treatment of ACE inhibitor–induced angioedema. Treatment of the underlying autoimmune disease or malignancy is indicated for acquired C1INH deficiency.

ALLERGIC RHINITIS

DEFINITION

Rhinitis is characterized by sneezing; rhinorrhea; obstruction of the nasal passages; conjunctival, nasal, and pharyngeal itching; and lacrimation. It can be classified as allergic or nonallergic based on the presence or absence of IgE specific for relevant antigens. A clinical history of rhinitis symptoms occurring in a temporal relationship to allergen exposure and documentation of sensitization to an environmental allergen are required for diagnosis. Although commonly seasonal due to elicitation by airborne pollens, it can be perennial in an environment of chronic exposure to house dust mites, animal danders, or insect (cockroach) products. The overall prevalence in North America has increased in the past 20 years and is 10–30%, with the peak prevalence (>30%) occurring in the fifth decade.

PREDISPOSING FACTORS AND ETIOLOGY

Allergic rhinitis generally occurs in atopic individuals, often in association with atopic dermatitis, food allergy, urticaria, and/or asthma **(Chap. 298)**. Up to 50% of patients with allergic rhinitis manifest asthma, whereas 70–80% of individuals with asthma and 80% of individuals with chronic bilateral sinusitis experience allergic rhinitis. Female sex, particulate air pollution exposure, and maternal tobacco smoking increase the risk of developing allergic rhinitis.

Wind-pollinated trees, grasses, and weeds produce sufficient quantities of pollen suitable for wide distribution by air currents to elicit seasonal allergic rhinitis. The dates of pollination of these species historically varied little from year to year in a particular locale but may differ in another climate. In the temperate areas of North America, trees typically pollinate from March through May, grasses in June and early July, and weeds from mid-August to early October. Molds, which are widespread in nature because they occur in soil or decaying organic matter, propagate spores in a pattern that depends on climatic conditions. Climate change is impacting these patterns with early tree pollination and prolonged ragweed season with the delay of the first frost. In laboratory studies, exposure to high carbon dioxide concentrations increases pollen production in ragweed and timothy grass. Perennial allergic rhinitis occurs in response to allergens that are present throughout the year, including animal dander, cockroach-derived proteins, mold spores, or dust mites such as *Dermatophagoides farinae* and *Dermatophagoides pteronyssinus*. Dust mites are scavengers of human skin and excrete cysteine protease allergens in their feces. Similarly, cockroach allergens are fecal cysteine proteases.

PATHOPHYSIOLOGY AND MANIFESTATIONS

Episodic rhinorrhea, sneezing, obstruction of the nasal passages with lacrimation, and pruritus of the conjunctiva, nasal mucosa, and oropharynx are the hallmarks of allergic rhinitis. The nasal mucosa is pale and boggy, the conjunctiva congested and edematous, and the pharynx generally unremarkable. Swelling of the turbinates and mucous membranes with obstruction of the sinus ostia and eustachian tubes precipitates secondary infections of the sinuses and middle ear, respectively. A growing number of patients with seasonal allergic rhinitis demonstrate pollen-associated food allergen syndrome characterized by oropharyngeal pruritus and/or mild swelling following the ingestion of plant-based foods in the same plant family as a tree, grass, or weed, which contain cross-reacting allergens.

The nose presents a large mucosal surface area through the folds of the turbinates and serves to adjust the temperature and moisture content of inhaled air and to filter out particulate materials >10 μm in size by impingement in a mucous blanket; ciliary action moves the entrapped particles toward the pharynx. Entrapment of pollen and digestion of the outer coat by mucosal enzymes such as lysozymes release protein allergens. The initial interaction occurs between the allergen and intraepithelial mast cells and then proceeds to involve deeper perivenular mast cells, both of which are sensitized with specific IgE. During the symptomatic season when the mucosae are already swollen and hyperemic, there is enhanced adverse reactivity to the seasonal pollen as well as irritants such as tobacco smoke and fragrances. Biopsy specimens of nasal mucosa during seasonal rhinitis show submucosal edema with infiltration by eosinophils, along with some basophils and neutrophils, and intraepithelial mast cells.

The mucosal surface fluid contains IgA and IgE, which apparently arrives by diffusion from plasma cells in proximity to mucosal surfaces. IgE fixes to mucosal and submucosal mast cells, and the intensity of the clinical response to inhaled allergens is quantitatively related to the naturally occurring pollen dose. In sensitive individuals, the introduction of allergen into the nose is associated with sneezing, nasal obstruction, and discharge, and the fluid contains histamine, PGD_2, and leukotrienes. Thus, the mast cells of the nasal mucosa and submucosa generate and release mediators through IgE-dependent reactions that are capable of producing tissue edema and eosinophilic infiltration.

DIAGNOSIS

The diagnosis of seasonal allergic rhinitis depends largely on an accurate history of symptoms lasting >4 weeks coincident with the pollination of the offending allergen. The continuous character of perennial allergic rhinitis due to allergens found in the home or place

of work makes historic analysis difficult, but there may be variability in symptoms that can be related to exposure to animal dander, dust mite and/or cockroach allergens, fungal spores, or work-related allergens such as latex. Patients with perennial rhinitis commonly develop the problem in adult life and manifest nasal congestion and a postnasal discharge, often associated with thickening of the sinus membranes demonstrated by radiography. Perennial nonallergic rhinitis with eosinophilia syndrome (NARES) occurs in the middle decades of life and is characterized by nasal obstruction, anosmia, chronic sinusitis, and prominent eosinophilic nasal discharge in the absence of allergen sensitization. The term *vasomotor rhinitis* or *perennial nonallergic rhinitis* designates a condition of enhanced reactivity of the nasopharynx in which a symptom complex resembling perennial allergic rhinitis occurs with nonspecific stimuli, including chemical odors, temperature and humidity variations, and position changes but occurs without tissue eosinophilia or an allergic etiology. Other entities to be excluded are structural abnormalities of the nasopharynx, including nasal foreign bodies in children, symptoms due to exposure to irritants, gustatory rhinitis associated with cholinergic activation that occurs while eating or ingesting alcohol, hypothyroidism, upper respiratory tract infection, hormonal rhinitis, including pregnancy, atrophic rhinitis in populations outside the United States and Europe, prolonged topical use of α-adrenergic agents in the form of nasal sprays (rhinitis medicamentosa), and the use of certain systemic agents such as β-adrenergic antagonists, ACE inhibitors, direct vasodilators (hydralazine), α_1-adrenergic receptor antagonists, estrogens, progesterone, nonsteroidal anti-inflammatory drugs, gabapentin, phosphodiesterase-5 inhibitors, and psychotropics (risperidone, chlorpromazine, amitriptyline).

The nasal secretions of allergic patients can be rich in eosinophils, and a modest peripheral eosinophilia can be observed. Local neutrophilia implies infection. Total serum IgE may be moderately elevated, but the demonstration of immunologic specificity for IgE is critical to an etiologic diagnosis. A skin test by the intracutaneous route (puncture or prick) with the allergens of interest provides a rapid and reliable approach to identifying allergen-specific IgE that has sensitized cutaneous mast cells. A positive intracutaneous skin test with 1:10–1:20 weight/volume of extract has a high predictive value for the presence of allergy. An intradermal test with a 1:500–1:1000 dilution of 0.05 mL may follow if indicated by history when the intracutaneous test is negative, but while more sensitive, it is less dependable due to the reactivity of some asymptomatic individuals at the test dose.

Enzyme-linked immunosorbent assays (ELISAs) employing anti-IgE bound to either a solid-phase or a liquid-phase particle provide rapid and cost-effective determinations of IgE. Measurements of specific anti-IgE in serum are obtained by its binding to an allergen and quantitation by subsequent uptake of labeled anti-IgE. As compared to the skin test, the assay of specific IgE in serum is less sensitive but has high specificity.

TREATMENT

Allergic Rhinitis

Although allergen avoidance is the most cost-effective means of managing allergic rhinitis, only in the case of animal dander and possibly dust mites is it feasible. Treatment with pharmacologic agents represents the standard initial approach to seasonal or perennial allergic rhinitis. Oral long-acting H_1 antihistamines, such as fexofenadine, loratadine, desloratadine, cetirizine, and levocetirizine, are effective for nasopharyngeal itching, sneezing, and watery rhinorrhea and for such ocular manifestations as itching, tearing, and erythema, but they are less efficacious for the nasal congestion. They reduce nasal and ocular symptoms by about one-third. These antihistamines are less lipophilic and more H_1 selective, thus minimizing their ability to cross the blood-brain barrier and therefore diminishing their sedating and anticholinergic effect; they do not differ appreciably in efficacy for relief of rhinitis and/or sneezing.

Intranasal high-potency glucocorticoids are the most effective drugs available for the relief of persistent rhinitis, seasonal or perennial, and are effective in relieving nasal congestion as well as ocular symptoms. They provide efficacy with substantially reduced side effects as compared with this same class of agent administered orally. Their most frequent side effect is local irritation, with fungal overgrowth being a rare occurrence. The currently available intranasal glucocorticoids are equally effective for nasal symptom relief, including nasal congestion, achieving up to 70% overall symptom relief with some variation in the onset of benefit. The nasal antihistamines azelastine and olopatadine as a first-line option may benefit individuals with nonallergic rhinitis and intermittent or mild allergic rhinitis, as well as have additive benefit to intranasal steroids in persistent allergic rhinitis, but they have an adverse effect of dysgeusia in some patients. Alternative nasal decongestants for significant mucosal edema or unresponsive nasal congestion include α-adrenergic agents such as phenylephrine or oxymetazoline; however, the duration of their efficacy is limited because of rebound rhinitis (i.e., 7- to 14-day use can lead to rhinitis medicamentosa) and such systemic responses as hypertension. Oral α-adrenergic agonist decongestants containing pseudoephedrine can improve management of nasal congestion, generally in combination with an antihistamine. These pseudoephedrine combination products can cause insomnia and are precluded from use in a variety of patient populations, such as those with narrow-angle glaucoma, urinary retention, uncontrolled hypertension, cerebrovascular disease, marked coronary artery disease, or a first-trimester pregnancy. The $CysLT_1$ antagonist montelukast is approved for treatment of both seasonal and perennial rhinitis. However, it is less effective than H_1 antihistamines and nasal glucocorticoids, and reports of neuropsychiatric events have led to increased U.S. Food and Drug Administration precautions. Cromolyn sodium nasal spray inhibits mast cell degranulation and can be used prophylactically on a continuous basis during allergen season or as needed before a known exposure. Topical ipratropium is an anticholinergic agent effective in reducing rhinorrhea, including that of patients with perennial nonallergic symptoms. For concomitant allergic conjunctivitis, topical treatment with cromolyn sodium is effective in treating mild allergic symptoms, and topical antihistamines such as olopatadine, azelastine, ketotifen, or epinastine administered to the eye provide rapid relief of itching and redness and are more effective than oral antihistamines.

Immunotherapy Immunotherapy consists of repeated exposure to the allergen(s) considered to be specifically responsible for the symptom complex. Two forms of immunotherapy, subcutaneous (SCIT) and sublingual (SLIT), are currently available. Randomized, controlled studies of ragweed, grass, dust mite, and cat dander allergens administered via SCIT for treatment of allergic rhinitis have demonstrated significant improved symptom control over medications alone with the advantage of providing a durable benefit, as well as a reduction in asthma symptoms, medication use, and bronchial hyperreactivity in allergic asthma. Clinical practice guidelines recommend a duration of SCIT of 3–5 years, with discontinuation being based on minimal symptoms over two consecutive seasons of exposure to the allergen. Clinical benefit appears related to the administration of a high dose of relevant allergen, gradually uptitrating concentration and advancing from weekly to monthly intervals. SCIT injections occur in a licensed treatment site; 2–3% of SCIT patients experience a systemic reaction, including anaphylaxis, over a 12-month period. The majority of these reactions occur soon after injection, and thus, patients should remain at the treatment site for at least 30 min after allergen administration. Local reactions with erythema and induration are not uncommon and may persist for 1–3 days. SLIT is prepared as a tablet to be dissolved under the tongue at home after the first dose. The efficacy of SLIT is comparable to SCIT but only for the three allergen formulations currently available: dust mite, timothy/northern grasses, and short ragweed. Systemic

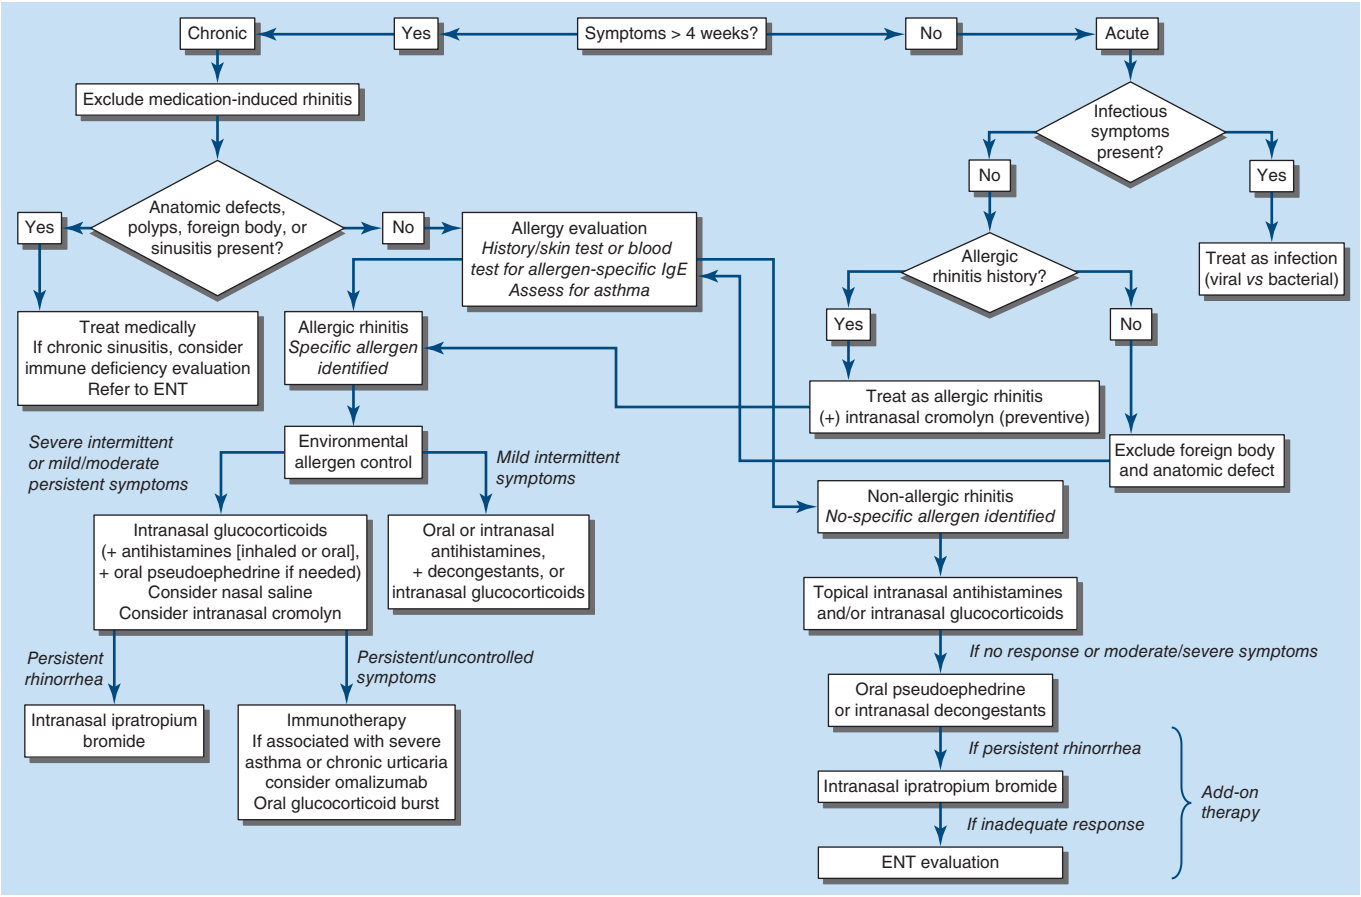

FIGURE 363-4 Algorithm for the diagnosis and management of rhinitis. Persistent is defined as >4 days per week for >4 weeks. Moderate/severe is defined as abnormal sleep, impaired daily activities (school, work, sport, leisure), and/or troublesome symptoms. CysLT, cysteinyl leukotriene; ENT, ear, nose, and throat; IgE, immunoglobulin E.

reactions are less frequent with SLIT, but transient oral pruritus is common. Immunotherapy is contraindicated in patients with significant cardiovascular disease or unstable asthma. Severe cases of anaphylaxis have occurred after allergen immunotherapy when patients were taking a β-adrenergic blocking agent. Thus, immunotherapy should be conducted with caution in any patient requiring β-adrenergic blocking therapy.

Immunotherapy should be reserved for clearly documented seasonal or perennial rhinitis that is clinically related to defined allergen exposure with confirmation by the presence of allergen-specific IgE through skin or serum-specific IgE testing. The response to immunotherapy is associated with a complex of cellular and humoral effects that includes a modulation in T lymphocyte cytokine production and allergen-specific IgG_4 expansion. Systemic treatment with omalizumab, an anti-IgE monoclonal antibody, is efficacious for allergic rhinitis and can be used with immunotherapy to enhance safety and efficacy. However, omalizumab is not currently approved for treatment of allergic rhinitis.

A sequence for the management of allergic or perennial rhinitis based on an allergen-specific diagnosis and stepwise management as required for symptom control would include the following: (1) identification of the offending allergen(s) by history with confirmation of the presence of allergen-specific IgE by skin test and/or serum assay; (2) avoidance of the offending allergen if possible; and (3) medical management in a stepwise fashion with treatment stepdown as symptoms permit **(Fig. 363-4)**. Mild symptoms of allergic rhinitis are treated with oral antihistamines, intranasal antihistamines, intranasal corticosteroids, or intranasal cromolyn (for short-term prevention). Moderate to more severe allergic rhinitis is managed with intranasal glucocorticoids and intranasal antihistamines; additional therapies include oral antihistamines, antihistamine-decongestant combinations, and intranasal anticholinergics. Persistent or seasonal moderate to severe allergic rhinitis that remains uncontrolled with maximal medical therapy or coexisting allergic rhinitis with asthma merit consideration of allergen-specific immunotherapy.

364 Anaphylaxis

David Hong, Joshua A. Boyce

BACKGROUND

Anaphylaxis is a potentially life-threatening systemic allergic reaction involving one or more organ systems that typically occurs within seconds to minutes of exposure to the anaphylactic trigger, most often a drug, food, or Hymenoptera sting. The term *anaphylaxis* was first described in 1902 by Charles Richet and Paul Portier who attempted to immunize dogs against sea anemone toxin in the same way Pasteur was able to vaccinate individuals against the smallpox virus. To their surprise, repeated administration of small, sublethal doses of sea anemone toxin reliably induced acute-onset death when readministered 2–3 weeks after initial "vaccination" to the toxin. The phenomenon was termed ana (anti)-phylaxis ("protection or guarding") because vaccination with anemone toxin resulted in the opposite intended immune effect. Charles Richet was awarded the Nobel Prize in Physiology or Medicine in 1913 for this work which led to further insights into hypersensitivity and mast cell biology.

CLINICAL MANIFESTATIONS

While 80–90% of anaphylactic episodes are uniphasic, about 10–20% of cases are biphasic, in which anaphylactic symptoms return about an hour or longer after resolution of initial symptoms. Anaphylactic reactions are particularly dangerous when hypotension or hypoxia occurs, leading potentially to cardiovascular collapse or respiratory failure, respectively. There may be upper or lower airway obstruction or both. Laryngeal edema may be experienced as a "lump" in the throat, hoarseness, or stridor, whereas bronchial obstruction is associated with a feeling of tightness in the chest and/or audible wheezing. Patients with underlying asthma are predisposed to severe involvement of the lower airways and increased mortality associated with anaphylaxis. In fatal cases with clinical bronchial obstruction, the lungs show marked hyperinflation on gross and microscopic examination. The microscopic findings in the bronchi, however, are limited to luminal secretions, peribronchial congestion, submucosal edema, and eosinophilic infiltration, and the acute emphysema is attributed to intractable bronchospasm that subsides with death. Angioedema resulting in death by mechanical obstruction occurs in the epiglottis and larynx. This process can also be evident in the hypopharynx and trachea. On microscopic examination, there is wide separation of the collagen fibers and the glandular elements. Vascular congestion and eosinophilic infiltration may also be present. Patients dying of vascular collapse without antecedent hypoxia from respiratory insufficiency have visceral congestion with a presumed loss of intravascular fluid volume. The associated electrocardiographic abnormalities in some patients, with or without infarction, may reflect a primary cardiac event mediated by mast cells (which are prominent near the coronary vessels) or may be secondary to a critical reduction in intravascular volume.

Gastrointestinal manifestations represent another severe presentation of anaphylaxis and include nausea, vomiting, crampy abdominal pain, and/or fecal incontinence. Angioedema of the bowel wall may also cause sufficient intravascular volume depletion to precipitate cardiovascular collapse.

Cutaneous manifestations are among the most common presentations of anaphylaxis (>90% of cases). Symptoms include urticarial eruptions, flushing with diffuse erythema, and/or a feeling of generalized warmth. Urticarial eruptions are intensely pruritic and may be localized or disseminated. They may coalesce to form large urticarial plaques but seldom persist beyond 48 h.

PATHOPHYSIOLOGY

Many of the important early mediators of anaphylaxis are derived from mast cells, basophils, and eosinophils. Mast cells contain preformed granules comprised of histamine, proteases (tryptase, chymase), proteoglycans (heparin, chondroitin sulfate), and tumor necrosis factor-α, which are rapidly released into surrounding tissue upon cell activation, a process known as degranulation. Basophils, like mast cells, contain and release histamine. Mast cells, basophils, and eosinophils are also sources of arachidonic acid–derived products, which include cysteinyl leukotrienes, prostaglandins, and platelet-activating factor (PAF). Histamine release results in flushing, urticaria, pruritus, and, in high concentrations, hypotension and tachycardia. Cysteinyl leukotrienes and prostaglandin D_2 cause bronchoconstriction and increased microvascular permeability. Prostaglandin D_2 causes cutaneous flushing and attracts eosinophils and basophils to the site of mast cell activation. Serum PAF levels correlate with anaphylaxis severity and are inversely proportional to the constitutive level of PAF acetylhydrolase, which is necessary for PAF inactivation. Tryptase and chymase can activate complement and coagulation pathways. Activation of these pathways results in production of the anaphylatoxins, C3a and C5a, and activation of the kallikrein-kinin system, which regulates blood pressure and vascular permeability. The actions of these anaphylactic mediators are likely additive or synergistic at the target tissues.

PREDISPOSING FACTORS AND MECHANISMS

Because the most dangerous manifestations of anaphylaxis involve the cardiovascular and/or respiratory systems, preexisting asthma and underlying cardiovascular disease could lead to more rapid decompensation from anaphylaxis. Atopy is not generally thought to be a risk factor for anaphylaxis from drug reactions or Hymenoptera stings, but it is associated with radiocontrast sensitivity, exercise-induced anaphylaxis, idiopathic anaphylaxis, and allergy to foods or latex. Severe Hymenoptera-induced anaphylaxis (generally with prominent hypotension) is the most common initial presentation for patients with underlying systemic mastocytosis. For this reason, it is important to check a baseline tryptase (a reflection of mast cell burden) in patients who present with sting-induced anaphylaxis to screen for this condition. Hymenoptera allergy is also more likely in patients whose occupations (i.e., beekeepers, trash haulers, and landscape workers) place them in regular proximity to stinging insects. Most commonly, allergen-induced cross-linking of IgE-bound FcεRI receptors on mast cells and basophils initiates the signal transduction events leading to hypersensitivity syndromes, including anaphylaxis. The generation of allergen-specific IgE is the end result of sensitization via the adaptive immune system. While the mechanisms underlying sensitization are beyond the scope of this chapter, environmental factors, innate immune responses, and cytokines are among the many variables leading to antigen-specific IgE production by B cells and plasma cells. IgE-mediated drug allergies are most common with antibiotics and certain chemotherapy drugs, though theoretically, they can occur with almost any medication. As is the case with environmental allergies, repeated exposure to the allergy-causing antigen is an important risk factor to keep in mind when evaluating patients with anaphylaxis. In the case of allergy to carboplatin, the incidence of hypersensitivity is 27% in patients who have had ≥7 lifetime infusions and as high as 46% in patients who have had ≥15 lifetime infusions. Similarly, patients with cystic fibrosis have a relatively high incidence of allergic reactions to IV antibiotics, particularly beta-lactams, that they receive periodically for intermittent "clean-outs" to maintain airway clearance. Drugs can also function as haptens that form immunogenic conjugates with host proteins. The conjugating hapten may be the parent compound, a nonenzymatically derived storage product, or a metabolite formed in the host. Recombinant biologics in some cases can also induce the formation of IgE against the proteins or against glycosylated structures that serve as immunogens. Outbreaks of anaphylaxis to the epidermal growth factor receptor (EGFR) antibody, cetuximab, have been reported in association with elevated titers of serum IgE to alpha-1,3-galactose (alpha-gal), an oligosaccharide found in nonprimate mammals. Cetuximab is derived from a mouse cell line expressing a transferase that tags the Fab′ portion of the cetuximab heavy chain with alpha-gal. Interestingly, patients with a history of multiple bites from *Amblyomma americanum* ticks commonly found in the Carolinas, Arkansas, and Tennessee are more likely to have anti-alpha-gal IgE as compared to patients living outside those states. A subset of individuals with anti-alpha-gal IgE

can develop episodes of delayed-onset anaphylaxis about 3–6 h after consuming mammalian meat (beef, lamb, or pork) in a condition now known as alpha-gal syndrome (AGS). The mechanisms behind AGS are not yet well understood.

It is also important to remember that allergic reactions caused by the effector cells and mediators described previously can be triggered by a variety of mechanisms that may not require the presence of sensitizing IgE. Non-IgE-mediated mast cell activation secondary to certain drugs is clinically indistinguishable from classical IgE-mediated hypersensitivity reactions but can occur with first known exposure since there is no prior need for mast cell sensitization by IgE. MRGPRX2, a G protein–coupled receptor that is highly expressed in skin mast cells, has been shown in mouse models and in vitro studies using human cells to induce mast cell activation and mediator release secondary to neuromuscular blocking drugs (NMBDs), quinolones, and icatibant. These findings are clinically significant since NMBDs are needed for procedures done under general anesthesia while quinolones are a commonly used antibiotic family. Icatibant, a bradykinin-2 receptor antagonist administered by subcutaneous injection for the treatment of acute attacks of hereditary angioedema, is known to frequently result in local injection site reactions. Another example of non-IgE-mediated anaphylaxis is demonstrated with paclitaxel, a chemotherapy agent most commonly used in combination with carboplatin to treat ovarian cancer. It is derived from yew tree bark and needles that require polyethoxylated castor oil (Cremophor) to be solubilized into aqueous solution. Cremophor has been shown in vitro to activate the complement cascade, resulting in complement-dependent histamine release from mast cells and basophils. A version of paclitaxel that is solubilized by being bound to albumin nanoparticles, Abraxane, has a far lower rate of hypersensitivity, especially for patients who have had infusion reactions to Cremophor-solubilized paclitaxel. Reactions such as flushing, hives, angioedema, and/or anaphylaxis to radiocontrast, opiates, vancomycin, and nonsteroidal anti-inflammatory drugs (NSAIDs) are other examples of non-IgE-mediated hypersensitivity.

An example of non-IgE-mediated food anaphylaxis is scombroid poisoning, caused by the ingestion of a pharmacologically significant dose of histamine from contaminated fish. This is most commonly associated with fish that are rich in histidine, such as mahi-mahi, mackerel, and tuna. If improperly stored, surface contaminant bacteria expressing histidine decarboxylase convert histidine into histamine, which is not broken down by baking or broiling. Scombroid poisoning leads to symptoms including flushing, oropharyngeal pruritis/angioedema, nausea/vomiting, and lightheadedness. Symptoms are often self-limited but still treatable with antihistamines and, if needed, epinephrine. Because the source of histamine is exogenous, tryptase levels are not elevated.

A final example of non-IgE-mediated anaphylaxis occurred in clustered cases of anaphylaxis to IV unfractionated heparin in Europe and North America in 2008. Cases were attributable to specific lots of heparin found to be enriched in a contaminant, oversulfated chondroitin sulfate (OSCS). OSCS is able to activate the contact activation system, leading to the generation of bradykinin and the anaphylatoxins C3a and C5a, which led to the anaphylactic symptoms. Heparin is now routinely screened for this contaminant to prevent further outbreaks.

DIAGNOSIS

The diagnosis of an anaphylactic reaction depends primarily on a history revealing the onset of symptoms and signs within seconds to minutes after the putative trigger is encountered. An exception is delayed anaphylaxis to mammalian meats in patients with AGS. Table 364-1 lists other possibilities to consider on the differential for IgE-mediated anaphylaxis. Every attempt to identify the specific cause or causes should be made to minimize the risk of recurrent anaphylaxis. If a particular drug or food is suspected, skin or serum-specific IgE testing can be useful to confirm clinical suspicions. If a specific trigger cannot be identified by history or testing, a workup of underlying baseline atopic diatheses may be useful to identify risk factors that could play potential contributory roles alone or in concert. In the acute setting, laboratory biomarkers of mast cell degranulation may be useful to document the severity of an anaphylactic episode. The most obvious serum biomarker to assay, histamine, has an extremely short serum half-life with a measurable time-window that expires <1 h from the onset of anaphylaxis. A more practical and reliable biomarker is serum tryptase, which is released from mast cells, peaks 60–90 min after the onset of anaphylaxis, and can be measured as long as 5 h after the onset of anaphylaxis. It may be useful to follow up an elevated tryptase measurement in the acute setting with another measurement when the patient is clinically stable to establish a baseline reference since there is considerable variability of baseline serum tryptase (BST) within the general population. For example, ~6% of Western populations have hereditary alpha-tryptasemia (HAT), a mostly benign condition featuring elevated BST due to expression of an extra allele of TPSAB1, the gene that encodes alpha-tryptase. Some studies suggest that HAT may be a risk factor for severe anaphylaxis and is also overrepresented in patients with indolent mastocytosis. Another cause for temporarily elevated BST is high environmental allergen exposure, something that can occur, for example, in regions with distinct pollen seasons. A working group on mast cell disorders in 2010 came up with a formula to better interpret tryptase levels since (1) the range of "normal" BST is wide within the general population and (2) an acutely elevated tryptase for a given patient may still fall within normal parameters if their BST is low. The "20% + 2" rule stipulates that a tryptase level drawn in the setting of possible anaphylaxis that is 20% above the patient's baseline plus 2 ng/mL is diagnostic for an acute event involving a clinically significant degree of mast cell activation.

TABLE 364-1 Differential Diagnoses for IgE-Mediated Anaphylaxis

CONDITION	DISTINGUISHED BY
Mastocytosis	Elevated baseline tryptase, spindle-shaped mast cells (MCs) on bone marrow
Pheochromocytoma	Elevated urine metanephrines
Carcinoid syndrome	Elevated urine 5-hydroxyindoleacetic acid
Hereditary angioedema	Decreased C4 during attacks
Acquired angioedema	Decreased C1q
Systemic capillary leak syndrome	Severe hypotension on presentation with lack of response to first-line hypersensitivity medications (epinephrine, antihistamines)
Scombroid poisoning	Tryptase not elevated; negative skin test and oral challenge to fish
Drugs (opiates, neuromuscular blocking agents, vancomycin), computed tomography radiocontrast	Direct MC degranulation triggered through MRGPRX2 receptor or other as-yet-undetermined mechanism

TREATMENT

Early recognition of an anaphylactic reaction and appropriate intervention are critically important because severe, even fatal, complications can occur within minutes after symptoms first appear. The treatment of first choice is intramuscular administration of 0.3–0.5 mL of 1:1000 (1 mg/mL) epinephrine, with repeated doses at 5- to 20-min intervals as needed for a severe reaction. The failure to use epinephrine within the first 20 min of symptoms is a risk factor for poor clinical outcomes in various studies of anaphylaxis. IV fluids and vasopressor agents may be administered in the acute medical setting if intractable hypotension occurs. Epinephrine provides both α- and β-adrenergic effects, resulting in vasoconstriction, bronchial smooth-muscle relaxation, and attenuation of enhanced venular permeability. Beta blockers may attenuate this response; therefore, an alternative antihypertensive may be considered in patients at high risk of needing emergency epinephrine. Oxygen alone via a nasal catheter or with nebulized albuterol may be helpful; however, either endotracheal intubation or a tracheostomy is mandatory for oxygen delivery if progressive hypoxia develops. Ancillary agents such as antihistamines, glucocorticoids, and bronchodilators are also useful therapeutics to treat urticaria/angioedema and bronchospasm once the patient is hemodynamically stable.

PREVENTION

Avoidance The simplest and most straightforward approach to the long-term management of a patient with a history of anaphylaxis is strict avoidance of known anaphylactic triggers and education on acute management, specifically, instructing the patient on proper use and indications for use of self-administered epinephrine. Lifelong avoidance is not easy if the trigger is an occupational exposure, Hymenoptera sting, a common food (i.e., peanut), or a drug representing the sole or best therapeutic option for the patient. Special management options may exist for these patients.

Venom Immunotherapy Patients of any age who have had documented anaphylaxis from Hymenoptera sting should be formally evaluated and started on venom immunotherapy (VIT) if skin or serologic IgE testing confirms the history. Immunotherapy is a means of "tolerizing" patients to allergen by means of serial subcutaneous administration of escalating doses of extract containing relevant allergen until a target maintenance dose is achieved. Anaphylaxis can sometimes occur during the course of administering immunotherapy extracts, so formulating extracts and administering them is typically done under the care of a specialist familiar with this type of treatment. In the case of Hymenoptera allergy, patients receive VIT extracts containing actual Hymenoptera venom with a maintenance dose equivalent to 2–5 stings. The recommended duration of treatment is 3–5 years; however, some patients who have experienced severe respiratory or cardiovascular anaphylaxis are put on lifelong therapy. Patients with mastocytosis may also require such lifelong treatment.

Preventative Tolerance Induction to Peanuts IgE sensitization to foods occurs most frequently in infants and young children, especially those with atopic dermatitis, and is a risk factor for anaphylaxis (although detection of specific IgE through skin or serum testing has relatively poor predictive value). While most allergy to egg, milk, soy, and/or wheat resolves spontaneously during childhood, ~80% of children with peanut allergy remain sensitive for life. A sharp rise in the prevalence of peanut allergy was also observed in the late 1990s to early 2000s, especially in countries with Western diets where the average age of peanut introduction was age ≥3 years. Curiously, in cultures where peanut was introduced much earlier into children's diets, the prevalence of peanut allergy remained low. The landmark Learning Early About Peanut Allergy (LEAP) study demonstrated that early introduction of peanut protein to the diet of high-risk infants (4–11 months of age with atopic dermatitis and/or egg allergy) prevented the development of most (80% or more) peanut allergy compared with children who did not consume peanuts (avoidance group), even when IgE sensitization (based on positive skin test) had already developed at the time of study entry. While the induction of tolerance at an early age seems to be key to preventing clinical reactivity later in life, it is not yet clear if this principle holds true for other foods commonly associated with hypersensitivity reactions.

A relatively new treatment for patients who already suffer from severe peanut allergy is peanut oral immunotherapy (OIT) in which patients receive a titrating regimen of precisely dosed peanut protein in the form of an oral capsule. The goal of peanut OIT is to raise a patient's threshold tolerance for accidental peanut exposure before anaphylaxis occurs, and it is not a cure for peanut allergy. At the current time, peanut is the only food for which a U.S. Food and Drug Administration (FDA)-approved treatment exists, but research on developing OIT for other foods, such as milk and egg, remains ongoing.

Desensitization For patients who have experienced anaphylaxis from drug allergy and whose treatment regimen requires the administration of the offending drug, desensitization may be a short-term treatment option to prevent reactions. Desensitization elicits a temporary state of tolerance to the drug in sensitized, clinically reactive patients. While it has been a proven technique for penicillin-allergic patients for decades, desensitization has more recently been proven to be effective for certain chemotherapy agents, especially platin-based chemotherapy agents that can induce IgE-mediated sensitization with repeated exposures. The exact mechanisms underlying desensitization are not fully understood; however, temporary tolerance can be achieved through the serial administration of gradually escalating doses of drug, starting from extremely low doses, over the course of hours. As long as the patient continues to receive the drug in question at regular intervals based on drug half-life, a "desensitized" state can also be maintained until the drug is no longer needed. While drug desensitization certainly works for IgE-mediated reactions, it has been performed in cases of non-IgE-mediated anaphylaxis from Cremophor-solubilized paclitaxel as described earlier in this chapter. Drug desensitization has also been shown by multiple groups to work for non-IgE-mediated reactions from a variety of biologic agents, various chemotherapy drugs, and NSAIDs. Given the complexity and variety of possible drug reactions, the decision to desensitize, challenge, or avoid should be made in conjunction with an allergy specialist for complete evaluation and proper risk stratification of the different possible approaches to take.

DRUG ALLERGY AND THE NEED FOR DRUG DESENSITIZATION

Drug allergy is a rising problem, paralleling the worldwide increased use of medications, the plethora of new targeted therapies, and the greater longevity of patients. Allergic drug reactions decrease patients' quality of life, limit treatment options, and can lead to vaccine hesitancy, as seen for the COVID-19 mRNA vaccines. The first cases of reported drug-induced anaphylaxis occurred shortly after the discovery and therapeutic applications of penicillin in 1945, and today, 10–20% of the world's population engaged in health care claims to have a penicillin allergy. Truly allergic patients cannot use penicillin and are negatively impacted by the decreased efficacy, increased costs, and limited availability of second-line antibiotics. Similarly, the need to avoid the offending medications in allergic patients with malignancies and chronic inflammatory diseases can increase morbidity and impact life expectancy.

To address the needs of drug-allergic patients, a novel modality of drug delivery aimed at curtailing allergic symptoms has culminated in drug desensitization (DD), a treatment option that takes advantage of immune inhibitory mechanisms. Rapid multistep protocols that deliver sequential small doses of drug until the target therapeutic dose is reached in a few hours have shown outstanding safety, efficacy, and wide applicability in thousands of patients with infections, chronic inflammatory diseases, malignancies, and other conditions.

DRUG ALLERGY DEFINITIONS AND RISK FACTORS

Drug allergy and drug hypersensitivity are interchangeable terms that refer to acute and delayed symptoms occurring after exposure to medications. While there is a need to address drug-allergic patients, those with unconfirmed allergy labels should be delabeled, and single-dose oral challenges have been shown to be safe in children and adults at low risk for penicillin allergy. Drug allergy is multifactorial and associated with female gender, specific human leukocyte antigen (HLA) haplotypes, atopy, polypharmacy, older age, chronic diseases, microbiome changes, and drug-dependent factors such as the route of administration, repeated and high doses, excipients, and glycosylation.

CLASSIFYING HYPERSENSITIVITY REACTIONS

The modern classification of reactions has incorporated timing, severity, biomarkers, and new presentations to the classical Gell and Coombs definitions. Acute or immediate reactions occur during or within 1–6 h of drug exposure, while delayed reactions occur 6 h to several days or weeks after drug exposure. Reactions can be mild (affecting one organ; grade 1), moderate (affecting two or more organs; grade 2), or severe (associated with changes in vital signs; grade 3).

PHENOTYPES, ENDOTYPES, AND BIOMARKERS

The symptom presentation (phenotype) depends on the mechanisms of the reactions (endotype). Acute reactions include infusion reactions, type I IgE-dependent and -independent reactions, cytokine release reactions (CRRs), and mixed reactions (type I and CRR symptoms). Delayed reactions include type II antibody-mediated cytotoxicity; type III immune complex–mediated reactions; and type IV reactions, which include benign reactions, typically skin limited, and severe cutaneous reactions with systemic symptoms (SCARS) such as Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), drug reaction with eosinophilia and systemic symptoms (DRESS), and acute generalized eosinophilic pustulosis (AGEP) **(Fig. 365-1)**. Symptoms are drug specific, and acute musculoskeletal pain is common in reactions to taxanes, oxaliplatin, doxorubicin, and rituximab.

Type I Reactions Type I reactions result from the activation of mast cells and basophils through IgE-dependent and -independent mechanisms. While IgE sensitization requires repeated exposures and is typical for antibiotics, chemotherapy, and some biologicals, IgE-independent reactions typically occur at first exposure through either complement activation, inhibition of COX-1, or activation of the MRGPRX2 receptor by quinolones, vancomycin, icatibant, and general anesthetics with THIQ binding motif and by basic compounds. Symptoms of type I reactions include itching, flushing, hives, angioedema, dyspnea, wheezing, oxygen desaturation, throat tightening, nausea, vomiting, and hypotension with cardiovascular collapse and are associated with elevated serum tryptase, a specific biomarker of anaphylaxis released from mast cells and basophils granules. Tryptase levels above the normal range (11.4 ng/mL) or above a patient's baseline (× 1.6) obtained within 30 min to 4 h of initial symptoms are diagnostic of type I and mixed reactions. Patients with baseline levels of 7.5 ng/mL or higher may have duplications of the *TPSAB1* tryptase gene located on chromosome 16, known as hereditary alpha tryptasemia (HαT), a familial autosomal dominant trait present in 4–6% of Caucasian populations, which modulates anaphylaxis severity. Other mast cell–derived mediators include urine *N*-methylhistamine, prostaglandins, and leukotrienes.

Cytokine Release Reactions CRRs can occur at first exposure or after several exposures and are thought to be due to activation of T cells and other immune cells. Patients present with fever; chills; back, chest, or pelvic pain; headache; oxygen desaturation; and hyper- or hypotension; these reactions are associated with a transient serum elevation of interleukin (IL) 6.

Mixed Reactions Mixed reactions present with symptoms of type I and CRR reactions and are associated with tryptase and IL-6 elevations (Fig. 365-1).

Delayed Type IV Reactions Delayed type IV reactions amenable to DD present as benign maculopapular rashes without associated systemic symptoms, whereas SCARS, type II, type III, vasculitis, and single-organ toxic reactions are contraindications for DD because minute amounts of medication can trigger severe reactions.

DIAGNOSTIC TESTING

Skin testing (ST) elicits a local wheal-and-flare reaction upon epicutaneous or intradermal injection of drugs inducing IgE-mediated reactions. Its use is limited by the availability of drug components including excipients, skin toxicity, costs, and the time elapsed since the patient's initial reaction (the longer the time, the lower the likelihood that an ST will be positive) and the severity of the reaction (anaphylactic reactions can deplete mediators inducing false-negative ST). Positive and negative predictive values are drug specific, and anaphylaxis to penicillin or carboplatin has not been reported in ST-negative patients.

The basophil activation test (BAT) provides evidence of IgE sensitization by challenging the patient's basophils in vitro with the culprit drug, eliminating the need for direct ST, which has a small risk for anaphylaxis. Serum-specific IgE antibodies to penicillin and platins are found in allergic patients with low sensitivity. Skin patch testing is helpful to evaluate β-lactams, anticonvulsants, corticosteroids, and other drugs that cause delayed type IV reactions with high specific but low sensitivity. Lymphocyte transformation tests (LTTs) measure the activation and/or cytokine release of lymphocytes exposed to culprit drugs and can be used to identify drugs inducing SCARS. Certain HLA haplotypes place patients at risk for SCARS when exposed to abacavir, anticonvulsants, allopurinol, vancomycin, and other drugs, and genotyping is available.

DRUG DESENSITIZATION

DEFINITIONS AND MECHANISMS

DD is a temporary immunotherapy modality, delivered through multistep protocols to safely and timely reintroduce a drug that has induced an acute or delayed allergic reaction. IgE-mediated desensitization takes advantage of inhibitory mast cell/basophil pathways, which are activated by low doses of drug antigens. Rapid delivery of incremental doses recruit phosphatases to IgE receptors, blocking signal transduction and the release of mediators when reaching the target dose and protecting against anaphylaxis. Desensitized patients have transient conversion from positive to negative ST.

PROTOCOLS

Based on inhibitory pathways in mast cell models, human protocols have been generated for type I phenotypes with low starting doses and multiple steps that progress by doubling the dose administered in the previous step at constant time intervals. The first standardized and most used protocol contains three bags of 1/100, 1/10, and undiluted concentrations of the target dose and 12 doubling steps delivered every 15 min so that the target dose is reached in 5.7 h **(Fig. 365-2)**, which has been adapted for IV, PO, SC, IM, intraperitoneal, intraocular, and intrathecal use. Protocols with four bags (starting with a 1/1000 dilution bag) are used for patients with severe initial reactions and associated comorbidities. The recent use of one-bag protocols for type I reactions has produced mixed outcomes, with an increased use of epinephrine during breakthrough reactions (BTRs) and inability to complete treatments in highly sensitized patients.

Phenotype	Infusion Reaction	Type I IgE/non-IgE	Mixed	Cytokine Release	Type II	Type III	Type IV
Endotype	Lymphocyte	Mast cell	Both	T cell	T cell; NK cell; Antibody dependent cell cyto-toxicity; Opsonization; C_{3a}	Neutrophil; C_{3a}; C_{3a}; Antigen/ antibody complexes	MΦ; T cell
Biomarkers	TNF-α, IL-6, IL-1β	Histamine, tryptase	Both	TNF-α, IL-6, IL-1β	IL-6, IL-1β	Specific antibody or antibody/antigen complex deposition	IFN-γ, IL-4, IL-5
Symptoms	Fever Chills/rigors Nausea Pain Headache	Flushing Pruritus Rash Urticaria Throat tightness Shortness of breath Nausea and/or vomiting Anaphylaxis and cardiovascular collapse	Both	Fever, Chills/rigors Nausea Pain Headache Dyspnea Hyper/ hypotension Back pain	Autoimmune Thrombocytopenia Anemia Neutropenia	Serum sickness Urticaria vasculitis Arthus reaction Nephritis Fever	Delayed maculopapular rash
Desensitization	Non indicated, regular infusion	Indicated	Indicated	Indicated	Not indicated, avoid medication	Not indicated, avoid medication	Indicated

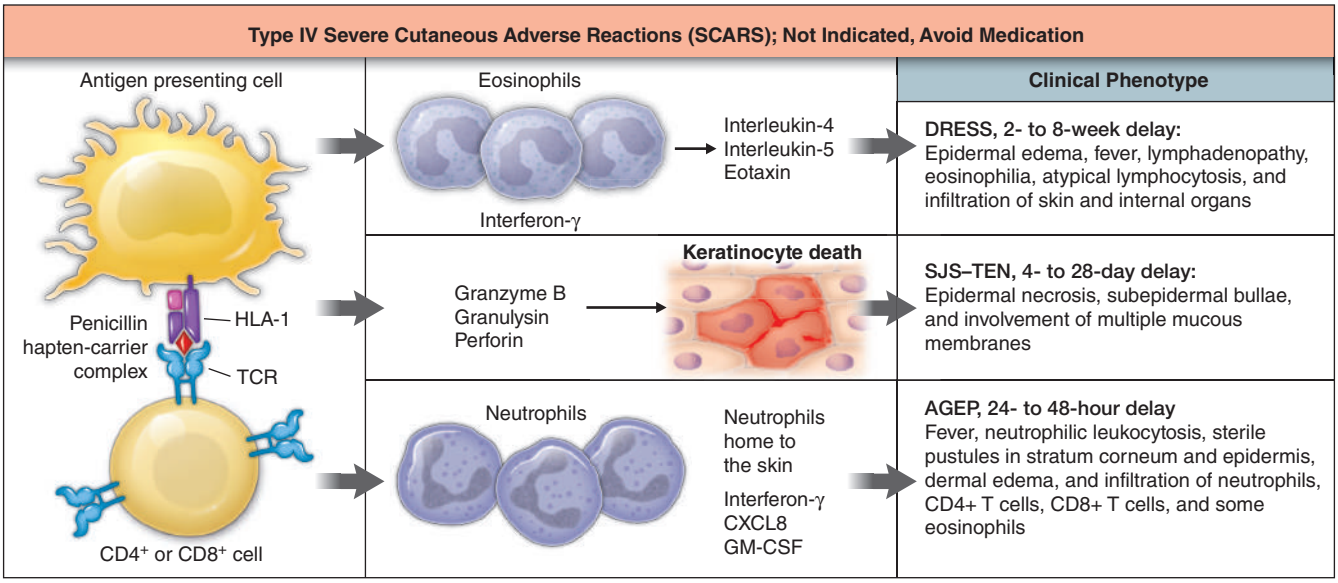

FIGURE 365-1 Drug allergy phenotypes, endotypes, and biomarkers and indications for desensitization. AGEP, acute generalized eosinophilic pustulosis; DRESS, drug reaction with eosinophilia and systemic symptoms; IL, interleukin; SJS-TEN, Stevens-Johnson syndrome–toxic epidermal necrolysis; TNF, tumor necrosis factor. *(From The New England Journal of Medicine, Penicillin Allergy, M Castells, DA Khan et al: 381: 2338. The mechanisms of desensitization for other phenotypes are poorly understood, and CRRs have been successfully treated with multistep one-bag protocols, whereas multiple doses over several days have been used for delayed reactions (see specific drugs). Premedications are tailored to the initial symptoms, and steroids do not protect against anaphylaxis. Omalizumab, a monoclonal anti-IgE antibody, has been used as an adjuvant in highly sensitized patients with type I severe IgE-mediated reactions, including life-threatening anaphylaxis. Desensitization is a temporary phenomenon that does not lead to sustained tolerance and must be repeated with each exposure or if there has been a pause between doses equal to two or more half-lives of the drug. However, the desensitized state can be maintained by continued drug exposure as with antibiotics and aspirin/COX-1 inhibitors. Some patients reactive to taxanes and certain biologicals with uneventful DD protocols may eventually return to regular infusions.

INDICATIONS, BREAKTHROUGH REACTIONS, AND OUTCOMES

■ INDICATIONS (FIG. 365-2)

Qualifications for DD depend on the need of the medication as first-line therapy, the initial reaction phenotype, and its severity. Infusion reactions, mild CRRs, and mild delayed reactions can be addressed by symptoms targeting adjuvant medications. DD is indicated for type I IgE-dependent and IgE-independent, CRR, mixed, and nonsevere delayed type IV phenotypes. Type I and mixed reactions

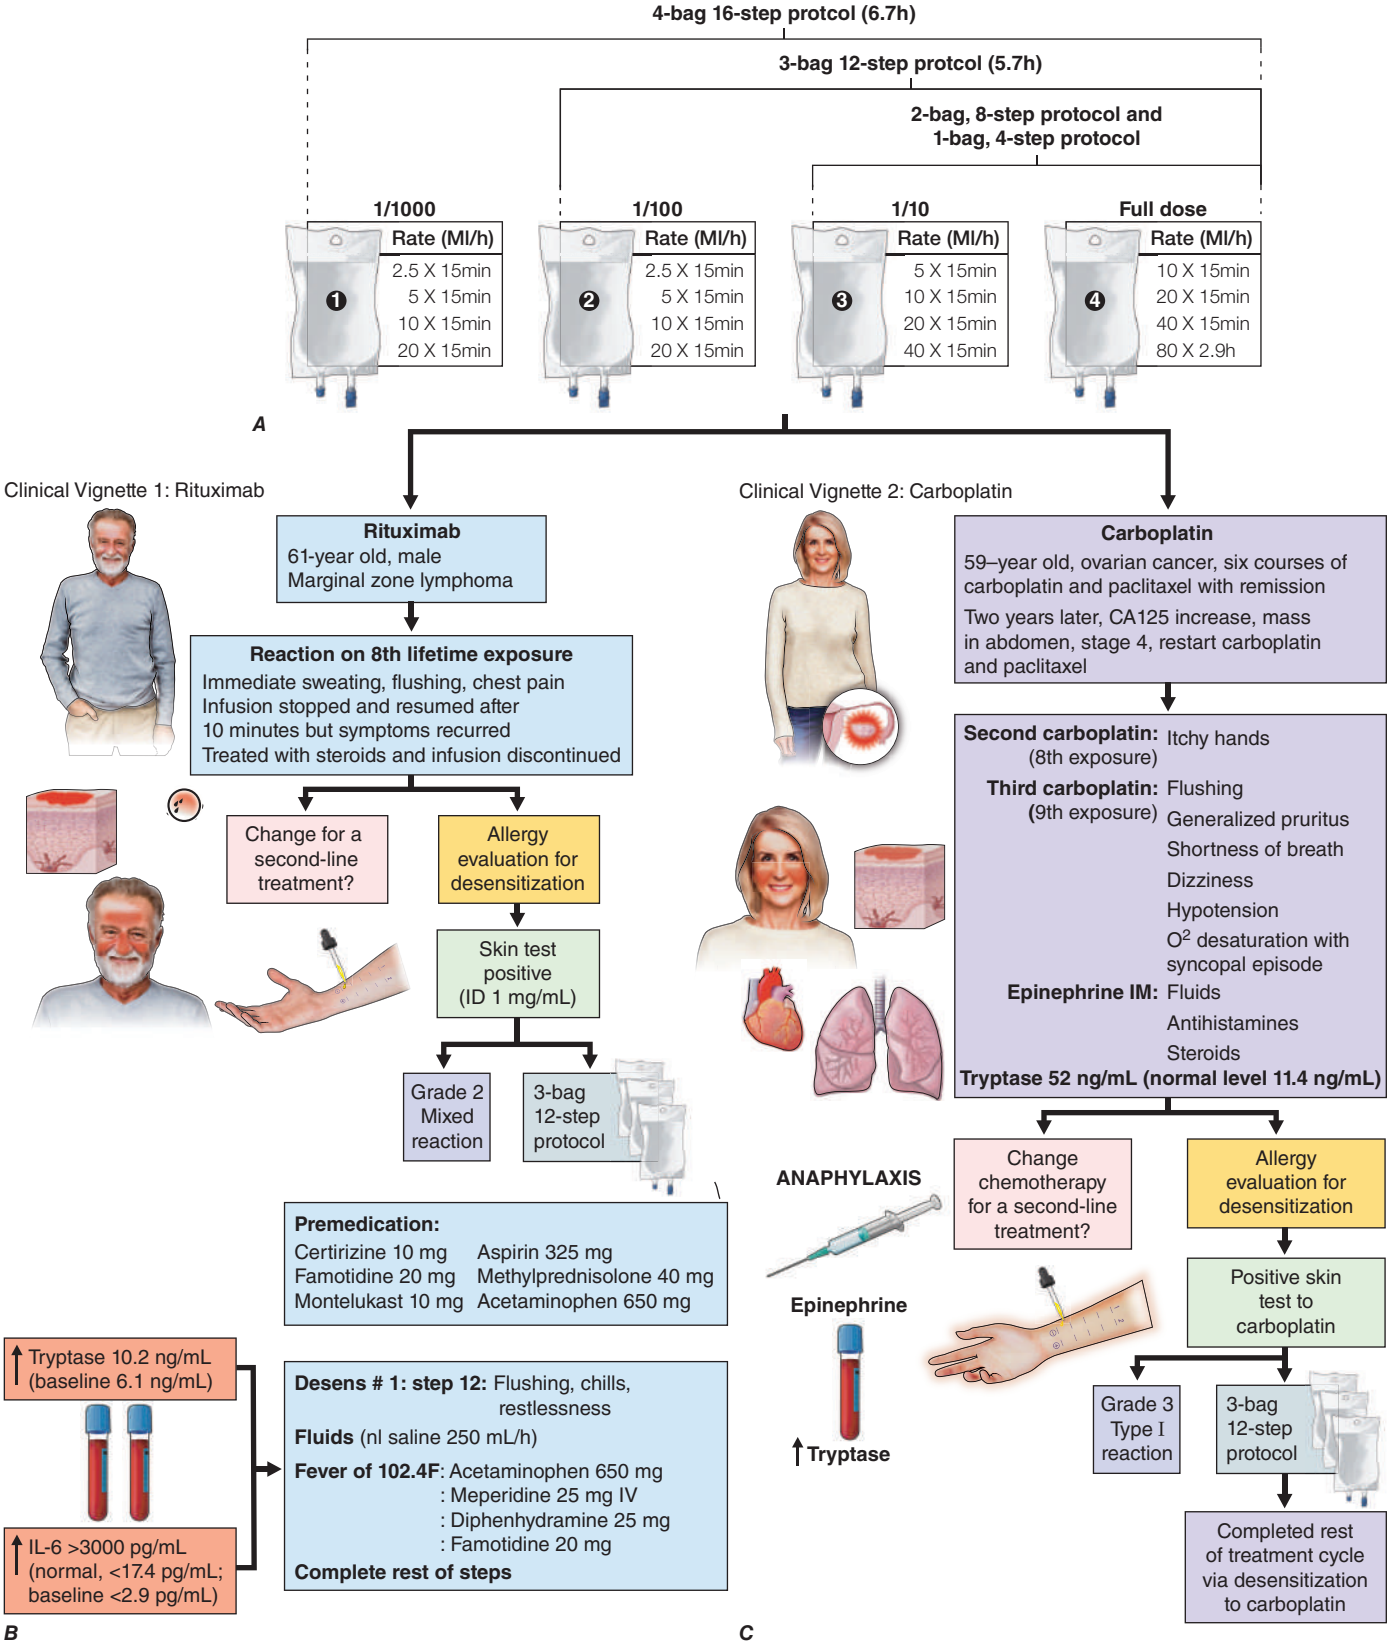

FIGURE 365-2 Desensitization: protocols and applications. ***A.*** Multibag, multistep intravenous desensitization protocols. ***B.*** Rituximab allergic reaction with mixed phenotype, positive skin test, and elevated tryptase and interleukin (IL) 6 biomarkers and successful treatment with a three-bag 12-step protocol. ***C.*** Carboplatin allergic reaction with type I phenotype, positive skin test, and elevated tryptase biomarker and successful treatment with a three-bag 12-step protocol. *(Reproduced with permission from L Campos et al: Curr Treat Options Allergy 6:519, 2019.)*

in patients with multiple exposures to antibiotics, chemotherapeutic drugs, and biologicals indicate IgE sensitization. ST-positive patients require DD for reexposure since the risk for anaphylaxis is high. In patients with mild reactions and negative biomarkers, controlled drug challenges are indicated to assess tolerance. Large clinical series support outpatient settings for the majority of DD, which decreases the starting treatment time and costs and improves patients' experiences.

DD BREAKTHROUGH REACTIONS AND OUTCOMES

BTRs are typically mild with symptoms similar to the initial reaction. They occur in 10–30% of protocols and require symptom-specific management including epinephrine for severe reactions. BTRs do not preclude the completion of the DD protocols in 99% of cases, and no deaths due to DD have been reported. Comorbidities such as pregnancy, cystic fibrosis, decreased lung function, cardiac diseases, advanced cancer, beta blocker and/or angiotensin-converting enzyme inhibitor use, and prior severe reactions increase the risk during BTRs (Fig. 365-3). The administration of antibiotics, monoclonal antibodies, and chemotherapy drugs through DD has shown equal efficacy as for standard administration, with the expected clearance of infections, decreased inflammation, and similar cancer responses. Kounis syndrome and takotsubo cardiomyopathy resulting from drug-induced anaphylaxis are contraindications for DD (Fig. 365-3).

APPROACH TO SPECIFIC DRUGS

ANTIBIOTICS

Antibiotics can induce all the reactions in Fig. 365-1, but the most common are type I IgE-dependent and type IV non-SCARS reactions, both of which can be addressed by DD.

β-Lactams The first description of penicillin desensitization was in a World War II allergic soldier who presented with wheezing and hypotension after penicillin injection and received oral incremental doses over 30 days until he was able to tolerate a treatment course. The initial success led to shorter protocols to treat patients with bacterial endocarditis and pregnant women with syphilis who had a history of penicillin-induced anaphylaxis and positive ST. Safe rapid PO and IV desensitization protocols are currently available for all antibiotic classes and can treat high-risk patients, including cystic fibrosis patients with low pulmonary function.

Sulfonamides Delayed type IV rashes to trimethoprim-sulfamethoxazole occurred in up to 40% of patients with <100 total CD4 T cells/μL during the early 1990s HIV/AIDS epidemic, and DD included incremental doses over multiple days. Reactions have decreased since retroviral treatments, and shorter protocols have evolved. One-day PO and IV multidose protocols have shown consistent safety and efficacy for delayed reactions in non-HIV patients.

CHEMOTHERAPY

Taxanes Over 40% of patients exposed to paclitaxel and docetaxel presented with acute reactions, which have been reduced to 1% by antihistamine and corticosteroid premedication. Moderate to severe reactions attributed to lipid excipients (Cremophor and polysorbate 80) and to IgE sensitization through cross-reactive foods and environmental allergens occur typically at first or second exposure with type I, mixed, and delayed phenotypes. Patients with delayed rashes can convert to acute reactions including anaphylaxis upon subsequent exposures. The first DD to paclitaxel was reported in 2002, and an early study of 940 DDs to paclitaxel and docetaxel in 138 patients described BTRs in 20% of cases, and 22% of desensitized patients returning to standard infusions. A review of 25 studies with 976 patients and 2396 DDs to paclitaxel and docetaxel, completed in 95–100% of cases, the majority with three-bag 12-step protocols, showed 32% paclitaxel and 20% docetaxel mild BTRs and no deaths.

Platinums Platinum drug (carboplatin, cisplatin, and oxaliplatin) IgE sensitization requires multiple exposures (typically six or more;

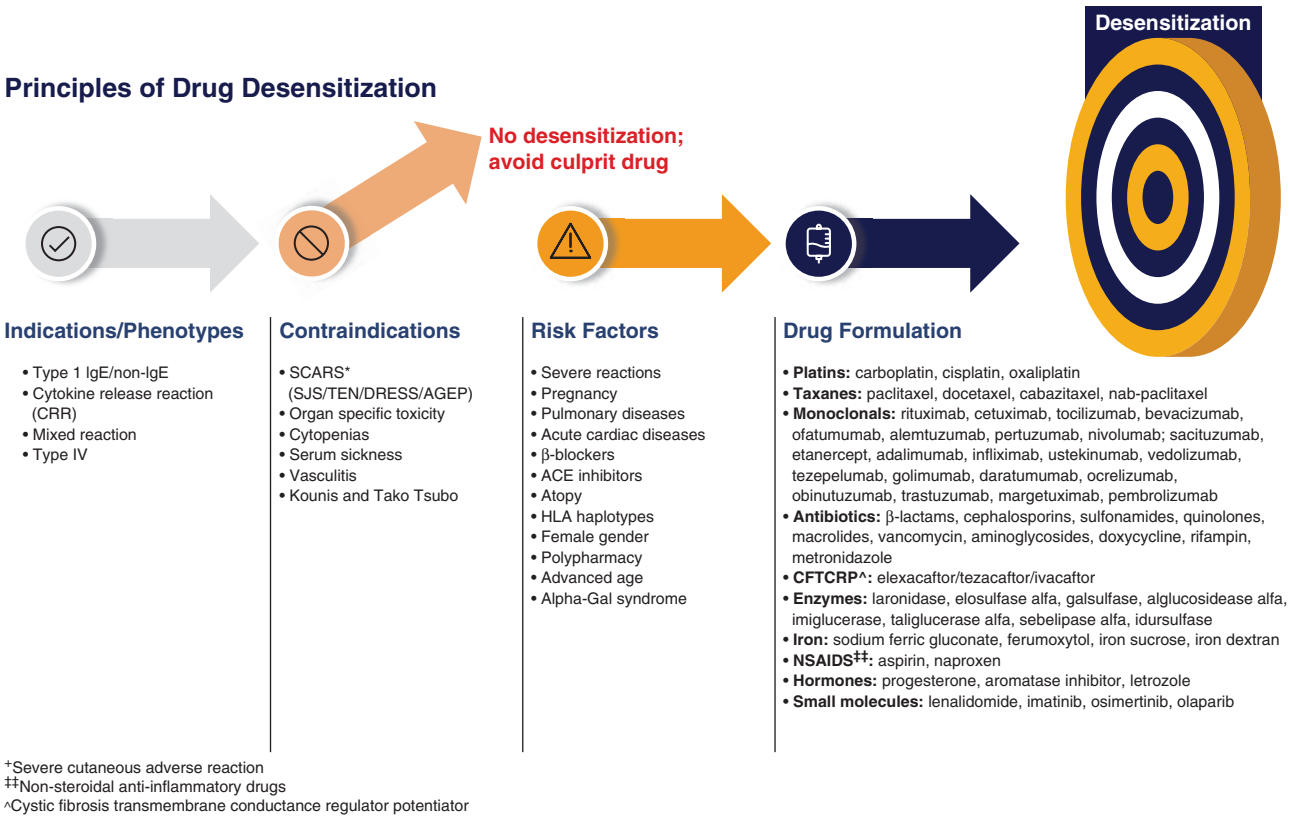

FIGURE 365-3 Principles of drug desensitization: Indications, contraindications, risk factors, and drugs with successful desensitizations. ACE, angiotensin-converting enzyme; AGEP, acute generalized eosinophilic pustulosis; DRESS, drug reaction with eosinophilia and systemic symptoms; HLA, human leukocyte antigen; SJS-TEN, Stevens-Johnson syndrome–toxic epidermal necrolysis.

less for *BRCA* mutation carriers), and sensitized patients typically have type I symptoms with pruritus, flushing, urticaria, throat tightening, and hypotension with elevated tryptase (Fig. 365-2). ST is positive in >85% of patients with recent reactions. In a prospective study of 126 women who received six or more carboplatin treatments, repeat ST before each exposure identified reactors, with seven anaphylactic reactions in seven patients who agreed to be reexposed to carboplatin despite positive ST. Oxaliplatin reaction phenotypes include CRR and mixed reactions with conversion from type I to CRR and mixed phenotypes during DD. Oxaliplatin-induced immune-mediated thrombocytopenia (OIIT) with bleeding is a rare complication that precludes further DD.

Carboplatin DD started in early 2000 and a large study in 2016 with 370 patients (212 carboplatin-allergic and 13 cisplatin-allergic patients), who underwent 2177 DDs, mostly in the outpatient setting with three- or four-bag protocols, showed 20% mild BTRs, non-superior costs compared to regular infusions, and a life expectancy advantage at 5 years in ovarian cancer patients compared to nonallergic patients. A study of 272 patients allergic to platins, taxanes, and monoclonals who underwent 1471 DDs with three-bag 12-step protocols reported similar safety. Oxaliplatin DD poses challenges due to the heterogeneity of phenotypes and phenotype switching. A study of 48 patients with 200 DDs who underwent three-bag 12-step protocols showed mild to moderate BTRs in 18 patients, 1 patient with OIIT, and 2 patients with hemolytic anemia. A study of patients with type I, CRR, and mixed reactions who underwent 273 DDs indicated a switch from type I to CRR and mixed reactions during DD, with elevated IL-6, and two patients developed OIIT. The survival of platinum-desensitized patients is noninferior to nonallergic patients.

Doxorubicin and Other Chemotherapy Drugs Doxorubicin reactions are rare, occurring at first exposure, and a study of 30 patients and 128 DDs, mostly with three-bag 12-step protocols, showed 16% mild BTRs, and one patient required epinephrine. DDs for etoposide, cyclophosphamide, methotrexate, gemcitabine, and other chemotherapy drugs have shown similar safety.

MONOCLONALS/BIOLOGICALS

Infusion reactions of the type I IgE/non-IgE mediated, CRR, mixed, and delayed-reaction phenotypes have been reported for monoclonal antibodies (MoAbs). Hypersensitivity reactions can occur on first exposure or after multiple exposures (Fig. 365-2). Reactions are more frequent with chimeric MoAbs but also occur with humanized and fully humanized MoAbs. Skin testing is limited by cost. Patients with cetuximab-induced anaphylaxis react to galactose-alpha-1-3-galactose, a nonhuman carbohydrate in the Fab chain of cetuximab, due to pre-existing IgE acquired through tick bite sensitization. DDs have been reported for most IV and SC available MoAbs (Fig. 365-3). The first series of MoAb desensitizations included 23 patients with moderate to severe type I and mixed reactions to trastuzumab, infliximab, and rituximab who underwent 105 DDs with three bags and 12 steps and had 29% mild BTRs. A study of 104 patients who reacted to 16 MoAbs with type I, CRR, mixed, and delayed reactions and received 526 DDs, mostly with three bags and 12 steps in the outpatient setting, presented with 23% mild BTRs. Tryptase was elevated in type I and IL-6 in CRR BTRs.

SMALL MOLECULES

Epidermal growth factor receptor and tyrosine kinase inhibitors such as imatinib, osimertinib, and olaparib can induce type I and type IV reaction phenotypes, and successful DDs with multiple oral doubling doses have been reported, allowing for continued long-term maintenance.

NONSTEROIDAL ANTINFLAMMATORY DRUGS (NSAIDS)

Aspirin (ASA) and other NSAIDs can induce type I reactions with urticaria and anaphylaxis thought to be IgE-mediated and, in patients with asthma and dysregulated lipid metabolism, a syndrome termed aspirin-exacerbated respiratory disease (AERD) with bronchospasm. Patients with AERD have universal intolerance to COX-1 inhibitors but tolerate COX-2 inhibitors. The American Academy of Allergy, Asthma, and Immunology Work Group Report in 2020 reviewed 14 series of ASA DDs with intranasal ketorolac or oral aspirin in >900 AERD patients. More than 70% of patients reported improvement of asthma, lack of polyp recurrence, recovery of sense of smell, and less steroid usage, with cross-desensitization and tolerance to all COX-1 inhibitors while maintained on daily ASA. For type I reactions in cardiac and neurologic patients, DD with rapid doubling doses has been proven safe and effective.

OTHER DRUGS

Symptoms of progestogen hypersensitivity (PH) are cyclical and include type I and delayed phenotypes. PH can lead to miscarriage, and oral and vaginal DD protocols have resulted in viable pregnancies. Reactions to iron formulations include type I, CRR, mixed, and delayed phenotypes that are responsive to DD. Allopurinol-induced delayed rashes respond to PO and IV DD protocols. Corticosteroids, glatiramer acetate, vaccines, and other medication DDs have been reported with doubling multistep PO, IV, and SC protocols.

IMPACT

Discontinuing drugs inducing allergic symptoms affects patients for whom second-line therapies may not be available, are more expensive, or do not provide similar therapeutic benefits. DD protocols allow for the safe reintroduction of first-line therapies, and their use should be extended to all patients in need.

366 Mastocytosis

Matthew P. Giannetti, Joshua A. Boyce

DEFINITION AND EPIDEMIOLOGY

Mastocytosis is defined by accumulation of clonally expanded mast cells in tissues such as skin, bone marrow, liver, spleen, and gut. Diagnostically, mast cell expansion is most readily identified in skin and/or bone marrow. Mastocytosis occurs at any age, although it is most commonly diagnosed in infancy and young adulthood. The prevalence of mastocytosis is estimated at ~1 in 10,000 people. Most forms of the disease are characterized by somatic gain-of-function mutations in the stem cell factor receptor (*KIT*) gene, and >90% of patients carry the *KIT* D816V mutation. Familial occurrence is rare, and atopy is not increased compared with the general population.

CLASSIFICATION AND PATHOPHYSIOLOGY

A consensus classification for mastocytosis recognizes cutaneous mastocytosis with variants, systemic mastocytosis with five variants, and mast cell sarcoma **(Table 366-1)**.

Cutaneous mastocytosis is the most common diagnosis in children and indicates disease limited to skin with absence of pathologic infiltrates in internal organs. It is usually diagnosed within the first year

TABLE 366-1 Classification of Mastocytosis

Cutaneous mastocytosis (CM)
Maculopapular cutaneous mastocytosis (MPCM)
Solitary mastocytoma of skin
Diffuse cutaneous mastocytosis
Systemic mastocytosis
Indolent systemic mastocytosis (ISM)
Smoldering systemic mastocytosis
Systemic mastocytosis with associated clonal hematologic non–mast cell lineage disease (SM-AHNMD)
Aggressive systemic mastocytosis (ASM)
Mast cell leukemia (MCL)
Mast cell sarcoma (MCS)

Source: Modified from DA Arber et al: International consensus classification of myeloid neoplasms and acute leukemias: integrating morphologic, clinical, and genomic data. Blood 140:1200, 2022.

of life with demonstration of fixed, maculopapular, polymorphic, and hyperpigmented lesions (known as maculopapular cutaneous mastocytosis [MPCM]), solitary mastocytoma(s), or diffuse cutaneous mastocytosis. Although mast cell accumulation is limited to the skin, children often have systemic symptoms. Systemic mastocytosis (SM) refers to involvement of an extracutaneous site (most often bone marrow). There are five distinct variants of SM. *Indolent systemic mastocytosis* (ISM) accounts for >70% of adult patients. ISM is diagnosed when there is no evidence of organ dysfunction due to mast cell infiltration, an associated hematologic disorder, or mast cell leukemia. ISM is associated with a normal life expectancy. *Smoldering systemic mastocytosis* (SSM) is characterized by high mast cell burden including bone marrow infiltration of >30% and a baseline serum tryptase >200 ng/mL (B findings), but absence of *systemic mastocytosis associated with clonal hematologic non–mast cell lineage disease* (SM-AHNMD) or *aggressive systemic mastocytosis* (ASM) **(Table 366-2)**. In SM-AHNMD, the prognosis is determined by the nature of the associated disorder, which can range from dysmyelopoiesis to leukemia. In ASM, mast cell infiltration may occur in multiple organs such as liver, spleen, gut, bone, and bone marrow resulting in one or more C findings and a poor prognosis (Table 366-2). *Mast cell leukemia* (MCL) is the rarest form of SM and is invariably fatal at present; the peripheral blood contains circulating, metachromatically staining, atypical mast cells. An aleukemic form of MCL is recognized without circulating mast cells when the percentage of high-grade immature mast cells in bone marrow smears exceeds 20% in a nonspicular area. Mast cell sarcoma is a rare solid mast cell tumor with malignant invasive features.

TABLE 366-2 B and C Findings for Diagnosis of SSM and ASM

B Findings (2 or more in the absence of any C findings are required for a diagnosis of SSM):

1. High MC burden: MC infiltration in bone marrow of >30%, basal serum tryptase level >200 ng/mL, and/or *KIT* D816V >10% VAF in bone marrow
2. Hypercellular bone marrow with signs of dysmyelopoiesis but without cytopenias meeting C criteria or WHO criteria for an MDS or MPN
3. Palpable hepatomegaly, palpable splenomegaly, or lymphadenopathy (on CT or ultrasound: >2 cm) without impaired liver function or hypersplenism

C Findings (1 or more required for a diagnosis of ASM). C findings should be reasonably attributable to high tissue MC infiltration:

1. Cytopenia(s): ANC <1000/μL or Hb <10 g/dL or PLT <100,000/μL
2. Hepatomegaly with ascites and impaired liver function
3. Palpable splenomegaly with associated hypersplenism
4. Malabsorption with hypoalbuminemia and weight loss
5. Skeletal lesions: large area(s) of osteolysis with pathologic fractures (presence of osteoporosis alone without osteolytic lesions does not satisfy this criterion)

Abbreviations: ANC, absolute neutrophil count; ASM, aggressive systemic mastocytosis; CT, computed tomography; Hb, hemoglobin; MC, mast cells; MDS, myelodysplastic syndromes; MPN, myeloproliferative disorders; PLT, platelets; SSM, smoldering systemic mastocytosis; VAF, variant allele frequency; WHO, World Health Organization.

Somatic activating mutations in the *KIT* gene are characteristic of mastocytosis. *KIT* D816V is most common, although other mutations have been reported. *KIT* mutations are found in mast cells and sometimes in other cell lineages in patients with mastocytosis. *KIT* mutations are observed in patients with all forms of SM but are also present in some children with cutaneous mastocytosis in lesional skin. Additional mutations in genes such as *TET2, SRSF2, ASLX1*, and *RUNX1* known to be associated with other hematologic neoplastic disorders can be detected in patients, usually with advanced variants of SM. The life expectancy for patients with cutaneous mastocytosis and for most patients with ISM is normal, whereas that for patients with SM-AHNMD is determined by the non–mast cell component. ASM and MCL have a poor prognosis, while patients with SSM have an intermediate prognosis. Progression from ISM to a more advanced form is uncommon (~5% lifetime risk); however, patients should be monitored for emergence of hematologic disease and end-organ manifestations of ASM. In infants and children with cutaneous manifestations, namely, maculopapular cutaneous mastocytosis, mastocytoma(s), or bullous lesions, visceral involvement is usually lacking, and spontaneous resolution is common prior to adolescence. Polymorphic maculopapular cutaneous mastocytosis usually resolves spontaneously. Progression from cutaneous mastocytosis (CM) to ISM may occur in ~10% of children, especially in those with high mast cell burden (diffuse cutaneous mastocytosis) or hematologic abnormalities and those who present with smaller uniform lesions with diameters measuring <2 cm (monomorphic MPCM).

CLINICAL MANIFESTATIONS

The clinical manifestations of SM are due to the release of bioactive substances acting at both local and distal sites, tissue infiltration by mast cells, and the tissue response to the cellular infiltrate. Clinical manifestations include intermittent urticaria, flushing, tachycardia and vascular collapse, gastric acid hypersecretion, crampy lower abdominal pain, and diarrhea. The increased local mast cell burden in the skin (MPCM), bone marrow, and gastrointestinal tract may be a direct cause of pruritus, bone pain, and malabsorption, respectively. Mast cell–mediated fibrotic changes may occur in liver, spleen, and bone marrow but not in gastrointestinal tissue or skin.

The cutaneous lesions of MPCM are reddish-brown macules, papules, or plaques that respond to trauma with urtication and erythema (Darier's sign). Two distinct forms of MPCM are recognized: polymorphic MPCM and monomorphic MPCM. Children with CM may present with MPCM, mastocytomas, or diffuse cutaneous mastocytosis (DCM). Mastocytomas are generally solitary elevated lesions that are yellow, brown, or red in color. Their size may vary from a few millimeters to several centimeters. Rubbing or irritation of a mastocytoma lesion may lead to systemic symptoms such as flushing and urticaria. Children with DCM present without distinct lesions, but rather a generalized thickening of skin and "peau d'orange" appearance due to diffuse mast cell infiltration. DCM is associated with bullae formation and more severe systemic symptoms, including upper gastrointestinal irritation and vascular collapse in the first few years of life. Maculopapular skin lesions of mastocytosis may be present in patients with adult-onset systemic disease. The apparent incidence of cutaneous lesions is ≥80% in patients with ISM and <50% in those with SM-AHNMD or ASM. In the upper gastrointestinal tract, gastritis and peptic ulcer are significant problems. In the lower intestinal tract, the occurrence of diarrhea and abdominal pain is attributed to increased motility due to mast cell mediators. The periportal fibrosis associated with mast cell infiltration may lead to portal hypertension and ascites. In some patients, anaphylaxis may occur with rapid and life-threatening vascular collapse. Anaphylaxis is most commonly induced by Hymenoptera stings and nonsteroidal anti-inflammatory drugs (NSAIDs). The neuropsychiatric disturbances are clinically most evident as impaired recent memory, decreased attention span, and "migraine-like" headaches. Patients may experience exacerbation of a specific clinical sign or symptom variably with alcohol ingestion, temperature changes, stress, use of mast cell–interactive opioids, or ingestion of NSAIDs.

TABLE 366-3 Diagnostic Criteria for Systemic Mastocytosis[a]

Major:
Multifocal dense infiltrates of mast cells (>15 mast cells per aggregate) in bone marrow or other extracutaneous tissues
Minor:
Abnormal mast cell morphology (spindle shape or atypical immature morphology) in >25% of mast cells
Aberrant mast cell phenotype with expression of CD25, CD2, or CD30
Detection of *KIT* D816V mutation or other activating *KIT* mutation in peripheral blood, bone marrow, or an extracutaneous organ
Total serum tryptase >20 ng/mL

[a]Diagnosis requires either the major criterion and one minor criterion or three minor criteria.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Cutaneous mastocytosis is diagnosed by observing the characteristic lesions of MPCM or mastocytoma(s). A skin biopsy may be obtained to confirm these subvariants of CM, whereas patients with suspected DCM and bullous mastocytosis require a skin biopsy to confirm the diagnosis. Although the diagnosis of SM is generally suspected based on clinical history, physical examination findings, and laboratory procedures, it can only be confirmed with a tissue diagnosis. The diagnosis of SM necessitates a lesional biopsy to meet the criteria of one major plus one minor or three minor findings **(Table 366-3)**. The major criterion requires mast cell aggregates of >15 mast cells, often in paratrabecular and perivascular locations with associated lymphocytes and eosinophils. Minor criteria include abnormal "spindled" mast cell morphology, aberrant mast cell membrane immunophenotype, or an activating *KIT* mutation (classically *KIT* D816V). A basal serum tryptase level is a noninvasive approach to consider before bone marrow biopsy. A rare histopathologic subvariant called *well-differentiated systemic mastocytosis* (WDSM) is characterized by clusters of mature-appearing, fully granulated and round mast cells, lack of aberrant CD25 and CD2 expression, and lack of D816V *KIT* mutation in most patients. These patients often have a history of childhood-onset cutaneous disease, and their mast cells may display aberrant CD30 expression and other markers of clonality such as atypical (non-D816V) *KIT* mutations. Additional studies directed by the presentation include a bone densitometry, bone scan, or skeletal survey; computed tomography scan or endoscopy; and a neuropsychiatric evaluation. Osteoporosis is increased in mastocytosis and may lead to pathologic fractures.

Some patients presenting with recurrent symptoms referrable to mast cell activation (particularly anaphylaxis with hypotensive syncope) have been found to have underlying mastocytosis. A subset of these patients may be found to have evidence of a clonal hematologic process such as the D816V *KIT* mutation, but lack full diagnostic criteria for SM. Such patients are termed to have *monoclonal mast cell activation syndrome*.

The differential diagnosis requires the exclusion of other disorders. A 24-h urine assessment of 5-hydroxy-indoleacetic acid and metanephrines should exclude a carcinoid tumor and pheochromocytoma, respectively. Hereditary α-tryptasemia may be characterized by symptoms consistent with mast cell activation in addition to multisystem involvement and elevated baseline serum tryptase. These patients have autosomal dominant inheritance of extra-allelic copies of the α-tryptase gene at the TPSAB1 locus. Most patients with recurrent IgE-induced or idiopathic anaphylaxis present with urticaria, angioedema, and/or bronchospasm, which are not typical manifestations of anaphylaxis in SM.

TREATMENT

Mastocytosis

The management of SM is symptom control using a stepwise symptom/sign–directed approach. Medications include an H_1 antihistamine for flushing and pruritus, an H_2 antihistamine or proton pump inhibitor for gastric acid hypersecretion, oral cromolyn sodium for diarrhea and abdominal pain, and occasionally aspirin (in those who are known to be tolerant of NSAIDs) for severe flushing to block biosynthesis of prostaglandin D_2. Systemic glucocorticoids appear to alleviate malabsorption. A self-injectable epinephrine prescription is recommended for most patients due to increased incidence of anaphylaxis. Patients with a history of systemic Hymenoptera venom reaction should be evaluated for venom-specific IgE and placed on lifelong venom immunotherapy if positive.

Mast cell cytoreductive therapy consisting of midostaurin, avapritinib, IFN-α, or cladribine has classically been reserved for advanced variants of SM. Targeted tyrosine kinase inhibitors (such as avapritinib) are now considered first-line therapy for those with advanced SM or refractory symptoms in ISM. In ISM, avapritinib reduces bone marrow mast cell burden and improves symptoms. The efficacy of cytoreductive therapy in mastocytosis is variable, perhaps because of side effects that limit dosage. Imatinib is not effective in most cases as the D816V *KIT* mutation mediates resistance. Combination chemotherapy is appropriate for the frank leukemias. Stem cell transplantation has been shown to be effective in a small subset of patients with advanced mastocytosis.

367 Autoimmunity and Autoimmune Diseases

Mariana J. Kaplan

DEFINITION, INCIDENCE, AND PREVALENCE

A key function of the human immune system is to protect the body from harmful external and internal insults, including infections, various toxins, and cancer cells. In addition to the chemical and structural barriers that protect from noxious agents, the immune system provides two mechanisms of defense: innate and adaptive immune responses. Importantly, an effective immune system should be able to distinguish self from nonself and avoid harmful responses to the body's tissues. As such, while self-recognition is important developmentally to clear dead cells throughout the body and to shape the lymphocytes' immune receptors repertoire, bona fide autoreactive responses that are harmful to the organism are suppressed under normal conditions.

Autoimmunity is defined as the development of adaptive immune responses (autoantibodies [autoAbs] or T lymphocyte responses) that

react with autoantigens (autoAgs). This phenomenon is present in all individuals, does not necessarily carry pathogenic consequences, and tends to be more prevalent with age. In contrast, in autoimmune diseases (ADs), an aberrant response of the innate and adaptive immune system develops, leading to a loss of tolerance to self that results in clinically relevant pathogenic responses. In these instances, the immune system attacks various cells, tissues, and organs by mistaking them for external organisms, causing damage and clinical manifestations. Approximately 150 ADs (organ-specific and systemic) have been described (some of them are highlighted in Table 367-1). With scientific and technologic advances, a better characterization of the pathogenic pathways leading to clinical manifestations in autoimmunity is being defined, and it is very likely that new definitions of diseases (based on clinical features and/or on pathophysiologic pathways) will continue to emerge. Overall, AD are chronic and incurable conditions that significantly affect the quality of life and, in many cases, are characterized by accelerated mortality.

From various epidemiologic studies, there appears to be an ongoing trend for increased incidence and prevalence of many ADs. It was estimated that, in the United States in 2009, the prevalence of AD was 7.6–9.4% of the general population, or ~25–31 million people, which is likely an underestimation. ADs can occur at any age, and many of them affect predominantly females. As a group, ADs are in the top 10 leading causes of death in women. An individual affected by an AD has a high risk of developing another autoimmune condition, of having other family members who will develop autoimmunity, and of developing certain cancers and premature cardiovascular disease.

TABLE 367-1 Examples of Some Organ-Specific and Systemic Autoimmune Diseases (ADs)

ORGAN-SPECIFIC AD	SYSTEMIC AD
Hashimoto's thyroiditis	Systemic lupus erythematosus
Graves' disease	Rheumatoid arthritis
Type 1 diabetes mellitus	Primary antiphospholipid syndrome
Addison's disease	Ankylosing spondylitis
Pernicious anemia	Idiopathic inflammatory myopathies
Celiac disease	Sjögren syndrome
Autoimmune hepatitis	Progressive systemic sclerosis
Primary biliary cholangitis	Mixed connective tissue disease
Primary sclerosing cholangitis	Giant cell arteritis
Vitiligo	Takayasu arteritis
Pemphigus and other autoimmune bullous diseases	Polyarteritis nodosa
Multiple sclerosis	ANCA-associated vasculitis
Myasthenia gravis	Anti glomerular basement membrane disease
Autoimmune polyglandular syndromes	Cryoglobulinemic vasculitis
Autoimmune oophoritis	IgA vasculitis (Henoch-Schönlein)
Autoimmune orchitis	Hypocomplementemic urticarial vasculitis
Primary CNS angiitis	Kawasaki disease
Isolated aortitis	Behcet's disease
Cutaneous arteritis	Cogan's syndrome
Cutaneous leukocytoclastic angiitis	Psoriasis/psoriatic arthritis
Guillain-Barré syndrome	Inflammatory bowel disease
Immune thrombocytopenic purpura	Rheumatic fever
Autoimmune hemolytic anemia	Sarcoidosis
Autoimmune pancreatitis	Undifferentiated connective tissue disease
Dermatitis herpetiformis	
Autoimmune autonomic ganglionopathy	
Autoimmune encephalitis	
Autoimmune inner ear disease	
Autoimmune myocarditis	
Autoimmune myelofibrosis	
Autoimmune retinopathy	
Autoimmune sudden sensorineural hearing loss	
Chronic inflammatory demyelinating polyneuropathy	
Cutaneous lupus	

Abbreviations: ANCA, antineutrophil cytoplasmic antibody; CNS, central nervous system; IgA, immunoglobulin A.

PATHOGENESIS

GENETIC AND EPIGENETIC FACTORS

The development of AD is considered a multistep process, where both genetic and environmental factors play key roles in leading to immune dysregulation and loss of tolerance, which can precede the development of clinical symptoms by many years. A variety of susceptibility genes associated to autoimmunity have been described, and there is familiar aggregation of AD. Furthermore, in type 1 diabetes mellitus (T1DM), rheumatoid arthritis (RA), multiple sclerosis (MS), and systemic lupus erythematosus (SLE), the disease concordance in monozygotic and dizygotic twins is between 15 and 30% and <5%, respectively. This suggests that epigenetic factors also play important roles in AD susceptibility. Many genes associated with enhanced risk for AD are known to regulate immune responses, and some of the identified genes are associated with more than one AD. In most cases, ADs are polygenic, although monogenic disorders that lead to autoimmunity have been described and helped clarify pathways that lead to loss of immunologic tolerance. Among the susceptibility genes that have been identified, specific human leukocyte antigen (HLA)-DR types, deficiency in complement component genes, and genes associated with the type I interferon (IFN) pathway and with B- and T-cell function have all been associated with enhanced autoimmunity risk. HLA haplotype is considered the best predictor of AD risk and has been linked to the development of autoAbs in family members of AD patients. One potential mechanism linked to HLA is that aberrant self-Ags (e.g., misfolded, posttranslationally modified during cell death, citrullinated) that are transported by major histocompatibility complex (MHC) class II can exhibit antigenic ability that is different from normal self-Ags and promote autoimmunity. This phenomenon has been reported, for example, in organ-specific autoimmunity such as Graves' disease and in systemic autoimmunity such as RA. Abs binding to autoAg complexes with MHC class II molecules are associated with enhanced risk of various systemic ADs such as RA and antineutrophil cytoplasmic antigen (ANCA)-associated vasculitis (AAV).

There is significant overlap between specific gene variants and several different ADs, indicating common genetic pathways that may explain risk for more than one disease. For example, a common haplotype of the signal transducer and activation of transcription 4 (*STAT4*) gene has been associated with susceptibility to SLE, RA, and primary Sjögren syndrome, whereas polymorphisms in protein tyrosine phosphatase nonreceptor type 22 (*PTPN22*) are associated with T1DM, SLE, RA, and other ADs. A list of some of the genes associated with AD risk is provided in Table 367-2.

Epigenetic factors have been implicated in early onset of some ADs, as well as in the development of lymphocyte autoreactivity and aberrant trained immunity in innate immune cells. Indeed, both metabolic and epigenetic programming characterized by various histone modifications, changes in DNA methylation, and other immunomodulatory alterations have been described in various ADs. Environmental factors that alter genes through epigenetic modifications may have subsequent effects on autoimmunity susceptibility in the offspring of individuals affected by AD.

ENVIRONMENTAL FACTORS

Many studies support the concept that several "hits" from the environment, as well as poorly understood stochastic events in genetically predisposed individuals, will contribute to the development of clinically relevant AD. Many environmental exposures have been linked to an enhanced risk for developing clinical autoimmunity, including ultraviolet light; infections (discussed in detail later in the chapter) and mucosal dysbiosis; tobacco use; exposure to silica, solvents, pesticides, or mercury; certain dietary exposures in childhood (sugar, cow's milk,

TABLE 367-2 Genetic Polymorphisms Associated with Autoimmune Disease Risk

GENE	DISEASE ASSOCIATIONS WITH SOME ADs
HLA-DRB1	MS, RA, T1DM, JIA, IIM, IBD, Graves' disease, Hashimoto's thyroiditis, Addison's disease

C4A	SLE
IL33	RA, ankylosing spondylitis,
STAT4	RA, SLE, primary Sjögren syndrome
PTPN22	SLE, RA, JIA, T1DM, vasculitides, autoimmune thyroid diseases, vitiligo

Abbreviations: AD, autoimmune disease; IBD, inflammatory bowel disease; IIM, idiopathic inflammatory myopathies; JIA, juvenile idiopathic arthritis; MS, multiple sclerosis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; T1DM, type 1 diabetes mellitus.

food additives) and adulthood; various medications; and recreational drugs. The mechanisms by which environmental factors promote autoimmunity are complex and incompletely defined and include synthesis of reactive oxygen species (ROS), induction of proinflammatory pathways leading to DNA damage, lipid peroxidation that induces protein modification, and neoAg formation. These inflammatory pathways may promote activation of innate and adaptive immune responses that contribute to AD development.

Cigarette smoking is a known risk factor for some ADs, including RA, Graves' disease, SLE, and MS. It has been hypothesized that smoking promotes citrullination and carbamylation of proteins in the lung, which, in individuals who carry certain genetic risk alleles and synthesize autoAbs characteristic of the disease (anticitrullinated protein peptide Abs [ACPAs]) or rheumatoid factor, can promote the development of full-blown disease. Other described associations include silica and SLE and solvents and systemic sclerosis.

Various proinflammatory dietary factors, including the consumption of sugary beverages and red meat, have been associated with increased risk for T1DM, inflammatory bowel disease (IBD), and RA. Deficiency of vitamin D has also been associated with enhanced risk for AD, including T1DM, Crohn's disease, SLE, and MS. Other dietary factors associated with T1DM include no breast feeding in infancy, higher gluten intake in early childhood, and lower omega-3 fatty acid intake. Overall, more research is needed to better understand the impact of diet and other environmental factors in AD risk in specific populations.

SEX

Many ADs show skewing toward enhanced incidence and prevalence in women. Sex hormones, X-chromosome dosing, presence of specific immune-related genes in sex chromosomes, and various environmental effects on sex hormones have been proposed to play important roles in modulating differences in immune responses and in autoimmunity development. Both innate and adaptive immune responses differ between healthy men and women, and this may have a significant effect in modulating autoimmunity. For example, Ag-specific responses to both foreign and self-Ags are enhanced in women compared to men, and young women appear to generate more autoAgs than young men.

Estrogen modulates neutrophil immunometabolism and maturation, activates B- and T-cell responses, and promotes Ab production. Androgens decrease B-cell and neutrophil maturation and can suppress autoAb synthesis in SLE. However, the specific roles of sex hormones in autoimmunity need to be better defined.

A higher incidence of autoimmunity has been associated with the presence of two X chromosomes (in women and in men with Klinefelter syndrome [XXY]) due to enhanced expression of X-linked immunity-related genes encoding for molecules such as Toll-like receptor (TLR)-7, TLR-8, and IRAK-1. Because TLR-7 recognizes endogenous RNA-containing self-Ags and promotes the synthesis of type I IFNs, a group of cytokines with crucial roles in SLE and other systemic ADs, this is an important putative mechanism for augmented autoimmunity risk. Indeed, a breakdown in X chromosome inactivation mechanisms has been implicated in autoimmunity.

AGING

Immune aging has been proposed as a mechanism promoting autoimmunity. Aging leads to accumulation of senescent innate and adaptive immune cells with proinflammatory features (inflammaging). In predisposed subjects, it is considered that inflammaging may promote overt AD. Among the observed features, genomic instability, mitochondrial dysfunction, and inefficient clearance of intracellular debris, including cellular stress responses, potentiate aberrant T-cell and myeloid cell dysfunction. Immune senescence has been implicated in ADs such as RA and giant cell arteritis.

THE INNATE IMMUNE SYSTEM AND AUTOIMMUNITY

ABERRANT CELL DEATH AND CELL DEATH CLEARANCE

The innate immune system cells express a variety of sensors that can detect nucleic acids derived from exogenous and endogenous sources. Genetic, epigenetic, and environmental factors can lead to various forms of dysregulated/proinflammatory cell death and/or impaired clearance of dead cell debris. Some specific forms of cell death may particularly promote autoAg generation and induction of autoimmune responses. Certain TLRs (7–9) can sense nucleic acids and may not properly distinguish between self- and microorganism-derived nucleic acids. Single-stranded RNA (TLR-7 ligand) and unmethylated CpG motifs (TLR-9 ligand) can be found as self-Ags derived from dead cells. Similarly, cytosolic sensors of DNA and RNA are widely expressed across various cell types and tissues and can detect various RNAs and DNAs (including mitochondrial DNA) that can access the cell to stimulate type I IFN synthesis and/or inflammasome assembly and secretion of proinflammatory cytokines. In the steady state, however, risk of responding to self-nucleic acids is usually contained due to their instability, presence of certain DNA sequences that inhibit TLR signaling, and sequestration of nucleic acid–sensing TLRs in the endosomes. However, in genetically predisposed individuals, these mechanisms may be impaired and tolerance break may occur. Factors such as ultraviolet light, infections, and other insults leading to tissue injury may promote enhanced cell death that can contribute to fueling the fire in individuals at risk. In genetically predisposed individuals, an imbalance in dead cell handling can promote the externalization and modification of DNA, RNA, and other intracellular autoAgs, leading to downstream innate and adaptive immune dysregulation, autoAb development, and the formation of immune complexes (ICs) that deposit in various organs, stimulate immune and stromal cells, and promote damage. Delay in the engulfment of apoptotic cells by phagocytes (through genetic or acquired defects) and/or impaired function of intracellular or extracellular nucleases that can clear the nucleic acids and other cellular debris can lead to prolonged exposure of modified autoAgs. Furthermore, a delayed clearance of dead cells promotes the breakdown of these apoptotic cells with release of proinflammatory components and nucleic acids to the extracellular space through secondary necrosis. Indeed, abnormalities in receptors or ligands that facilitate cell death

clearance are associated with increased predisposition to SLE and other ADs, both in humans and in animal models of disease. There is a high frequency of SLE in patients with various deficiencies of complement pathway components, which is considered linked to impaired clearance of dying cells. Dysregulation of other types of cell death such as pyroptosis, necroptosis, and NETosis has been associated with autoimmune and chronic inflammatory conditions. For example, oxidation of nucleic acids by ROS or enzymes during NETosis can enhance the half-life of modified RNA and DNA and prevent their degradation.

DYSREGULATION OF INNATE IMMUNE CELLS AND INNATE IMMUNE PATHWAYS

Many innate immune cells and/or innate immune pathways show evidence of dysregulation in patients with AD, but also in those at risk or in relatives of patients with these conditions. Dysregulation in the type I IFN pathway driven by genetic, epigenetic, and environmental factors has been proposed to play a role in the pathogenesis of several ADs and their associated organ damage, including SLE, primary Sjögren syndrome, and idiopathic inflammatory myopathies (IIMs). Type I IFNs play important roles in antiviral defense, but many of the effects of chronic exposure or enhanced cellular response to type I IFNs can promote several features characteristic of immune dysregulation in various systemic ADs. Activation of the inflammasome, complement pathway, and various mechanisms of neuro-immunomodulation in innate immune cells have also been implicated in autoimmunity initiation and perpetuation.

Neutrophils Neutrophils, the first innate immune system cellular responders to noxious stimuli, are implicated in the initiation of, perpetuation of, and organ damage in many systemic ADs. Certain proinflammatory subsets of neutrophils (low-density granulocytes [LDGs]), as well as dysregulation in mechanisms of neutrophil cell death including the formation of neutrophil extracellular traps (NETs; a meshwork composed of various modified nucleic acids and granule proteins), have been proposed to play important roles in disease pathogenesis. Dysregulated NET formation promotes the externalization of modified autoAgs and the induction of aberrant innate and tissue stromal inflammatory responses. Abnormal NET formation and clearance have been implicated in the pathogenesis of SLE, AAV, IIM, primary antiphospholipid syndrome (APS), and RA.

Dendritic Cells (DCs) Both conventional (myeloid) DCs and plasmacytoid DCs (which synthesize large amounts of IFN-α) have been implicated in the pathogenesis of a variety of ADs, particularly SLE. While myeloid DCs can promote tolerogenic responses, such as the generation and maintenance of T regulatory cells (Tregs), their strong antigen-presenting cell (APC) capabilities can lead to priming and differentiation of autoreactive lymphocytes. Myeloid DCs have been reported to have abnormal phenotype and function in many DCs. Plasmacytoid DCs, major producers of type I IFNs in the body, have also been implicated in the pathogenesis of SLE and found to have abnormal phenotype and function in several ADs.

Monocytes, Macrophages, and Natural Killer (NK) Cells A causal link between the dysregulation of monocytes and macrophages and the development of AD has been proposed. In many ADs, these cells infiltrate affected tissues and show evidence of activation and dysregulation. Subsets of inflammatory monocytes are expanded in several ADs. Defective phagocytosis by macrophages, neutrophils, and other phagocytes has been proposed to play an important role in AD by extending the half-life of modified autoAgs. NK cells have also been reported to be dysregulated in ADs and to play a putative pathogenic role in AD.

Trained Immunity This concept describes innate immune responses that are faster and more robust to a second stimulus than to the first one. Trained immunity is acquired through an initial exposure to a stimulus that triggers an immune response that "trains" the stimulated cells. This leads to significant changes in the epigenetic landscape of innate immune cells with modifications in their chromatin structure (decondensation, histone modifications that include methylation and acetylation, and DNA hypomethylation). These changes can occur in hematopoietic cells (and therefore are transmitted to their progeny) or directly in tissue-resident cells. While trained immunity can be beneficial in the case of infections, it can also lead to aberrant inflammation and autoimmunity in maladaptive conditions.

THE ADAPTIVE IMMUNE SYSTEM AND AUTOIMMUNITY

LYMPHOCYTE AUTOREACTIVITY

Ag specificities generate randomly, and many lymphocytes can generate autoreactive responses directed at autoAgs. Several regulatory mechanisms are in place to induce self-tolerance, but if they become dysregulated, autoimmune responses can follow. Central and peripheral tolerance mechanisms exist in mammals to avoid autoreactivity. Among central tolerance mechanisms, autoreactive T cells and high-affinity autoreactive B cells are deleted in the thymus and the bone marrow, respectively. Regarding peripheral tolerance, several mechanisms have been proposed, including lymphocyte anergy due to lack of costimulation, cell death and removal of autoreactive lymphocytes, suppression of autoreactive responses by regulatory lymphocytes, and inhibitory costimulatory signals. Other factors include idiotypic network interactions (where Abs are directed against autoAbs), cytokine switching leading to immunosuppression, competition for Ag among different lymphocyte clones, and decreased frequency of lymphocyte precursors. In AD, central and/or peripheral tolerance are impaired due to a variety of putative mechanisms. The break of tolerance against self-Ags can trigger and/or contribute to autoimmunity. These Ags may be found in all cell types (e.g., chromatin, DNA) or be highly specific for a specific cell type (e.g., thyroglobulin, myelin basic protein).

T Lymphocytes T lymphocytes have important pathogenic roles in AD through a variety of mechanisms, including direct cell cytotoxicity, release of proinflammatory cytokines, reactive nitrogen or oxygen species, and promoting B-cell dysregulation. Abnormalities in the number and function of Tregs can have amplifying effects in autoimmunity in SLE, RA, and IBD. A tight balance must exist between T-cell-activating/costimulatory pathways and T-cell inhibitory receptors such as programmed cell death protein 1 (PD-1) and cytotoxic T lymphocyte-associated antigen 4 (CTLA-4) and T-cell-related cytokines (interleukin [IL]-2, IL-6, IL-17, IL-33) to prevent the development of autoimmunity. As such, dysregulation in one or more of these pathways, in a predisposed host, may promote immune dysregulation and autoimmune responses. Polymorphisms in various genes responsible for T-cell regulation and function have been implicated in AD risk. Autoreactive CD4 and/or CD8 T cells have been described in AD, including SLE and RA. A variety of therapies that target aberrant T-cell function have been proven effective in many ADs, strongly supporting the role of T cells in autoimmunity.

B Cells and AutoAbs Abs that react with self-molecules can be detected in healthy individuals. These so-called natural autoAbs are primarily IgM, are encoded by unmutated V(D)J genes, and display a moderate affinity for self-Ags. They are considered to provide a first line of defense against infections as well as contributing to the immune system's homeostasis. On the other hand, high-affinity, somatically mutated IgG autoAbs can perturb various homeostatic pathways, including cell clearance, cell effector functions, and Ag-receptor signaling. These pathogenic high-affinity autoAbs found in AD can form through somatic-hypermutation, class-switch DNA recombination, and Ag-driven clonal selection. AutoAbs are ubiquitous in AD, and they play important roles in disease diagnosis and, in some cases, assessment of disease severity. IgA autoAbs have also been described to play a putative role in AD, particularly in conditions where mucosal immune responses are proposed to play pathogenic roles.

Some autoAbs can be pathogenic in a variety of different ways, including interfering with the function of various cells or soluble molecules, activation of inflammatory cascades through the complement pathway, opsonization of cells or various soluble factors, and activation of cells through the promotion of IC formation by engaging activating

TABLE 367-3 Examples of Autoantibody-Mediated Disease Mechanisms

DISEASE	AUTOANTIBODIES	PATHOGENIC MECHANISM
Rheumatoid arthritis	ANCA, anti-carbamylated Abs, rheumatoid factor	Osteoclast activation promoting bone resorption; activation of macrophages, synovial fibroblasts, neutrophils, mast cells, DCs, platelets; immune complex formation with modified autoAgs with activating properties
Systemic lupus erythematosus	Anti-RNP, anti-dsDNA, etc.	Formation of immune complexes with activation of various immune cells; deposition of immune complexes in tissue promoting tissue damage; induction of type I IFNs through immune complex formation
Goodpasture's disease	Anti-type IV collagen Abs	Abs target basal membrane and promote kidney and lung injury
T1DM	Anti-insulin, glutamic acid decarboxylase, protein tyrosine phosphatase	Association with insulitis and diabetes onset
Pernicious anemia	Anti–parietal cell antibodies	Damage to parietal cells by Abs leads to lack of intrinsic factor
Idiopathic inflammatory myopathies	Anti-aminoacyl-transfer RNA synthetase Abs, anti-Mi2, anti-MDA5, anti-TIF1 gamma, anti-HMGCR, etc.	Activation of inflammatory immune cells, NET formation, induction of muscle atrophy pathways, induction of ROS
Sjögren syndrome	Anti-Ro, anti-La, rheumatoid factor	Anti-Ro Abs can induce neonatal lupus in offspring of SLE and Sjögren patients. IgG anti-Ro can cross the placenta and damage the fetal heart, inducing congenital heart block
ANCA-associated vasculitis	Anti-myeloperoxidase; anti-proteinase 3	Induction of NET, activation of neutrophils, endothelial cell damage
Graves' disease	Anti-TSHR	Anti-TSHR Abs target TSHR on thyroid cells, leading to enhanced thyroid hormones' synthesis
Hashimoto's thyroiditis	Anti-thyroid peroxidase and anti- thyroglobulin	AutoAbs promote complement fixation to thyroid cells, leading to proinflammatory responses and T-cell-mediated cytotoxic injury of thyroid cells
Myasthenia gravis	Anti-acetylcholine receptor	Antagonizes acetylcholine receptor on cells

Abbreviations: Abs, antibodies; Ags, antigens; ANCA, antineutrophil cytoplasmic antibody; DCs, dendritic cells; dsDNA, double-stranded DNA; HMGCR, hydroxymethylglutaryl coenzyme A reductase; IFN, interferon; IgG, immunoglobulin G; MDA5, melanoma differentiation-associated protein 5; NET, neutrophil extracellular trap; RNA, ribonucleic acid; RNP, ribonucleoprotein; ROS, reactive oxygen species; SLE, systemic lupus erythematosus T1DM, type 1 diabetes mellitus; TIF1, transcription intermediary factor 1; TSHR, thyroid-stimulating hormone receptor.

Fc receptors. Of interest, autoAbs not only develop in patients with AD but also are more likely to develop in their family members. In other cases, autoAbs are used as diagnostic tools or as markers of disease activity or worse disease outcomes, but a specific pathogenic role has not been identified. Examples of diseases that are mediated by these autoAb-related mechanisms are listed in **Table 367-3**.

In several organ-specific and systemic ADs, distinct autoAgs that are targeted by the immune system have been described. For example, in Graves' disease (an autoimmune condition that leads to hyperthyroidism and ophthalmopathy), autoAbs are directed against thyroid-stimulating hormone (TSH) receptor on thyroid cells, and engagement of this receptor leads to enhanced thyroid hormone synthesis. In turn, it has been proposed that TSH receptor and MHC class II complexes present on thyroid epithelial cells can induce autoAb synthesis through presentation of cryptic epitopes. In Hashimoto's thyroiditis, there is formation of autoAbs to thyroid peroxidase and thyroglobulin that promote complement fixation to thyroid cells, leading to a proinflammatory response and T-cell-mediated cytotoxic injury of thyroid cells. In myasthenia gravis, autoAbs can interact and disrupt the function of the acetylcholine receptor, muscle-specific kinase receptor, and other cell surface receptors in the postsynaptic muscle membrane, leading to muscle weakness. Cardiac myosin has been identified as an important autoAg in myocarditis. In T1DM, autoAbs that target β-cell antigens lead to destruction of pancreatic cells that synthesize insulin. Individuals at risk of developing T1DM already can have detectable islet-antigen-specific Abs preceding clinical disease by several years, and their titers may increase as risk of disease progresses. Abs to other autoAgs besides insulin can be detected in this disease and include glutamic acid decarboxylase and insulinoma Ag. Those that develop Abs to multiple targets have a higher risk of evolving into clinically apparent T1DM. In MS, autoAbs to myelin basic protein (MBP) and myelin oligodendrocyte glycoprotein and higher frequencies of T cells that are specific for MBP have been detected and considered pathogenic. In addition, myelin-specific and lipid-specific Abs that can fix complement and induce Ab-dependent cytotoxicity have been described in MS. In pernicious anemia/autoimmune gastritis, the most common cause for vitamin B_{12} deficiency and the end stage of autoimmune gastritis, there is autoAb production and T-cell responses to gastric parietal cells that make intrinsic factor, the protein that promotes absorption of vitamin B_{12} by the intestine. This immune-mediated destruction of gastric parietal cells (targeting the H^+/K^+-ATP in their cell membranes) reduces their ability to secrete intrinsic factor in the stomach. Between 70 and 90% of patients with pernicious anemia have autoAbs to these structures. In primary biliary cholangitis, elevated levels of antimitochondrial (primarily to pyruvate dehydrogenase complex) Abs are characteristic and can precede disease onset by a decade, although whether they have a pathogenic role remains unclear. AutoAbs that recognize citrullinated peptides (ACPA), carbamylated peptides, and IgG (rheumatoid factor) are characteristic of many patients with RA and are associated with worse prognosis. The presence of ACPAs is quite specific for RA, and these autoAbs can be detected in serum of individuals up to a decade before diagnosis. A role for lung and synovial NETs in generating citrullinated and carbamylated autoAgs and promoting autoAb formation has been reported. ACPAs can be directly pathogenic in RA and promote macrophage, synovial fibroblast, and osteoclast activation and NET formation, promoting inflammation and bone damage. Furthermore, anticarbamylated peptide autoAbs are associated with bone damage in RA. Myositis-specific autoantibodies (MSAs) are present in most juvenile and adult cases of IIM. Some interesting examples for associations of autoAbs with disease manifestations arise in these group of muscle diseases. For example, in adult IIM, anti-TIF1γ Abs are associated with myositis-associated cancer, anti-HMGCR Abs with statin-induced myositis, and anti-cN1A Abs with inclusion body myositis. In SLE, Sjögren syndrome, RA, systemic sclerosis, and celiac disease, autoAbs can be detected in serum harvested years before clinical diagnosis of AD is made. It is important to emphasize that the autoAgs associated with many ADs remain unknown.

Age-associated B cells (ABCs) represent a distinct B-cell population that is found expanded in several ADs such as SLE, MS, and RA. ABCs have pathogenic roles in these conditions, through cytokine and autoAb production and T-cell stimulation. Autoreactive long-lived plasma cells, which are more refractory to conventional immunosuppression than other cells, are considered to have an essential role in the maintenance of AD and, potentially, in the development of disease

flares. On the other hand, regulatory B cells (Bregs) suppress immune responses and can restrain tissue pathology; as such, their dysfunction may be implicated in autoimmunity predisposition and propagation. Dysregulation of B-cell and plasma cell subsets appears to be a shared feature among many ADs.

Immune Complexes (ICs) ICs have a key role in many ADs, especially those that affect the kidney. They can also modulate immune function in direct and indirect ways, including promoting the uptake of nucleic acids into innate immune cells where they stimulate type I IFN synthesis. ICs can stimulate many immune and stromal cells, producing immune stimulation and tissue damage (Table 367-3).

Inflammatory Cytokines Inflammatory cytokines including TNF, IL-1b, IL-6, IL-17, and type I IFNs are involved in the development and perpetuation of various ADs. Indeed, discoveries related to the role of cytokines in AD have led to major therapeutic advances. For example, blocking TNF is highly effective in significant percentages of patients with RA, psoriasis, seronegative spondyloarthropathies, and IBD. Identifying type I IFNs as major players in autoimmunity has led to the development and use of strategies to downregulate downstream signaling pathways for this group of cytokines. This has included the use of Janus kinase (JAK) inhibitors in several ADs such as RA, psoriatic arthritis, IBD, SLE, and primary Sjögren syndrome, as well as in some organ-specific ADs such as vitiligo and alopecia areata. Drugs that specifically target type I IFN receptor or type I IFNs themselves are being used in the clinic or tested in clinical trials. Other drugs that target aberrant T-cell responses and their downstream effects, including IL-17, IL-23, IL-12/23, and IFN-γ, are also available for use or are being developed. Furthermore, therapies that target abnormal B-cell and plasma cell responses, including anti-CD19, anti-CD20, and anti-BLys, have been developed and approved for SLE, RA, and/or AAV or are being tested in clinical trials.

SOME PROPOSED SPECIFIC MECHANISMS THAT PROMOTE AUTOIMMUNITY

INFECTIONS AND AUTOIMMUNITY

Infections have been extensively described as triggers of AD and as inducers of clinical flares in people with established autoimmunity. Various mechanisms have been proposed, including molecular mimicry, release of hidden self-Ags, epitope spreading, adjuvant effects, epigenetic modifications, and dysregulation of innate immune responses triggered, for example, by direct viral damage.

Molecular Mimicry, Bystander Mechanisms, and Epitope Spreading Molecular mimicry may play a potential role in a variety of ADs; here, self-epitopes that share structural similarities to microbial Ags are presented by APCs. A well-established example of molecular mimicry is rheumatic fever, where Abs to the M-protein of group A *Streptococcus* cross-react with myosin, laminin, and other proteins present in the heart, as well as with neuronal Ags. When these Abs deposit in the heart, they can initiate an inflammatory response, leading to carditis and valvular damage, whereas their deposit in the brain can promote Sydenham's chorea, a specific manifestation of rheumatic fever.

Ab deposition can also lead to enhanced cell death with new autoAg release and a perpetuation of a vicious inflammatory cycle. In this case, during epitope spreading, autoimmune responses develop to self-epitopes that are different from the initiating microbe-specific epitope during an infection. Several viral infections have been hypothesized to trigger autoimmunity through molecular mimicry and/or epitope spreading, including Epstein-Barr virus (EBV; linked to SLE, MS, RA, celiac disease, and Sjögren syndrome), coxsackievirus (linked to myocarditis, Hashimoto's thyroiditis, and T1DM), and influenza A virus (linked to T1DM and IgA vasculitis [Henoch-Schönlein]). Besides molecular mimicry, EBV has been linked to MS through reprogramming of B cells that have been latently infected. Molecular mimicry has also been associated with the etiology of RA, including a potential role for *Porphyromonas gingivalis* through the generation of enzymes that promote Ag citrullination in the gingiva.

Gastrointestinal dysbiosis may also play a role in the development of the early stages of RA. Microbial superAgs, including staphylococcal protein A and staphylococcal enterotoxins, can stimulate a broad number of T and B cells by interacting with immune receptors, independent of Ag specificity. If autoreactive lymphocytes express these receptors, autoimmune responses may be triggered through these bacterial molecules.

Another mechanism by which infections have been implicated in autoimmunity is by enhancing the immunogenicity of autoAgs through innate immune signals triggered by the microbe or its products. This bystander mechanism is many times mediated by cytokine release and activation of autoreactive lymphocytes. Infections can also promote an adjuvant effect, when the microbial Ag activates innate immunity to self-organs, as supported by animal models of RA and MS. It is important to note that, often, the link between infections and AD development is circumstantial and causality has not been proven. Support of causality has come from animal models, such as the case of autoimmune myocarditis triggered by coxsackievirus B3 or cytomegalovirus. More recently, SARS-CoV-2 infection has been linked to myocarditis development, autoAb synthesis, and, in some cases, new-onset autoimmunity including APS, multisystem inflammatory syndrome in children (MIS-C), Kawasaki disease, and Guillain-Barré syndrome.

The "Hygiene Hypothesis" This hypothesis is linked to the role of parasites in preventing autoimmune and allergic responses in developing countries, where the prevalence of parasitic infections is high. This mechanism has been implicated in potential higher risk for certain ADs in developed countries with less prevalence of various infections with parasites, viruses, and bacteria known to dampen immune responses or shift to anti-inflammatory milieus by stimulation of immune regulatory pathways. This may apply to both pathogenic microbes and gut commensal bacteria. This hypothesis may help explain geographical variations in the distribution of some ADs. While the hygiene hypothesis is supported by epidemiologic data, the mechanisms triggering this immunosuppressive effect remain to be better characterized.

Sequestered AutoAg Exposure from Immune-Privileged Sites This phenomenon has been proposed to protect vital tissues and organs (eye, brain, and testis) from injury by inflammatory responses directed at foreign microbial antigens. This special immunologic status is associated with long survival rates of allografts and xenografts, when compared to nonprivileged sites. The eye is considered an immune-privileged site as an evolutionary mechanism to prevent vision loss from inflammatory injury. A variety of mechanisms in the eye confer immune privilege (immunosuppressive cytokines, low MHC expression, lack of lymphatic drainage). Immune privilege in the testis confers protection from systemic immune attack to preserve male fertility. Several mechanisms have been proposed to play a role, including physical structure, local anti-inflammatory milieu (including sex hormones), and systemic immune tolerance.

PARANEOPLASTIC SYNDROMES, CANCER, AND AUTOIMMUNITY

Various tumor Ags can be targets of adaptive autoimmunity; these can include Ags expressed in nonmalignant cells within the tumor. A variety of cancers are associated with autoimmune responses that present as paraneoplastic syndromes and other autoimmune responses. Frequently, these syndromes can present before the diagnosis of the underlying neoplasia. A variety of mechanisms have been implicated, including disruption of central tolerance, peripheral immune dysregulation, and modification of self-Ags with cross-reactivity. Some paraneoplastic autoimmune conditions include Lambert-Eaton myasthenic syndrome, paraneoplastic pemphigus, dermatomyositis, Sweet's syndrome, thymoma-associated multiorgan autoimmunity, autoimmune hemolytic anemia, immune thrombocytopenia, vitiligo, and

thyroiditis. Cancers commonly associated with autoimmunity include melanoma, thyroid cancer, and non-small-cell lung cancer. One specific example is the development of encephalitis through generation of Abs to *N*-methyl-D-aspartate glutamate receptor in women affected by ovarian cancer. In some cases, these events may be associated with favorable disease outcomes that may suggest a beneficial effect from the autoimmune response. The autoimmune manifestations can be severe, and management of these patients is difficult given the coexistent malignancy.

IATROGENIC AUTOIMMUNITY

Checkpoint Inhibitors Immune checkpoint inhibitors (ICIs) have revolutionized cancer treatment. They act by blocking inhibitory molecules involved in regulating T lymphocytes, promoting the destruction of tumors by the adaptive immune system. Immune-related adverse events (irAEs) have been described as toxic complications related to tissue-specific autoimmunity from the use of ICIs, and they can persist after withholding therapy and using immunomodulatory therapy to control them. Among these complications, DM, arthritis, thyroiditis, and colitis are prevalent. Up to 85% of individuals treated with an ICI may develop irAEs. Most of these are mild, and overall survival and time to malignancy progression are not influenced by the development of these immune complications.

Drug-Induced Autoimmunity In addition to ICIs, many drugs have been linked to the development of autoimmunity. These include antibiotics, antihypertensives, antiarrhythmics, TNF inhibitors, and antiseizure medications, among many others. Drug-induced lupus is a well-described entity, and patients developing this condition have characteristic detection of antihistone Abs. In many cases, discontinuation of the drug may be sufficient for symptoms to be abrogated or decreased.

PREVENTION AND TREATMENT OF AUTOIMMUNITY

The hope is that better understanding of the pathophysiology of overt development of ADs and their associated organ damage will lead to primary or secondary prevention strategies in conditions such as T1DM, RA, and SLE. One promising example is where infants at risk of developing multiple T1DM autoAbs and clinical disease are being studied to determine if certain interventions (oral insulin) can delay or stop progression to overt disease. Studies have also been performed on people considered at risk for RA to assess delayed disease progression, but more studies are needed to better characterize the utility of these preventive strategies. Overall, opportunities to initiate early therapy depend on the availability of serologic tests that can predict disease, to initiate treatments that have a good efficacy-to-safety ratio.

Specific treatments for ADs are included in chapters focusing on individual diseases and include a variety of immunomodulatory agents (e.g., antimalarials) and immunosuppressive drugs (spanning those drugs with broad effects on the immune system, such as corticosteroids or cyclophosphamide, to highly specific biologic agents targeting specific cytokines or immune cells). It is the hope that the development of personalized medicine approaches will lead in the future to the specific targeting of dysregulated immune cell components while sparing other critical cells and functions of the immune system.

368 Systemic Lupus Erythematosus

Chelsey J.F. Smith, Paul J. Hoover, Kenneth Kalunian

DEFINITION, PREVALENCE, AND EPIDEMIOLOGY

Systemic lupus erythematosus (SLE) is an autoimmune disease in which overactive innate and adaptive immune systems cause tissue damage through the effects of autoantibodies and immune complexes. Many organ systems can be affected, with cutaneous, musculoskeletal, and renal systems most involved, followed by pulmonary, hematologic, cardiovascular, serosal, and central nervous system involvement. Constitutional symptoms are often present. Autoantibodies can be detected years prior to a clinical diagnosis. Approximately 90% of affected individuals are women, most of childbearing age; however, the disease can also affect neonates and older children, men, and elderly individuals. Certain ethnic and racial groups are at higher risk for more prevalent disease and more severe disease. The Centers for Disease Control and Prevention (CDC) National Lupus Registry estimates the prevalence in the United States to be 204,295 cases, with overall prevalence being nine times higher in women compared to men. The highest prevalence is seen in Black women, followed by Hispanic, White, and Asian/Pacific Islander women. Among men with SLE, Black men have the highest prevalence and White men have the lowest. Prognosis and survival from SLE can vary widely by geographic region, race, ethnicity, and access to both care and medications.

DIAGNOSIS AND CLASSIFICATION

For the diagnosis of SLE, an individualized approach should be taken based on available clinical data and excluding other disease entities. Classification criteria for SLE have been developed for the purposes of enrollment of patients into clinical trials rather than criteria for diagnosis. Currently, the 2019 European League Against Rheumatism (EULAR)/American College of Rheumatology (ACR) classification criteria for SLE and the 2012 Systemic Lupus International Collaborating Clinics (SLICC) SLE classification criteria are both utilized for enrollment of patients into clinical trials. For the EULAR/ACR criteria, an antinuclear antibody (ANA) titer of at least 1:80 is required. Clinical criteria are then weighed by points within several clinical domains, and a patient requires at least 10 points to meet criteria. No single clinical or laboratory value leads to 10 points except for a renal biopsy revealing class III or IV lupus nephritis.

Certain subsets of patients with SLE are currently not included in clinical trials, including patients with incomplete lupus or features of SLE without an established diagnosis and the ~5% of SLE patients who are ANA negative. Researchers have suggested that if predictive or diagnostic biomarkers for progression are developed, then early treatment for patients with incomplete lupus could prevent progression to SLE. Furthermore, because the EULAR/ACR criteria exclude ANA-negative patients from participating in clinical trials, the opportunity to understand whether new drugs have a role in this disease subset is also underserved.

SLE has been classified into two broad categories based on symptoms. Those with predominant classic findings of SLE that have a clear relationship to immune dysregulation, such as nephritis, arthritis, and vasculitis, have been categorized as having type 1 lupus, whereas those with predominant symptoms of fatigue, diffuse body pain, depression, cognitive dysfunction, sleep disturbances, anxiety, and/or brain fog have been categorized as having type 2 lupus. Type 1 symptoms arise from autoimmune inflammation and/or organ damage and often respond to standard immunosuppression, whereas type 2 patients are less responsive to immunosuppressive therapy. This categorization presents an opportunity to explore the genetic and immune association

of each category as well as develop biomarkers and treatments for the distinct types.

PATHOGENESIS

OVERVIEW

SLE reflects multiple immunoregulatory defects and is characterized by the production of autoantibodies to cellular components, especially nucleic acids and nuclear proteins, that promote inflammation and tissue damage. The interaction of environmental factors with the stochastic dysregulation of genes controlled by common genetic variations underpins the development of SLE **(Fig. 368-1)**.

GENETICS

SLE has a strong genetic component as evidenced by familial clustering, a greater incidence in monozygotic twins versus dizygotic (24% vs 2%), and the identification of >150 susceptibility loci from genome-wide association studies (GWAS). Genetic studies have identified groups of immunoregulatory genes associated with SLE, reflecting common pathways that may contribute to pathogenesis. It is possible that each pathway differentially contributes to the expression of disease, accounting for clinical heterogeneity. The most common genetic association is within the major histocompatibility complex that contains genes for antigen presentation molecules (class I and class II), several complement components, and cytokines. Nearly half of the susceptibility loci are associated with type 1 interferon (IFN) production or its downstream signaling. For example, some susceptibility genes lead to increased IFN through defects in nucleic acid sensing and metabolism (*TLR7, ADAR, IFIH1, SAMHD1, RNASEH2B, TREX1*) or nucleic acid degradation (*DNASE1, DNASE1L3*), whereas other IFN-related susceptibility genes amplify the IFN response (*IRF5, IRF7, IRF8, STAT4*). Many predisposing genes are immune cell type specific, affecting activation and survival of T cells (*OX40L*) or B cells (*BANK1, BACH2*). The complement cascade (C1Q, C1r, C1s, C2, C4), which is essential for clearance of apoptotic cellular debris and immune complexes, is often affected in monogenic cases, leading to severe SLE.

ENVIRONMENT

About a quarter of monozygotic twins are clinically concordant for SLE, implicating environmental factors in disease expression. Low socioeconomic status is associated with the development of SLE and may include exposures to environmental toxins, including mercury, pesticides, and diet. Viral infections such as Epstein-Barr virus likely contribute to disease development by inducing the IFN response during an acute infection or by expressing viral proteins that activate SLE susceptibility genes. Ultraviolet light can impact DNA methylation, generate self-stimulatory nucleic acids, activate keratinocyte immune responses, and produce autoreactive T cells. Finally, emerging evidence suggests that the gut microbiome may increase gut permeability, promoting the translocation of certain gut microbes into the blood with the development of lupus-specific autoantibodies contributing to SLE pathogenesis.

INNATE IMMUNITY

Multiple innate immune cell defects contribute to increased cellular breakdown and reduced cell debris clearance, culminating in the production of autoantibodies. Neutrophils are typically short-lived and abundant immune cells, representing a large burden of cellular debris that is usually cleared without inducing an immune response. Patients with SLE, however, have neutrophils with higher turnover, delivering a large load of stimulatory nucleic acids and autoantigens. Cellular debris and immune complexes are typically cleared by macrophages and dendritic cells through complement-mediated phagocytosis and nucleic acid digestion; these mechanisms are dysregulated in SLE. In turn, the burden of cellular debris exceeds that which can be cleared in SLE, triggering nucleic acid sensors and toll-like receptors (TLRs) in plasmacytoid dendritic cells to express type 1 IFN. Consequently, IFN primes neutrophils for further turnover and sensitizes the adaptive

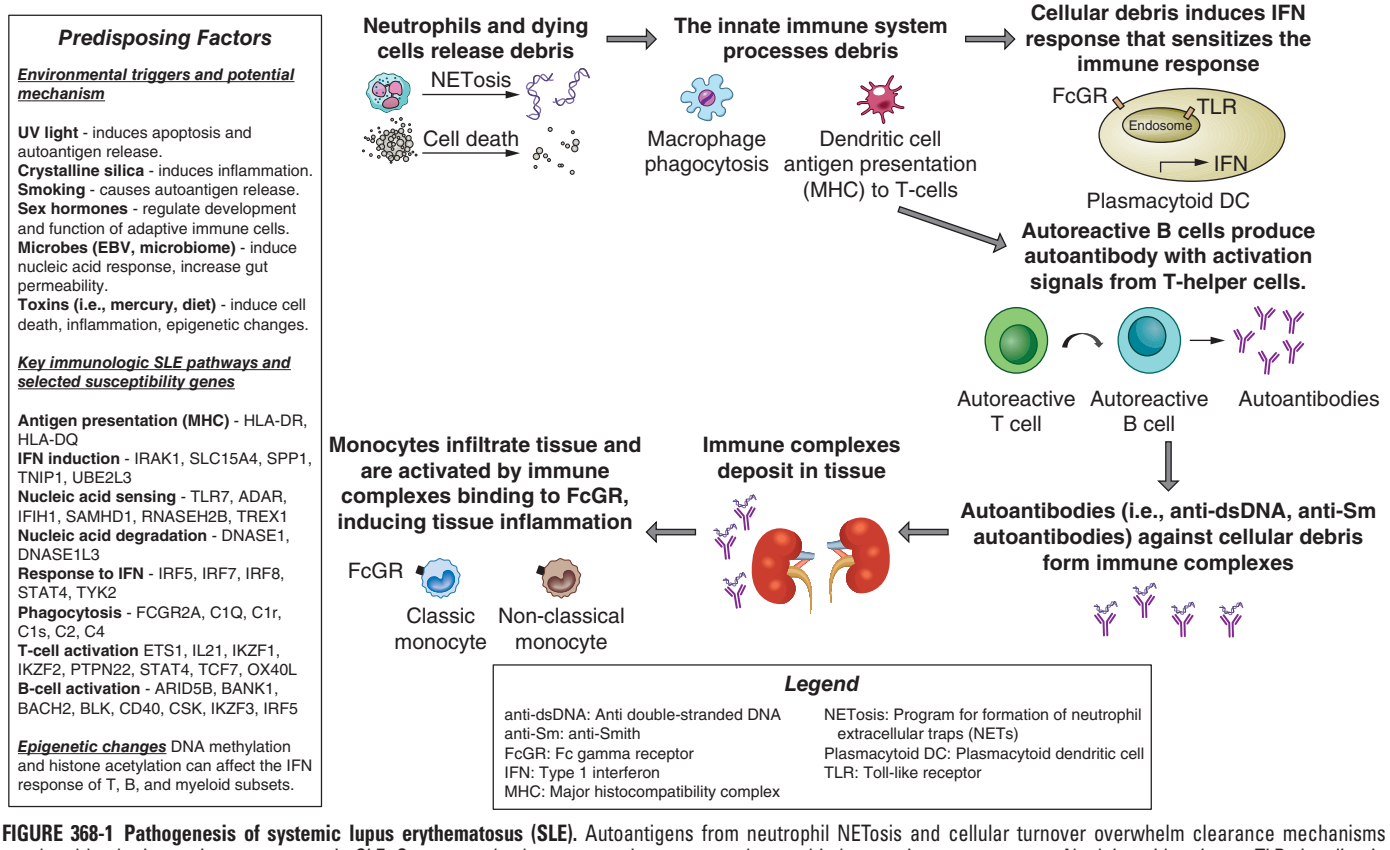

FIGURE 368-1 Pathogenesis of systemic lupus erythematosus (SLE). Autoantigens from neutrophil NETosis and cellular turnover overwhelm clearance mechanisms regulated by the innate immune system in SLE. Consequently, these autoantigens accumulate and induce an immune response. Nucleic acid activates TLR signaling in plasmacytoid dendritic cells (DCs), producing type 1 IFN, sensitizing the innate and adaptive immune responses. DCs present autoantigens to autoreactive T cells, leading to B-cell stimulation and the production of immune complexes against these autoantigens. Immune complexes deposit in tissue and induce local immune responses that lead to inflammation and repair and, eventually, fibrosis after recurrent SLE flares. EBV, Epstein-Barr virus.

immune system. Other innate immune cells with aberrant function in SLE include classical monocytes that infiltrate and repair injured tissue due to immune complex deposition and nonclassical monocytes that patrol the vascular lumen for injury. Sustained activation of these subsets from SLE leads to tissue inflammation and scarring.

ADAPTIVE IMMUNITY

B cells play a central role in the SLE pathogenesis based on the production of autoantibodies due to their loss of tolerance. Autoantibodies, especially those complexed with nucleic acid, are pathogenic mediators of tissue inflammation and damage in SLE. These autoantibodies induce type 1 IFN and other inflammatory mediators and activate patrolling monocytes in tissue. A subset of circulating age-associated B cells (ABCs) expands in SLE patients and eventually matures into autoantibody-secreting plasma cells, indicating that SLE patients have an increased population of B cells primed to generate pathogenic autoantibodies. Similar to B cells, T cells lose tolerance and play a central role in the autoimmune response. In particular, both T follicular and T peripheral helper cells promote B-cell differentiation into pathogenic, high-affinity, autoantibody-secreting plasma cells. T regulatory cells meant to maintain tolerance in both T and B cells are defective in SLE.

CLINICAL MANIFESTATIONS

OVERVIEW AND SYSTEMIC MANIFESTATIONS

The initial presentation of SLE is variable and may present as nonspecific constitutional symptoms with or without single-organ or multiorgan involvement. Autoantibody presence is helpful in attributing nonspecific symptoms to SLE. Symptoms can be mild to severe at any time over the course of the disease, including at initial presentation. Patients with severe disease often have systemic symptoms such as fever, anorexia, and unintentional weight loss. Approximately 15% of patients have relatively mild disease, which may or may not be accompanied by fatigue, brain fog, and/or mild arthralgia. The majority of SLE patients have active disease despite therapy or have frequent flares of their disease requiring treatment adjustment. Goals for SLE treatment are low-level disease activity or remission on ongoing therapy. (See "Outcomes" section for more details.)

MUSCULOSKELETAL MANIFESTATIONS

Nonspecific arthralgia and myalgia are common in SLE. Lupus arthritis is characterized by a polyarthritis most commonly involving the wrists, the metacarpal-phalangeal and proximal interphalangeal joints of the hands, and the knees. In some cases, damage of the periarticular ligaments may lead to Jaccoud-like changes **(Fig. 368-2*A*)**. Rheumatoid arthritis and SLE can occur simultaneously, and this overlap is denoted by the term *rhupus*. While radiographs rarely demonstrate erosive changes in lupus arthritis, emerging studies with magnetic resonance imaging (MRI) and ultrasound imaging suggest a possible erosive pattern that is less severe than that seen with rheumatoid arthritis. Pain in a single hip, shoulder, or knee out of proportion to other joints should prompt consideration of avascular necrosis of bone, particularly with history of corticosteroid usage. Inflammatory muscle disease is also seen in lupus, characterized by symmetrical proximal weakness, elevated creatine kinase and aldolase levels, and inflammatory changes on muscle biopsy. Corticosteroids used to treat SLE may cause myopathy, as can antimalarials, although this is rare.

CUTANEOUS MANIFESTATIONS

Three major categories of SLE skin manifestations include acute cutaneous lupus erythematosus (ACLE), subacute cutaneous lupus erythematosus (SCLE), and chronic cutaneous lupus **(Fig. 368-2*B*-*F*)**. ACLE occurs with SLE disease activity, whereas SCLE and certain forms of chronic cutaneous lupus may be seen in the absence of systemic disease. The most classic form of ACLE is the malar rash, which appears in a "butterfly" distribution across the cheeks of the face with nasolabial sparing. Due to its photosensitive nature, slightly raised lesions, and location on the face, this may be confused with rosacea, which involves the nasolabial folds. ACLE may also present as a generalized maculopapular rash in sun-exposed areas of the body, bullous lupus, toxic epidermal necrolysis variant, and generalized photosensitivity. SCLE is a photosensitive rash associated with anti-Ro or SSA antibodies that is characterized by flat, red-rimmed annular or psoriasiform lesions. Discoid lesions are rough, circular lesions that are slightly raised, scaly, and hyperpigmented with depigmented, atrophic centers and erythematous rims, and are the most common chronic dermatitis seen in SLE. Other chronic forms of cutaneous lupus include hypertrophic or verrucous lupus, lupus panniculitis, tumid lupus, chilblains lupus, and discoid lupus/lichen planus overlap. Nonspecific cutaneous manifestations that may be seen in SLE include nonscarring alopecia, oral and nasal painful or nonpainful mucosal ulcers, and the less common leukocytoclastic and urticarial vasculitides. Approximately one-third of SLE patients also experience Raynaud's phenomenon, a condition in which small blood vessels undergo vasospasm with exposure to cold environment or stress, causing a classically triphasic color change of the fingers and/or toes, inducing white (blanching), blue (cyanosis), and red (hyperemia) coloring of the extremities.

RENAL MANIFESTATIONS

Nephritis occurs in ~35% of patients with SLE and is more severe in non-White patients, more frequently leading to end-stage renal disease (ESRD) despite therapy. Nephritis can be seen with or without extrarenal SLE disease and may be present in an asymptomatic patient. Patients should therefore be screened at regular 3-month intervals with a random urine protein-to-creatinine ratio (UPCr) or a 24-h urine protein and creatinine determination. Usually, nephritis is seen in patients with elevated serum anti–double-stranded DNA (dsDNA) antibody titers and decreased serum levels of C3 and/or C4, and trends of these biomarkers over time may serve as warning signs of impending active nephritis. Renal biopsy is generally prompted by a UPCr of >0.5 and/or declining kidney function. Classification is based on renal pathology from a renal biopsy and is defined by the International Society of Nephrology/Renal Pathology Society criteria. Aggressive therapy is generally reserved for patients with class III (focal proliferative glomerulonephritis), class IV (diffuse proliferative glomerulonephritis), or a combination of class III or IV with class V disease (membranous) **(Fig. 368-3, Chap. A4)**. Approximately 20% of lupus nephritis patients with significant proteinuria tend to have class V disease and more often have nephrotic syndrome. Patients with class V lupus nephritis have a better overall prognosis than patients with class III or IV lupus nephritis and are treated in the same manner as class III and IV. Patients who do not respond to treatment may require a repeat biopsy to evaluate for a change in class. In the United States, ~20% of SLE patients with class IV lupus nephritis die or develop ESRD within 10 years. Newer approaches are being developed to both increase renal survival and spare patients from accelerated atherosclerosis, hypertension, hyperglycemia, and hyperlipidemia, all of which can be accelerated by renal disease and corticosteroid usage.

NERVOUS SYSTEM MANIFESTATIONS

Lupus patients experience neuropsychiatric manifestations of disease that are characterized by diffuse or focal symptoms. The most common diffuse symptom is "brain fog," a cognitive dysfunction or slowing of thought. The etiology is not well understood but may be related to autoantibodies crossing the blood-brain barrier, leading to local inflammation and neuronal damage. Headache is common and often severe, although it may be difficult to distinguish from migraine or tension headache. Seizures of any type may be seen in neuropsychiatric lupus. Acute psychosis and confusional states are uncommon but can occur in SLE without any structural abnormalities. In these cases, glucocorticoid-induced psychosis and infectious encephalitis should be ruled out. Transverse myelitis is a rare SLE complication that manifests as bilateral neurologic deficits such as symmetric motor weakness and decreased sensation due to spinal cord inflammation.

VASCULAR OCCLUSION: MYOCARDIAL INFARCTIONS AND STROKE

Coronary heart disease from accelerated atherosclerosis in SLE is a significant cause of morbidity and premature death, especially in young patients without other risk factors. Vascular injury due to excessive

FIGURE 368-2 Characteristic musculoskeletal and cutaneous manifestations seen in systemic lupus erythematosus (SLE). ***A.*** Jaccoud arthropathy, characterized by chronic, nonerosive, and reversible deviations caused by joint capsule inflammation with subsequent fibrotic retraction and metacarpophalangeal joint subluxation. ***B.*** Patchy, nonscarring alopecia. ***C.*** Patchy scarring alopecia. ***D.*** Patchy alopecia associated with chronic, scarring discoid lupus changes. ***E.*** Classic photosensitive malar rash. ***F.*** Subacute cutaneous lupus erythematosus (SCLE) with widespread, nonscarring photosensitive features. *(Panels B–E reproduced with permission from Victoria Werth, MD. Panels A and F reproduced with permission from DoQuyen Huynh, MD.)*

type 1 IFN and cellular death may predispose to atherosclerosis. The risk of coronary artery disease and vascular thrombosis is further increased in SLE patients with antiphospholipid syndrome (APS), an autoimmune syndrome that commonly occurs in SLE and is characterized by arterial, venous, or small vessel thromboembolic events in the presence of antiphospholipid antibodies with prothrombotic properties **(Chap. 369)**. Stroke has been reported in up to 19% of patients with SLE, a result of atherosclerosis and increased risk from APS. In addition to stroke, APS appears to be a significant risk factor for other focal central nervous system manifestations including seizures and transverse myelitis.

PULMONARY MANIFESTATIONS

The most common pulmonary manifestation of SLE is pleuritis, which can occur with or without exudative pleural effusions. Acute pneumonitis may present in active SLE, with pulmonary infiltrates often appearing indistinguishable from infection on imaging. Diffuse alveolar hemorrhage with capillaritis and interstitial lung disease may also be seen. Restrictive lung defect from reduced lung volumes, also known as shrinking lung syndrome, is uncommon but may occur. Pulmonary arterial hypertension and pulmonary embolism may be present with or without APS.

CARDIAC MANIFESTATIONS

All layers of the heart may be involved in SLE, with pericardial involvement being the most frequent. Pericarditis can typically be managed with anti-inflammatory medications, colchicine, and anti-IL-1–directed therapies, or without glucocorticoids, and rarely leads to tamponade physiology. Myocarditis is rarer and may lead to left-sided heart failure and/or arrhythmia. Libman-Sacks endocarditis, a fibrinous sterile form of endocarditis that may be associated with antiphospholipid antibodies, may increase the risk for embolic events. Right-sided heart failure may be present with pulmonary arterial hypertension or chronic lung disease.

HEMATOLOGIC MANIFESTATIONS

Cytopenias in SLE are often multifactorial and may be associated with disease activity, medication use, or infection. Anemia is the most common hematologic manifestation of SLE and is present in >50% of SLE cases, with anemia of chronic disease representing approximately

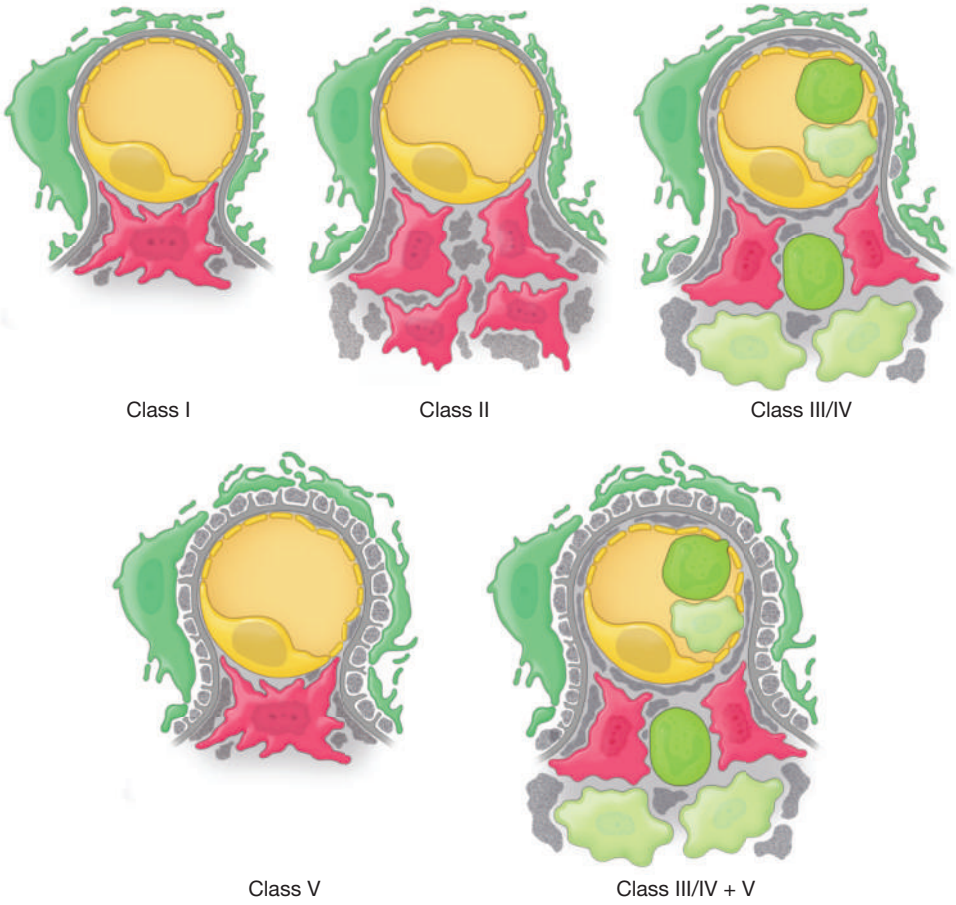

FIGURE 368-3 Ultrastructural features of lupus glomerulonephritis. Class I: Mesangial immune deposits (*black*) without mesangial cell (*red*) hypercellularity or leukocyte infiltration. Class II: Mesangial immune deposits with mesangial cell hypercellularity, no leukocyte infiltration. Class III/IV: Subendothelial immune deposits visible by light microscopy, with infiltration of mesangial and capillary leukocytes (dark green neutrophils and light green monocytes/macrophages). Class III/IV + V: Leukocyte infiltration with subepithelial and subendothelial immune deposits. Class V: Subepithelial immune deposits, no leukocyte infiltration. *(Reproduced with permission from IM Bajema et al: Revision of the International Society of Nephrology/Renal Pathology Society classification for lupus nephritis: Clarification of definitions, and modified National Institutes of Health activity and chronicity indices. Kidney Int 93:789, 2018, Figure 2.)*

one-third of cases; other causes for anemia in SLE include iron deficiency, autoimmune hemolytic anemia, aplastic anemia, microangiopathic hemolytic anemia, and medication effect. Leukopenia (<4000/μL) is common, occurring in about half of SLE patients, and usually consists of lymphopenia (<1500/μL), rather than neutropenia. Thrombocytopenia (<150,000/μL) is usually mild but can also be severe (<50,000/μL) and pose significant bleeding risk. It is most commonly due to immune mechanisms and may be associated with APS or antiphospholipid antibodies against platelet antigens. Splenomegaly, splenic atrophy, and asplenism may all be seen in SLE. Depending on severity of the abnormal blood counts, treatment considerations include glucocorticoids, anti-CD20 biologic agents, platelet growth factors, intravenous immunoglobulin, and/or splenectomy in resistant cases. Rarely, atypical hemolytic-uremic syndrome (formerly designated as thrombotic thrombocytopenic purpura or the syndrome of microvascular thrombotic crisis) may occur. This is a condition that presents with hemolysis, thrombocytopenia, and microvascular thrombosis, as well as brain and other tissue involvement. Laboratory testing shows schistocytes in the peripheral blood smear, low levels of ADAMTS13 activity, and elevated serum lactate dehydrogenase levels.

GASTROINTESTINAL MANIFESTATIONS

Lupus can involve any part of the gastrointestinal tract. Flaring SLE activity has been associated with nonspecific gastrointestinal symptoms including nausea, vomiting, and diarrhea. Abdominal pain may be caused by lupus peritonitis, enteritis, pancreatitis, or vasculitis. Mesenteric vasculitis can lead to intestinal perforation, bleeding, and ischemia and requires high doses of glucocorticoids for treatment. Impaired intestinal motility and protein-losing enteropathy may also occur. Elevated liver enzymes are common and may be associated with flaring disease activity, medications, and/or coexisting autoimmune hepatobiliary disease. Mesenteric thrombosis, Budd-Chiari syndrome, and hepatic venoocclusive disease can be observed with concomitant APS.

OCULAR MANIFESTATIONS

Keratoconjunctivitis sicca is common in SLE, even in the absence of secondary Sjögren's syndrome. Retinal vasculitis, optic neuritis, uveitis, scleritis, peripheral ulcerative keratitis, episcleritis, and nonspecific conjunctivitis may all be seen. Retinal vasculitis is rare but, when present, requires aggressive immunosuppression to prevent blindness. Adverse ocular effects from medications include cataracts and glaucoma from glucocorticoid treatment and hydroxychloroquine (HCQ)-induced maculopathy **(Table 368-1)**.

LABORATORY TESTS

AUTOANTIBODIES

An elevated titer of ANA reflects the underlying immune dysregulation in SLE. Measuring ANA presence and titer is the best screening test for SLE because ANAs are seen in almost all SLE patients. Repeated negative tests by immunofluorescence make a diagnosis unlikely, but rare cases of ANA-negative SLE do occur. Classification of SLE by current EULAR/ACR criteria requires the presence of an ANA titer of 1:80 for enrollment of patients into SLE clinical trials; however, the diagnosis is based on clinical and laboratory features and ultimately, clinical judgement (see "Diagnosis and Classification" section). Numerous ANAs have been identified that target nuclear antigens; in particular, components of the nucleosome (DNA wrapped around a histone

TABLE 368-1 Clinical Manifestations of Systemic Lupus Erythematosus

Constitutional	Fatigue, malaise, fever, weight loss, anorexia
Cutaneous	
Generalized	Photosensitivity, oral and nasal ulcers, alopecia
Acute cutaneous lupus	Malar rash, maculopapular rash, bullous lupus, toxic epidermal necrolysis variant
Subacute cutaneous lupus	
Chronic forms of cutaneous lupus	Discoid rash, panniculitis, tumid lupus, chilblains, verrucous lupus, cutaneous vasculitis
Musculoskeletal	Arthralgia, myalgia, polyarthritis, Jaccoud hand deformity, inflammatory myopathy, avascular necrosis of bone
Hematologic	Anemia, leukopenia, lymphopenia, thrombocytopenia, lymphadenopathy, splenomegaly, venous or arterial thrombosis, atypical hemolytic-uremic syndrome
Cardiopulmonary	Pleurisy, pericarditis, pleural and pericardial effusions, myocarditis, endocarditis, pneumonitis, coronary artery disease, interstitial fibrosis, pulmonary hypertension, diffuse alveolar hemorrhage, shrinking lung syndrome
Vascular	Pulmonary hypertension, stroke, myocardial infarction, peripheral arterial disease, pulmonary embolism, deep vein thrombosis, Raynaud's phenomenon
Neurologic	Cognitive dysfunction, mood disorder, depression, headache, seizures, mononeuropathy, polyneuropathy, stroke, transient ischemic attack, psychosis, aseptic meningitis, transverse myelitis
Renal	Proteinuria ≥500 mg/24 h, cellular casts, nephrotic syndrome, end-stage renal disease
Gastrointestinal	Nausea, abdominal pain, diarrhea, elevated liver enzymes, lupus peritonitis or enteritis, vasculitis, pancreatitis
Ocular	Sicca syndrome, conjunctivitis, episcleritis, scleritis, uveitis, retinal vasculitis

TABLE 368-2 Autoantibodies in Systemic Lupus Erythematosus

ANTIBODY	PREVALENCE, %	CLINICAL ASSOCIATIONS
ANA	95	Titers of 1:80 or higher are considered positive and are sensitive for SLE but not specific.
Anti-dsDNA	70	Higher titers are more specific for SLE. Levels correlate with disease activity and nephritis.
Anti-Sm	30	Most specific autoantibody for SLE and more common in black and Asian patients. May correlate with CNS manifestations and incidence of nephritis.
Anti-RNP	25	Not SLE-specific. Associated with overlap syndromes and increased risk for pulmonary hypertension. Correlates with high interferon gene signature.
Anti-Ro (SS-A)	30	Not SLE-specific. Associated with sicca syndrome, neonatal lupus and congenital heart block, and subacute cutaneous lupus.
Anti-La (SS-B)	20	Associated with anti-Ro.
Antiribosomal P	15	May be associated with CNS involvement. Specific for SLE but not sensitive.
Antihistone	70	Associated with drug-induced lupus.
Anti–U1-RNP	13	Associated with musculoskeletal and lung impairment.
Antiphospholipid *Anticardiolipin* *Anti–β_2-glycoprotein* *Lupus anticoagulant*	50	Arterial or venous thrombosis, pregnancy morbidity and fetal loss, thrombocytopenia. Associated with CNS manifestations, Libman-Sacks endocarditis, hypertension, pulmonary hypertension.

Abbreviations: ANA, antinuclear antibody; CNS, central nervous system; dsDNA, double-stranded DNA; RNP, ribonucleoprotein; SLE, systemic lupus erythematosus; Sm, Smith.

octamer) or RNA-binding proteins (RBPs). In SLE, the most common antinucleosome antibodies are anti-dsDNA antibodies that are present in ~40–60% of patients and highly specific (75–99%). Anti-Smith (anti-Sm) antibodies are the most common anti-RBP, present in ~30% of patients, and are highly specific for SLE (55–100%). Given their high specificity, both anti-dsDNA and anti-Sm antibodies are the only ANA subtypes that are included in the current EULAR/ACR criteria. Anti-Ro (SS-A) antibodies, which recognize a protein complexed primarily to 60-kDa and 52-kDa RNAs, are often seen in ANA-negative SLE patients and are associated with risk for neonatal lupus, sicca symptoms, photosensitivity, and SCLE. Antihistone antibodies may be associated with drug-induced lupus (see "Drug-Induced Lupus" section). Antiphospholipid antibodies, as measured by IgG, IgM, and IgA isotypes of anticardiolipin and anti–beta-2 glycoprotein-1 antibodies (anti-β_2GP-1), and the lupus anticoagulant usually obtained using the dilute Russell venom viper time (dRVVT) are present in ~50% of SLE patients. These antibodies, especially the IgG and IgA isotypes of cardiolipin and β_2GP-1, and the lupus anticoagulant are associated with arterial and venous thrombosis, thrombocytopenia, and recurrent fetal loss **(Table 368-2)**. Many ANA subtypes can be present in SLE and other systemic autoimmune diseases including myositis, rheumatoid arthritis, Sjögren's syndrome, and systemic scleroderma, as well as organ-specific autoimmune diseases such as autoimmune hepatitis, Hashimoto's thyroiditis, and primary biliary cholangitis.

STANDARD DIAGNOSTIC TESTS

Immunologic, renal, and hematologic domains make up the laboratory testing for the diagnosis of SLE. Among the immunologic domain, elevated titers of ANA confer a high likelihood of SLE. Although ANAs are present at low levels in healthy patients, the threshold for a positive test of 1:80 or higher favors SLE. In the setting of ANA negativity with a clinical presentation highly suggestive of SLE, anti-Ro (SSA) confers a high likelihood of SLE. Further immunologic testing for anti-dsDNA and anti-Sm autoantibodies confers specificity. Anti-dsDNA antibodies and reduced levels of complement components C3 and C4 suggest a propensity for lupus nephritis, as these tests indirectly reflect the pathogenic production of autoantibodies and the high load of cellular debris. Laboratory testing is required at initial presentation to screen for hematologic abnormalities including leukopenia, lymphopenia, thrombocytopenia and anemia of chronic inflammation, hemolytic anemia, and atypical hemolytic-uremic syndrome. Initial testing for renal abnormalities is necessary to determine an estimated glomerular filtration rate (eGFR), serum creatinine, and either a random or 24-h UPCr. When commercially available, consideration should be given to measuring urinary biomarkers recently noted to be associated with renal inflammatory and fibrotic disease, including urinary interleukin 16, CD163, type 1 IFN, and transforming growth factor-beta (TGF-β).

TESTS FOR FOLLOWING DISEASE COURSE

Clinical manifestations of SLE vary over time, likely in response to the aberrant immunologic mechanisms that are driving disease. In particular, anti-dsDNA antibody titers are important to track disease activity. These autoantibodies are produced by a short-lived population of B-cell plasmablasts that turn over rapidly, reflecting the presence or absence of immunologic activity. Levels of the complement factors C3 and C4 can drop during episodes of high disease activity, as these are affected by the formation of autoimmune immune complexes and apoptotic cells. In lupus nephritis, the extent of proteinuria and the eGFR are also frequently monitored. Quarterly testing is suggested in asymptomatic patients because hematologic and renal manifestations can be present in the absence of symptoms. Testing should be performed to consider the presence of leukopenia, lymphopenia,

thrombocytopenia, anemia (both anemia of chronic inflammation and hemolytic anemia), and rarely, atypical hemolytic-uremic syndrome. Testing for eGFR, serum creatinine, and a random or 24-h UPCr level is essential for routine follow-up care with consideration of a renal biopsy when urinary protein exceeds a new level of UPCr of 0.5 to rule out active lupus nephritis. Consideration should be given to measuring urinary biomarkers on a quarterly basis when available.

MANAGEMENT

EULAR recently updated recommendations for the management of SLE and lupus nephritis. Goals for SLE treatment include improved disease activity with minimal symptoms, prevention of damage, and improved quality of life **(Figs. 368-4 and 368-5)**. Adherence to treatment plans is essential. Achieving these goals with safe treatments and minimal corticosteroids is an integral aspect of achieving low levels of disease activity and remission. If corticosteroids are utilized for active or flaring disease, the goal should be to utilize the lowest possible dosage to suppress disease activity. Aggressive therapy should be reserved for life-threatening manifestations or those that could lead to damage. Consideration should be given to minimize both the effects of active disease and complications from treatment. Renal treatment goals based on EULAR recommendations include (1) a goal that all patients should at least achieve a state of low disease activity, defined by a Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) score of 0–4; or (2) remission, defined as a SLEDAI score of 0, both with stable use of HCQ, immunosuppressives or biologics, and a daily dose of 5 mg of prednisone (or glucocorticoid equivalent) or less (see "Outcomes" section).

ESSENTIAL LUPUS THERAPEUTIC APPROACHES AND ANTIMALARIALS

All SLE patients should use daily sunscreen on sun-exposed areas, maintain a healthy diet and weight, avoid smoking, exercise regularly, maintain compliance with vaccination recommendations, and regularly monitor and achieve control of their blood pressure, lipid, and glucose levels. Antimalarials should be used in all patients unless contraindicated, as they have been shown to prevent flares, increase overall survival, and decrease the risk of developing renal disease and accelerated atherosclerosis, among other benefits. HCQ, one of the first drugs approved by the U.S. Food and Drug Administration (FDA) for use in SLE, is the most common antimalarial used and is first-line therapy for patients with skin manifestations and arthritis. It is the most useful drug to improve fatigue in SLE. Use during pregnancy and during breastfeeding has been demonstrated to be safe. Appropriate dosing of HCQ is under investigation, as higher doses may be associated with better disease control. Current recommendations are for dosing up to 5 mg/kg per day (actual body weight) with performance of retinal evaluations at baseline and at yearly intervals to monitor for macular effects, which are associated with prolonged usage. Risk factors for retinal toxicity from HCQ include higher dose and longer duration of use; however, higher doses may also confer better disease control, and overall risk for maculopathy remains low. The most appropriate dose of HCQ for SLE treatment thus remains unclear. Other side effects of HCQ may include rash, nausea, vomiting and diarrhea, and skin dyspigmentation. Tobacco use may interfere with the efficacy of antimalarials. Alternative antimalarials include chloroquine, which has a higher risk of retinal toxicity, and quinacrine, which has a higher

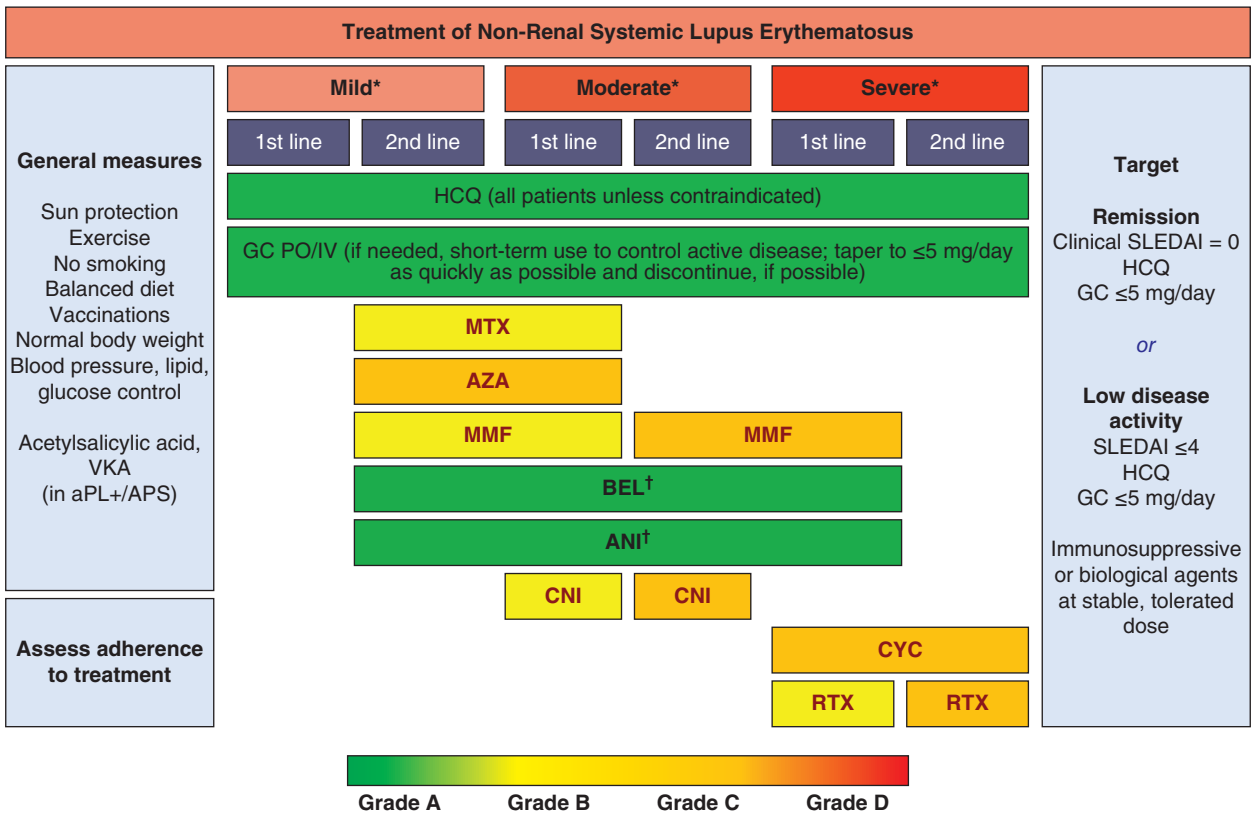

FIGURE 368-4 Treatment of nonrenal systemic lupus erythematosus (SLE). Notes: Top-to-bottom sequence does not imply order of preference (e.g., MTX, AZA, and MMF are equal options for second-line therapy in mild disease or first-line therapy in moderate disease). *Mild disease: constitutional symptoms; mild arthritis; rash ≤9% body surface area; platelet count (PLTs) 50–100× 10^9/L; SLEDAI ≤6; BILAG C or ≤1 BILAG B manifestation. *Moderate disease: moderate-to-severe arthritis ("rheumatoid arthritis–like"; rash 9–18% body surface area [BSA]; PLTs 20–50 × 10^9/L; serositis; SLEDAI 7–12; ≥2 BILAG B manifestations). *Severe disease: major organ-threatening disease (e.g., cerebritis, myelitis, pneumonitis, mesenteric vasculitis); thrombocytopenia with platelets <20 × 10^9/L; thrombotic thrombocytopenic purpura–like disease or acute hemophagocytic syndrome; rash >18% BSA; SLEDAI >12; ≥1 BILAG A manifestation. †Recommendation of belimumab and anifrolumab as first-line therapy in severe disease refers to cases of extrarenal SLE with nonmajor organ involvement but extensive disease from skin, joints, and so on. The use of anifrolumab as add-on therapy in severe disease refers mainly to severe skin disease. For patients with severe neuropsychiatric disease, anifrolumab and belimumab are not recommended. ANI, anifrolumab; aPL, antiphospholipid antibodies; APS, antiphospholipid syndrome; AZA, azathioprine; BEL, belimumab; BILAG, British Isles Lupus Assessment Group; CNI, calcineurin inhibitor; CYC, cyclophosphamide; GC, glucocorticoids; HCQ, hydroxychloroquine; IV, intravenous; MMF, mycophenolate mofetil; MTX, methotrexate; PO, per os; RTX, rituximab; SLEDAI, SLE Disease Activity Index; VKA, vitamin K antagonists. *(Reproduced with permission from A Fanouriakis et al: Ann Rheum Dis 83:15, 2024.)*

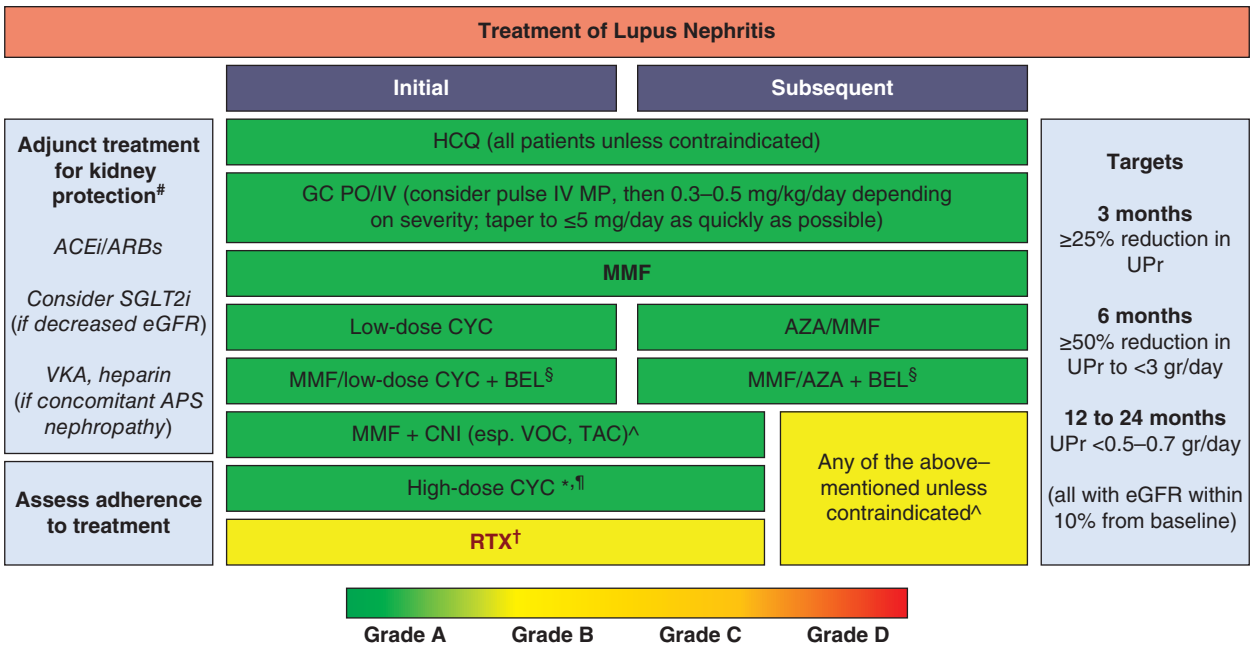

FIGURE 368-5 Treatment of lupus nephritis. Notes: Top-to-bottom sequence does not imply order of preference. #In addition to general protective measures, as outlined in Figure 368-3. §BEL should always be given in combination with MMF or low-dose CYC as initial therapy and with MMF or AZA as maintenance therapy. ^CNIs should be given in combination with MMF. *Particularly recommended in the presence of poor prognostic factors: reduced eGFR, histologic presence of cellular crescents or fibrinoid necrosis, or severe interstitial inflammation. ¶Extension of high-dose CYC to subsequent phase refers to severe lupus nephritis cases, in which bimonthly or quarterly CYC pulses may be given following 6 monthly pulses. †In relapsing/refractory disease, especially after failure of CYC-based regimens. ACEi, angiotensin-converting enzyme inhibitors; APS, antiphospholipid syndrome; ARB, angiotensin receptor blockers; AZA, azathioprine; BEL, belimumab; CNI, calcineurin inhibitor; CYC, cyclophosphamide; eGFR, estimated glomerular filtration rate; GC, glucocorticoids; HCQ, hydroxychloroquine; IV, intravenous; MMF, mycophenolate mofetil; MP, methylprednisolone; PO, per os; RTX, rituximab; SGLT2i, sodium-glucose cotransporter 2 inhibitors; TAC, tacrolimus; Upr, urine protein; VKA, vitamin K antagonists; VOC, voclosporin. *(Reproduced with permission from A Fanouriakis et al: Ann Rheum Dis 83:15, 2024.)*

risk of skin dyspigmentation. Quinacrine can be used as alternative therapy in cases of toxic retinopathy or as add-on therapy to HCQ for patients with inadequate response. For arthritis and arthralgia, nonsteroidal anti-inflammatory drugs (NSAIDs) can be useful but should be used with caution in SLE patients due to increased risk for aseptic meningitis, hypertension, renal dysfunction, elevated serum transaminases, and increased myocardial infarction risk with cyclooxygenase-2 inhibition.

GLUCOCORTICOIDS

Glucocorticoid dosing is based on the organ-specific needs and severity of disease. While effective at reducing inflammation quickly, their use is associated with dose-dependent side effects including cushingoid metabolic effects, hyperglycemia, hypertension, osteoporosis, and avascular necrosis. If needed, corticosteroids should be tapered as quickly as possible to maintenance doses of 5 mg or less of daily prednisone or its equivalent, and withdrawn as soon as feasible. Use of intravenous methylprednisolone (usually 125–1000 mg daily for 1–3 days) is limited to emergent needs such as active nephritis, severe central nervous system or vascular involvement, and hematologic manifestations such as life-threatening hemolytic anemia or thrombocytopenia. A major goal of novel SLE therapies is the ability to develop treatment algorithms that are less dependent on chronic glucocorticoid use.

SKIN AND MUSCULOSKELETAL MANIFESTATIONS: IMMUNOMODULATING AND IMMUNOSUPPRESSANT DRUGS

All SLE patients and especially those with skin manifestations of disease should be treated with topical sunscreens and antimalarials. If unresponsive to these approaches, topical glucocorticoids and/or calcineurin inhibitors can be utilized. Persistent mucocutaneous disease and/or arthritis may prompt consideration of additional oral immunomodulating drugs such as azathioprine (6-thioguanine purine analogue), leflunomide (lymphocyte-specific pyrimidine synthesis inhibitor), mycophenolate mofetil (MMF), or mycophenolic acid (purine synthesis inhibitors). Biological drugs such as belimumab (anti-BAFF, administered intravenously or subcutaneously) and anifrolumab (anti–type 1 IFN receptor, administered intravenously) are FDA-approved approaches shown to improve outcomes in these clinical domains, with better ability to taper glucocorticoids. Thalidomide and lenalidomide may be used for some cutaneous subtypes but with caution due to risk for polyneuropathy and teratogenicity. Methotrexate (a folinic acid antagonist) is another option for arthritis associated with SLE.

RENAL DISEASE: SUCCESSES WITH COMBINATION THERAPIES

Treatment approaches have been recommended by EULAR for class III and IV lupus nephritis, as well as combination of class V lupus nephritis with either class III or IV (Fig. 368-5). The recommended targets are a 3-month target of 25% or more reduction in UPCr level, a 6-month target of 50% or more reduction in UPCr to <3 g/d, and a 12- to 24-month target in UPCr to <0.5–0.7 g/d, with each of these targets associated with an eGFR within 10% from baseline. All patients with class III, IV, or V nephritis should receive an angiotensin-converting enzyme (ACE) inhibiting agent or an angiotensin receptor blocking (ARB) agent to decrease proteinuria and reduce systemic and glomerular hypertension. With a baseline decreased eGFR, use of a sodium-glucose cotransporter 2 (SGLT2) inhibitor should be considered to reduce glomerular hyperfiltration, lower blood pressure, and decrease proteinuria. Patients with active lupus nephritis with concomitant antiphospholipid nephropathy as noted by biopsy should receive a vitamin K antagonist or heparin.

Current initial regimens include either cyclophosphamide (an alkylating agent administered intravenously) or MMF (administered orally) plus glucocorticoids to reduce progression to ESRD and death. Rates of infection and death are similar in both treatment approaches. Induction in Black or Hispanic patients with MMF 2–3 g daily is appropriate given better response to MMF in these ethnic groups, while use of either MMF or cyclophosphamide may be an option for White and Asian patients. Low doses of cyclophosphamide (500 mg every 2 weeks for six doses) followed by either azathioprine or MMF maintenance are

as effective as standard high doses of cyclophosphamide with improved tolerability. High-dose cyclophosphamide monthly for 6 months followed by azathioprine or MMF may be more appropriate for patients with crescentic proliferative glomerulonephritis or rapidly progressive glomerulonephritis. Ovarian failure is a potential consequence of high-dose cyclophosphamide, and therefore, a gonadotropin-releasing hormone agonist may be given prior to each cyclophosphamide dose. Dosing of glucocorticoids as part of the initial therapeutic approach is controversial, with more recent data suggesting the use of intermediate doses for shorter periods of time with more rapid dose reduction. For subsequent therapy, MMF is superior to azathioprine in maintaining renal function and survival, but both may be used, and azathioprine is the preferred agent for lupus nephritis in pregnancy. Patients using azathioprine should be screened for homozygous deficiency of the thiopurine *S*-methyltransferase (*TMPT*) gene, which increases the risk for severe bone marrow suppression, as this gene is responsible for the TPMT enzyme necessary for metabolizing thiopurine drugs. Calcineurin inhibitors such as tacrolimus and cyclosporine may be beneficial for decreasing proteinuria, and tacrolimus can be used in pregnancy.

Two immunomodulating therapies have recently been approved by the FDA for use in lupus nephritis for patients on standard therapy for active nephritis: belimumab, approved in 2020, and the cyclosporine analogue voclosporin, approved in 2021. The randomized controlled trials for these medications demonstrate favorable outcomes without the use of high-dose steroids. Voclosporin-based triple immunotherapy (with MMF and glucocorticoids) or belimumab-based triple therapy (with either low-dose cyclophosphamide or MMF and glucocorticoids) can be considered as an initial approach in active lupus nephritis. Patients with active lupus nephritis and inadequate response to conventional therapies may also consider alternative biologics targeting B cells such as rituximab. While rituximab studies in lupus nephritis did not demonstrate efficacy compared to standard therapies, issues with the trial designs may have hampered the demonstration of an effect.

Treatment approaches for patients with pure class V membranous glomerulonephritis have not been well studied, and commonly patients with this presentation are treated only in the setting of significant proteinuria. All patients with class III, IV, or V nephritis, including combinations of class III or IV with class V, should be considered for treatment with ARB or ACE inhibition to reduce proteinuria.

THERAPIES FOR OTHER ORGAN-BASED SYSTEMS

Few studies have focused on central and peripheral nervous system, cardiac, pulmonary, serosal, gastrointestinal, or hematologic manifestations of SLE. Anti-CD20 agents such as rituximab are used for lupus-related hemolytic anemia and severe thrombocytopenia. Colchicine can be used to treat pleural, pericardial, or peritoneal inflammatory symptoms. MMF, cyclophosphamide, and rituximab plus corticosteroids are the mainstay of treatment for serious central and peripheral inflammatory nervous system presentations including psychosis, vasculitis, and transverse myelitis. Plasmapheresis and high levels of glucocorticoids can be lifesaving in atypical hemolytic-uremic syndrome. In refractory patients, rituximab and a C5 inhibitor, eculizumab, are used. Concomitant APS should be treated with warfarin for long-term anticoagulation rather than direct oral anticoagulants **(Chap. 369)**.

EMERGING THERAPIES AND TREATMENT APPROACHES

SGLT2 inhibitors are being studied in lupus nephritis for their effects on preserving function through tubular protection with effects on inflammation and fibrosis. Obinutuzumab, a CD20-targeted monoclonal antibody that is commercially available for oncologic indications, has recently demonstrated efficacy in a phase 3 study for lupus nephritis, and is also being investigated for use in SLE without nephritis. Anecdotal experience with obinutuzumab by rheumatologists in treating SLE patients off-label suggests that this drug may be more clinically effective than rituximab due to improved CD20 tissue depletion. Deucravacitinib, an oral Tyk2 inhibitor, is in phase 3 study for SLE. Telitacicept, a TACI-Fc fusion protein that targets BLyS and APRIL growth factors for B cells, has been approved in China for use in patients with SLE, and global phase 3 studies are underway. Litifilimab, a drug in late-stage development with initial promising results, is a monoclonal antibody targeting BDCA2, a protein expressed on plasmacytoid dendritic cells, that suppresses activation of type I interferons and other proinflammatory cytokines. Initial results show achievement of remission, according to the Definition of Remission in Systemic Lupus Erythematosus (DORIS), from nonrandomized CD19-directed chimeric antigen receptor T-cell treatment, which has prompted interest in further study of this approach. Other cell-based therapeutic programs under investigation include both allogenic and autologous natural killer cell–based programs and mesenchymal embryonic stem cell transplantation for severe SLE.

GUIDELINES

Besides the recent EULAR (2013) and Pan-American League of Associations for Rheumatology (2018) guidelines for SLE and lupus nephritis, the ACR (2012) and the Kidney Disease Improving Global Outcomes (KDIGO) organization (2021) have published guidelines specifically for lupus nephritis. These guidelines address medication-based, lifestyle, and nonpharmacologic approaches, as well as infection screening and vaccination recommendations. The KDIGO guidelines include recommendations prior to the approval of belimumab and voclosporin. An important concept that the KDIGO group emphasizes is the unsettled question of duration of immunosuppression. The group notes that the risk of lupus relapse should be balanced with risk of adverse events secondary to immunosuppressive drugs. They suggest that for patients who have achieved a complete renal response and have no ongoing extrarenal SLE manifestations, the total duration of immunosuppression (initial plus maintenance) should not be <36 months. The EULAR guidelines provide consensus guidance for SLE management that combines evidence and expert opinion concerning the use of HCQ, glucocorticoids, immunosuppressive drugs, calcineurin inhibitors, and biologics, with suggestions for treatment strategies, response assessment, combination approaches, and therapy tapering (see Figures 368-4 and 368-5). Most of the concepts and strategies presented in these guidelines are described in the sections above.

DRUG-INDUCED LUPUS

Drug-induced lupus (DIL) is an autoimmune phenomenon in which a positive ANA and clinical features of SLE arise from a drug exposure. DIL accounts for ~6–12% of all lupus cases. Symptoms may include fever, rash, arthralgia, myalgia, and serositis. Antihistone antibodies are commonly associated with DIL, with dsDNA antibodies occurring less frequently. DIL tends to be less severe than SLE, rarely involving kidneys or brain, and symptoms typically resolve within several weeks after discontinuation of the offending agent.

The first agent identified to cause lupus symptoms was hydralazine in 1954. Over the years, >100 drugs have been identified as potential triggers for DIL. The highest incidence of DIL occurs with the antiarrhythmic procainamide, with risk reported to be as high as 30%. Other substances associated with DIL include the antihypertensives hydralazine and methyldopa; other antiarrhythmics; antibiotics including minocycline, isoniazid, rifampin, and nitrofurantoin; the antirheumatic drug sulfasalazine; anticonvulsants such as phenytoin and carbamazepine; antipsychotics including chlorpromazine and lithium; several ACE inhibitors and beta blockers; the diuretic hydrochlorothiazide; the antithyroid propylthiouracil; proton pump inhibitors; NSAIDs; and oral contraceptives. Biologic agents include antitumor necrosis factor α medications, particularly infliximab and etanercept, and IFN-α.

Diagnosis can be difficult, as DIL symptoms may start weeks to several months after drug initiation. Furthermore, skin biopsy may be indistinguishable from SLE, and laboratory characteristics including histone antibody may be seen in the majority of SLE cases. In DIL, the ANA pattern is most commonly homogeneous, and histone is positive in 75% of DIL cases. Cytopenias may be present but are typically mild. The presence of other autoantibodies may help to distinguish SLE from DIL, as these are rarely seen in DIL. The ANA test typically appears before symptoms, although many of the same medications will

induce a positive ANA in patients who never develop symptoms. If DIL is suspected, these laboratory tests should help to inform the clinical picture to decide if medication discontinuation is appropriate. If symptoms resolve after medication discontinuation, this helps to confirm a diagnosis of DIL.

PREGNANCY AND REPRODUCTIVE HEALTH

FERTILITY

Lupus activity can affect the menstrual and ovulation cycle. Lower measures of ovarian reserve are seen in SLE patients compared to healthy controls. Women with SLE have a higher risk for infertility if they have active disease, comorbidities such as APS or nephritis, and prior exposure to treatments such as cyclophosphamide. Cyclophosphamide use may lead to amenorrhea, ovarian insufficiency, and early menopause.

CONTRACEPTION/HORMONE REPLACEMENT

Contraception and family planning should be discussed with all women of reproductive age with SLE. SLE patients with antiphospholipid antibodies and those with moderate-to-severe or active lupus should avoid estrogen compounds due to increased risk for thromboembolism. Progestin-only contraceptive options such as the levonorgestrel intrauterine device or etonogestrel implant, as well as emergency contraception, may be used safely in women with SLE. Estrogen compounds as a part of postmenopausal hormone replacement therapy should similarly be avoided in the presence of antiphospholipid antibodies.

PREGNANCY

SLE pregnancies are high risk. Disease activity in pregnancy is unpredictable, and the disease can flare during any trimester. Active disease at time of conception is associated with more flares during pregnancy. HCQ reduces the risk of flares during pregnancy and postpartum. Women with SLE are at a higher risk for adverse pregnancy outcomes including pregnancy loss, preterm birth, preeclampsia and pregnancy-induced hypertension, intrauterine growth restriction, cesarean section, and maternal death. Flaring or active disease increases the risk for these adverse outcomes. The presence of maternal hypertension, use of glucocorticoids during pregnancy, maternal renal disease, discontinuation of HCQ, non-White ethnicity, and lupus anticoagulant positivity are all associated with worse pregnancy outcomes. SLE patients at the highest risk for maternal death are those with pulmonary arterial hypertension, prior arterial thrombosis, and severe end-organ damage, and these patients should strongly consider avoiding pregnancy.

Outcomes are generally favorable for women with SLE with mild-to-moderate disease activity on pregnancy-compatible medications. Low-dose aspirin is used during pregnancy for preeclampsia prevention. HCQ is safe and the standard of care for all SLE pregnancies. Azathioprine and tacrolimus may be used safely in pregnancy for more severe disease and/or renal disease. MMF and methotrexate are teratogenic and should be avoided. Belimumab, anifrolumab, and voclosporin should currently be avoided due to lack of safety data. Patients who get pregnant on these medications may be switched to azathioprine or tacrolimus. Rituximab should be discontinued at conception but may be used during pregnancy in organ-threatening disease. Prednisone may be used for disease flares and can suppress disease activity, but the dose should be tapered to the lowest effective dose by adding pregnancy-compatible immunosuppressant medications. Warfarin is teratogenic; low-molecular-weight heparin is used in SLE pregnancies with APS or prior pregnancy morbidity.

NEONATAL LUPUS

SS-A (Ro) antibodies may cross the placenta into the fetal circulation and put the infant at risk for neonatal lupus. Neonatal lupus can consist of a transient cutaneous rash or lab abnormalities that present after birth or, less commonly, congenital heart block that presents in utero. The presence of Ro antibodies, particularly in high titer, should prompt referral to high-risk obstetricians who can perform fetal echocardiography to screen for congenital heart block. The use of fluorinated steroids may be considered if first- or second-degree heart block is detected. The use of HCQ in pregnancy significantly reduces the risk of congenital heart block in women who have had a prior fetus with congenital heart block.

OUTCOMES

Measuring SLE outcomes both in clinical trials and in clinical practice is complex given the multisystem nature of the disease. Various aspects of disease require unique treatment approaches and often at differing rates, which makes measuring response challenging. Modern SLE treatment outcomes include improvement in inflammatory type 1 and chronic type 2 symptoms, quality of life, and the prevention of frailty and damage.

New drugs and interventions are constantly being explored as potential treatments for SLE in clinical trials. Goals of clinical trials for novel therapies include improved disease activity and acceptable safety. Long-term extension studies focus on long-term safety and maintenance of improved disease activity. The Systemic Lupus Erythematosus Responder Index (SRI) and the British Isles Lupus Assessment Group (BILAG)-based Composite Lupus Assessment (BICLA) are validated instruments for use in clinical trials. The Cutaneous Lupus Disease Area and Severity Index (CLASI) is also utilized specifically for trials involving cutaneous lupus. Several instruments are utilized in clinical trials to assess quality of life and fatigue, although few are specific to SLE.

TREAT-TO-TARGET APPROACHES

Treat-to-target goals for clinical trials and clinical practice have been developed and validated, including the definition of a lupus low disease activity state (LLDAS) and remission (DORIS). Both LLDAS and DORIS remission scoring utilize the SLEDAI-2K instrument, a validated instrument that measures SLE disease activity. Achievement of remission by these measures is defined by low disease activity (LLDAS) or no disease activity (DORIS), with minimal use of steroids and stable use of antimalarials, immunosuppressants, and/or biologics and by low levels (LLDAS) or no evidence of disease activity (DORIS) as assessed by the evaluating physician. LLDAS has been shown to be attainable in up to 80% of patients, and the achievement of sustained LLDAS for 2 more years is associated with significantly less overall damage.

DAMAGE

Organ or structural damage occurs in SLE due to the use of medications to treat the disease or because of persistent disease activity. Use of glucocorticoids is associated with the development of irreversible organ damage that is independent of disease activity. Cataracts, osteoporosis-associated fractures, avascular necrosis, and diabetes mellitus are the complications from glucocorticoid treatment that are most commonly observed. Development of damage accrues in a dose-dependent manner, but even low doses of 5 mg of prednisone or equivalent appear to be associated with damage accrual. Accelerated atherosclerosis is a major cause of death after 5 years of SLE disease duration. Increased myocardial infarction and cerebrovascular event rates are due to both traditional cardiovascular risk factors and non-traditional factors including presence of antiphospholipid antibodies, increased disease activity, low C3 levels, high glucocorticoid dose, and high homocysteine and leptin levels. Statin use has been demonstrated to reduce all-cause mortality in SLE patients with renal transplantation. Studies of malignancy rates in SLE have been inconsistent; however, recent meta-analyses suggest an increased risk of overall cancer and cancer-related death in SLE patients. Seventeen site-specific cancers noted include digestive cancers (esophagus, colon, anus, hepatobiliary, liver, and pancreas), hematologic cancers (lymphoma, Hodgkin's lymphoma, non-Hodgkin's lymphoma, leukemia, and multiple myeloma), and cancer involving lung, larynx, cervix, vagina/vulva, kidney, bladder, skin, and thyroid.

369 Antiphospholipid Syndrome

Haralampos M. Moutsopoulos, Maria G. Tektonidou

DEFINITIONS

Antiphospholipid syndrome (APS) is an autoantibody-mediated acquired thrombophilia characterized by recurrent arterial or venous thrombosis, microvascular manifestations, and/or pregnancy morbidity. It affects primarily young females. APS may occur alone (primary) or in association with other autoimmune diseases, mainly systemic lupus erythematosus (SLE). Catastrophic APS (CAPS) is a rare, life-threatening, rapidly progressive thromboembolic disease involving simultaneously three or more organs.

The major autoantibodies detected in APS patients are directed against phospholipid-binding plasma proteins such as β_2-glycoprotein I (β_2GPI) and prothrombin. The plasma protein β_2GPI is a 43-kDa plasma apolipoprotein, which consists of 326 amino acids arranged in five domains (I through V). The presence of anti–domain I IgG antibodies has been associated with increased thrombotic risk. Recent evidence from animal studies has shown that the antithrombotic function of β_2GPI is dependent on its fifth domain (domain V). Another group of antibodies against phospholipid-binding proteins, termed *lupus anticoagulant* (LA), prolongs clotting time in vitro, which is not corrected by adding normal plasma.

Anticardiolipin and anti-β_2GPI IgG/IgM antibodies are measured by standardized enzyme-linked immunosorbent assays (ELISA); β_2GPI in combination with cardiolipin or β_2GPI in the absence of cardiolipin serve as target antigens, respectively. LA testing includes a three-step procedure: (1) screening including testing with activated partial thromboplastin time (aPTT) and dilute Russel viper venom test (DRVVT); (2) mixing study; and (3) confirmation. In patients receiving anticoagulation treatment, LA test positivity should be interpreted with caution. In patients with features highly reminiscent of APS in the absence of classical antiphospholipid antibodies (aPL), testing for antiphosphatidylserine/prothrombin antibodies may have a valuable diagnostic role.

EPIDEMIOLOGY

The incidence of APS is estimated to be 1–2 cases per 100,000 persons per year. The prevalence of APS in the general population is estimated to be 40–50 per 100,000. APL antibodies occur in 1–5% of the general population. Their prevalence increases with age; however, it is questionable whether they are able to induce thrombotic events in elderly individuals. Moreover, one-third of patients with SLE **(Chap. 368)** possess these antibodies and 10–15% of them develop APS.

PATHOGENESIS

The initiating events for the induction of antibodies to phospholipid-binding proteins seem to be endothelial injury induced by infections, oxidative stress, and major physical stresses such as surgery or trauma in an appropriate genetic background, given the previously demonstrated associations with alleles within the human leukocyte antigen (HLA) locus. These contributors seem to induce increased apoptosis of the vessel endothelial cells, autoantigen presentation, and subsequent initiation of autoimmune response. The binding of aPL to the disrupted endothelial cells leads to a proinflammatory and prothrombotic state involving monocytes and platelets activation, adhesion molecules and proinflammatory cytokines production, complement and neutrophil activation, neutrophil extracellular trap (NET) formation, and thrombus formation. Recently, type I interferon pathway activation and an imbalance between type I and III interferons have been proposed as potential mechanisms of thrombotic events and APS-related obstetric complications.

CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS

Clinical manifestations include venous or arterial thrombosis, microvascular events, and/or pregnancy morbidity **(Table 369-1)**. Deep venous thrombosis occurs primarily in the lower extremities and often causes pulmonary emboli. Thrombosis of the pulmonary arteries leads to pulmonary hypertension and thrombosis of hepatic veins to Budd-Chiari syndrome. Cerebral venous thrombosis presents with signs and symptoms of intracranial hypertension and focal neurologic deficits. Other venous thrombosis manifestations include retinal vein thrombosis and renal, mesenteric, or splanchnic vein thrombosis. Arterial thrombosis affects more commonly the arteries of the brain and is manifested as transient ischemic attack, stroke, migraines, or cognitive dysfunction. Peripheral artery thrombosis presents with acute limb ischemia, ischemic leg ulcers, or digital gangrene. Thrombosis of other arteries leads to myocardial infarction, retinal artery occlusion, renal artery stenosis, and infarcts of spleen, liver, and adrenals.

Microvascular manifestations include livedo reticularis, which consists of a mottled reticular vascular pattern that appears as a lace-like, purplish discoloration of the skin; livedo racemosa, characterized by a broken, irregular, and asymmetric pattern; and livedoid vasculopathy, which presents with painful papules or lower limb ulcers. Another microvascular feature of APS is the so-called aPL-nephropathy, manifested with hypertension, proteinuria (mild to nephrotic range), hematuria, and mild renal insufficiency. Histologically, the acute phase is characterized by thrombotic microangiopathy lesions in the glomerular capillaries and/or arterioles. In a chronic phase, fibrous intima hyperplasia, fibrous and/or fibrocellular arteriolar occlusions, and focal cortical atrophy are present (Table 369-1). Additional rare microvascular manifestations are pulmonary hemorrhage, myocardial disease confirmed by magnetic resonance imaging or histologically, and adrenal hemorrhage.

Pregnancy morbidity manifests with prefetal (<10 weeks of gestation) or fetal death, preeclampsia, eclampsia, and placental insufficiency with intrauterine fetal growth restriction, abnormal umbilical arterial Doppler, and/or infarctions of the placenta

Cardiac valve manifestations include valve thickening or vegetations. Libman-Sacks endocarditis consists of small (usually <1 cm) valve vegetations, histologically characterized by organized platelet-fibrin microthrombi surrounded by growing fibroblasts and macrophages. Premature atherosclerosis has been also recognized as a feature of APS. Thrombocytopenia and autoimmune hemolytic anemia are the main hematologic manifestations of APS. Musculoskeletal

TABLE 369-1 Clinical Features of Antiphospholipid Syndrome

MANIFESTATION	%
Venous Thrombosis and Skin Manifestations	
Deep-vein thrombosis	39
Livedo reticularis	24
Pulmonary embolism	14
Superficial thrombophlebitis	12
Thrombosis in various other sites	11
Arterial Thrombosis and Cardiac Manifestations	
Stroke	20
Cardiac valve thickening/dysfunction and/or Libman-Sacks vegetations	14
Transient ischemic attack	11
Myocardial ischemia (infarction or angina) and coronary bypass graft thrombosis	10
Leg ulcers and/or digital gangrene	9
Arterial thrombosis in the extremities	7
Retinal artery thrombosis/amaurosis fugax	7
Ischemia of visceral organs or avascular necrosis of bone	6
Multi-infarct dementia	3
Neurologic Manifestations of Uncertain Etiology	
Migraine	20
Epilepsy	7
Chorea	1

manifestations may also occur in APS including arthralgias/arthritis, avascular bone necrosis, bone marrow necrosis, nontraumatic fractures, and osteoporosis.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of APS should be seriously considered in cases of thrombosis, cerebral vascular accidents in individuals <55 years of age, or pregnancy morbidity, in the presence of livedo reticularis or thrombocytopenia. In these cases, aPL antibodies should be measured. According to the 2023 American College of Rheumatology/European Alliance of Associations for Rheumatology (ACR/EULAR) classification criteria for APS, the presence of at least 3 points from clinical domains and 3 points from laboratory domains is required to classify APS. Clinical manifestations with other equally or more likely explanations than APS will not be counted. Clinical domains include (1) venous thromboembolism; (2) arterial thrombosis; (3) microvascular events; (4) obstetric complications; (5) cardiac valve disease; and (6) hematologic manifestations, as shown in Table 369-2. Laboratory domains include (1) LA, (2) anticardiolipin (aCL), and/or (3) anti-β_2GPI antibodies, at moderate (40-79 units) or high titers (≥ 80 units) on two occasions 12 weeks apart.

Differential diagnosis is based on the exclusion of other inherited or acquired causes of thrombophilia (Chap. 121), Coombs-positive hemolytic anemia (Chap. 105), and thrombocytopenia (Chap. 120). Livedo reticularis with or without a painful ulceration on the lower extremities may be also a manifestation of disorders affecting (1) the vascular wall, such as atherosclerosis, polyarteritis nodosa, SLE, cryoglobulinemia, and lymphomas; or (2) the vascular lumen, such as

TABLE 369-2 2023 American College of Rheumatology/European Alliance of Associations for Rheumatology (ACR/EULAR) Classification Criteria for Antiphospholipid Syndrome

Clinical Domains	
DOMAINS/CRITERIA	**POINTS**

myeloproliferative disorders, hypercholesterolemia, or other causes of thrombophilia.

Diagnosis of CAPS should be considered in patients with mainly microvascular thrombotic disease involving multiple organs in a short time period. A patient is classified as definite CAPS if all four of the following criteria are fulfilled and as probable CAPS when a combination of these criteria is present: (1) thrombosis in three or more organs/systems; (2) development in less than a week; (3) histologic evidence of small-vessel thrombosis in at least one organ; and (4) aPL presence. Because thrombotic microangiopathy (microangiopathic hemolytic anemia and severe thrombocytopenia) is a typical finding in CAPS, the differential diagnosis includes thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, disseminated intravascular coagulation, and heparin-induced thrombocytopenia.

TREATMENT

Antiphospholipid Syndrome

It has been increasingly appreciated that the risk of thrombotic and obstetric events is closely related to the underlying aPL profile. The latter depends on the type of autoantibodies (IgG high risk vs IgM low risk), the number of aPL antibodies (simultaneous presence of two or three classical autoantibodies vs a single antibody denotes a higher risk profile), their titer (moderate-high titer vs low), and the persistence of aPL positivity in repeated measurements.

Following the first thrombotic event, APS patients should be placed on vitamin K antagonists (VKAs) for life, aiming to achieve an international normalized ratio (INR) ranging from 2.0 to 3.0 in case of an unprovoked venous thrombosis. For patients with arterial thrombosis, the corresponding INR target should be 3.0–4.0 or 2.0–3.0 with or without low-dose aspirin (LDA, 75–100 mg daily), depending on the thrombotic/hemorrhagic patient profile. Administration of direct oral anticoagulants (DOACs) recently has been shown to increase the risk of arterial events, especially in patients with triple positivity or previous arterial thrombosis. A recent meta-analysis of four open-label randomized controlled trials showed that prior thrombosis type (arterial vs venous) did not affect the increased odds of arterial thrombosis associated with DOACs compared to VKAs in APS. In pregnant women with a history of obstetric APS, combination treatment with LDA and prophylactic dose of low-molecular-weight heparin (LMWH) is recommended, whereas in cases of thrombotic APS, LDA plus therapeutic LMWH dose should be administered. When recurrent obstetric complications occur despite standard treatment, increasing the LMWH dose (from prophylactic to therapeutic) or administering oral hydroxychloroquine 400 mg/d or low-dose prednisolone in the first trimester are alternative options.

For asymptomatic individuals or SLE patients with a high-risk aPL profile and no evidence of a previous thrombotic event or pregnancy morbidity, prophylactic treatment with LDA is recommended. In nonpregnant women with a history of APS-related obstetric complications, independently of the presence of underlying SLE diagnosis, treatment with LDA seems to reduce the risk of a subsequent thrombotic event.

Patients with CAPS should be treated with combination therapy including glucocorticoids, heparin, and plasma exchange or intravenous immunoglobulin (IVIG) together with appropriate management of triggering events such as infections. For refractory CAPS, B-cell depletion (e.g., with rituximab) or complement inhibition (e.g., with eculizumab) therapies are alternative options.

370 Rheumatoid Arthritis

Ankoor Shah, E. William St. Clair

INTRODUCTION

Rheumatoid arthritis (RA) is a chronic inflammatory disease characterized by a symmetric, erosive polyarthritis. It is the most common form of chronic inflammatory arthritis. Since persistently active RA often results in articular cartilage and bone destruction and functional disability, it is vital to diagnose and treat this disease early and aggressively before damage ensues. Although predominately affecting joints, RA is a systemic disease that may lead to a variety of extraarticular manifestations, including fatigue, subcutaneous nodules, lung involvement, pericarditis, peripheral neuropathy, vasculitis, and hematologic abnormalities.

Insights gained over the past two decades have revolutionized the contemporary paradigms for the diagnosis and management of RA. Testing for serum antibodies to anti-citrullinated protein antibodies (ACPA) and rheumatoid factor continues to be valuable in the diagnostic evaluation of patients with suspected RA, and these autoantibodies serve as biomarkers of prognostic significance. Advances in imaging modalities assist clinical decision-making by improving the detection of joint inflammation and monitoring the progression of damage. The science of RA has taken major leaps forward by illuminating new disease-related genes, environmental interactions, and the molecular components and pathways of disease pathogenesis. The relative contribution of these cellular and inflammatory mediators in disease pathogenesis has been further brought to light by the efficacy of the approved biologic and targeted synthetic disease-modifying therapies. Despite these major strides, incomplete understanding of the initiating events of RA and the factors perpetuating the chronic inflammatory response remains a barrier to finding a cure.

The past 20 years have witnessed a remarkable improvement in the outcomes of RA. The crippling arthritis of years past is encountered much less frequently today. Much of this progress can be traced to the expanded therapeutic armamentarium and the renewed sense of urgency to identify patients earlier in the disease process, enabling prompt treatment intervention. This shift in treatment strategy dictates a new mindset for primary care practitioners—namely, one that demands early referral of patients with inflammatory arthritis to a rheumatologist for confirmation of the diagnosis and initiation of disease-modifying therapy, since delays in starting effective treatment are associated with worse outcomes. Reaching a clinical state of low disease activity and remission is now an achievable goal for most patients.

CLINICAL FEATURES

The incidence of RA increases between 25 and 55 years of age, after which it plateaus until the age of 75 and then decreases. The presenting symptoms are typically related to inflammation of the joints, tendons, and bursae. Patients often complain of early morning joint stiffness lasting >1 h that eases with physical activity. The earliest involved joints are mostly the small joints of the hands and feet. The initial pattern of joint involvement may be monoarticular, oligoarticular (≤4 joints), or polyarticular (>5 joints), usually in a symmetric distribution. Some patients with inflammatory arthritis will present with too few affected joints to be classified as having RA—so-called undifferentiated inflammatory arthritis. Those with an undifferentiated arthritis who are most likely to be diagnosed later with RA have a higher number of tender and swollen joints, test positive for serum rheumatoid factor (RF) or ACPA, and have higher scores for physical disability.

In established RA, the most frequently involved joints are the wrists and metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints **(Fig. 370-1)**. Distal interphalangeal (DIP) joint involvement may occur in patients with RA, but it is usually due to coexistent osteoarthritis. Flexor tendon tenosynovitis is a frequent hallmark of RA and leads to decreased range of motion, reduced grip strength,

FIGURE 370-1 Metacarpophalangeal joint swelling and subluxation. *(Reproduced with permission from RP Usatine, MA Smith, EJ Mayeaux: The Color Atlas and Synopsis of Family Medicine, 3rd ed. New York, McGraw Hill, 2019; Fig. 97.5.)*

and "trigger" fingers. Flexor tendon involvement may also lead to tendon rupture, most commonly the flexor pollicis longus. Progressive destruction of the joints and soft tissues may result in chronic, irreversible deformities. Ulnar deviation is a common deformity of long-standing RA that is caused by subluxation of the MCP joints, with subluxation, or partial dislocation, of the proximal phalanx to the volar side of the hand. Hyperextension of the PIP joint with flexion of the DIP joint ("swan-neck deformity"), flexion of the PIP joint with hyperextension of the DIP joint ("boutonnière deformity"), and subluxation of the first MCP joint with hyperextension of the first interphalangeal (IP) joint ("Z-line deformity") also may result from damage to the tendons, joint capsule, and other soft tissues. Inflammation about the ulnar styloid and tenosynovitis of the extensor carpi ulnaris may cause subluxation of the distal ulna, resulting in a "piano-key movement" of the ulnar styloid. Although metatarsophalangeal (MTP) joint involvement is an early feature of disease, chronic inflammation of the ankle and midtarsal regions usually comes later and may lead to pes planovalgus ("flat feet"). Large joints, including the knees and shoulders, are often affected in established disease and may remain asymptomatic for many years after onset.

Atlantoaxial involvement of the cervical spine is clinically noteworthy because of its potential to cause compressive myelopathy and neurologic dysfunction. Neurologic manifestations are rarely a presenting sign or symptom of atlantoaxial disease, but they may slowly evolve over time with progressive instability of C1 on C2. The prevalence of atlantoaxial subluxation has been declining in recent years and occurs now in <10% of patients. Unlike the spondyloarthritides **(Chap. 374)**, RA rarely affects the thoracic and lumbar spine.

Extraarticular manifestations may develop during the clinical course of RA in up to 40% of patients, even prior to the onset of arthritis **(Fig. 370-2)**. Patients most likely to develop extraarticular disease have a history of cigarette smoking, have early onset of significant physical disability, and test positive for serum RF or ACPA. Subcutaneous nodules, Sjögren's disease, interstitial lung disease (ILD), pulmonary nodules, and anemia are among the most frequently observed extraarticular manifestations. Recent studies have shown a decrease in the incidence and severity of at least some extraarticular manifestations, particularly Felty's syndrome and vasculitis.

The most common systemic and extraarticular features of RA are described in more detail in the sections below.

CONSTITUTIONAL

These signs and symptoms include weight loss, fever, fatigue, malaise, depression, and in the most severe cases, cachexia; they generally reflect a high degree of inflammation and may even precede the onset of joint symptoms. In general, the presence of a fever of >38.3°C (101°F) at any time during the clinical course should raise suspicion of systemic vasculitis (see below) or infection.

NODULES

Subcutaneous nodules have been reported to occur in 30–40% of patients and more commonly in those with the highest levels of disease activity, who carry the disease-related shared epitope (SE) (see below), who have a positive test for serum RF, and who show radiographic evidence of joint erosions. However, more recent cohort studies suggest a declining prevalence of subcutaneous nodules, perhaps related to early and more aggressive disease-modifying therapy. When palpated, the nodules are generally firm; nontender; and adherent to periosteum, tendons, or bursae; they develop in areas of the skeleton subject to repeated trauma or irritation such as the forearm, sacral prominences, and Achilles tendon. They may also occur in the lungs, pleura, pericardium, and peritoneum. Nodules are typically benign, although they can be associated with infection, ulceration, and gangrene. Accelerated growth of smaller nodules may occur in up to 10% of patients taking long-term methotrexate, although the mechanisms behind this phenomenon are unclear.

SJÖGREN'S SYNDROME

Secondary Sjögren's syndrome, or Sjögren's disease **(Chap. 373)**, is defined by the presence of either keratoconjunctivitis sicca (dry eyes) or xerostomia (dry mouth) in association with another connective tissue disease, such as RA. Approximately 10% of patients with RA have secondary Sjögren's syndrome.

PULMONARY

Pleuritis, the most common pulmonary manifestation of RA, may result in pleuritic chest pain and dyspnea, as well as a finding of a pleural friction rub and radiographic evidence of a pleural effusion. Pleural effusions tend to be exudative with increased numbers of monocytes and neutrophils. ILD may also occur in patients with RA and is heralded by symptoms of dry cough and progressive shortness of breath. ILD can be associated with cigarette smoking and is generally found in patients with higher disease activity, although it may be diagnosed in up to 3.5% of patients prior to the onset of joint symptoms. Recent studies have shown the overall prevalence of ILD in RA to be as high as 12%. Diagnosis is readily made by high-resolution chest computed tomography (CT) scan, which shows infiltrative opacification, or ground-glass opacities, in the periphery of both lungs. Usual interstitial pneumonia (UIP) and nonspecific interstitial pneumonia (NSIP) are the main histologic and radiologic patterns of ILD. UIP causes progressive scarring of the lungs that, on chest CT scan, produces honeycomb changes in the periphery and lower portions of the lungs. In contrast, the most common radiographic changes in NSIP are relatively symmetric and bilateral ground-glass opacities with associated fine reticulations, volume loss, and traction bronchiectasis. In both cases, pulmonary function testing shows a restrictive pattern (e.g., reduced total lung capacity) and a reduced diffusing capacity for carbon monoxide (DL_{CO}). The presence of ILD confers a poor prognosis. The prognosis of ILD in RA, however, is not quite as poor as that of idiopathic pulmonary fibrosis (e.g., usual interstitial pneumonitis) and responds better to immunosuppressive therapy **(Chap. 304)**. Pulmonary nodules are also common in patients with RA and may be solitary or multiple. Caplan's syndrome is a rare subset of pulmonary nodulosis characterized by the development of nodules and pneumoconiosis following silica exposure. Less commonly, RA may be associated with respiratory bronchiolitis and bronchiectasis.

CARDIAC

The most frequent site of cardiac involvement in RA is the pericardium. However, clinical manifestations of pericarditis occur in <10% of patients with RA despite pericardial involvement being detectable in nearly one-half of cases by echocardiogram or at autopsy. Up to 20% of patients with RA may have asymptomatic pericardial effusions on echocardiography. Cardiomyopathy, another clinically important manifestation of RA, may result from necrotizing or granulomatous myocarditis, coronary artery disease, or diastolic dysfunction. This

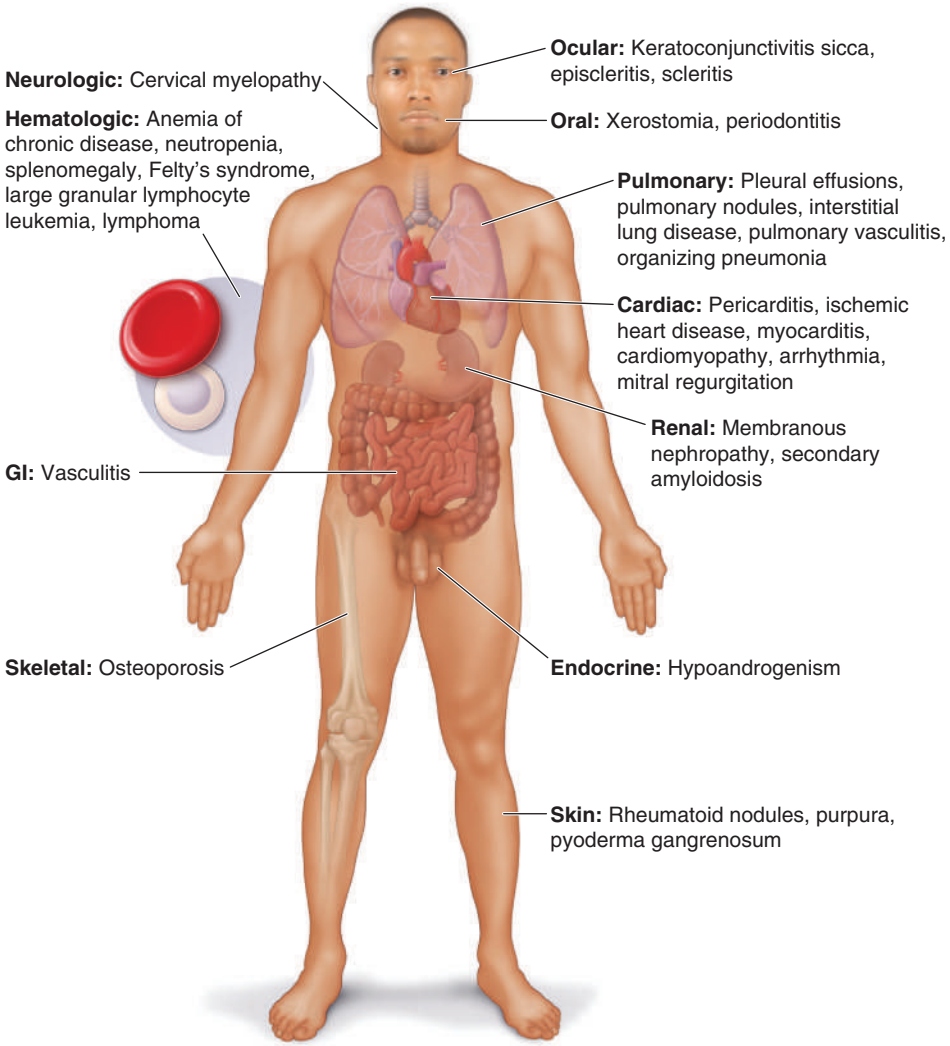

FIGURE 370-2 Extraarticular manifestations of rheumatoid arthritis.

involvement, too, may be subclinical and only identified by echocardiography or cardiac magnetic resonance imaging (MRI). Rarely, the heart muscle may contain rheumatoid nodules or be infiltrated with amyloid.

VASCULITIS

Rheumatoid vasculitis (Chap. 375) typically occurs in patients with long-standing disease, a positive test for serum RF or ACPA, and hypocomplementemia. The overall incidence has decreased significantly in the past decade to <1% of patients. The cutaneous signs vary and include petechiae, purpura, digital infarcts, gangrene, livedo reticularis, and in severe cases large, painful lower extremity ulcerations. Vasculitic ulcers, which may be difficult to distinguish from those caused by venous insufficiency, may be treated successfully with immunosuppressive agents including cytotoxic treatment and skin grafting in severe cases. Sensorimotor polyneuropathies, such as mononeuritis multiplex, may occur in association with systemic rheumatoid vasculitis; they usually present with new onset of numbness, tingling, or focal muscle weakness.

HEMATOLOGIC

A normochromic, normocytic anemia often develops in patients with RA and is the most common hematologic abnormality. The degree of anemia parallels the degree of inflammation, correlating with the levels of serum C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR). Platelet counts may also be elevated in RA as an acute-phase reactant; immune-mediated thrombocytopenia is rare.

Felty's syndrome is defined by the clinical triad of neutropenia, splenomegaly, and nodular RA and is seen in <1% of patients, although its incidence appears to be declining in the face of more aggressive treatment of the joint disease. It typically occurs in the late stages of severe RA and is more common in whites than other racial groups. T-cell large granular lymphocyte leukemia (T-LGL) may have a similar clinical presentation and often occurs in association with RA. T-LGL is characterized by a chronic, indolent clonal growth of LGL cells, leading to neutropenia and splenomegaly. As opposed to Felty's syndrome, T-LGL may develop early in the course of RA. Leukopenia apart from these disorders is uncommon and most often a side effect of drug therapy.

LYMPHOMA

Large cohort studies have shown a two- to fourfold increased risk of lymphoma in RA patients compared with the general population. The most common histopathologic type of lymphoma is a diffuse large B-cell lymphoma. The risk of developing lymphoma increases if the patient has high levels of disease activity or Felty's syndrome.

ASSOCIATED CONDITIONS

In addition to extraarticular manifestations, several conditions associated with RA contribute to disease morbidity and mortality rates. They are worthy of mention because they affect chronic disease management.

Cardiovascular Disease The most common cause of death in patients with RA is cardiovascular disease. The incidence of coronary

artery disease and carotid atherosclerosis is higher in RA patients than in the general population even when controlling for traditional cardiac risk factors, such as hypertension, obesity, hypercholesterolemia, diabetes, and cigarette smoking. Furthermore, congestive heart failure (including both systolic and diastolic dysfunction) occurs at an approximately twofold higher rate in RA than in the general population. The presence of elevated serum inflammatory markers appears to confer an increased risk of cardiovascular disease.

Osteoporosis Osteoporosis is more common in patients with RA than an age- and sex-matched population, with an incidence rate of nearly double that of the healthy population and a prevalence of approximately one-third in postmenopausal women with RA. There is also an increased risk of fragility fracture, with a greater risk among women. The inflammatory milieu of the joint promotes generalized bone loss by activating osteoclasts. Both trabecular and cortical bone are affected by the inflammatory response, with cortical sites more susceptible to bone loss. Chronic use of glucocorticoids and disability-related immobility also contribute to osteoporosis. Hip fractures are more likely to occur in patients with RA and are significant predictors of increased disability and mortality rate in this disease.

EPIDEMIOLOGY

RA affects ~0.5–1% of the adult population worldwide, although the majority of epidemiologic studies have been done in Western countries. There is evidence that the overall incidence of RA has been decreasing in recent decades, whereas the prevalence has remained the same because individuals with RA are living longer. The incidence and prevalence of RA vary based on geographic location, both globally and among certain ethnic groups within a country **(Fig. 370-3)**. For example, the indigenous Yakima, Pima, and Chippewa tribes of North America have reported prevalence rates in some studies of nearly 7%. In contrast, many population studies from Africa and Asia show lower prevalence rates for RA in the range of 0.2–0.4%.

Like many other autoimmune diseases, RA occurs more commonly in females than in males, with a 2–3:1 ratio. Interestingly, studies of RA from some of the Latin American and African countries show an even greater predominance of disease in females compared to males, with ratios of 6–8:1. Given this preponderance of females, various theories have been proposed to explain the possible role of estrogen in disease pathogenesis. Broadly speaking, most of the theories center on the role of estrogens and androgens in enhancing and suppressing the immune response, respectively. However, estrogens have both stimulatory and inhibitory effects on the immune system, and their role, if any, on the development of RA is unknown.

GENETIC CONSIDERATIONS

It has been recognized for >30 years that genetic factors contribute to the occurrence of RA as well as to its severity. The likelihood that a first-degree relative of a patient will share the diagnosis of RA is 2–10 times greater than in the general population. There remains, however, some uncertainty in the extent to which genetics plays a role in the causative mechanisms of RA. Heritability estimates range from 40 to 60%, although this may be higher in ACPA-positive patients compared to those without ACPA. The estimate of genetic influence has varied across studies, probably due to gene–environment interactions.

The alleles known to confer the greatest risk of RA are located within the major histocompatibility complex (MHC) and, in particular, those encoding the MHC class II molecules. MHC class II molecules are typically expressed on antigen-presenting cells and are comprised of α and β chains. Most, but probably not all, of this risk is associated with allelic variation in the HLA-DRB1 gene, which encodes the MHC II β-chain molecule. The disease-associated HLA-DRB1 alleles share an amino acid sequence at positions 70–74 in the third hypervariable regions of the HLA-DR β-chain, termed the *shared epitope* (SE). These amino acids are located in the antigen-binding grove within the hypervariable regions of the HLA-DRβ1 molecule. These hypervariable regions are important not only for determining antigen recognition but also for binding of the MHC-peptide complex to the T-cell receptor (TCR). Peptides derived from posttranslationally modified proteins (via citrullination, acetylation, or carbamylation, for example) may bind with greater avidity to the SE, providing a potential explanation for increased disease risk at a molecular level. The risk of RA is four times higher in persons carrying a single SE allele and eight times higher in those carrying two alleles compared to SE-negative individuals.

Carriership of the SE alleles is associated with production of ACPAs and worse disease outcomes. Some HLA-DRB1 alleles bestow a high risk of disease (*0401), whereas others confer a more moderate risk (*0101, 0404, 1001, and 0901). Over 90% of patients with RA express at least one of these variants. Interestingly, HLA-DRB1*1301 and to a lesser extent HLA-DRB1*1302 confer protection from ACPA-positive RA.

Additionally, there is geographic variation in disease susceptibility and the identity of the HLA-DRB1 risk alleles. In Greece, for example,

European ancestry:
HLA-DRB1:
*0401
*0404
*0301
*0101

PTPN22: European
STAT4: North American
TNFAIP3: North American
TRAFI/CF: North American
CTLA4: European

Asian ancestry:
HLA-DRB1:

*0405
*0901 (Japanese, Malaysian, Korean)

PADI4
CD244

Other:
CD40

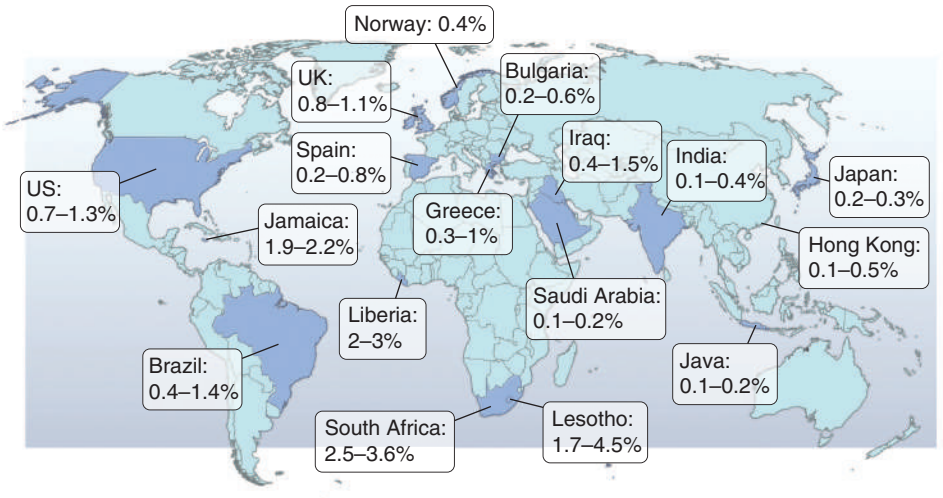

FIGURE 370-3 Global prevalence rates of rheumatoid arthritis (RA) with genetic associations. Listed are the major genetic alleles associated with RA. Although human leukocyte antigen (HLA)-DRB1 mutations are found globally, some alleles have been associated with RA in only certain ethnic groups.

where RA tends to be milder than in western European countries, RA susceptibility has been associated with the *0101 SE allele. By comparison, the *0401 or *0404 alleles are found in ~50–70% of northern Europeans and are the predominant risk alleles in this group. The most common disease susceptibility SE alleles in Asians, namely the Japanese, Koreans, and Chinese, are *0405 and *0901. Lastly, disease susceptibility of Native American populations such as the Pima and Tlingit Indians, where the prevalence of RA can be as high as 7%, is associated with the SE allele *1042. The risk of RA conferred by these SE alleles is less in African and Hispanic Americans than in individuals of European ancestry.

Genome-wide association studies (GWAS) have made possible the identification of several non-MHC-related genes that contribute to RA susceptibility. GWASs are based on the detection of single nucleotide polymorphisms (SNPs), which allow for examination of the genetic architecture of complex diseases such as RA. Overall, several themes have emerged from GWAS in RA. First, among the >100 non-MHC loci identified as risk alleles for RA, they individually have only a modest effect on risk; they also contribute to the risk for developing other autoimmune diseases, such as type 1 diabetes mellitus, systemic lupus erythematosus, and multiple sclerosis. Second, although most of the non-HLA associations are described in patients with ACPA-positive disease, there are several risk loci that are unique to ACPA-negative disease. Third, risk alleles vary among ethnic groups. And fourth, the risk loci mostly reside in genes encoding proteins involved in the regulation of the immune response. However, the risk alleles identified by GWAS only account at present for ~5% of the genetic risk, suggesting that rare variants or other classes of DNA variants, such as variants in copy number, may be yet found that significantly contribute to the overall risk model.

Among the best examples of the non-MHC genes contributing to the risk of RA is the gene encoding protein tyrosine phosphatase non-receptor 22 (*PTPN22*). This gene varies in frequency among patients from different parts of Europe (e.g., 3–10%) but is absent in patients of East Asian ancestry. *PTPN22* encodes lymphoid tyrosine phosphatase, a protein that regulates T- and B-cell function. Inheritance of the risk allele for *PTPN22* produces a gain-of-function in the protein that is hypothesized to result in the abnormal thymic selection of autoreactive T and B cells and appears to be associated exclusively with ACPA-positive disease. The peptidyl arginine deiminase type IV (*PADI4*) gene is another risk allele that encodes an enzyme involved in the conversion of arginine to citrulline and is postulated to play a role in the development of antibodies to citrullinated antigens. A polymorphism in *PADI4* has been associated with a twofold increase in the risk of RA, primarily in those of East Asian descent. Recently, polymorphisms in apolipoprotein M (*APOM*) in an East Asian population were found confer an increased risk for RA as well as risk for dyslipidemia, independent of RA disease activity.

Epigenetics is the study of heritable traits that affect gene expression but do not modify DNA sequence. Epigenetic mechanisms are theoretically involved in three important aspects of RA: contribution to disease etiology, perpetuation of chronic inflammatory responses, and disease severity. The best-studied epigenetic mechanisms are those regulating posttranslational histone modifications and DNA methylation. DNA methylation patterns have been shown to differ between RA patients and healthy controls, including monozygotic twins, as well as from patients with osteoarthritis. Epigenetics may also offer a mechanistic explanation for how cigarette smoking confers an increased risk for ACPA-positive RA (see below) as those patients with the SE have higher levels of DNA methylation compared to nonsmokers. MicroRNAs, which are noncoding RNAs that function as posttranscriptional regulators of gene expression, represent an additional epigenetic mechanism that may potentially influence cellular responses.

ENVIRONMENTAL FACTORS

In addition to genetic predisposition, a host of environmental factors have been implicated in the pathogenesis of RA. The most reproducible of these environmental links is cigarette smoking. Numerous cohort and case-control studies have demonstrated that smoking confers a relative risk for developing RA of 1.5–3.5 times. Smoking-related risk interacts in a synergistic manner with MHC risk alleles. The classic SE alleles alone increase the likelihood of developing RA by four- to sixfold; however, this risk increases to 20- to 40-fold when combined with smoking. In particular, women who smoke cigarettes have a nearly 2.5 times greater risk of RA, a risk that persists even 15 years after smoking cessation. A twin who smokes will have a significantly higher risk for RA than their monozygotic co-twin, theoretically with the same genetic risk, who does not smoke. Interestingly, the risk from smoking is almost exclusively related to RF and ACPA-positive disease. However, it has not been shown that smoking cessation, while having many health benefits, reduces the severity or extent of joint inflammation. Inhalant-related occupations and silica inhalants also may increase RA risk. These observations have led to the theory that subclinical lung disease may play a critical early role in the initial development of autoreactive immune cells and account for the occurrence of autoantibodies more than a decade prior to the clinical development of joint disease.

Researchers began to aggressively seek an infectious etiology for RA after the discovery in 1931 that sera from patients with this disease could agglutinate strains of streptococci. Certain viruses such as Epstein-Barr virus (EBV) have garnered the most interest over the past 30 years given their ubiquity, ability to persist for many years in the host, and frequent association with arthritic complaints. For example, titers of IgG antibodies against EBV antigens in the peripheral blood and saliva are significantly higher in patients with RA than in the general population. EBV DNA has also been found in synovial fluid and synovial cells of RA patients. Because the evidence for these links is largely circumstantial, it has not been possible to directly implicate infection as a causative factor in RA.

An attractive hypothesis raised by newer studies is that microbial dysbiosis of the oral or gut microbiome may predispose to the development of RA. Recent work suggests that periodontitis in the oral cavity may play a role in disease mechanisms. Multiple studies provide evidence for a link between ACPA-positive RA and cigarette smoking, periodontal disease, and the oral microbiome, specifically *Porphyromonas gingivalis*. It has been hypothesized that the immune response to *P. gingivalis* may trigger the development of RA and the bacterial enzyme peptidyl arginine deiminase (PAD) induces ACPA by catalyzing the citrullination of arginine residues on the stimulating autoantigens. Interestingly, *P. gingivalis* is the only oral bacterial species known to harbor this enzyme. Some studies have shown a relationship between the presence of circulating antibodies to *P. gingivalis* and RA, as well as with first-degree relatives at risk for this disease. However, it remains unproven whether the observed dysbiosis in the oral cavity precedes the development of disease.

There are also limited data suggesting a role for the gut microbiome in the etiology of RA. Some studies have found that the gut microbiome is different in patients with early RA compared with controls. In particular, *Prevotella copri* was reported to be enriched in early untreated RA as well as in an "at-risk" population. On the other hand, a common dysbiotic signature does not seem to predominate in patients with RA, and evidence is lacking for a direct immune-modulating effect.

PATHOLOGY

RA affects the synovial lining tissue of the diarthrodial joints and the underlying cartilage and bone. The synovial membrane, which covers most articular surfaces, tendon sheaths, and bursae, normally is a thin layer of connective tissue. In joints, it faces the bone and cartilage, bridging the opposing bony surfaces and inserting at periosteal regions close to the articular cartilage. It consists primarily of two cell types—type A synoviocytes (macrophage-derived) and type B synoviocytes (fibroblast-derived). The synovial fibroblasts are the most abundant and produce the structural components of joints, including collagen, fibronectin, and laminin, as well as other extracellular constituents of the synovial matrix. The sublining layer consists of blood vessels and a sparse population of mononuclear cells within a loose network of connective tissue. Synovial fluid, an ultrafiltrate of blood, diffuses through the subsynovial lining tissue across the synovial membrane

and into the joint cavity. Its main constituents are hyaluronan and lubricin. Hyaluronan is a glycosaminoglycan that contributes to the viscous nature of synovial fluid, which, along with lubricin, lubricates the surface of the articular cartilage.

The pathologic hallmarks of RA are synovial inflammation and proliferation, focal bone erosions, and thinning of articular cartilage. Chronic inflammation leads to synovial lining hyperplasia and the formation of pannus, a thickened cellular membrane consisting of multiple layers of fibroblast-like synoviocytes and granulation-reactive fibrovascular tissue that has a propensity for invading underlying cartilage and bone. The inflammatory infiltrate is made up of no less than six cell types: T cells, B cells, plasma cells, dendritic cells, mast cells, and, to a lesser extent, granulocytes. The T cells compose 30–50% of the infiltrate, with the other cells accounting for the remainder. The topographical organization of these cells is complex and may vary among individuals with RA. Most often, the lymphocytes are diffusely organized among the tissue resident cells; however, in some cases, the B cells, T cells, and dendritic cells may form higher levels of organization, such as lymphoid follicles and germinal center–like structures. Growth factors secreted by synovial fibroblasts and macrophages promote the formation of new blood vessels in the synovial sublining that supply the increasing demands for oxygenation and nutrition required by the infiltrating leukocytes and expanding synovial tissue.

The structural damage to the mineralized cartilage and subchondral bone is mediated by the osteoclast. Osteoclasts are multinucleated giant cells that appear at the pannus-bone interface where they eventually form resorption lacunae. These lesions typically localize where the synovial membrane inserts into the periosteal surface at the edges of bone close to the rim of articular cartilage and at the attachment sites of ligaments and tendon sheaths. This process most likely explains why bone erosions usually develop at the radial sites of the MCP joints juxtaposed to the insertion sites of the tendons, collateral ligaments, and synovial membrane. Periarticular osteopenia, another form of bone loss, occurs in joints with active inflammation. It is associated with substantial thinning of the bony trabeculae along the metaphyses of bones from inflammation of the bone marrow cavity. These lesions can be visualized on MRI scans, where they appear as signal alterations in the bone marrow adjacent to inflamed joints. Their signal characteristics show they are water-rich with a low-fat content and are consistent with highly vascularized inflammatory tissue. These bone marrow lesions are often the forerunner of bone erosions. The cortical bone layer that separates the bone marrow from the invading pannus is relatively thin and susceptible to penetration by the inflamed synovium. The bone marrow lesions visualized on MRI scans are associated with an endosteal bone response characterized by the accumulation of osteoblasts and deposition of osteoid. Finally, generalized osteoporosis, which results in the thinning of trabecular bone throughout the body, is a third form of bone loss found in patients with RA and can lead to fragility fractures.

Articular cartilage is an avascular tissue comprised of a specialized matrix of collagens, proteoglycans, and other proteins. It is organized in four distinct regions (superficial, middle, deep, and calcified cartilage zones)—chondrocytes constitute the unique cellular component in these layers. Originally, cartilage was considered to be an inert tissue, but it is now known to be a highly responsive tissue that reacts to inflammatory mediators and mechanical factors, which, in turn, alter the balance between cartilage anabolism and catabolism. In RA, the initial areas of cartilage degradation are juxtaposed to the synovial pannus. The cartilage matrix is characterized by a generalized loss of proteoglycan, most evident in the superficial zones adjacent to the synovial fluid. Degradation of cartilage may also take place in the perichondrocytic zone and in regions adjacent to the subchondral bone.

PATHOGENESIS

The pathogenic mechanisms of synovial inflammation are likely the result of a complex interplay of genetic, environmental, and immunologic factors that cause immune system dysregulation and a breakdown in self-tolerance **(Fig. 370-4)**. Precisely what triggers these initiating events and what genetic and environmental factors disrupt the immune system remains a mystery. However, a detailed molecular picture is emerging of the mechanisms underlying the chronic inflammatory response and the resulting destruction of the articular cartilage and bone.

In RA, the preclinical stage appears to be characterized by a breakdown in self-tolerance. This idea is supported by the finding that autoantibodies, such as RF and ACPA, may be found in sera from patients many years before onset of clinical disease. However, the antigenic targets of ACPA and RF are not restricted to the joint. ACPAs are directed against deaminated peptides, which result from posttranslational modification by the enzyme PADI4. They recognize citrulline-containing regions of several different matrix proteins, including filaggrin, keratin, fibrinogen, and vimentin, and are present at higher levels in the joint fluid compared to the serum. Antibodies binding to carbamylated peptides and mutant citrullinated vimentin, as well as the 14-3-3 family of proteins, have also been detected in a minority of RA patients.

In theory, environmental triggers may synergize with other factors to bring about inflammation in RA. People who smoke display higher citrullination of proteins in bronchoalveolar fluid than those who do not smoke. Thus, it has been speculated that long-term exposure to tobacco smoke might induce citrullination of cellular proteins via increased PADI expression in the lung and generate a neoepitope capable of inducing self-reactivity, which in turns, leads to formation of immune complexes that trigger joint inflammation and joint damage.

Microbiota may also be involved in the initiating events of RA. The immune system is alerted to the presence of microbial infections when pathogen-associated molecular patterns (PAMPs) on their surface bind to Toll-like receptors (TLRs) on host cells. There are 10 TLRs in humans that recognize a variety of microbial products, including bacterial cell-surface lipopolysaccharides and heat-shock proteins (TLR4), lipoproteins (TLR2), double-strand RNA viruses (TLR3), and unmethylated CpG DNA from bacteria (TLR9). TLR2, 3, and 4 are abundantly expressed by synovial fibroblasts in early RA and, when bound by their ligands, upregulate the cell's production of proinflammatory cytokines. Although TLR ligands may theoretically amplify inflammatory pathways in RA, their specific role in disease pathogenesis remains uncertain.

The pathogenesis of RA is built upon the concept that self-reactive T cells drive the chronic inflammatory response. In theory, self-reactive T cells might arise in RA from abnormal central (thymic) selection or intrinsic defects lowering the threshold in the periphery for T-cell activation. Either mechanism might result in abnormal expansion of a self-reactive T-cell repertoire and a breakdown in T-cell tolerance. The support for these ideas comes mainly from studies of arthritis in mouse models. It has not been shown that patients with RA have abnormal thymic selection of T cells or defective apoptotic pathways regulating cell death. At least some antigen stimulation inside the joint seems likely, owing to the fact that T cells in the synovium express a cell-surface phenotype indicating prior antigen exposure and show evidence of clonal expansion.

There is substantial evidence of a role for CD4+ T cells in the pathogenesis of RA. First, the co-receptor CD4 on the surface of T cells binds to invariant sites on MHC class II molecules, stabilizing the MHC-peptide–T-cell receptor complex during T-cell activation. Because the SE on MHC class II molecules is a risk factor for RA, it follows that CD4+ T-cell activation plays a role in the pathogenesis of this disease. Second, CD4+ memory T cells are enriched in the synovial tissue from patients with RA and therefore are implicated through "guilt by association." Third, CD4+ T cells have been shown to be important in the initiation of arthritis in animal models. Fourth, some, but not all, T cell–directed therapies have shown clinical efficacy in this disease. Taken together, these lines of evidence suggest that CD4+ T cells play an important role in orchestrating the chronic inflammatory response in RA. However, other cell types, such as CD8+ T cells, natural killer (NK) cells, and B cells are present in synovial tissue and may also influence pathogenic responses.

In the rheumatoid joint, by mechanisms of cell-cell contact and release of soluble mediators, activated T cells stimulate macrophages and fibroblast-like synoviocytes to generate proinflammatory

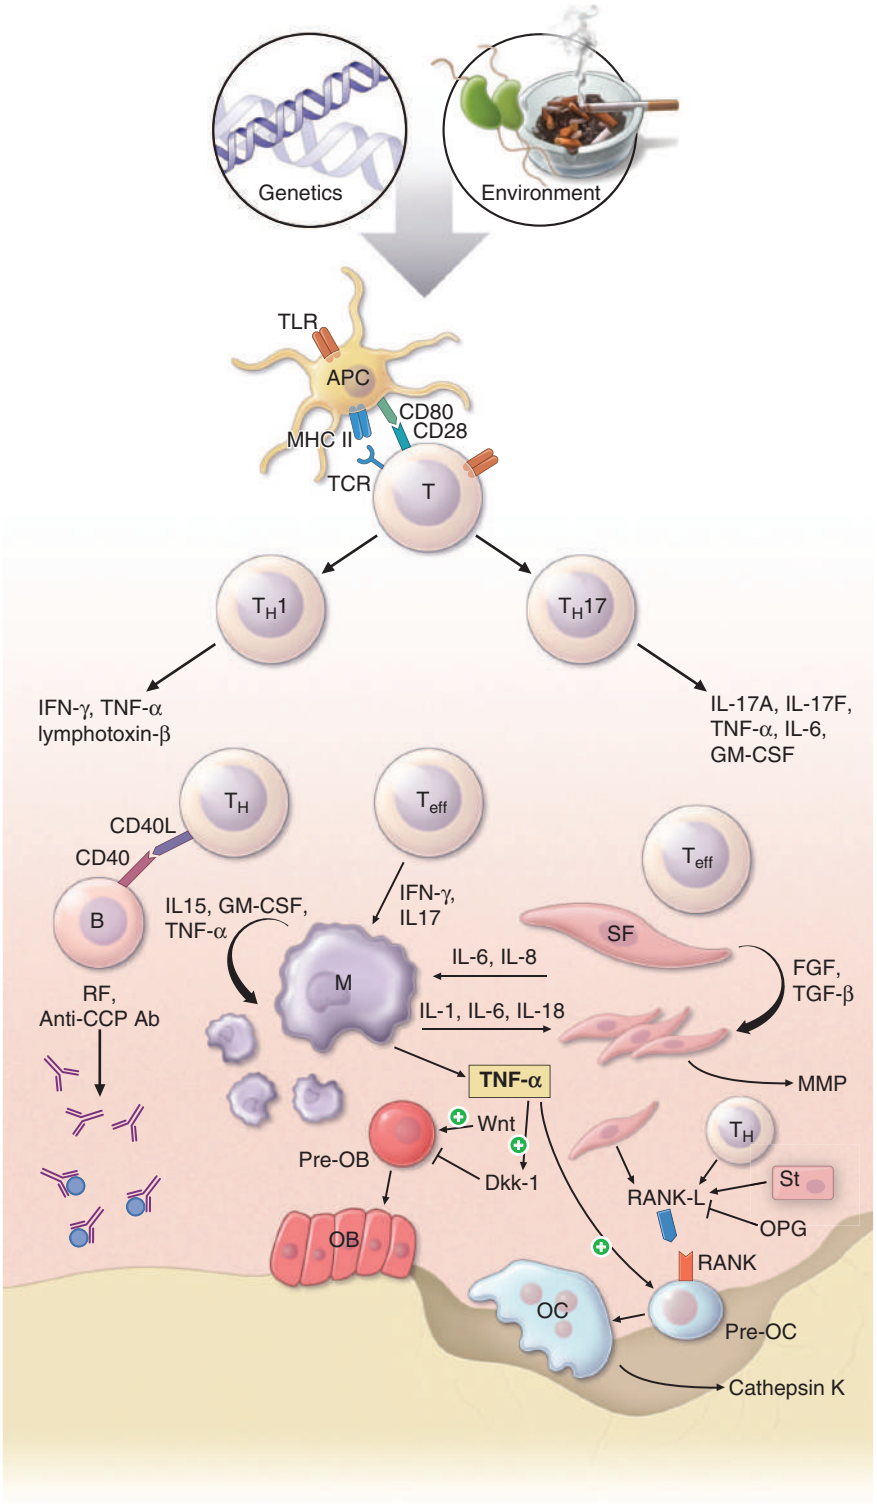

FIGURE 370-4 Pathophysiologic mechanisms of inflammation and joint destruction. Genetic predisposition along with environmental factors may trigger the development of rheumatoid arthritis (RA), with subsequent synovial T-cell activation. CD4+ T cells become activated by antigen-presenting cells (APCs) through interactions between the T-cell receptor and class II MHC-peptide antigen (signal 1) with co-stimulation through the CD28-CD80/86 pathway, as well as other pathways (signal 2). In theory, ligands binding Toll-like receptors (TLRs) may further stimulate activation of APCs inside the joint. Synovial CD4+ T cells differentiate into T_H1 and T_H17 cells, each with their distinctive cytokine profile. CD4+ T_H cells in turn activate B cells, some of which are destined to differentiate into autoantibody-producing plasma cells. Immune complexes, possibly comprised of rheumatoid factors (RFs) and anti–cyclic citrullinated peptides (CCP) antibodies, may form inside the joint, activating the complement pathway and amplifying inflammation. T effector cells stimulate synovial macrophages (M) and fibroblasts (SF) to secrete proinflammatory mediators, among which is tumor necrosis factor α (TNF-α). TNF-α upregulates adhesion molecules on endothelial cells, promoting leukocyte influx into the joint. It also stimulates the production of other inflammatory mediators, such as interleukin 1 (IL-1), IL-6, and granulocyte-macrophage colony-stimulating factor (GM-CSF). TNF-α has a critically important function in regulating the balance between bone destruction and formation. It upregulates the expression of dickkopf-1 (DKK-1), which can then internalize Wnt receptors on osteoblast precursors. Wnt is a soluble mediator that promotes osteoblastogenesis and bone formation. In RA, bone formation is inhibited through the Wnt pathway, presumably due to the action of elevated levels of DKK-1. In addition to inhibiting bone formation, TNF-α stimulates osteoclastogenesis. However, it is not sufficient by itself to induce the differentiation of osteoclast precursors (Pre-OC) into activated osteoclasts capable of eroding bone. Osteoclast differentiation requires the presence of macrophage colony-stimulating factor (M-CSF) and receptor activator of nuclear factor-κB (RANK) ligand (RANKL), which binds to RANK on the surface of Pre-OC. Inside the joint, RANKL is mainly derived from stromal cells, synovial fibroblasts, and T cells. Osteoprotegerin (OPG) acts as a decoy receptor for RANKL, thereby inhibiting osteoclastogenesis and bone loss. FGF, fibroblast growth factor; IFN, interferon; MMP, matrix metalloproteinase; TGF, transforming growth factor.

mediators and proteases that drive the synovial inflammatory response and destroy the cartilage and bone. CD4+ T-cell activation is dependent on two signals: (1) T-cell receptor binding to peptide-MHC on antigen-presenting cells; and (2) CD28 binding to CD80/86 on antigen-presenting cells. This interaction then leads to downstream signals that differentiate CD4+ T cells into effector and memory cell populations, as well as activate CD8+ T cells. Certain subsets of CD4+ T cells, called T helper cells, enable B cells to differentiate into antibody-secreting cells. An earlier T cell–centric model for the pathogenesis of RA was based on a T_H1-driven paradigm, which came from studies indicating that CD4+ T helper (T_H) cells differentiated into T_H1 and T_H2 subsets, each with their distinctive cytokine profiles. T_H1 cells were found to mainly produce interferon γ (IFN-γ), lymphotoxin β, and tumor necrosis factor (TNF)-α, whereas T_H2 cells predominately secreted interleukin (IL)-4, IL-5, IL-6, IL-10, and IL-13. In humans, naïve T cells may also be induced to differentiate into T_H17 cells by exposure to transforming growth factor β (TGF-β), IL-1, IL-6, and IL-23. Upon activation, T_H17 cells secrete a variety of proinflammatory mediators such as IL-17, IL-21, IL-22, TNF-α, IL-26, IL-6, and granulocyte-macrophage colony-stimulating factor (GM-CSF). Substantial evidence now exists from studies in both animal models and humans that IL-17 plays an important role not only in promoting joint inflammation but also in destroying cartilage and subchondral bone. However, therapeutic antibodies that interfere with the IL-17/IL-17 receptor pathway were not particularly effective in clinical trials for reducing joint inflammation in RA.

The immune system has evolved mechanisms to counterbalance the potentially harmful immune-mediated inflammatory responses provoked by infectious agents and other triggers. Among these negative regulators are regulatory T (Treg) cells, which are produced in the thymus and induced in the periphery to suppress immune-mediated inflammation. They are characterized by the surface expression of CD25 and the expression of the transcription factor forkhead box P3 (FOXP3). Tregs orchestrate dominant tolerance through contact with other immune cells and secretion of inhibitory cytokines, such as TGF-β, IL-10, and IL-35. They are heterogeneous and capable of suppressing distinct classes (T_H1, T_H2, T_H17) of the immune response, although data supporting their role in suppressing inflammation in RA are inconclusive.

Cytokines, chemokines, antibodies, and endogenous danger signals bind to receptors on the surface of immune cells and stimulate a cascade of intracellular signaling events that can amplify the inflammatory response. Examples of signaling molecules in these critical inflammatory pathways include Janus kinase (JAK)/signal transducers and activators of transcription (STAT), spleen tyrosine kinase (Syk), mitogen-activated protein kinases (MAPKs), and nuclear factor-κB (NF-κB). These pathways exhibit significant crosstalk and are found in many cell types. Some signal transducers, such as the JAKs, are expressed in hematopoietic cells and play an important role in the inflammatory response in RA.

Activated, autoreactive B cells are also important players in the chronic inflammatory process. B cells give rise to plasma cells, which, in turn, produce antibodies, including RF and ACPA. RFs may form large immune complexes inside the joint that contribute to the pathogenic process by fixing complement and promoting the release of proinflammatory cytokines and chemokines. In mouse models of arthritis, RF-containing immune complexes and ACPA-containing immune complexes synergize with other mechanisms to exacerbate the synovial inflammatory response.

RA is often considered to be a macrophage-driven disease because this cell type is the predominant source of proinflammatory cytokines inside the joint. Key proinflammatory cytokines released by macrophage-like synoviocytes include TNF-α, IL-1, IL-6, IL-12, IL-15, IL-18, and IL-23. Synovial fibroblasts, the other major cell type in this microenvironment, produce the cytokines IL-1 and IL-6 as well as TNF-α. TNF-α is a pivotal cytokine in the pathobiology of synovial inflammation and has many proinflammatory effects. It upregulates adhesion molecules on endothelial cells, promoting the influx of leukocytes into the synovial microenvironment; activates synovial fibroblasts; stimulates angiogenesis; promotes pain receptor sensitizing pathways; and drives osteoclastogenesis. Fibroblasts secrete matrix metalloproteinases (MMPs) as well as other proteases that are chiefly responsible for the breakdown of articular cartilage; they also promote inflammation and synovial proliferation by secreting cytokines such as IL-6, IL-1, IL-18, and GM-CSF, chemokines, and vascular endothelial growth factor.

Recent studies of synovial tissue samples from patients with RA have combined histology and single-cell RNA expression data to identify distinct cell populations that drive joint inflammation. These studies reveal that synovial tissue samples can be distinguished among patients with RA by the relative abundance of myeloid cells, T cells, B cells, synovial fibroblasts, and endothelial cells and hence can be divided into different subsets. Thus far, these data highlight the importance of IFN-γ-secreting granzyme K+ CD8+ T cells, peripheral helper CD4+ T cells, activated sublining fibroblasts, and proinflammatory monocytes as key mediators of joint inflammation. In these studies, most of the synovial tissue samples were found to be populated by T cells, fibroblasts, and myeloid cells and had cellular phenotypes classified as predominately myeloid, T and B cell, and T cell and myeloid, while others had a paucity of immune cells and were dominated by endothelial cells and fibroblasts. Further research along these lines will enrich our understanding of the active immune pathways in RA and may help to determine in the future if knowledge of these cellular phenotypes can be used to guide a personalized treatment approach.

Osteoclast activation at the site of the pannus is closely tied to the presence of focal bone erosion. Receptor activator of nuclear factor-κB ligand (RANKL) is expressed by stromal cells, synovial fibroblasts, and T cells. Upon binding to its receptor RANK on osteoclast progenitors, RANKL stimulates osteoclast differentiation and bone resorption. RANKL activity is regulated by osteoprotegerin (OPG), a decoy receptor of RANKL that blocks osteoclast formation. Monocytic cells in the synovium serve as the precursors of osteoclasts and, when exposed to macrophage colony-stimulating factor (M-CSF) and RANKL, fuse to form polykaryons termed *preosteoclasts*. These precursor cells undergo further differentiation into osteoclasts with a characteristic ruffled membrane. Cytokines such as TNF-α, IL-1, IL-6, and IL-17 can promote osteoclastogenesis by increasing the expression of RANKL inside the joint. Osteoclasts also secrete cathepsin K, a cysteine protease that degrades the bone matrix by cleaving collagen and thus contributes to generalized bone loss and osteoporosis.

Increased bone loss is only part of the story in RA, as decreased bone formation plays a crucial role in bone remodeling at sites of inflammation. Recent evidence shows that inflammation suppresses bone formation. TNF-α plays a key role in actively suppressing bone formation by enhancing the expression of dickkopf-1 (DKK-1). DKK-1 is an important inhibitor of the Wnt pathway, which acts to promote osteoblast differentiation and bone formation. The Wnt system is a family of soluble glycoproteins that binds to cell-surface receptors known as frizzled (fz) and low-density lipoprotein (LDL) receptor–related proteins (LRPs) and promotes cell growth. In animal models, increased levels of DKK-1 are associated with decreased bone formation, whereas inhibition of DKK-1 protects against structural damage in the joint. Wnt proteins also induce the formation of OPG and thereby shut down bone resorption, emphasizing their key role in tightly regulating the balance between bone resorption and formation.

DIAGNOSIS

The clinical diagnosis of RA is largely made by recognizing the signs and symptoms of a chronic inflammatory arthritis and the typical pattern of joint involvement, with laboratory and radiographic results providing important corroborating information. In 2010, a collaborative effort between the American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR) revised the 1987 ACR classification criteria for RA in an effort to improve early diagnosis with the goal of identifying patients who would benefit from early introduction of disease-modifying therapy **(Table 370-1)**. The items in the newly revised criteria yield a score of 0–10, with a score of ≥6 fulfilling the requirements for definite RA. The new classification

TABLE 370-1 Classification Criteria for Rheumatoid Arthritis

		SCORE
Joint involvement	1 large joint (shoulder, elbow, hip, knee, ankle)	0
	2–10 large joints	1
	1–3 small joints (MCP, PIP, thumb IP, MTP, wrists)	2
	4–10 small joints	3
	>10 joints (at least 1 small joint)	5
Serology	Negative RF and negative ACPA	0
	Low-positive RF or low-positive anti-CCP antibodies (≤3 times ULN)	2
	High-positive RF or high-positive anti-CCP antibodies (>3 times ULN)	3
Acute-phase reactants	Normal CRP and normal ESR	0
	Abnormal CRP or abnormal ESR	1
Duration of symptoms	<6 weeks	0
	≥6 weeks	1

Note: These criteria are aimed at classification of newly presenting patients who have at least one joint with definite clinical synovitis that is not better explained by another disease. A score of ≥6 fulfills requirements for definite RA.

Abbreviations: ACPA, anti-citrullinated peptide antibodies; CCP, cyclic citrullinated peptides; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; IP, interphalangeal joint; MCP, metacarpophalangeal joint; MTP, metatarsophalangeal joint; PIP, proximal interphalangeal joint; RF, rheumatoid factor; ULN, upper limit of normal.

criteria differ in several ways from the older criteria sets. Previous classification schemes required symptoms to be present for >6 weeks. There are several conditions, including virus-related syndromes, that may cause a polyarthritis mimicking RA and be associated with transient production of RF. Such conditions usually last only 2–3 weeks. The 2010 criteria, however, do not mandate symptoms be present for >6 weeks. They also include as an item a positive test for serum ACPA, which carries greater specificity for the diagnosis of RA than a positive test for RF. About three-fourths of patients with the clinical and radiographic features of RA test positive for RF and/or ACPA (seropositive), while the remaining one-fourth of patients with RA test negative for RF and/or ACPA (seronegative). The presence of rheumatoid nodules or radiographic joint damage as items were not included as they occur only rarely in early RA. It is important to emphasize that the 2010 ACR-EULAR criteria are "classification criteria" as opposed to "diagnostic criteria" and serve to distinguish patients at the onset of disease who have a high likelihood of evolution to chronic disease with persistent synovitis and joint damage. The presence of radiographic joint erosions or subcutaneous nodules may inform the diagnosis in the later stages of the disease.

The differential diagnosis for RA includes all types of acute and chronic inflammatory arthritides, many of which may be differentiated from RA based on the clinical course, pattern of joint involvement, the presence of disease in other organ systems, and ancillary laboratory studies. Patients with primary Sjögren's syndrome whose predominate clinical manifestations are dry eyes and dry mouth often also have symptoms of polyarthralgia and may show a mild inflammatory synovitis similar to RA. Moreover, 50% of patients with primary Sjögren's syndrome test positive for RF and, therefore, may be confused with early RA. However, most patients with primary Sjögren's syndrome test positive for ANA and approximately two-thirds have detectable anti-Ro/SSA antibodies. Spondyloarthropathies, such as psoriatic arthritis or enteropathy-associated arthritis, may present similarly to RA and may be distinguished by the presence of sacroiliitis, other enthesopathic features, and the presence of psoriasis or inflammatory bowel disease, respectively. In elderly patients, seronegative RA may be difficult at times to distinguish from polymyalgia rheumatica (PMR), a chronic inflammatory condition of the elderly characterized by neck/shoulder girdle and lower back/hip girdle pain and stiffness **(Chap. 375)**. While PMR may occasionally feature distal limb involvement, RA predominately affects the wrists/hands and ankles/feet, especially at disease onset. Similarly, the relatively rare condition called remitting seronegative symmetrical synovitis with pitting edema (RS3PE) and paraneoplastic syndromes may also be confused with early RA. RS3PE is typically characterized by prominent distal limb pitting edema, which is unusual in RA, and responds promptly to treatment with low doses of prednisone. Chronic tophaceous gout may mimic severe RA in some cases, and tophi may be confused with rheumatoid nodules. Hepatitis C–related arthropathy often involves the small joints of the hands and is associated in half the cases with a positive RF, but generally not ACPA.

LABORATORY FEATURES

Patients with systemic inflammatory diseases such as RA will often present with elevated nonspecific inflammatory markers such as an ESR or CRP. Testing for serum RF and anti-cyclic citrullinated peptide (CCP) antibodies is important in differentiating RA from other polyarticular diseases, although RF lacks diagnostic specificity and may be found in association with other chronic inflammatory diseases in which arthritis figures in the clinical manifestations.

IgM, IgG, and IgA isotypes of RF occur in sera from patients with RA, although the IgM isotype is the one most frequently measured by commercial laboratories. Serum IgM RF has been found in 75% of patients with RA; therefore, a negative result does not exclude the presence of this disease. It is also found in other connective tissue diseases, such as primary Sjögren's syndrome, systemic lupus erythematosus, and type II mixed essential cryoglobulinemia, as well as chronic infections such as subacute bacterial endocarditis and hepatitis B and C. Serum RF, mostly at low levels, may also be detected in 1–5% of the healthy population.

The presence of serum anti-CCP antibodies has about the same sensitivity as serum RF for the diagnosis of RA. However, its diagnostic specificity approaches 95%, so a positive test for anti-CCP antibodies in the setting of an early inflammatory arthritis is useful for distinguishing RA from other forms of arthritis. There is some incremental value in testing for the presence of both RF and anti-CCP, as some patients with RA are positive for RF but negative for anti-CCP and vice versa. The presence of RF or anti-CCP antibodies also has prognostic significance, with anti-CCP antibodies showing the most value for predicting worse outcomes.

Patients with RA may also have other antibodies associated with autoimmune disease. Approximately 30% of patients with RA test positive for antinuclear antibodies (ANAs), and some sera from some patients contain antineutrophil cytoplasmic antibodies (ANCAs; particularly p-ANCAs). However, patients with RA would not be expected to test positive for anti-MPO or anti-PR3 antibodies as they would if they had an ANCA-associated vasculitis.

SYNOVIAL FLUID ANALYSIS

Typically, the cellular composition of synovial fluid from patients with RA reflects an acute inflammatory state. Synovial fluid white blood cell (WBC) counts can vary widely but generally range between 5000 and 50,000 WBC/μL, compared with <2000 WBC/μL for a noninflammatory condition such as osteoarthritis. In contrast to the synovial tissue, the overwhelming cell type in the synovial fluid is the neutrophil. Clinically, the analysis of synovial fluid is most useful for confirming an inflammatory arthritis (as opposed to osteoarthritis), while at the same time excluding infection or a crystal-induced arthritis such as gout or pseudogout **(Chap. 384)**.

JOINT IMAGING

Joint imaging is a valuable tool not only for diagnosing RA but also for tracking progression of any joint damage. Plain x-ray is the most common imaging modality, but it is limited to visualization of the bony structures and inferences about the state of the articular cartilage based on the amount of joint space narrowing. MRI and ultrasound techniques offer the added value of detecting changes in the soft tissues such as synovitis, tenosynovitis, and effusions, as well as providing greater sensitivity for identifying bony abnormalities. Plain

FIGURE 370-5 X-ray of the right hand demonstrating features of advanced rheumatoid arthritis. This x-ray is notable for carpal crowding of the wrist (*yellow arrow*), loss of joint space and subluxation of the fifth metacarpophalangeal joint (*green arrow*), and an erosion of the fourth proximal interphalangeal joint (*red arrow*).

radiographs are usually relied upon in clinical practice for the purpose of diagnosis and monitoring affected joints. However, in selected cases, MRI and ultrasound can provide additional diagnostic information that may guide clinical decision-making. Musculoskeletal ultrasound with power Doppler is increasingly used in rheumatology clinical practice for detecting synovitis and bone erosion.

Plain Radiography Classically in RA, the initial radiographic finding is periarticular osteopenia. Practically speaking, however, this finding is difficult to appreciate on plain films and particularly their digitalized images. Other findings on plain radiographs include soft tissue swelling, symmetric joint space loss, and juxtaarticular and subchondral erosions, most frequently in the wrists and hands (MCPs and PIPs) and the feet (MTPs). In the feet, the lateral aspect of the fifth MTP is often targeted first, but other MTP joints may be involved at the same time. X-ray imaging of advanced RA may reveal signs of severe destruction, including joint subluxation and collapse **(Fig. 370-5)**.

MRI MRI offers the greatest sensitivity for detecting synovitis and joint effusions, as well as early bone and bone marrow changes. These soft tissue abnormalities often occur before osseous changes are noted on x-ray. Presence of bone marrow edema has been recognized to be an early sign of inflammatory joint disease and can predict the subsequent development of erosions on plain radiographs as well as MRI scans. Cost and availability of MRI are the main factors limiting its routine clinical use.

Ultrasound Ultrasound, including power color Doppler, can detect more erosions than plain radiography, especially in easily accessible joints. It can also reliably detect synovitis, including increased joint vascularity indicative of inflammation. The usefulness of ultrasound is dependent on the experience of the sonographer; however, it does offer the advantages of portability, lack of radiation, and low expense relative to MRI, factors that make it attractive as a clinical tool **(Fig. 370-6)**. See **Videos 370-1, 370-2, and 370-3.**

CLINICAL COURSE

The natural history of RA is complex and affected by a number of factors including age of onset, gender, genotype, phenotype (i.e., extraarticular manifestations or variants of RA), and comorbid conditions, which make for a truly heterogeneous disease. It is important to realize

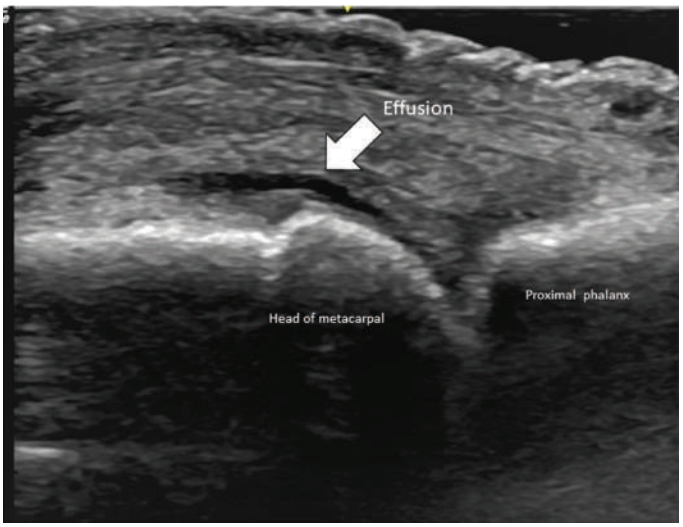

FIGURE 370-6 Ultrasound demonstrating an effusion (*arrow*) within the metacarpophalangeal joint. *(Courtesy of Dr. Ryan Jessee.)*

that as many as 10% of patients with inflammatory arthritis fulfilling ACR classification criteria for RA will undergo a spontaneous remission within 6 months (particularly seronegative patients). However, the vast majority of patients will exhibit a pattern of persistent and progressive disease activity that waxes and wanes in intensity over time. A minority of patients will show intermittent and recurrent explosive attacks of inflammatory arthritis interspersed with periods of disease quiescence. Finally, an aggressive form of RA may occur in an unfortunate few with inexorable progression of severe erosive joint disease, although this highly destructive course is less common in the modern treatment era.

Disability, as measured by the Health Assessment Questionnaire (HAQ), shows gradual worsening over time in the face of poorly controlled disease activity and disease progression. Disability may result from both a disease activity–related component that is potentially reversible with therapy and a joint damage–related component owing to the cumulative and largely irreversible effects of soft tissue, cartilage, and bone breakdown. Early in the course of disease, the extent of joint inflammation is the primary determinant of disability, while in the later stages of disease, the amount of joint damage is the dominant contributing factor. Previous studies have shown that more than one-half of patients with RA are unable to work 10 years after the onset of their disease; however, increased employability and less work absenteeism have been reported recently with the use of newer therapies and earlier treatment intervention.

The overall mortality rate in RA is two times greater than in the general population. In particular, patients are at significantly increased risk for death due to respiratory illness, cardiovascular disease, and infection. Median life expectancy is shortened by an average of 7 years for men and 3 years for women compared with control populations. Patients at higher risk for shortened survival are those with systemic extraarticular involvement, low functional capacity, low socioeconomic status, low education, and chronic prednisone use.

TREATMENT

Rheumatoid Arthritis

The amount of clinical disease activity in patients with RA reflects the overall burden of inflammation and is the variable that most influences treatment decisions. Joint inflammation is the main driver of joint damage and is the most important cause of functional disability in the early stages of disease. Several composite indices have been developed to assess clinical disease activity. The ACR 20, 50, and 70 improvement criteria (which correspond to a 20, 50, and 70% improvement, respectively, in joint counts, physician/patient assessment of disease severity, pain scale, serum levels of

acute-phase reactants [ESR or CRP], and a functional assessment of disability using a self-administered patient questionnaire) are a composite index with a dichotomous response variable. The ACR improvement criteria are commonly used in clinical trials as an endpoint for comparing the proportion of responders between treatment groups. In contrast, the Disease Activity Score (DAS), Simplified Disease Activity Index (SDAI), the Clinical Disease Activity Index (CDAI), and the Routine Assessment of Patient Index Data 3 (RAPID3) are continuous measures of disease activity that are used in clinical practice for tracking disease status and documenting treatment response.

The identification of genetic and environmental risk factors as well as the presence of autoantibodies creates a phenotype of a person who may be at higher risk for development of RA, or "preclinical RA." Several trials have enrolled patients meeting a definition of preclinical RA in an attempt to prevent development of disease with disease-modifying therapies approved for the treatment of RA. While some of these disease-modifying therapies may delay the development of RA compared to a placebo, no strategy has yet been successful in preventing disease.

Several developments during the past two decades have changed the therapeutic landscape in RA. They include (1) the emergence of methotrexate as the disease-modifying antirheumatic drug (DMARD) of first choice for the treatment of early RA; (2) the development of novel highly efficacious biologicals that can be used alone or in combination with methotrexate; and (3) the proven superiority of combination DMARD regimens over methotrexate alone. The medications used for the treatment of RA may be divided into broad categories: nonsteroidal anti-inflammatory drugs (NSAIDs); glucocorticoids, such as prednisone and methylprednisolone; conventional DMARDs; and biologic DMARDs **(Table 370-2)**. Although disease for some patients with RA is managed adequately with a single DMARD, such as methotrexate, it calls in most cases for the use of a combination DMARD regimen that may vary in its components over the treatment course depending on fluctuations in disease activity, loss of treatment efficacy, and emergence of drug-related toxicities and comorbidities.

NSAIDS

NSAIDs were formerly viewed as the core of RA therapy, but they are now considered to be adjunctive agents for management of symptoms uncontrolled by other measures. NSAIDs exhibit both analgesic and anti-inflammatory properties. The anti-inflammatory effects of NSAIDs derive from their ability to nonselectively inhibit cyclooxygenase (COX)-1 and COX-2. Although the results of clinical trials suggest that NSAIDs are roughly equivalent in their efficacy, experience suggests that some individuals may preferentially respond to a particular NSAID. Chronic use should be minimized due to the possibility of side effects, particularly gastritis and peptic ulcer disease and kidney injury.

GLUCOCORTICOIDS

Glucocorticoids may serve in several ways to control disease activity in RA. First, they may be administered in low to moderate doses to achieve rapid disease control before the onset of fully effective DMARD therapy, which often takes several weeks or even months. Second, a 1- to 2-week burst of glucocorticoids may be prescribed for the management of acute disease flares, with dose and duration guided by the severity of the exacerbation. Chronic administration of low doses (5–10 mg/d) of prednisone (or its equivalent) may also be warranted to control disease activity in patients with an inadequate response to DMARD therapy. As much as possible, chronic glucocorticoid therapy should be avoided in favor of finding an effective DMARD regimen that adequately controls the disease. Best practices minimize chronic use of low-dose prednisone therapy owing to the risk of osteoporosis and other long-term complications; however, the use of chronic prednisone therapy is unavoidable in some cases. High-dose glucocorticoids may be necessary for the treatment of severe extraarticular manifestations of RA, such as ILD. Finally, if a patient exhibits one or a few actively inflamed joints, the clinician may consider intraarticular injection of an intermediate-acting glucocorticoid such as triamcinolone acetonide. This approach may allow for rapid control of inflammation in a limited number of affected joints. Caution must be exercised to appropriately exclude joint infection as it often mimics a monoarticular RA flare.

Osteoporosis ranks as an important long-term complication of chronic prednisone use. Based on a patient's risk factors, including total prednisone dosage, length of treatment, gender, race, and bone density, treatment with an oral (e.g., alendronate, risedronate) or parenteral (e.g., zoledronic acid) bisphosphonate may be appropriate for primary prevention of glucocorticoid-induced osteoporosis. Other agents, including denosumab and teriparatide, have also been approved for the treatment of steroid-induced osteoporosis and may be indicated in certain cases. Although prednisone use is known to increase the risk of peptic ulcer disease, especially with concomitant NSAIDs, no evidence-based guidelines recommend routine co-administration of proton pump inhibitors for gastrointestinal ulcer prophylaxis.

DMARDS

DMARDs are so named because of their ability to slow or prevent structural progression of RA. The conventional DMARDs include hydroxychloroquine, sulfasalazine, methotrexate, and leflunomide; they exhibit a delayed onset of action of ~6–12 weeks or longer. Methotrexate is the DMARD of choice for the treatment of RA and is the anchor drug for most combination therapies. It was approved for the treatment of RA in 1988 and remains a benchmark for comparison with the newer disease-modifying therapies. At the dosages used for the treatment of RA, methotrexate has been shown to stimulate adenosine release from cells, producing an anti-inflammatory effect. Methotrexate is administered weekly by the oral or subcutaneous route. Folic acid is taken as co-therapy to mitigate some of methotrexate's side effects. The clinical efficacy of leflunomide, an inhibitor of pyrimidine synthesis, appears similar to that of methotrexate; it has been shown in well-designed trials to be effective for the treatment of RA as monotherapy or in combination with methotrexate and other DMARDs.

Although similar to the other DMARDs in its slow onset of action, hydroxychloroquine has not been shown to delay radiographic progression of disease and thus is not considered to be a true DMARD. In clinical practice, hydroxychloroquine is generally used for treatment of early, mild disease or as adjunctive therapy in combination with other DMARDs. It is prescribed at a dosage of 5 mg/kg of body weight or less to decrease the risk of retinal toxicity. Sulfasalazine has been shown in randomized, controlled trials to reduce joint inflammation and radiographic progression of disease. A regimen termed oral triple therapy, which is comprised of hydroxychloroquine, sulfasalazine, and methotrexate, is an effective combination regimen often used in patients with an inadequate response to treatment with methotrexate alone.

BIOLOGICALS

Biologic DMARDs have revolutionized the treatment of RA over the past two decades (Table 370-2). They are protein therapeutics designed to target cytokines and cell-surface molecules. The TNF inhibitors were the first biologicals approved for the treatment of RA, but several others have come to market since their introduction in 1999. Additionally, biosimilars are agents that have been designed with the same active properties as the licensed biopharmaceutical product. Several of these biosimilars have been studied for the treatment of RA and demonstrate a similar efficacy and side-effect profile to the reference biological.

Anti-TNF Agents The development of TNF inhibitors was originally spurred by the experimental finding that TNF-α is a critical upstream mediator of joint inflammation. Five original "innovator" TNF inhibitors with various molecular designs have been approved for the treatment of RA. Three of these products are anti-TNF

TABLE 370-2 DMARDs Used for the Treatment of Rheumatoid Arthritis

DRUG	DOSAGE	SERIOUS TOXICITIES	OTHER COMMON SIDE EFFECTS	INITIAL EVALUATION	MONITORING
Hydroxychloroquine	200–400 mg/d orally (≤5 mg/kg)	Irreversible retinal damage Cardiotoxicity Blood dyscrasia	Nausea Diarrhea Headache Rash	Eye examination if >40 years old or prior ocular disease	Optical coherence tomography and visual field testing every 12 months
Sulfasalazine	Initial: 500 mg orally twice daily Maintenance: 1000–1500 mg twice daily	Granulocytopenia Hemolytic anemia (with G6PD deficiency)	Nausea Diarrhea Headache	CBC, LFTs G6PD level	CBC every 2–4 weeks for first 3 months, then every 3 months
Methotrexate	10–25 mg/week orally or SQ Folic acid 1 mg/d to reduce toxicities	Hepatotoxicity Myelosuppression Infection Interstitial pneumonitis Pregnancy category X	Nausea Diarrhea Stomatitis/mouth ulcers Alopecia Fatigue	CBC, LFTs Viral hepatitis panel[a] Chest x-ray	CBC, creatinine, LFTs every 2–3 months
Leflunomide	10–20 mg/d	Hepatotoxicity Myelosuppression Infection Pregnancy category X	Alopecia Diarrhea	CBC, LFTs Viral hepatitis panel[a]	CBC, creatinine, LFTs every 2–3 months
TNF-α inhibitors	Infliximab: 3 mg/kg IV at weeks 0, 2, 6, then every 8 weeks. May increase dose up to 10 mg/kg every 4 weeks	↑ Risk bacterial, fungal infections Reactivation of latent tuberculosis ↑ Lymphoma risk (controversial) Drug-induced lupus Neurologic deficits	Infusion reaction ↑ LFTs	Tuberculosis screening[b]	LFTs periodically
	Etanercept: 50 mg SQ weekly, or 25 mg SQ biweekly	As above	Injection site reaction	Tuberculosis screening	Monitor for injection site reactions
	Adalimumab: 40 mg SQ every other week	As above	Injection site reaction	Tuberculosis screening	Monitor for injection site reactions
	Golimumab: 50 mg SQ monthly	As above	Injection site reaction	Tuberculosis screening	Monitor for injection site reactions
	Certolizumab: 400 mg SQ weeks 0, 2, 4, then 200 mg every other week	As above	Injection site reaction	Tuberculosis screening	Monitor for injection site reactions
Abatacept	Weight based: <60 kg: 500 mg 60–100 kg: 750 mg >100 kg: 1000 mg IV dose at weeks 0, 2, and 4, and then every 4 weeks OR 125 mg SQ weekly	↑ Risk bacterial, viral infections	Headache Nausea	Tuberculosis screening	Monitor for infusion reactions
Anakinra	100 mg SQ daily	↑ Risk bacterial, viral infections Reactivation of latent tuberculosis Neutropenia	Injection site reaction Headache	Tuberculosis screening CBC with differential	CBC every month for 3 months, then every 4 months for 1 year Monitor for injection site reactions
Rituximab	1000 mg IV × 2, days 0 and 14 May repeat course every 24 weeks or more Premedicate with methylprednisolone 100 mg to decrease infusion reaction	↑ Risk bacterial, viral infections Infusion reaction Cytopenia Hepatitis B reactivation	Rash Fever	CBC Viral hepatitis panel[a]	CBC at regular intervals
Interleukin-6 inhibitors	Tocilizumab: 4–8 mg/kg IV monthly OR 162 mg SQ every other week (<100 kg weight) 162 mg SQ every week (≥100 kg weight) Sarilumab: 200 mg SQ every other week	Risk of infection Infusion reaction LFT elevation Dyslipidemia Cytopenias		Tuberculosis screening	CBC and LFTs at regular intervals

(*Continued*)

TABLE 370-2 DMARDs Used for the Treatment of Rheumatoid Arthritis (Continued)

DRUG	DOSAGE	SERIOUS TOXICITIES	OTHER COMMON SIDE EFFECTS	INITIAL EVALUATION	MONITORING
JAK inhibitors	Tofacitinib: 5 mg orally twice daily OR 11 mg orally daily Upadacitinib: 15 mg orally daily Baricitinib: 2 mg orally daily	Risk of infection LFT elevation Dyslipidemia Neutropenia Thrombosis	Upper respiratory tract infections Diarrhea Headache Nasopharyngitis	Tuberculosis screening	CBC, LFTs, and lipids at regular intervals

[a]Viral hepatitis panel: hepatitis B surface antigen, hepatitis C viral antibody. [b]Tuberculosis screening can be performed using a Mantoux tuberculin skin test or blood interferon-gamma release assay.

Abbreviations: CBC, complete blood count; DMARDs, disease-modifying antirheumatic drugs; G6PD, glucose-6-phosphate dehydrogenase; IV, intravenous; LFTs, liver function tests; JAK, Janus kinase; SQ, subcutaneous.

monoclonal antibodies: infliximab, a chimeric (part mouse and human) monoclonal antibody; and adalimumab and golimumab, humanized monoclonal antibodies. Certolizumab pegol, a fourth product, is a pegylated Fab′ fragment of a humanized monoclonal antibody, while the other, etanercept, is a soluble fusion protein consisting of the TNF receptor 2 in covalent linkage with the Fc portion of IgG1. All of these TNF inhibitors have been shown in randomized controlled clinical trials to reduce the signs and symptoms of RA, slow radiographic progression of joint damage, and improve physical function and quality of life. Anti-TNF drugs may be used alone or in combination with background methotrexate therapy. Patients with RA who have an inadequate response to methotrexate therapy are often treated with a TNF inhibitor, usually in combination with methotrexate.

Anti-TNF agents should be avoided in patients with active infection or a history of hypersensitivity to these agents and are contraindicated in patients with chronic hepatitis B infection or class III/IV congestive heart failure. A major concern is the increased risk for infection, including serious bacterial infections, opportunistic fungal infection, and reactivation of latent tuberculosis infection (LTBI). For this reason, all patients are screened for LTBI according to national guidelines with either an intradermal injection of purified protein derivative (PPD) or an IFN-γ release assay prior to starting anti-TNF therapy **(Chap. 183)**. If positive, treatment for LTBI is given for at least 1 month prior to starting anti-TNF therapy.

Anakinra Anakinra is the recombinant form of the naturally occurring IL-1 receptor antagonist. Anakinra has seen limited use for the treatment of RA because other biologic DMARDs have seen greater efficacy in practice.

Abatacept Abatacept is a soluble fusion protein consisting of the extracellular domain of human CTLA-4 linked to the modified portion of human IgG. It inhibits the co-stimulation of T cells by blocking CD28-CD80/86 interactions and may also inhibit the function of antigen-presenting cells by reverse signaling through CD80 and CD86. Abatacept has been shown in clinical trials to reduce disease activity, slow radiographic progression of damage, and improve functional disability. Most patients receive abatacept in combination with a conventional DMARD. Abatacept therapy has been associated with an increased risk of infection and can inhibit a vaccine response.

Rituximab Rituximab is a chimeric monoclonal antibody directed against CD20, a cell-surface molecule expressed by most mature B lymphocytes. It works by depleting B cells, which, in turn, leads to a reduction in the inflammatory response by unknown mechanisms. These mechanisms may include a reduction in autoantibodies, inhibition of T-cell activation, and alteration of cytokine production. Rituximab has been approved for the treatment of refractory RA (failure of treatment with a TNF-α inhibitor) in combination with methotrexate and has been shown to be more effective for patients with seropositive than seronegative disease. Its administration has been associated with mild to moderate infusion reactions, as well as an increased risk of infection. Notably, there have been rare isolated reports of a potentially lethal brain disorder, progressive multifocal leukoencephalopathy (PML), in association with rituximab therapy, although the absolute risk of this complication appears to be very low in patients with RA (~1:25,000). Most of these cases have occurred on a background of previous or current exposure to other potent immunosuppressive drugs. Studies in recent years have also demonstrated that rituximab significantly inhibits a vaccine response (e.g., response to SARS-CoV-2 vaccination).

Anti-IL-6 Receptor Agents IL-6 is a proinflammatory cytokine implicated in the pathogenesis of RA, with effects on both joint inflammation and damage. IL-6 binding to its receptor activates intracellular signaling pathways that affect the acute-phase response, cytokine production, and osteoclast activation. Tocilizumab and sarilumab are both monoclonal antibodies directed against the membrane and soluble forms of the IL-6 receptor. Clinical trials attest to the clinical efficacy of these therapies for RA, both as monotherapy and in combination with methotrexate and other conventional DMARDs. Anti-IL-6 receptor agents have been associated with an increased risk of infection, neutropenia, and thrombocytopenia; the hematologic abnormalities appear to be reversible upon stopping the drug. In addition, this agent has been shown to increase LDL cholesterol. However, it is not known if this effect on lipid levels increases the risk for atherosclerotic disease. Anti-IL-6 receptor agents have also been associated with an increased rate of gastrointestinal perforation and should be avoided if possible in patients with a history of diverticulitis and a recent gastric or duodenal ulcer.

TARGETED SYNTHETIC DMARDs

Because treatment with conventional DMARDs and/or biologic therapies may not result in optimal disease control, other therapeutic strategies have been investigated to fill this gap. The so-called targeted synthetic DMARDs have been designed to target intracellular signaling pathways, which transduce the positive signals from cell-surface receptors activated by cytokines and other inflammatory mediators. They have an advantage over biologics in their oral formulation.

JAK Inhibitors Although several different kinases have been evaluated as potential treatment targets, only inhibitors of the JAKs have demonstrated safety and efficacy for the treatment of RA. The JAK family comprises four members (JAK1, JAK2, JAK3, and tyrosine kinase 2 [Tyk2]) and link a host of extracellular cytokine receptors with their intracellular signaling domains. They form homodimeric and heterodimeric duplexes that mediate signaling of the receptors for the common γ-chain-related cytokines IL-2, -4, -7, -9, -15, and -21, as well as IFN-γ, IL-6, IL-12, IL-23, IL-10, the type I IFNs, and the hemopoietic cytokines and growth factors. Many of these cytokines play critical roles in promoting T- and B-cell activation as well as chronic inflammation in RA.

Tofacitinib is a potent JAK1 and JAK3 inhibitor with minor inhibitory effects on JAK2 and Tyk2; baricitinib is a JAK1 and JAK2 inhibitor with moderate inhibition of Tyk2 and minimal inhibition of JAK3; and upadacitinib is a predominately selective inhibitor of JAK1. Each of the JAK inhibitors can be used as monotherapy or in combination with methotrexate. However, they are associated with an increased risk of infections, including bacterial infections and herpes zoster. Other possible side effects of these agents include elevated liver transaminases, neutropenia, increased cholesterol levels, hypertension, and elevations in serum creatinine. Recent studies have also found an increased risk of thrombosis, major adverse cardiovascular events, and malignancies in patients taking tofacitinib compared with TNF inhibitors, with the highest of these risks in the elderly.

TREATMENT OF EXTRAARTICULAR MANIFESTATIONS

In general, treatment of the underlying RA favorably modifies its extraarticular manifestations, and observational studies suggest aggressive management of early disease can potentially prevent their occurrence in established disease. The treatment of patients with RA-ILD, however, can be particularly challenging because some of the DMARDs used for the treatment of RA are also associated with pulmonary toxicity, such as methotrexate and leflunomide. RA-ILD is often treated with high doses of corticosteroids and adjunctive immunosuppressive agents, such as azathioprine, mycophenolate mofetil, or rituximab.

APPROACH TO THE PATIENT

Rheumatoid Arthritis

The treatment of RA adheres to the following principles and goals: (1) early, aggressive therapy to prevent joint damage and disability; (2) frequent modification of DMARD therapy to achieve treatment goals with utilization of combination therapy where appropriate; (3) individualization of DMARD therapy in an attempt to maximize response and minimize side effects; (4) minimal use of long-term glucocorticoid therapy; and (5) achieving, whenever possible, low disease activity or clinical remission. A considerable amount of evidence supports this intensive treatment approach and has been termed "treat to target," with a target of achieving low disease activity or remission.

As mentioned earlier, methotrexate is the DMARD of first choice for initial treatment of moderate to severe RA. Failure to achieve adequate improvement with methotrexate therapy calls for a change in DMARD therapy, usually a transition to an effective combination regimen. Effective combinations include methotrexate, sulfasalazine, and hydroxychloroquine (oral triple therapy); methotrexate and leflunomide; and methotrexate plus a biological. The combination of methotrexate and an anti-TNF agent, for example, has been shown in randomized controlled trials to be superior to methotrexate alone, not only for reducing signs and symptoms of disease but also for retarding the progression of structural joint damage. Predicting which patients are at higher risk for developing radiologic joint damage is imprecise at best, although some factors such as an elevated serum level of acute-phase reactants, high burden of joint inflammation, and the presence of erosive disease are associated with increased likelihood of developing structural injury.

In 2021, the ACR updated their guidelines for the treatment of RA. These recommendations do not make a distinction between the treatment of patients with early (<6 months of disease duration) or established disease and highlight the use of a treat-to-target approach and the need to switch or add therapies for worsening or persistent moderate/high disease activity. For example, in patients with early RA who have persistent moderate/high disease activity despite DMARD monotherapy, providers should consider escalation to combination DMARD therapy or switching to an anti-TNF +/– methotrexate or a non-TNF biologic +/– methotrexate. Since a more intensive initial approach (e.g., combination DMARD therapy) has been shown to produce superior long-term outcomes compared with starting methotrexate alone, the usual approach is to begin with methotrexate and, in the absence of an adequate therapeutic response, rapidly step up (e.g., after 3–6 months) to a combination of conventional DMARDs or add an anti-TNF or non-TNF biological agent.

Some patients may not respond to an anti-TNF drug or may be intolerant of its side effects. Initial responders to an anti-TNF agent who later experience worsening of their condition may benefit from switching to another anti-TNF agent or an alternative biological with a different mechanism of action. Indeed, some studies suggest that switching to an alternative biological such as abatacept is more effective than switching to another anti-TNF drug. Unacceptable toxicity from an anti-TNF agent may also call for switching to another biological or targeted synthetic DMARD with a different mechanism of action or a conventional DMARD regimen.

Studies have also shown that oral triple therapy (hydroxychloroquine, methotrexate, and sulfasalazine) may be used effectively for the treatment of early RA. Treatment may be initiated with methotrexate alone and, lacking an adequate treatment response, followed within 6 months by a step-up to oral triple therapy.

A clinical state defined as low disease activity or remission is the optimal goal of therapy, although most patients never achieve complete remission despite every effort to achieve it. Composite indices, such as the Disease Activity Score-28 (DAS-28), are useful for classifying states of low disease activity and remission; however, they are imperfect tools due to the limitations of the clinical joint examination in which low-grade synovitis may escape detection. Complete remission has been stringently defined as the total absence of all articular and extraarticular inflammation and immunologic activity related to RA. However, evidence for this state can be difficult to demonstrate in clinical practice. In an effort to standardize and simplify the definition of remission for clinical trials, the ACR and EULAR developed two provisional operational definitions of remission in RA **(Table 370-3)**. A patient may be considered in remission if the patient (1) meets all the clinical and laboratory criteria listed in Table 370-3 or (2) has a composite SDAI score of <3.3. The SDAI is calculated by taking the sum of a tender joint and swollen joint count (using 28 joints), patient global assessment (0–10 scale), physician global assessment (0–10 scale), and CRP (in mg/dL). This definition of remission does not consider the possibility of subclinical synovitis or that damage alone may produce a tender or swollen joint. Ignoring the semantics of these definitions, the aforementioned remission criteria are nonetheless useful for setting a level of disease control that will likely result in minimal or no progression of structural damage and disability. With an early, aggressive approach to treatment, a significant number of patients who reach remission may have a reduction in treatment without an increased risk of flare or loss of remission. However, complete withdrawal of DMARD therapy during established disease almost invariably leads to a relapse.

TABLE 370-3 ACR/EULAR Provisional Definition of Remission in Rheumatoid Arthritis

At any time point, patient must satisfy all of the following:
Tender joint count ≤1
Swollen joint count ≤1
C-reactive protein ≤1 mg/dL
Patient global assessment ≤1 (on a 0–10 scale)
OR
At any time point, patient must have a Simplified Disease Activity Index score of ≤3.3

PHYSICAL ACTIVITY AND ASSISTIVE DEVICES

In principle, all patients with RA should receive a prescription for exercise and physical activity. The ACR has developed guidelines for integrative interventions to accompany disease-modifying therapy and includes evidence-based recommendations for diet and exercise. Dynamic strength training, community-based comprehensive physical therapy, and physical-activity coaching (emphasizing achieving 150 min of moderate-to-vigorous physical activity per week) have all been shown to improve muscle strength and perceived health status, as well as improve DAS-28 scores and inflammatory markers. Foot orthotics for painful valgus deformity decrease foot pain and may reduce disability and functional limitations. Judicious use of wrist splints can also decrease pain; however, their benefits may be offset by decreased dexterity and variably curb grip strength.

SURGERY

Surgical procedures may improve pain and disability in RA with varying degrees of reported long-term success—most notably for the hands, wrists, and feet. For large joints, such as the knee, hip, shoulder, or elbow, the preferred option for advanced joint disease may be total joint arthroplasty. A few surgical options exist for dealing with the smaller hand joints. Silicone implants are the most common prosthetic for MCP arthroplasty and are generally implanted in patients with severe decreased arc of motion, marked flexion contractures, MCP joint pain with radiographic abnormalities, and severe ulnar drift. Arthrodesis and total wrist arthroplasty are reserved for patients with severe disease who have substantial pain and functional impairment. Numerous surgical options exist for correction of hallux valgus in the forefoot, including arthrodesis and arthroplasty, as well as primarily arthrodesis for refractory hindfoot pain.

OTHER MANAGEMENT CONSIDERATIONS

Pregnancy Up to 75% of female RA patients will note overall improvement in symptoms during pregnancy but they will often flare shortly after delivery. Flares during pregnancy are generally treated with low doses of prednisone. Hydroxychloroquine and sulfasalazine are probably the safest DMARDs to use during pregnancy, although anti-TNF agents are generally accepted to be safe in this setting. However, current guidelines call for anti-TNF drugs to be discontinued during the third trimester of pregnancy. Methotrexate and leflunomide therapy are contraindicated during pregnancy due to their teratogenicity in animals and humans. The experience with other biologic agents, such as abatacept, anti-IL-6 receptor antibodies, rituximab, and JAK inhibitors has been insufficient to make specific recommendations for their use during pregnancy and are discontinued at conception. Active inflammatory disease is associated with worse pregnancy outcomes, and thus, controlling disease activity remains a priority.

Elderly Patients RA presents in up to one-third of patients after the age of 60; however, older individuals may receive less aggressive treatment due to concerns about increased risks of drug toxicity. Studies suggest that conventional DMARDs and biological agents are equally effective and safe in younger and older patients (with the possible exception of JAK inhibitors). Due to comorbidities, many elderly patients have an increased risk of infection. Aging also leads to a gradual decline in renal function that may raise the risk for side effects from NSAIDs and some DMARDS, such as methotrexate. Renal function must be taken into consideration before prescribing methotrexate, which is mostly cleared by the kidneys. To reduce the risks of side effects, methotrexate doses may need to be adjusted downward for the drop in renal function that usually comes with the seventh and eighth decades of life.

GLOBAL CHALLENGES

Developing countries are finding an increase in the incidence of noncommunicable, chronic diseases such as diabetes, cardiovascular disease, and RA in the face of ongoing poverty, rampant infectious disease, and poor access to modern health care facilities. In these areas, patients tend to have a greater delay in diagnosis and limited access to specialists and, thus, greater disease activity and disability at presentation. In addition, infection risk remains a significant issue for the treatment of RA in developing countries because of the immunosuppression associated with the use of glucocorticoids and most DMARDs. For example, in some developing countries, patients undergoing treatment for RA have a substantial increase in the incidence of tuberculosis, which demands the implementation of far more comprehensive screening practices and liberal use of isoniazid prophylaxis than in developed countries. The increased prevalence of hepatitis B and C, as well as human immunodeficiency virus (HIV), in these developing countries also poses challenges. Reactivation of viral hepatitis has been observed in association with some of the DMARDs, such as rituximab. Also, reduced access to antiretroviral therapy may limit the control of HIV infection and therefore the choice of DMARD therapies.

Despite these challenges, one should attempt to initiate early treatment of RA in the developing countries with the resources at hand. Hydroxychloroquine, sulfasalazine, and methotrexate are all reasonably accessible throughout the world where they can be used as both monotherapy and in combination with other drugs. The availability of biological agents is increasing in the developed countries as well as in other areas around the world, although their use is limited by high cost; national protocols restrict their use, and concerns remain about the risk for opportunistic infections.

SUMMARY

Improved understanding of the pathogenesis of RA and its treatment has dramatically revolutionized the management of this disease. The outcomes of patients with RA are vastly superior to those of the prebiologic modifier era; more patients than in years past are able to avoid significant disability and continue working, albeit with some job modifications. The need for early and aggressive treatment of RA as well as frequent follow-up visits for monitoring of drug therapy has implications for our health care system. Primary care physicians and rheumatologists must be prepared to work together as a team to implement a treat-to-target approach with the goal of reaching remission or low disease activity. In many settings, rheumatologists have reengineered their practice in a way that places high priority on consultations for any new patient with early inflammatory arthritis.

The therapeutic regimens for RA are becoming increasingly complex with the rapidly expanding armamentarium. Patients receiving these therapies must be carefully monitored by both the primary care physician and the rheumatologist to minimize the risk of side effects and identify quickly any complications of chronic immunosuppression. Also, prevention and treatment of RA-associated conditions such as ischemic heart disease and osteoporosis will likely benefit from a team approach owing to the value of multidisciplinary care.

Research will continue to search for new therapies with superior efficacy and safety profiles and investigate treatment strategies that can bring the disease under control more rapidly and nearer to remission. However, prevention and cure of RA will likely require new breakthroughs in our understanding of disease pathogenesis. Several prevention trials in RA are currently underway and focus on a variety of prevention strategies in individuals who have serologic and/or clinical features at higher risk than the general population for developing RA. Equally important is the identification of predictive biomarkers in RA that will enable a personalized approach to DMARD therapy, a foreseeable goal in the future that will take advantage of the advances in technology and scientific understanding of the disease.

371 Acute Rheumatic Fever

Joseph Kado, Jonathan Carapetis

Acute rheumatic fever (ARF) is a multisystem disease resulting from an autoimmune reaction to infection with group A *Streptococcus*. Although many parts of the body may be affected, almost all of the manifestations resolve completely. The major exception is cardiac valvular damage (rheumatic heart disease [RHD]), which may persist after the other features have disappeared.

GLOBAL CONSIDERATIONS

ARF and RHD are diseases of poverty. They were common in all countries until the early twentieth century, when their incidence began to decline in industrialized nations. This decline was largely attributable to improved living conditions—particularly less crowded housing and better hygiene—which resulted in reduced transmission of group A streptococci. The introduction of antibiotics and improved systems of medical care had a supplemental effect.

The virtual disappearance of ARF and reduction in the incidence of RHD in high-income countries during the first half of the twentieth century unfortunately was not replicated in low- and middle-income countries (LMICs), where these diseases continue unabated. RHD is the most common cause of acquired heart disease in children in LMICs and is a major cause of mortality and morbidity in adults as well. It is estimated that >40 million people worldwide are affected by RHD, with >300,000 deaths occurring each year. Some 95% of ARF cases and RHD deaths now occur in developing countries, with particularly high burdens in sub-Saharan Africa, Pacific nations, Australasia, China, and South and Central Asia. The pathogenetic pathway from exposure to group A *Streptococcus* followed by pharyngeal or superficial skin infection and subsequent development of ARF, ARF recurrences, and development of RHD and its complications is associated with a range of risk factors and, therefore, potential interventions at each point **(Fig. 371-1)**. In affluent countries, many of these risk factors are well controlled, and where needed, interventions are in place. Unfortunately, the greatest burden of disease is found in LMICs, most of which do not have the resources, capacity, and/or interest to tackle this multifaceted disease. In particular, few of these countries have coordinated, register-based RHD control programs, which have been proven to be cost-effective in reducing the burden of RHD. Enhancing awareness of RHD and mobilizing resources for its control in LMICs are issues requiring international attention. In 2018, member states of the World Health Organization (WHO) unanimously adopted a Global Resolution on Rheumatic Fever and Rheumatic Heart Disease, calling on all states as well as international stakeholders and the WHO itself to take practical actions to control these diseases.

EPIDEMIOLOGY

ARF is mainly a disease of children aged 5–14 years. Initial episodes become less common in older adolescents and young adults and are rare in persons aged >30 years. By contrast, recurrent episodes of ARF remain relatively common in adolescents and young adults. This pattern contrasts with the prevalence of RHD, which peaks between 25 and 40 years. There is no clear gender association for ARF, but RHD more commonly affects females, sometimes up to twice as frequently as males.

PATHOGENESIS

ORGANISM FACTORS

Conventional teaching has it that ARF is exclusively caused by infection of the upper respiratory tract with group A streptococci **(Chap. 153)**. Although classically, certain M-serotypes (particularly types 1, 3, 5, 6, 14, 18, 19, 24, 27, and 29) were associated with ARF, recent evidence demonstrates that many more M-serotypes are rheumatogenic and that so-called "rheumatogenic motifs" are found in only a minority of serotypes associated with rheumatic fever. This epidemiologic evidence also points to a clear role of skin infection in the pathogenesis of ARF. The potential role of groups C and G streptococci is unclear at this time.

HOST FACTORS

Based on epidemiologic evidence, ~3–6% of any population may be susceptible to ARF, and this proportion does not vary dramatically between populations. Findings of familial clustering of cases and concordance in monozygotic twins—particularly for chorea—confirm that susceptibility to ARF is an inherited characteristic, with 44% concordance in monozygotic twins compared to 12% in dizygotic twins and heritability more recently estimated at 60%. Most evidence for host factors focuses on immunologic determinants. Initial studies found associations with human leukocyte antigen (HLA) class II alleles, some protective and some associated with increased susceptibility, as well as polymorphisms in tumor necrosis factor and mannose binding lectin. Recent genome-wide association studies and genomic sequencing analyses have identified associations with a range of genes including the immunoglobulin heavy chain (IGH) locus (specifically the IGHV4-61*02 allele), complement factor H, and some HLA class II (a range of HLA-DQ A and B alleles) and III loci. The associations are often population dependent, although increasing consistency is being found across populations in meta-analyses of genomic studies. Over coming years, further genomic analyses are expected to provide additional insights into ARF and RHD pathogenesis, as well as host protective and susceptibility factors.

THE IMMUNE RESPONSE

The most widely accepted theory of rheumatic fever pathogenesis is based on the concept of molecular mimicry, whereby an immune response targeted at streptococcal antigens (mainly thought to be on the M protein) also recognizes human tissues. In this model, antigen processing cells of the innate immune system present streptococcal antigens after throat (and possibly skin) group A streptococcal infection to T cells, which then lead to activation of both humoral and cellular immunity. Cross-reactive antibodies bind to endothelial cells on the heart valve, leading to activation of the adhesion molecule VCAM-1, with resulting recruitment of activated lymphocytes and lysis of endothelial cells in the presence of complement. The latter leads to release of peptides including laminin, keratin, and tropomyosin, which, in turn, activates cross-reactive T cells that invade the heart, amplifying the damage and causing epitope spreading. An alternative hypothesis proposes that the initial damage is due to streptococcal invasion of epithelial surfaces, with binding of M protein to type IV collagen

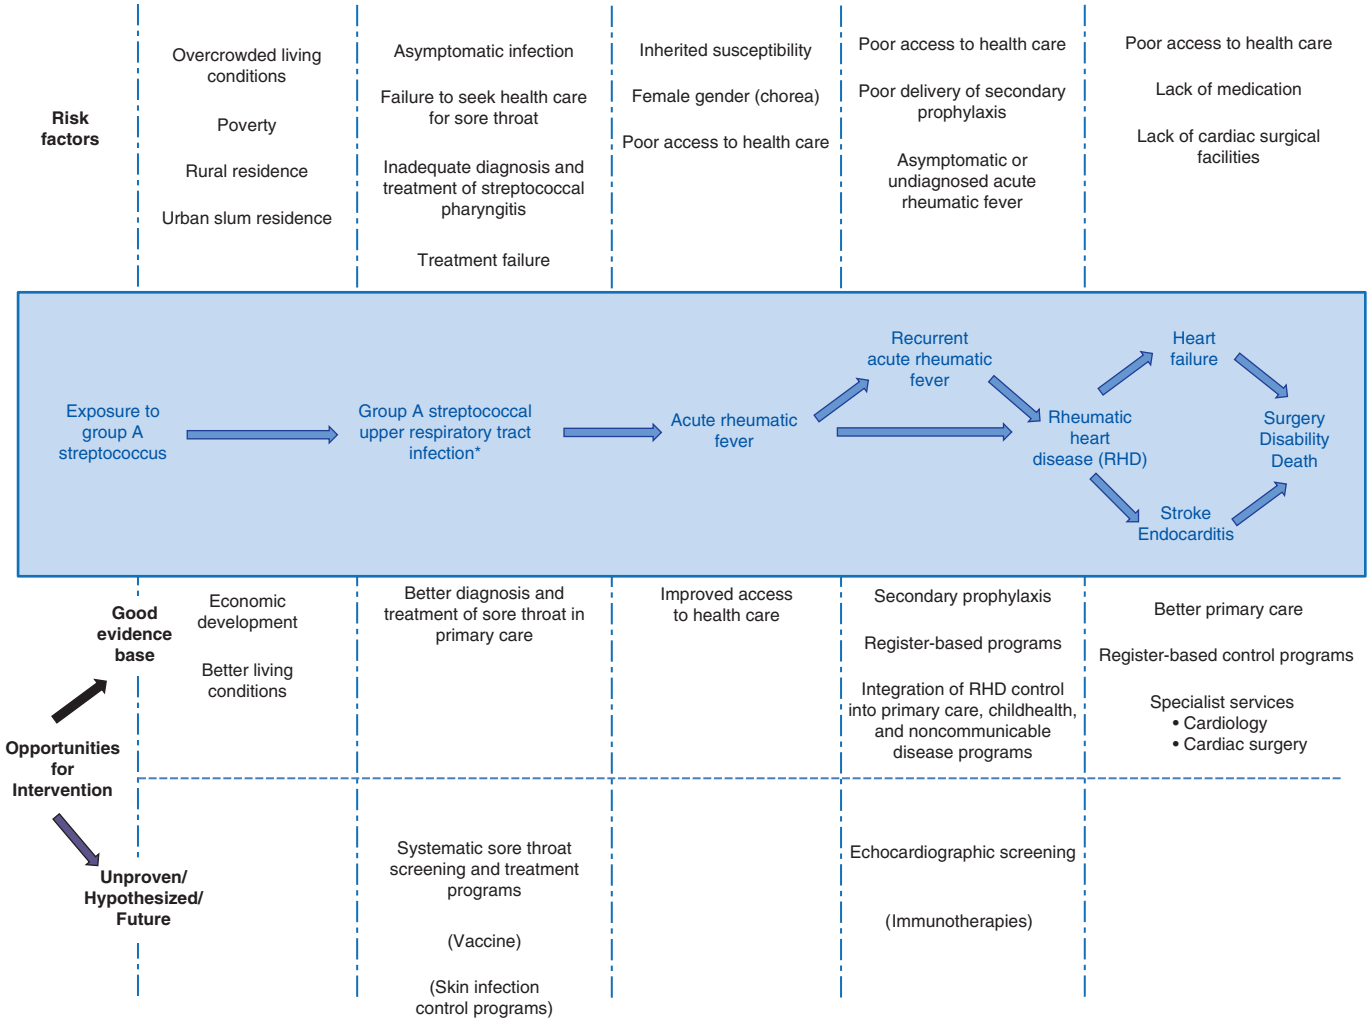

FIGURE 371-1 Pathogenetic pathway for acute rheumatic fever and rheumatic heart disease (RHD), with associated risk factors and opportunities for intervention at each step. Interventions in *parentheses* are either unproven or currently unavailable.

allowing it to become immunogenic, but not through the mechanism of molecular mimicry.

CLINICAL FEATURES

There is a latent period of ~3 weeks (1–5 weeks) between the precipitating group A streptococcal infection and the appearance of the clinical features of ARF. The exceptions are chorea and indolent carditis, which may follow prolonged latent periods lasting up to 6 months. Although many patients report a prior sore throat, the preceding group A streptococcal infection is commonly subclinical; in these cases, it can only be confirmed using streptococcal antibody testing. The most common clinical features are polyarthritis (present in 60–75% of cases) and carditis (50–75%). The prevalence of chorea in ARF varies substantially between populations, ranging from <2 to 30%. Erythema marginatum and subcutaneous nodules are now rare, being found in <5% of cases.

HEART INVOLVEMENT

Up to 75% of patients with ARF progress to RHD. The endocardium, pericardium, or myocardium may be affected. Valvular damage is the hallmark of rheumatic carditis. The mitral valve is almost always affected, sometimes together with the aortic valve; isolated aortic valve involvement is rare. Damage to the pulmonary or tricuspid valves is usually secondary to increased pulmonary pressures resulting from left-sided valvular disease. Early valvular damage leads to regurgitation. Over ensuing years, usually as a result of recurrent episodes, leaflet thickening, scarring, calcification, and valvular stenosis may develop **(Fig. 371-2)**. **See Videos 371-1 and 371-2.** Therefore, the characteristic manifestation of carditis in previously unaffected individuals is mitral regurgitation, sometimes accompanied by aortic regurgitation. Myocardial inflammation may affect electrical conduction pathways, leading to P-R interval prolongation (first-degree atrioventricular block or rarely higher-level block) and softening of the first heart sound.

People with RHD are often asymptomatic for many years before their valvular disease progresses to cause cardiac failure. Moreover, particularly in resource-poor settings, the diagnosis of ARF is often not made, so children, adolescents, and young adults may have RHD but not know it. These cases can be diagnosed using echocardiography; auscultation is poorly sensitive and specific for RHD diagnosis in asymptomatic patients. Echocardiographic screening of school-aged children in populations with high rates of RHD is becoming more widespread and has been facilitated by improving technologies in portable echocardiography and the availability of consensus guidelines for the diagnosis of RHD on echocardiography **(Table 371-1)**. These guidelines replace the previous "definite," "borderline," and "latent" diagnostic category terms with a classification based on the risk of progression to more advanced valvular heart disease and provide recommendations on secondary prophylaxis for each group.

JOINT INVOLVEMENT

The most common form of joint involvement in ARF is arthritis, i.e., objective evidence of inflammation, with hot, swollen, red, and/or tender joints, and involvement of more than one joint (i.e., polyarthritis). Polyarthritis is typically migratory, moving from one joint to another over a period of hours. ARF almost always affects the large joints—most commonly the knees, ankles, hips, and elbows—and is asymmetric. The pain is severe and usually disabling until anti-inflammatory medication is commenced.

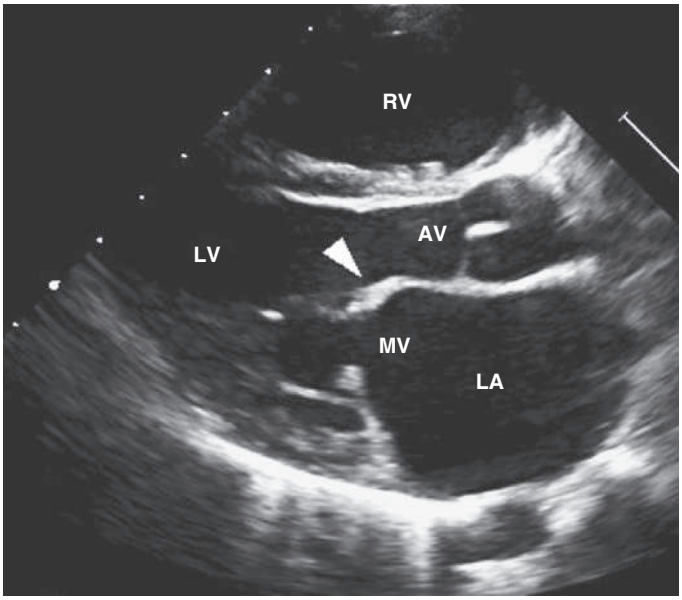

FIGURE 371-2 Transthoracic echocardiographic image from a 5-year-old boy with chronic rheumatic heart disease. This diastolic image demonstrates leaflet thickening, restriction of the anterior mitral valve leaflet tip, and doming of the body of the leaflet toward the interventricular septum. This appearance (marked by the *arrowhead*) is commonly described as a "hockey stick" or an "elbow" deformity. AV, aortic valve; LA, left atrium; LV, left ventricle; MV, mitral valve; RV, right ventricle. *(Courtesy of Dr. Bo Remenyi, Department of Paediatric and Congenital Cardiac Services, Starship Children's Hospital, Auckland, New Zealand.)*

Less severe joint involvement is also relatively common and has been recognized as a potential major manifestation in high-risk populations in the most recent revision of the Jones criteria. Arthralgia without objective joint inflammation usually affects large joints in the same migratory pattern as polyarthritis. In some populations, aseptic monoarthritis may be a presenting feature of ARF, which may, in turn, result from early commencement of anti-inflammatory medication before the typical migratory pattern is established.

The joint manifestations of ARF are highly responsive to salicylates and other nonsteroidal anti-inflammatory drugs (NSAIDs).

CHOREA

Sydenham's chorea commonly occurs in the absence of other manifestations, follows a prolonged latent period after group A streptococcal infection, and is found mainly in females. The choreiform movements affect particularly the head (causing characteristic darting movements of the tongue) and the upper limbs **(Chap. 447)**. They may be generalized or restricted to one side of the body (hemi-chorea). In mild cases, chorea may be evident only on careful examination, whereas in the most severe cases, the affected individuals are unable to perform activities of daily living. There is often associated emotional lability or obsessive-compulsive traits, which may last longer than the choreiform movements (which usually resolve within 6 weeks but sometimes may take up to 6 months). More than 50% of patients presenting with chorea will have carditis, for which reason echocardiography should be part of the workup.

SKIN MANIFESTATIONS

The classic rash of ARF is *erythema marginatum* **(Chap. 21)**, which begins as pink macules that clear centrally, leaving a serpiginous, spreading edge. The rash is evanescent, appearing and disappearing before the examiner's eyes. It occurs usually on the trunk, sometimes on the limbs, but almost never on the face.

Subcutaneous nodules occur as painless, small (0.5–2 cm), mobile lumps beneath the skin overlying bony prominences, particularly of the hands, feet, elbows, occiput, and occasionally the vertebrae. They are a delayed manifestation, appearing 2–3 weeks after the onset of disease, last for just a few days up to 3 weeks, and are commonly associated with carditis.

TABLE 371-1 Staging of Rheumatic Heart Disease Detected by Echocardiography[a,b]

Stage A: Minimal Echocardiographic Criteria for RHD
Applies only to individuals aged ≤20 years old • Clinical risk: might be at risk of valvular heart disease progression • Echocardiographic features: the presence of mild[c] MR or AR without morphologic features
Stage B: Mild RHD
Can apply to any age • Clinical risk: at moderate or high risk of progression and at risk of developing symptoms of valvular heart disease • Echocardiographic features: evidence of mild[c] valvular regurgitation plus at least one morphologic feature in individuals aged ≤20 years and at least two morphologic features in individuals aged >20 years[d]; or mild regurgitation in both mitral and aortic valves
Stage C: Advanced RHD at Risk of Clinical Complications
Can apply to any age • Clinical risk: at high risk of developing clinical complications that require medical or surgical intervention • Echocardiographic features: moderate or severe MR, moderate or severe AR, any MS or AS[e], pulmonary hypertension, and decreased LV systolic function
Stage D: Advanced RHD with Clinical Complications
Can apply to any age • Clinical risk: established clinical complications include cardiac surgery, heart failure, arrhythmia, stroke, and infective endocarditis • Echocardiographic features: moderate or severe MR, moderate or severe AR, any MS or AS[e], pulmonary hypertension, and decreased LV systolic function

[a]To be applied in high-risk settings and requires other causes of valvular heart disease to have been excluded. [b]After the application of the confirmatory echocardiographic criteria, diagnostic categories might include "normal" and "other," which encompasses other diseases such as congenital heart disease, cardiomyopathies, and pericardial effusion. [c]Fulfilling the confirmatory criteria for pathologic regurgitation (see Source). [d]This cutoff value is derived from expert consensus. [e]Aortic stenosis is defined in accordance with international guidelines on valvular heart disease. A diagnosis of rheumatic aortic stenosis requires the exclusion of other causes, including bicuspid aortic valve and degenerative calcific AS.

Abbreviations: AR, aortic regurgitation; AS, aortic stenosis; LV, left ventricular; MR, mitral regurgitation; MS, mitral stenosis, RHD, rheumatic heart disease.

OTHER FEATURES

Fever occurs in most cases of ARF, although rarely in cases of pure chorea. Although high-grade fever (≥39°C) is the rule, lower grade temperature elevations are not uncommon. Elevated acute-phase reactants are also present in most cases.

EVIDENCE OF A PRECEDING GROUP A STREPTOCOCCAL INFECTION

With the exception of chorea and low-grade carditis, both of which may become manifest many months later, evidence of a preceding group A streptococcal infection is essential in making the diagnosis of ARF. Because most cases do not have a positive throat swab culture or rapid antigen test, serologic evidence is usually needed. The most common serologic tests are the anti-streptolysin O (ASO) and anti-DNase B (ADB) titers. Where possible, age-specific reference ranges should be determined in a local population of healthy people without a recent group A streptococcal infection.

CONFIRMING THE DIAGNOSIS

Because there is no definitive test, the diagnosis of ARF relies on the presence of a combination of typical clinical features together with evidence of the precipitating group A streptococcal infection, and the exclusion of other diagnoses. This uncertainty led Dr. T. Duckett Jones in 1944 to develop a set of criteria (subsequently known as the *Jones criteria*) to aid in the diagnosis. The most recent revision of the Jones criteria **(Table 371-2)** requires the clinician to determine if the patient is from a setting or population known to experience low rates of ARF.

TABLE 371-2 Jones Criteria

A. For All Patient Populations with Evidence of Preceding Group A Streptococcal Infection	
Diagnosis: initial ARF	2 major manifestations or 1 major plus 2 minor manifestations
Diagnosis: recurrent ARF	2 major or 1 major and 2 minor or 3 minor
B. Major Criteria	
Low-risk populations[a]	Moderate- and high-risk populations
Carditis[b]	Carditis
• Clinical and/or subclinical	• Clinical and/or subclinical
Arthritis	Arthritis
• Polyarthritis only	• Monoarthritis or polyarthritis
	• Polyarthralgia[c]
Chorea	Chorea
Erythema marginatum	Erythema marginatum
SC nodules	SC nodules
C. Minor Criteria	
Low-risk populations[a]	Moderate- and high-risk populations
Polyarthralgia	Monoarthralgia
Fever (≥38.5°C)	Fever (≥38°C)
ESR ≥60 mm in the first hour and/or CRP ≥3.0 mg/dL[d]	ESR ≥30 mm/h and/or CRP ≥3.0 mg/dL[d]
Prolonged PR interval[e], after accounting for age variability (unless carditis is a major criterion)	Prolonged PR interval[e], after accounting for age variability (unless carditis is a major criterion)

[a]Low-risk populations are those with ARF incidence ≤2 per 100,000 school-age children or all-age rheumatic heart disease prevalence of ≤1 per 1000 population per year. [b]Subclinical carditis indicates echocardiographic valvulitis. (See source document.) [c]Polyarthralgia should only be considered as a major manifestation in moderate- to high-risk populations after exclusion of other causes. As in past versions of the criteria, erythema marginatum and SC nodules are rarely "stand-alone" major criteria. Additionally, joint manifestations can only be considered in either the major or minor categories but not both in the same patient. (See source document for more information.) [d]CRP value must be greater than upper limit of normal for laboratory. Also, because ESR may evolve during the course of ARF, peak ESR values should be used. [e]Prolonged PR interval can only be considered in the absence of carditis as a major criterion.

Abbreviations: ARF, acute rheumatic fever; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; SC, subcutaneous.

Source: Reproduced with permission from MH Gewitz et al: Revision of the Jones criteria for the diagnosis of acute rheumatic fever in the era of Doppler echocardiography: A scientific statement from the American Heart Association. Circulation 131(20):1806, 2015. *https://www.ahajournals.org/doi/full/10.1161/CIR.0000000000000205.*

For this group, there is a set of "low-risk" criteria; for all others, there is a set of more sensitive criteria.

TREATMENT

Acute Rheumatic Fever

Patients with possible ARF should be followed closely to ensure that the diagnosis is confirmed, treatment of heart failure and other symptoms is undertaken, and preventive measures including commencement of secondary prophylaxis, inclusion on an ARF registry, and health education are commenced. Echocardiography should be performed on all possible cases to aid in making the diagnosis and to determine the severity at baseline of any carditis. Other tests that should be performed are listed in **Table 371-3**.

There is no treatment for ARF that has been proven to alter the likelihood of developing, or the severity of, RHD. With the exception of treatment of heart failure, which may be lifesaving in cases of severe carditis, the treatment of ARF is symptomatic.

ANTIBIOTICS

All patients with ARF should receive antibiotics sufficient to treat the precipitating group A streptococcal infection **(Chap. 153)**. Penicillin is the drug of choice and can be given orally (as phenoxymethyl penicillin, 500 mg [250 mg for children ≤27 kg] PO twice daily, or amoxicillin, 50 mg/kg [maximum, 1 g] daily, for 10 days) or as a single dose of 1.2 million units (600,000 units for children ≤27 kg) IM benzathine penicillin G.

TABLE 371-3 Testing and Monitoring of ARF in the Acute Setting

Investigations

Always request:
- Electrocardiogram (ECG)
- Echocardiogram
- Complete blood count (CBC)
- C-reactive protein (CRP)
- Streptococcal serology (antistreptolysin and anti-DNase B)

In relevant situations:
- Throat swab
- Skin sore swab
- Blood cultures
- Synovial fluid aspirate
  - Ensure sample does not clot by using correct tubes that have been well mixed and transported promptly to the laboratory
  - Include request for cell count, microscopy, culture, and gonococcal polymerase chain reaction (PCR)
- Pregnancy test
- Creatinine test (UEC [urea, electrolytes, creatinine]) since nonsteroidal anti-inflammatory drugs can affect renal function

Tests to exclude alternative diagnoses, depending on clinical presentation and locally endemic infections:
- Autoantibodies, double-stranded DNA, anti–cyclic citrullinated peptide (anti-CCP) antibodies
- Urine for *Neisseria gonorrhoeae* molecular test
- Urine for *Chlamydia trachomatis* molecular test
- Serologic or other testing for viral hepatitis, *Yersinia* spp., cytomegalovirus (CMV), parvovirus B19, respiratory viruses, Ross River virus, Barmah Forest virus

Available at *https://www.rhdaustralia.org.au/arf-rhd-guideline*.

SALICYLATES AND NSAIDS

These may be used for the treatment of arthritis, arthralgia, and fever once the diagnosis is confirmed. They are of no proven value in the treatment of carditis or chorea. Aspirin has traditionally been the first-line choice, delivered at a dose of 50–60 mg/kg per day, up to a maximum of 80–100 mg/kg per day (4–8 g/d in adults) in 4–5 divided doses. At higher doses, the patient should be monitored for symptoms of salicylate toxicity such as nausea, vomiting, or tinnitus; if symptoms appear, lower doses should be used. Owing to the frequency of gastrointestinal side effects and the potential of more severe adverse effects of aspirin, many clinicians now prefer to use naproxen at a dose of 10–20 mg/kg per day because it may be safer than aspirin and has the advantage of twice-daily dosing. When the acute symptoms are substantially resolved, usually within the first 2 weeks, patients on higher doses of anti-inflammatory medications can have the dose reduced for a further 2–4 weeks. Fever, joint manifestations, and elevated acute-phase reactants sometimes recur up to 3 weeks after the medication is discontinued. This does not indicate a recurrence and can be managed by recommencing anti-inflammatory agents for a brief period.

CONGESTIVE HEART FAILURE

Glucocorticoids The use of glucocorticoids in ARF remains controversial. Two meta-analyses have failed to demonstrate a benefit of glucocorticoids compared to placebo or salicylates in improving the short- or longer-term outcome of carditis. However, the studies included in these meta-analyses all took place >40 years ago and did not use medications in common usage today. There are some recent data that suggest corticosteroids improve laboratory, radiologic,

and echocardiographic parameters in carditis. Many clinicians treat cases of severe carditis (causing heart failure) with glucocorticoids in the belief that they may reduce the acute inflammation and result in more rapid resolution of failure. However, the potential benefits of this treatment should be balanced against the possible adverse effects. If used, prednisone or prednisolone is recommended at a dose of 1–2 mg/kg per day (maximum, 80 mg), usually for a few days or up to a maximum of 3 weeks.

MANAGEMENT OF HEART FAILURE

See Chap. 265.

BED REST

Traditional recommendations for long-term bed rest, once the cornerstone of management, are no longer widely practiced. Instead, bed rest should be prescribed as needed while arthritis and arthralgia are present and for patients with heart failure. Once symptoms are well controlled, gradual mobilization can commence as tolerated.

CHOREA

Medications to control the abnormal movements do not alter the duration or outcome of chorea. Milder cases can usually be managed by providing a calm environment. In patients with severe chorea, carbamazepine or sodium valproate is preferred to haloperidol. A response may not be seen for 1–2 weeks, and medication should be continued for 1–2 weeks after symptoms subside. There is recent evidence that corticosteroids are effective and lead to more rapid symptom reduction in chorea. They should be considered in severe or refractory cases. Prednisone or prednisolone may be commenced at 0.5 mg/kg daily, with weaning as early as possible, preferably after 1 week if symptoms are reduced, although slower weaning or temporary dose escalation may be required if symptoms worsen.

INTRAVENOUS IMMUNOGLOBULIN (IVIG)

Small studies have suggested that IVIg may lead to more rapid resolution of chorea but have shown no benefit on the short- or long-term outcome of carditis in ARF without chorea. In the absence of better data, IVIg is *not* recommended except in cases of severe chorea refractory to other treatments.

PROGNOSIS

Untreated, ARF lasts on average 12 weeks. With treatment, patients are usually discharged from hospital within 1–2 weeks. Inflammatory markers should be monitored every 1–2 weeks until they have normalized (usually within 4–6 weeks), and an echocardiogram should be performed after 1 month to determine if there has been progression of carditis. Cases with more severe carditis need close clinical and echocardiographic monitoring in the longer term.

Once the acute episode has resolved, the priority in management is to ensure long-term clinical follow-up and adherence to a regimen of secondary prophylaxis. Patients should be entered onto the local ARF registry (if present) and contact made with primary care practitioners to ensure a plan for follow-up and administration of secondary prophylaxis before the patient is discharged. Patients and their families should also be educated about their disease, emphasizing the importance of adherence to secondary prophylaxis.

PREVENTION

PRIMARY PREVENTION

Ideally, primary prevention would entail elimination of the major risk factors for streptococcal infection, particularly overcrowded housing. This is difficult to achieve in most places where ARF is common but must remain a priority in ongoing efforts to achieve global control of ARF and RHD.

Concerted international efforts are underway to develop a vaccine against group A *Streptococcus* that would prevent infection of the throat or skin and consequently prevent ARF in the absence of a suitable vaccine; however, the mainstay of primary prevention for ARF remains primary prophylaxis (i.e., the timely and complete treatment of group A streptococcal sore throat with antibiotics). If commenced within 9 days of sore throat onset, a course of penicillin (as outlined above for treatment of ARF) will prevent almost all cases of ARF that would otherwise have developed. In settings where ARF and RHD are common but microbiologic diagnosis of group A streptococcal pharyngitis is not available, such as in resource-poor countries, primary care guidelines sometimes recommend that all patients with sore throat be treated with penicillin (an approach that has the potential drawbacks that come from antibiotic overuse, including side effects and increasing pressure on antimicrobial resistance in group A *Streptococcus* or bystander pathogens) or, alternatively, that a clinical algorithm be used to identify patients with a higher likelihood of group A streptococcal pharyngitis. Although imperfect, such approaches recognize the importance of ARF prevention at the expense of overtreating many cases of sore throat that are not caused by group A *Streptococcus*. Although there is no proof that antibiotic treatment of group A streptococcal skin infections can prevent ARF, the increasing evidence that impetigo is strongly associated with ARF in some populations argues for a focus on treatment and prevention of group A streptococcal skin infections as part of a comprehensive ARF control strategy in regions with endemic impetigo.

SECONDARY PREVENTION

The mainstay of controlling ARF and RHD is secondary prevention. Because patients with ARF are at dramatically higher risk than the general population of developing a further episode of ARF after a group A streptococcal infection, they should receive long-term penicillin prophylaxis to prevent recurrences. The best antibiotic for secondary prophylaxis is benzathine penicillin G (1.2 million units, or 600,000 units if ≤27 kg) delivered intramuscularly every 4 weeks. It can be given every 3 weeks, or even every 2 weeks, to persons considered to be at particularly high risk, although in settings where good compliance with an every-4-week dosing schedule can be achieved, more frequent dosing is rarely needed. Evidence has emerged recently that subcutaneous delivery of benzathine penicillin G provides more optimal pharmacokinetics than intramuscular delivery and may have added advantages of reducing pain and allowing for larger doses to be delivered less frequently, although this approach is yet to be recommended in clinical guidelines. Oral penicillin V (250 mg) can be given twice daily instead but is less effective than benzathine penicillin G. Penicillin-allergic patients can receive erythromycin (250 mg) twice daily.

The duration of secondary prophylaxis is determined by many factors, in particular the duration since the last episode of ARF (recurrences become less likely with increasing time), age (recurrences are less likely with increasing age), and the severity of RHD (if severe, it may be prudent to avoid even a very small risk of recurrence because of the potentially serious consequences) **(Table 371-4)**. Secondary prophylaxis is best delivered as part of a coordinated RHD control program, based around a registry of patients. Registries improve the ability to follow patients and identify those who default from prophylaxis and to institute strategies to improve adherence.

TABLE 371-4 American Heart Association Recommendations for Duration of Secondary Prophylaxis[a]

CATEGORY OF PATIENT	DURATION OF PROPHYLAXIS
Rheumatic fever without carditis	For 5 years after the last attack or 21 years of age (whichever is longer)
Rheumatic fever with carditis but no residual valvular disease	For 10 years after the last attack, or 21 years of age (whichever is longer)
Rheumatic fever with persistent valvular disease, evident clinically or on echocardiography	For 10 years after the last attack, or 40 years of age (whichever is longer); sometimes lifelong prophylaxis

[a]These are only recommendations and must be modified by individual circumstances as warranted. Note that some organizations recommend a minimum of 10 years of prophylaxis after the most recent episode, or until 21 years of age (whichever is longer), regardless of the presence of carditis with the initial episode.

This appearance is commonly described as a "hockey stick" or an "elbow" deformity. ***B.*** Chronic rheumatic heart disease (apical two-chamber view echocardiogram).

372 Systemic Sclerosis (Scleroderma) and Related Disorders

John Varga

DEFINITION AND CLASSIFICATION

Systemic sclerosis (SSc) is an orphan disease of unknown etiology, complex pathogenesis, and variable clinical presentations. SSc follows a chronic and often progressive course and is associated with significant disability and mortality. Virtually every organ can be affected **(Fig. 372-1)**.

There is marked variability among SSc patients in patterns of skin involvement and organ complications, rates of disease progression, response to treatment, disease severity, and survival. The early stages of SSc may be associated with prominent inflammatory features such as edema, but over time, structural alterations in multiple vascular beds and visceral organ dysfunction due to fibrosis and atrophy progressively dominate the clinical picture. Classification criteria for the diagnosis of SSc (shown in **Table 372-1**) are >90% specific and sensitive, although they are intended to be used in clinical research rather than clinical practice.

Although thickened and indurated skin (*scleroderma*) is the distinguishing hallmark of SSc, similar skin changes can also be seen in localized forms of scleroderma, along with a variety of metabolic, inherited, autoimmune, and iatrogenic conditions **(Table 372-2)**. Patients with SSc can be broadly segregated into two major subsets defined by the pattern of skin involvement and associated with characteristic clinical and serologic features and natural history **(Table 372-3)**. Patients with diffuse cutaneous SSc (dcSSc) have extensive skin induration, starting in the fingers (sclerodactyly) and ascending from distal to proximal limbs and the trunk. In these patients, progressive skin disease, interstitial lung disease (ILD), and less commonly acute renal involvement may develop relatively early. In contrast, in patients with limited cutaneous SSc (lcSSc), Raynaud's phenomenon generally precedes sclerodactyly and other disease manifestations, sometimes by years. In these patients, skin involvement remains confined to the fingers, distal limbs, and face, while the trunk is spared. A subset of patients with lcSSc display a distinct constellation of findings (calcinosis cutis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia), historically termed the *CREST syndrome*. In lcSSc, visceral organ involvement tends to follow a more insidious and occasionally benign course, while digital ischemic ulcers, pulmonary arterial hypertension (PAH), hypothyroidism, Sjogren's symptoms, and primary biliary cirrhosis may occur as late complications. In some patients, Raynaud's phenomenon and characteristic clinical and laboratory features of SSc occur in the absence of detectable skin thickening. This relatively benign disease subset has been termed *SSc sine scleroderma.*

INCIDENCE AND PREVALENCE

SSc is an acquired sporadic disease with a worldwide distribution affecting all races and has a rising incidence rate. In the United States, the incidence is 9–46 cases per million per year. There are an estimated 100,000 U.S. cases, although this number may be significantly higher if patients who do not fulfill formal SSc classification criteria are also included. There are large regional variations in incidence rates of SSc, potentially reflecting differences in case definition, environmental exposures, or genetic susceptibility genes in populations with different ancestries. Prevalence rates in England, northern Europe, and Japan appear to be lower than in North America and Australia. Age, sex, and ancestry influence disease susceptibility, and black people have higher age-specific incidence rates and mortality. In common with most autoimmune diseases, SSc shows a strong female sex bias (4.6:1),

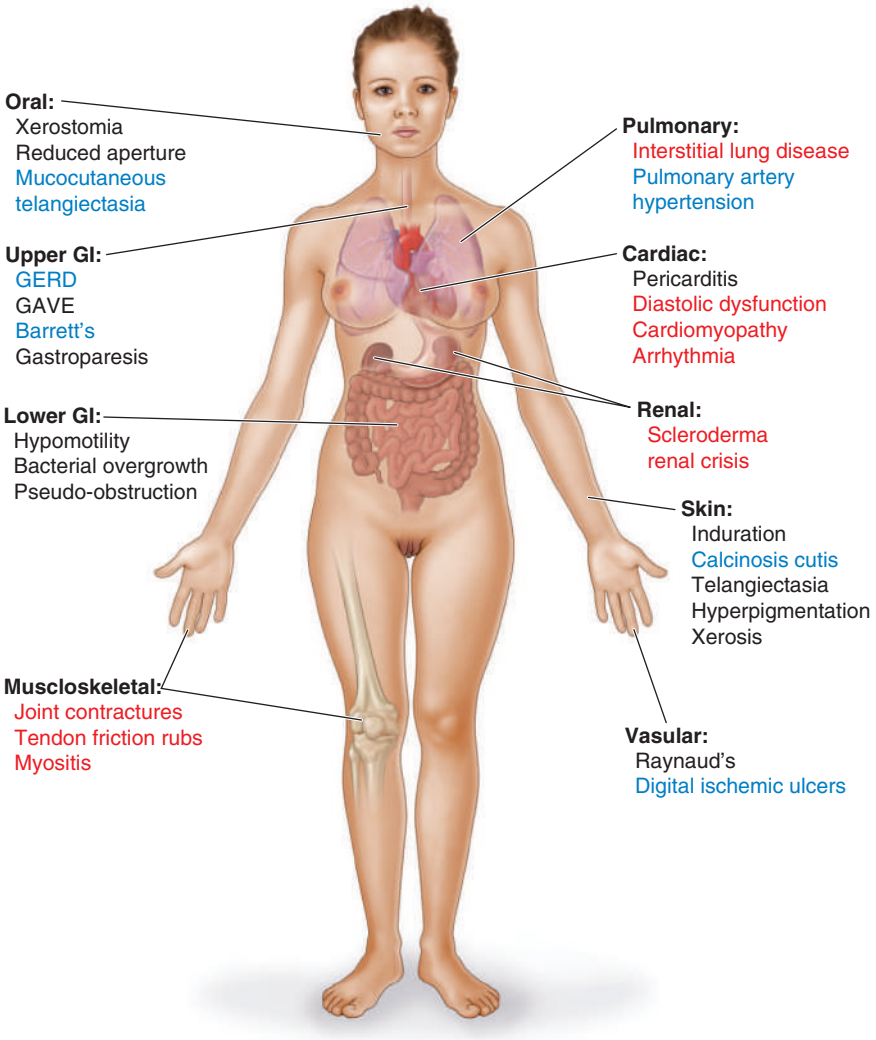

FIGURE 372-1 Multiorgan involvement in systemic sclerosis (SSc). Complications of SSc; *Red*, complications more prominent in patients with diffuse cutaneous SSc; *Blue*, those more prominent in limited cutaneous SSc; *Black*, complications common in both limited and diffuse cutaneous SSc subsets. GAVE, gastric antral vascular ectasia; GERD, gastroesophageal reflux disease; GI, gastrointestinal.

TABLE 372-1 ACR/EULAR Classification Criteria for Diagnosis of Systemic Sclerosis (SSc)

ITEM	SUBITEM	WEIGHT/SCORE
Skin thickening (bilateral)—fingers extending proximal to MCP joints		9
Skin thickening of fingers only	Puffy fingers Sclerodactyly (skin thickened distal to MCP joints)	2 4
Fingertip lesions	Digital tip ulcer or pitting scar	2 3
Mucocutaneous telangiectasia		2
Abnormal nailfold capillary pattern		2
Lung involvement	PAH Interstitial lung disease	2 2
Raynaud's phenomenon		3
SSc-specific autoantibodies	ACA Scl-70 RNA polymerase III	3

Abbreviations: ACA, anticentromere antibodies; ACR, American College of Rheumatology; EULAR, European Alliance of Associations for Rheumatology; MCP, metacarpophalangeal joint; PAH, pulmonary arterial hypertension.

TABLE 372-2 Conditions Associated with Scleroderma-Like Skin Induration

Systemic sclerosis (SSc)
Limited cutaneous SSc
Diffuse cutaneous SSc
Localized scleroderma
Guttate (plaque) morphea, diffuse (panssclerotic) morphea, bullous morphea
Linear scleroderma, coup de sabre, hemifacial atrophy
Pansclerotic morphea
Overlap syndromes
Mixed connective tissue disease
SSc/polymyositis
Diabetic scleredema and scleredema of Buschke
Scleromyxedema (papular mucinosis)
Chronic graft-versus-host disease
Diffuse fasciitis with eosinophilia (Shulman's disease, eosinophilic fasciitis)
Stiff skin syndrome
Pachydermatoperiostosis (primary hypertrophic osteoarthropathy)
Chemically induced and drug-associated scleroderma-like conditions
Vinyl chloride–induced disease
Eosinophilia-myalgia syndrome (associated with L-tryptophan contaminant exposure)
Nephrogenic systemic fibrosis (associated with gadolinium exposure)
Paraneoplastic syndrome

TABLE 372-3 Subsets of Systemic Sclerosis (SSc): Features of Limited Cutaneous Versus Diffuse Cutaneous Disease

CHARACTERISTIC FEATURE	LIMITED CUTANEOUS SSc	DIFFUSE CUTANEOUS SSc
Skin involvement	Indolent onset. Limited to fingers, distal to elbows, face; slow progression	Rapid onset. Diffuse: fingers, extremities, face, trunk; rapid progression
Raynaud phenomenon	Antedates skin involvement, sometimes by years; may be associated with critical ischemia in the digits	Onset coincident with skin involvement; critical ischemia less common
Musculoskeletal	Mild arthralgia	Severe arthralgia, carpal tunnel syndrome, tendon friction rubs
Interstitial lung disease	Slowly progressive, generally mild	Frequent, early onset and progression, can be severe
Pulmonary arterial hypertension	Frequent, late, may occur as an isolated complication	Often occurs in association with interstitial lung disease
Scleroderma renal crisis	Very rare	Occurs in 15%; generally early (<4 years from disease onset)
Calcinosis cutis	Frequent, prominent	Less common, mild
Characteristic autoantibodies	Anti-centromere	Anti–topoisomerase I (Scl-70), anti-RNA polymerase III

which is most pronounced in the childbearing years and declines after menopause. Males and females show numerous differences in immune cell composition and function, with females exhibiting greater innate, humoral, and cellular immune responses. The female bias in SSc may be in part due to sex hormones, as estrogens have immunostimulatory effects, including stimulation of interleukin (IL)-6, RF5, and TLR7 expression. An alternate, but not mutually exclusive, hypothesis for sex-biased disease susceptibility implicated skewed inactivation of the X chromosome in females, resulting in aberrant expression of immune-related genes residing on the X chromosome, including TLR7 and TLR8 and CD40L. Moreover, while autosomal genes are the same in males and females, their cell type–specific expression can vary between the sexes. Finally, differing environmental exposures between males and females might also contribute to sexual dimorphism in SSc susceptibility, disease course, and response to therapy. Having an affected first-degree family member with SSc increases disease risk 13-fold. Although SSc can present at any age, the peak age of onset in women with both limited and diffuse cutaneous forms is 65–74 years, although in black patients, disease onset occurs at an earlier age. Furthermore, black patients with SSc are more likely to have diffuse cutaneous disease, ILD, a worse prognosis, and greater premature death.

GENETIC CONTRIBUTION TO DISEASE SUSCEPTIBILITY

In general, the genetic associations of SSc identified to date make only a relatively modest contribution to disease susceptibility. Studies of SSc showed low rates of disease concordance (4.7%) in monozygotic twins, a rate much lower than in other autoimmune diseases such as rheumatoid arthritis (12.3%). On the other hand, supporting the genetic contribution to disease susceptibility is the observation that 1.6% of SSc patients have a first-degree relative with SSc, a prevalence rate that is markedly increased compared to the general population (0.026). Moreover, the risk of Raynaud's phenomenon, ILD, and other autoimmune diseases, including systemic lupus erythematosus (SLE) **(Chap. 368)**, rheumatoid arthritis **(Chap. 370)**, and autoimmune thyroiditis **(Chap. 395)**, is also increased in first-degree relatives of patients with SSc. Current approaches to uncover the genetic factor contribution to SSc include DNA sequencing and single nucleotide polymorphism (SNP) analysis of candidate genes and SNP analysis of the entire genome in a hypothesis-free manner. Genome-wide association studies (GWAS) involve large multicenter, multinational, and multiethnic cohorts. A majority of the robustly validated genetic susceptibility loci for SSc are genes at the highly polymorphic human leukocyte antigen (HLA) region and other genes involved in innate and adaptive immunity and interferon responses, highlighting the importance of autoimmunity as the initial trigger for the disease. Genetic studies have shown associations with common (small effect size) variants related to B and T lymphocyte activation (*BANK1*, *BLK*, *CD247*, *IL2RA*, *CCR6, IDO1, TNFSF4/OX40L, PTPN22,* and *TNIP1*), as well as *STAT4* and *IRF5*, both implicated in the secretion of type I interferon from plasmacytoid dendritic cells. In addition, candidate gene studies and GWAS identified a strong and consistent association with HLA class II haplotypes on chromosome 6, including *HLA-DRB1*11:04, DQA1*05:01,* and *DQB1*03:01*, and the non-HLA major histocompatibility complex (MHC) genes *NOTCH4* and *PSORSC1*. Other genetic variants associated with SSc are involved in innate immunity (*IRF7*, *TNFAIP3*, and *TLR2*) and secretion of type interferons, particularly from plasmacytoid dendritic cells (*STAT4, IRF5*). Additional associations with *IL12RB2, IL-21,* the autophagy and apoptosis-related genes *DNASE1L3* and *SOX5*, and the extracellular matrix–related genes *CSK, CAV1, PPARG,* and *GRB10* have been reported. In addition to SSc susceptibility, some of these genetic loci are associated with particular disease manifestations or serologic subsets, including ILD (*CTGF*, *CD226*), PAH (*TNIP1*), scleroderma renal crisis (*HLA-DRB1**), and anticentromere antibodies (*HLA-DPB1*05:01*). While the functional consequences of these gene variants and their potential roles in pathogenesis are not well understood, it seems likely that in combination they cause a state of altered immune regulation, leading to increased susceptibility to autoimmunity and persistent inflammation. Of note, several of the SSc genetic variants are also linked with other autoimmune disorders, including SLE, Sjögren's syndrome, rheumatoid arthritis, multiple sclerosis, and psoriasis, suggesting common pathogenic pathways shared among these phenotypically dissimilar conditions. A population electronic health record–based GWAS identified *ADRA2A*, implicated in α_{2a}-adrenoreceptor signaling, as a candidate causal gene for Raynaud's phenomenon. Notably, the genetic associations identified to date only explain a fraction of the heritability of SSc and focus on common variants. By contrast, next-generation sequencing, such as whole exome sequencing, may help identify additional genetic susceptibility factors in SSc, particularly rare (and potentially causal) coding variants and their association with specific phenotypes.

ENVIRONMENTAL FACTORS AND OCCUPATIONAL EXPOSURES

The etiology of SSc is unknown. Given the relatively modest genetic contribution to susceptibility in SSc, environmental exposures, such as infectious agents, microbiome, and occupational, dietary, lifestyle, and drug exposures, are likely to play a major role. Studies suggest potential links with viruses including parvovirus B19, Epstein-Barr virus (EBV), adeno-associated virus 5, and cytomegalovirus (CMV). However, evidence to directly implicate these infectious agents in the pathogenesis of SSc is lacking. Occupational exposures tentatively linked with SSc include particulate silica (quartz), polyvinyl chloride, epoxy resins, welding fumes and organic solvents, and aromatic hydrocarbons including paint thinners, toluene, xylene, and trichloroethylene. These exposures might elicit cell type–specific stable and heritable epigenetic modifications such as DNA methylation and histone modifications to drive altered cellular gene expression **(Fig. 372-2)**. Because epigenetic modifications are often reversible, they represent potential targets for therapy. Drugs implicated in SSc-like illnesses include bleomycin, pentazocine, cocaine, and appetite suppressants linked with PAH. Most recently, immune checkpoint inhibitors, such as PD-1 blockers used in cancer therapy, have been implicated as triggers for SSc-like illnesses. Radiation therapy for cancer has been linked with de novo onset of SSc as well as with exacerbation of preexisting SSc. In contrast to rheumatoid arthritis, cigarette smoking does not increase the risk of SSc. Although case reports and series describing the occurrence of SSc in women with silicone breast implants had raised concern regarding a putative pathogenic role of silicone, large-scale epidemiologic

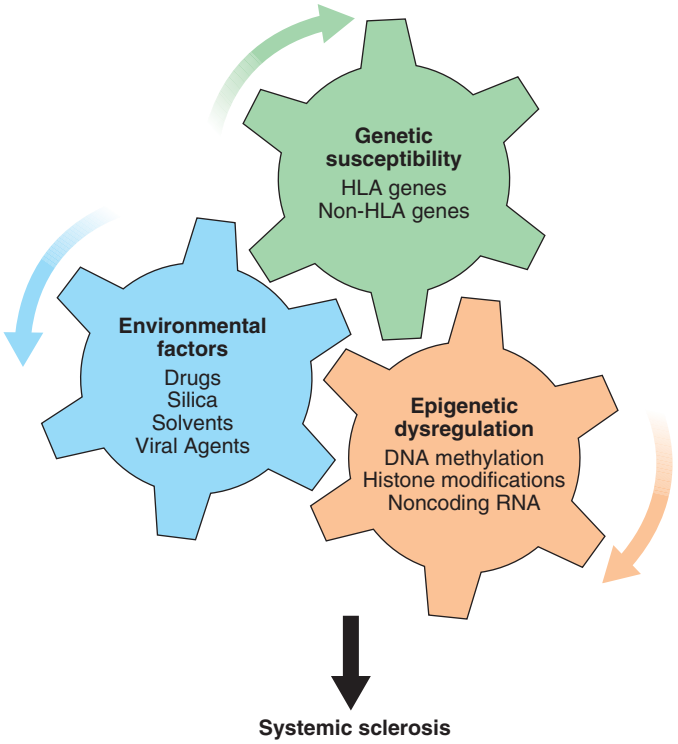

FIGURE 372-2 The interplay of genetic risk factors and environmental exposure-induced epigenetic modifications underlying the complex pathogenesis of systemic sclerosis. HLA, human leukocyte antigen. *(Reproduced with permission from Drs. Amr Sawalha and Pei-Suen Tsou, University of Michigan.)*

investigations did not find increased prevalence of SSc in such populations.

PATHOGENESIS

The pathogenesis of SSc involves putative environmental insults that trigger epigenetic modifications in a genetically predisposed host, causing alterations in gene expression underlying durable changes in the behavior of multiple cell types (Fig. 372-2).

Three cardinal pathomechanistic processes underlie the protean clinical manifestations and pathologic changes of SSc: (1) diffuse microangiopathy, (2) inflammation and autoimmunity, and (3) visceral and vascular fibrosis affecting multiple organs **(Fig. 372-3)**. While each of these distinct processes may be synchronously active in a given SSc patient, their relative severity progression and contribution to the overall clinical picture varies among individual patients and over time. In general, autoimmunity and reversible vascular reactivity are early features of SSc, while fibrosis and atrophy occur later in the disease.

MODELS OF DISEASE

There is no single animal model of SSc that fully reproduces the three cardinal processes that underlie pathogenesis or phenocopies their temporal evolution. In mice, skin and lung fibrosis accompanied by variable vasculopathy and autoimmunity can be elicited by repeated injection of bleomycin or angiotensin II or by transplantation of HLA-mismatched bone marrow or spleen cells, which elicit a chronic graft-versus-host disease–like condition. Targeted genetic modifications in mice give rise to new disease models for investigating the pathogenetic roles of individual molecules, pathways, and cell types. These animal models have utility as experimental tools to discover and validate novel therapeutic targets, cell types, and biomarkers. Recent efforts focus on the development of three-dimensional ex vivo disease models, including skin equivalents and organoids.

MICROANGIOPATHY

In a progressive model of disease pathogenesis **(Fig. 372-4)**, vascular injury is an early and possibly primary pathogenic event that underlies

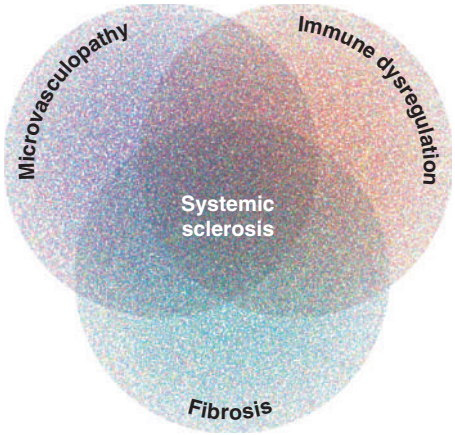

FIGURE 372-3 The pathogenic systemic sclerosis (SSc) triad. The characteristic constellation of synchronously occurring vasculopathy, autoimmunity/inflammation, and fibrosis distinguishes SSc and underlies its protean clinical manifestations.

protean manifestations of small vessel vasculopathy, including mucocutaneous telangiectasia, Raynaud's phenomenon, ischemic digital ulcers, acro-osteolysis, scleroderma renal crisis, myocardial involvement, and PAH.

Raynaud's phenomenon, commonly the earliest clinical manifestation of SSc, is characterized by altered blood-flow response to cold challenge in small digital arteries. This reversible functional abnormality is associated with autonomic and peripheral nervous system alterations, including impaired production of the neuropeptide calcitonin gene-related peptide from sensory afferent nerves and heightened sensitivity of α_2-adrenergic receptors on vascular smooth-muscle cells. Isolated (or primary) Raynaud's disease is common, generally benign, and nonprogressive. In contrast, SSc-associated (or secondary) Raynaud's phenomenon often progresses to irreversible structural changes in the small blood vessels, culminating in ischemic digital tip ulcers, necrosis, and finger amputation. Genetic studies have identified *ADRA2A* as a candidate causative gene in Raynaud's phenomenon.

Viruses, cytotoxic factors, chemokines, thrombogenic circulating microvesicles, alternate complement pathway activation, neutrophil extracellular trap (NET) formation (NETosis), and autoantibodies targeting endothelial cells, phospholipids, and β_2-glycoprotein I (β_2GPI) have all been considered as possible triggers of endothelial cell injury in patients with SSc. Endothelial damage disrupts the production of vasodilatory (nitric oxide and prostacyclin) and vasoconstricting (endothelin-1) substances, while causing upregulation of intercellular adhesion molecule 1 (ICAM-1) and other surface adhesion molecules. Microvessels show enhanced permeability and transendothelial leukocyte diapedesis, activation of coagulation cascades, formation of NETs, elevated thrombin production, and impaired fibrinolysis. Spontaneous platelet aggregation causes release of serotonin, platelet-derived growth factor (PDGF), platelet factor 4 (PF4, also known as CXCL4), and platelet alpha granules including thromboxane, a potent vasoconstrictor. Smooth-muscle cell–like myointimal cells arising from endothelial cells through a process called endothelial-mesenchymal transition (EndoMT) accumulate within the vascular media. The basement membrane is thickened and reduplicated, and perivascular adventitial fibrosis develops. The vasculopathic process primarily affects capillaries, arterioles, and, less commonly, even large vessels in many organs, resulting in impaired blood flow and tissue ischemia. Progressive luminal occlusion due to intimal and medial hypertrophy, combined with persistent endothelial cell damage and adventitial fibrosis, establishes a vicious cycle that underlies fibroproliferative vasculopathy and culminates in the striking absence of small blood vessels (rarefaction) in late-stage disease. Recurrent ischemia-reperfusion generates reactive oxygen species (ROS) that further damage the endothelium through peroxidation of membrane lipids. Paradoxically, the process of revascularization

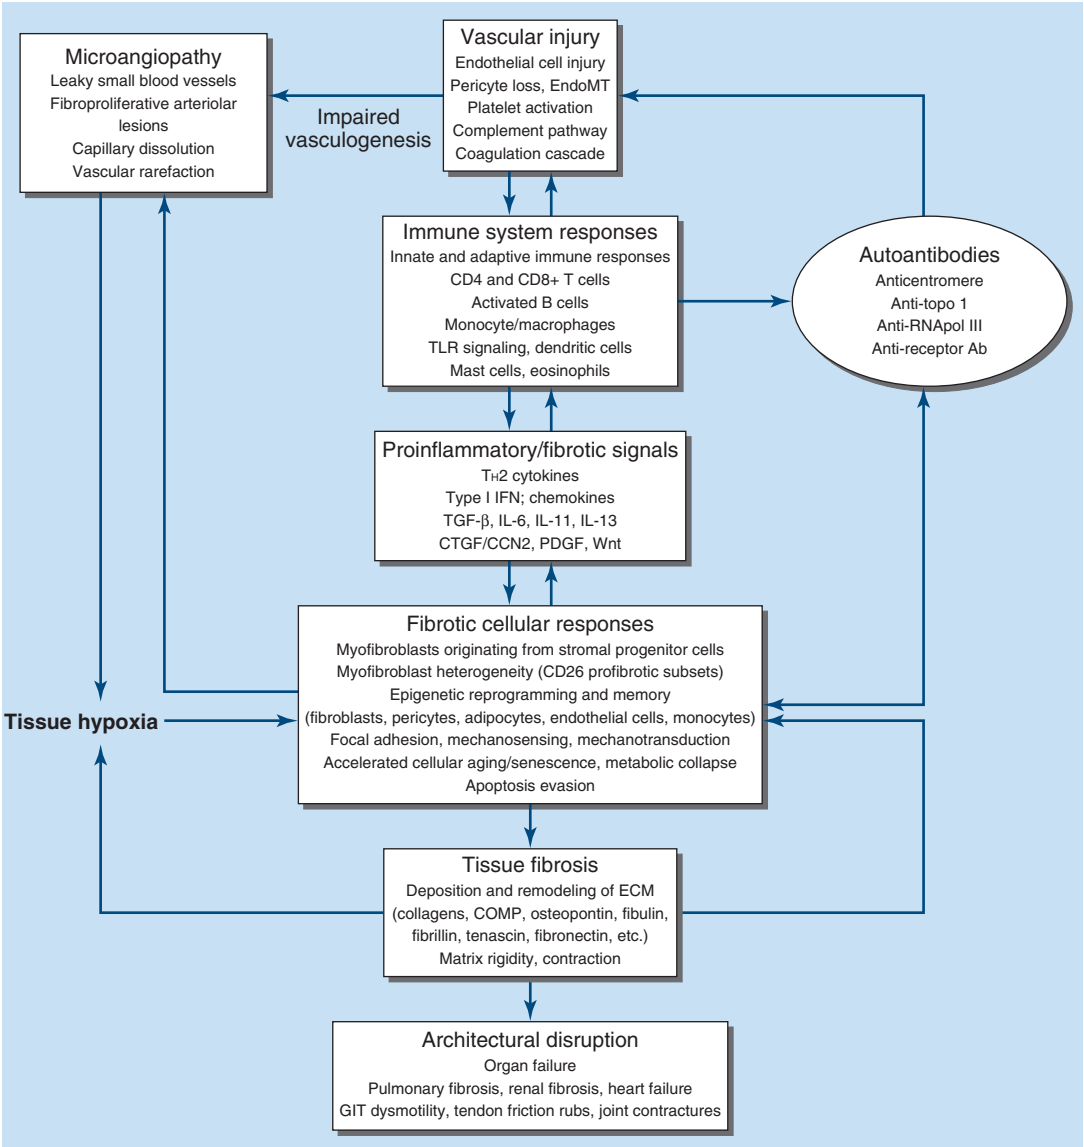

FIGURE 372-4 Integrated progressive model of systemic sclerosis (SSc) pathogenesis. Initial vascular insult in a genetically predisposed individual triggers a cascade of functional and structural vascular alterations associated with inflammation and autoimmunity. Early immune responses elicit fibroblast activation and differentiation, resulting in sustained and progressive fibrogenesis, irreversible tissue damage, and functional failure of affected organs. Vascular damage also leads to platelet activation, hypercoagulability, and tissue ischemia that further contributes to progressive fibrosis and atrophy. Ab, antibody; CTGF, connective tissue growth factor; ECM, extracellular matrix; EndoMT, endothelial-mesenchymal transition; GIT, gastrointestinal tract; IFN, interferon; IL, interleukin; PDGF, platelet-derived growth factor; TGF-β, transforming growth factor β; TLR, toll-like receptor.

that normally reestablishes blood flow to ischemic tissue is defective in SSc despite elevated levels of other angiogenic factors. Moreover, bone marrow–derived circulating endothelial progenitor cells are reduced in number and impaired in function.

There is increasing evidence implicating EndoMT in the pathogenesis of SSc vasculopathy. The process is characterized by transition of endothelial cells into myofibroblasts accompanied by loss of endothelial cell markers and nuclear localization of the transcription factor Snail1. In arterioles and small arteries, EndoMT leads to accumulation of endothelial cell–derived myofibroblasts in the intima and media, resulting in fibroproliferative vasculopathy and luminal occlusion. In contrast, EndoMT affecting the capillary vessels leads to a destructive vasculopathy characterized by loss of endothelial cells and accumulation of profibrotic interstitial myofibroblasts derived from endothelial cells, resulting in fibrosis and microvessel rarefaction, as can be observed by nailfold capillaroscopy. Widespread capillary loss combined with fibroproliferative vasculopathy affecting arterioles and arteries and impaired ability to repair and replace damaged vessels are hallmarks of SSc.

INFLAMMATION AND AUTOIMMUNITY

Cellular Immunity While the initial events triggering both innate and adaptive autoimmune responses in SSc are unknown, a number of observations support the inflammatory/autoimmune nature of SSc. These include the near-universal presence of circulating autoantibodies with defined specificities; clustering of SSc with other autoimmune diseases; activated immune cells, including autoreactive T cells with oligoclonal antigen receptors, within target organs; prominent type I interferon (IFN) signatures, characterized by elevated expression of IFN-regulated genes, in a variety of immune cell types in circulation and in skin biopsies; elevated circulating levels and spontaneous mononuclear cell secretion of cytokines such as IL-6, tumor necrosis factor α, IL-4, IL-10, IL-17, IL-33, and chemokines CCL2, CCL9, and CXCL4; genetic association of SSc (shared with other autoimmune diseases) with variants of MHC and other immune response genes; and the rapid clinical response, fibrosis resolution, and vascular regeneration observed in some SSc patients treated with immunomodulatory or immunoablative and chimeric antigen receptor (CAR) T-cell (CAR-T) therapies.

In early (edematous) stage SSc, mononuclear cell infiltrates composed of activated T cells, monocytes/macrophages, and dendritic cells can be detected in skin, lungs, and other affected organs even prior to fibrosis or vascular damage. Dendritic cells are professional antigen-presenting cells that bridge the adaptive and innate immune systems. They respond to injury by sensing tissue damage via their pattern recognition receptors such as Toll-like receptors (TLRs), NOD-like receptors (NLRs), and RIG-I like receptors. In SSc skin biopsies, dendritic cells located in close proximity to activated myofibroblasts express TLR8 and other endosomal TLRs that are activated by self-nucleic acids. TLR stimulation induces mediators including IFN, IL-10, and thymic stromal lymphopoietin (TSLP). A principal product secreted from SSc plasmacytoid dendritic cells is the atypical pleiotropic chemokine CXCL4, also known as platelet factor 4 (PAF). Produced in platelets and other cell types, CXCL4 is a short cationic peptide implicated in multiple autoimmune, inflammatory, and fibrotic diseases. In contrast to other chemokines that signal through G protein–coupled receptors on leukocytes, endothelial cells, and other target cells, CXCL4 can, independent of its receptor CXCR3, bind to extracellular self-nucleic acids and act as a chaperone to facilitate their cellular uptake and activation of endosomal TLRs. By inducing potent proinflammatory and antiangiogenic activities mediated via type 2 cytokines and IL-6, CXCL4 elicits a profibrotic monocyte phenotype and directly promotes myofibroblast differentiation from stromal progenitor cells. Levels of CXCL4 are elevated in the serum of patients with SSc and can predict future disease progression. In light of their crucial pathogenic roles in SSc, plasmacytoid dendritic cells and CXCL4 are potential therapeutic targets. Tissue-infiltrating T cells express CD45 and HLA-DR activation markers and display restricted T-cell receptor signatures indicative of oligoclonal expansion in response to recognition of as-yet-unknown antigen. Of note, in patients who are diagnosed with RNA polymerase III antibody–positive SSc in close temporal association with cancer, the tumor commonly harbors genomic alterations in RNApol3, which leads to the generation of autoantigen-specific T-cell immunity and cross-reactive antibodies.

Circulating T cells in SSc express chemokine receptors and α_1 integrin, accounting for their enhanced binding to endothelium and to fibroblasts, while endothelial cells express ICAM-1 and other adhesion molecules that facilitate leukocyte diapedesis. Activated T cells show a T_H2-polarized immune response driven by dendritic cells. The T_H2 cytokines IL-4, IL-13, IL-33, and TSLP induce fibroblast activation, whereas the T_H1 cytokine IFN-γ blocks cytokine-mediated fibroblast activation and exhibits antifibrotic properties. Alternately activated macrophages expressing CD163, which produce transforming growth factor (TGF)-β and promote angiogenesis and tissue remodeling, are increased in the skin and lung in SSc. Regulatory T cells (Tregs) enforce immune tolerance; although the frequency is elevated in the circulation and tissues in SSc patients, their immunosuppressive function appears to be defective. A recent report demonstrated that Tregs play a critical role in preventing spontaneous fibrosis in the skin and fascia, possibly by sequestering activated TGF-β. Studies implicate altered B-cell homeostasis and function in SSc. Circulating B cells show elevated CD19 and co-stimulatory molecules CD80 and CD86, suggesting B-cell chronic activation. Serum levels of proliferation-inducing ligand (APRIL) and B-cell activating factor (BAFF) are elevated in SSc and associated with extent of skin and lung involvement. In addition to autoantibodies, B cells also secrete IL-6, TGF-β, and other profibrotic cytokines implicated in pathogenesis. Thus, B-cell hyperactivity might directly contribute to the inflammatory and fibrotic processes in SSc, as well as generation of autoantibodies.

While polymorphonuclear leukocytes have not been extensively investigated in SSc, neutrophils can secrete fibrogenic TGF-β and IL-6, and release ROS; moreover, SSc neutrophils are prone to release extracellular traps that can trigger thrombotic and immune responses. Mast cells attracted into the fibrotic skin via plasminogen activator inhibitor (PAI-1) signaling from keratinocytes can release fibrogenic mediators including TGF-β. Moreover, mast cells can directly activate fibroblasts via serpine 1.

Humoral Autoimmunity Circulating antinuclear antibodies (ANAs) can be detected in virtually all patients with SSc, even in early and possibly preclinical stages of disease. In addition, several SSc-specific autoantibodies with distinct patterns of immunofluorescence show strong associations with unique disease phenotypes as well as HLA haplotype (Table 372-4). Owing to their exquisite specificity, mutual exclusivity, and association with distinct disease manifestations, SSc-associated autoantibodies have clinical utility for diagnosis and risk stratification. Recently, circulating antibodies directed against fibrillin-1, matrix metalloproteinases, cell surface markers, and stimulatory antibodies to angiotensin II receptor, endothelin-1 receptor, or the PDGF receptor have been identified in patients with SSc, although their clinical relevance is not yet established. These functional antibodies show receptor agonist activity in a variety of cell types and might have direct pathogenic roles.

A variety of mechanisms have been proposed to account for the generation of SSc-associated autoantibodies. Proteolytic cleavage, increased expression or altered subcellular localization of normal proteins, or their alterations due to mutation in the case of certain tumors could lead to their immune recognition as neoepitopes, resulting in break of immune tolerance.

FIBROSIS

Fibrosis synchronously affecting multiple organs is a distinguishing feature of SSc. The process is characterized by replacement of normal tissue architecture with rigid, avascular, and relatively acellular connective tissue. Fibrosis in SSc follows, and is a consequence of, inflammation and microvascular damage (Fig. 372-4). Fibroblasts are mesenchymal cells primarily responsible for the functional and structural integrity of connective tissue. Upon their activation by extracellular or mechanical

TABLE 372-4 Major Systemic Sclerosis (SSc)-Specific Autoantibodies and Principal Associated Features

TARGET ANTIGEN; CHARACTERISTIC IMMUNOFLUORESCENCE PATTERN	—	SSc SUBSET	PROMINENT CHARACTERISTIC CLINICAL ASSOCIATION
Topoisomerase I (Scl-70) Speckled pattern	—	dcSSc	Tendon friction rubs, digital ischemic ulcers, extensive skin involvement, early-onset ILD, cardiac involvement, scleroderma renal crisis
Centromere proteins Discreet speckled (centromere) pattern	—	lcSSc	Digital ischemic ulcers, calcinosis cutis, isolated PAH; renal crisis rare
RNA polymerase III Speckled pattern	—	dcSSc	Rapidly progressive skin involvement, tendon friction rubs, joint contractures, GAVE, renal crisis, contemporaneous cancers; digital ulcers rare
U3-RNP (fibrillarin) Nucleolar pattern	—	dc/lcSSc	PAH, ILD, scleroderma renal crisis, gastrointestinal tract involvement, myositis

cues, fibroblasts proliferate; migrate; secrete collagens and other extracellular matrix molecules, growth factors, chemokines, and cytokines; and transdifferentiate into contractile myofibroblasts with prominent cytoskeletal stress fibers. Under normal conditions, these are responses self-limited to accomplish proper (adaptive) tissue repair and regeneration. In contrast, when these responses become sustained and amplified (maladaptive repair), pathologic fibrosis results. A panoply of stimulatory signals are potentially implicated in SSc pathogenesis. In addition to TGF-β, which plays a central role in fibrogenesis, mediating fibrosis in SSc are soluble mediators including IL-6, IL-11, IL-13, and IL-23; the chemokine CXCL4; morphogens and Wnt ligands; connective tissue growth factor (CTGF); PDGF; lysophosphatidic acid; and endothelin. Moreover, hypoxia, ROS, thrombin, and mechanical forces might also contribute to sustained fibroblast activation underlying maladaptive repair in SSc. Damage-associated endogenous ligands for the innate immune receptor TLR4, such as the extracellular matrix–associated macromolecules EDA-fibronectin and tenascin-C, HMGB1, and endogenous ligands for TLR8 and TLR9 (mitochondrial DNA and other self-nucleic acids), further contribute to nonresolving fibrosis via unchecked TLR-mediated fibroblast activation and innate immune signaling.

In addition to tissue-resident fibroblasts and transformed myofibroblasts, bone marrow–derived circulating mesenchymal progenitor cells also contribute to fibrosis. The factors that regulate the differentiation of circulating mesenchymal progenitor cells and their trafficking into lesional tissue are unknown. Endothelial cells in injured arterioles and small arteries undergo EndoMT, giving rise to myofibroblasts that drive perivascular fibrosis. Studies also demonstrate that intradermal and subcutaneous mesenchymal stem cells and mature adipocytes can undergo transdifferentiation into myofibroblasts in the skin. This process of adipocyte-mesenchymal transition could explain the attenuation of subcutaneous white adipose tissue characteristic of fibrotic skin in SSc patients and in mouse models of the disease. Epithelial cells and tissue fibroblasts are all putative sources of pathogenic myofibroblasts. Although myofibroblasts are transiently found in normal wound healing, their persistence in fibrotic tissue, possibly due to their ability to evade apoptosis via upregulation of the antiapoptotic protein BCL-X_L, contributes to scar formation.

Explanted SSc fibroblasts display an abnormally activated phenotype ex vivo, characterized by increased collagen production, spontaneous ROS generation, shortening of their primary (nonmotile) cilia, prominent stress fibers, and constitutive expression of alpha smooth-muscle actin. Persistence of the "scleroderma phenotype" during serial ex vivo passage of SSc fibroblasts may reflect autocrine TGF-β stimulatory loops, deregulated microRNA expressions, cell-autonomous metabolic changes, or stable acquired epigenetic modifications. Single-cell RNA sequencing of SSc skin biopsies has revealed marked functional heterogeneity and diverse cell states across fibroblasts.

PATHOLOGY

While pathologic findings vary across anatomic sites, the distinguishing hallmark of SSc irrespective of the organ system is widespread microangiopathy (fibroproliferative vasculopathy) capillary loss and obliteration, combined with fibrosis. In early-stage disease, perivascular inflammatory cell infiltrates composed of T and B lymphocytes, activated monocytes and macrophages, and mast cells may be detected as distinct cellular niches in multiple organs. A noninflammatory obliterative microangiopathy in the heart, lungs, kidneys, and gastrointestinal tract is a prominent late finding. Fibrosis most prominently affects the skin, lungs, cardiovascular system, gastrointestinal tract, tendon sheaths, perifascicular tissue surrounding skeletal muscle, and some endocrine organs such as the thyroid gland.

SKIN

In the skin, the dermis is thickened due to accumulation of broad bundles of homogenized collagen oriented parallel to the epithelium (Fig. 372-5*A*). Adnexal glands are atrophic, and loss of periadnexal and intradermal white adipose tissue and its replacement with collagen can be striking. While perivascular mononuclear cell infiltrates may be seen early, established skin fibrosis shows absence of inflammation.

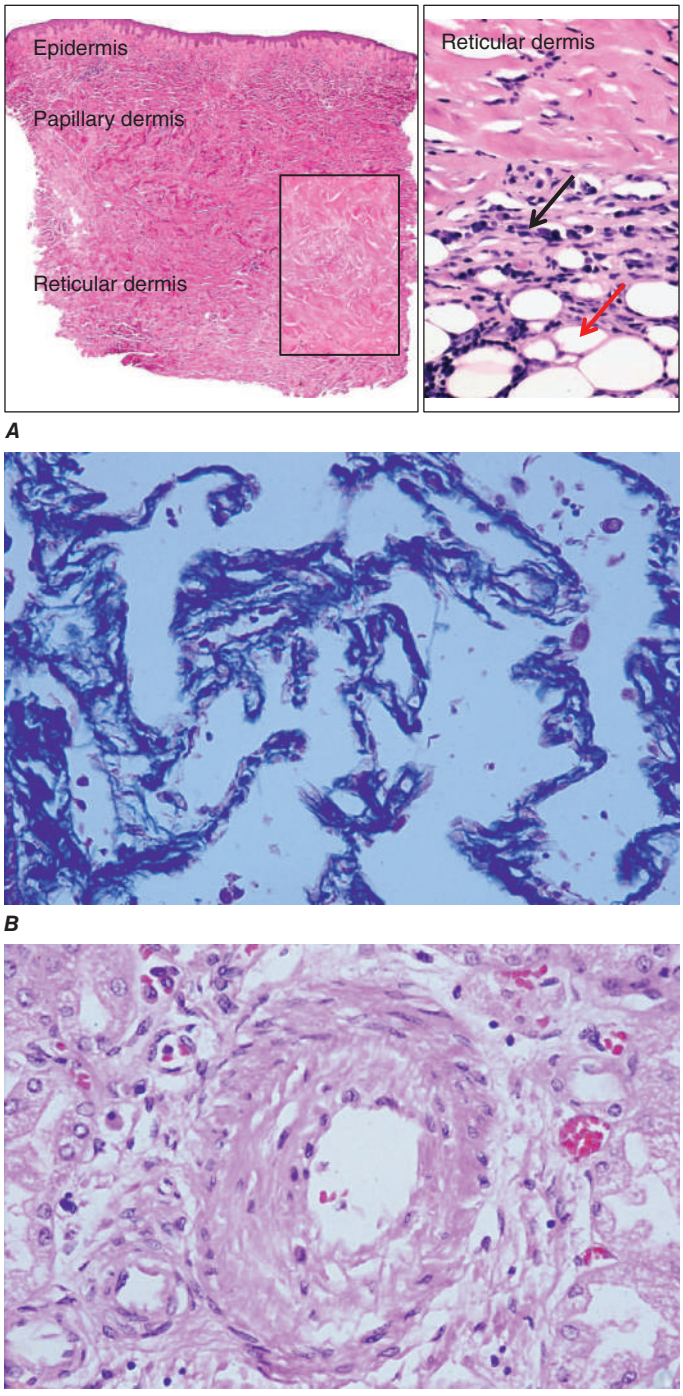

FIGURE 372-5 Pathologic findings in multiple organs in systemic sclerosis (SSc). ***A. Left panel:*** Skin is thickened due to fibrotic expansion of the dermis. Inset, higher magnification showing thick hyalinized collagen bundles replacing skin appendages. ***Right panel:*** Mononuclear inflammatory cells within the dermis and intradermal adipose tissue (indicated by *arrow*). ***B.*** Early SSc interstitial lung disease. Diffuse fibrosis of the alveolar septae and chronic inflammatory cell infiltrates. Trichrome stain. ***C.*** Pulmonary artery obliterative vasculopathy. Striking intimal and medial hyperplasia and luminal narrowing of small artery, with sparse inflammation and minimal interstitial lung fibrosis, in a patient with SSc pulmonary arterial hypertension.

LUNGS

Autopsy studies universally show evidence of lung involvement in both limited and diffuse cutaneous subsets of SSc. Most common is nonspecific interstitial pneumonia (NSIP) pattern characterized by variable interstitial fibrosis and mild chronic inflammation with

T lymphocytes, macrophages, and eosinophils. With progression, interstitial fibrosis and vascular damage dominate, often coexisting within the same biopsy. The usual interstitial pneumonia (UIP) pattern of spatial and temporal heterogeneity of inflammation and fibrosis and fibrotic foci, a hallmark of idiopathic pulmonary fibrosis, is less common in SSc (**Fig. 372-5*B***). Fibrosis of the alveolar septae results in obliteration of the airspaces and loss of pulmonary blood vessels. This process impairs gas exchange and contributes to pulmonary hypertension. Intimal thickening of the pulmonary arteries, best seen with elastin stain, underlies SSc-associated PAH (**Fig. 372-5*C***) and, at autopsy, is often associated with pulmonary emboli and myocardial fibrosis. Patients with SSc-associated PAH also show fibrosis and intimal proliferation in preseptal venules and veins in the lung, accounting for venoocclusive disease. Lymphocytic bronchiolitis involving the submucosa of the terminal bronchioles is occasionally seen.

GASTROINTESTINAL TRACT

Pathologic changes can be found at any level from the mouth to the rectum. Atrophy and fibrosis of the muscularis propria and characteristic vascular lesions are prominent in the lower esophagus, while striated muscle in the upper third of the esophagus is generally spared. Collagenous replacement of the intestinal tract architecture results in impaired smooth-muscle contractility and diminished peristaltic activity, underlying gut dysmotility, bacterial overgrowth, small-bowel pseudo-obstruction, and perforation.

KIDNEYS

In the kidneys, vascular lesions affecting the interlobular and arcuate arteries predominate. Chronic renal ischemia is associated with shrunken glomeruli. Patients with scleroderma renal crisis, a life-threatening acute complication of SSc, show acute fibrinoid necrosis of afferent arterioles, followed by intimal proliferation (onion-skin pattern) and ischemic collapse of glomeruli. These changes are reminiscent of thrombotic microangiopathies such as atypical hemolytic-uremic syndrome (**Chaps. 105 and 120**) and are accompanied by thrombosis, thrombocytopenia due to platelet consumption, and intravascular hemolysis. Evidence of complement activation may be seen in kidney biopsies. Extensive vascular thrombosis, glomerular collapse, and peritubular capillary deposits predict irreversible renal failure.

HEART

Subclinical cardiac pathology is common in SSc and may affect the myocardium and pericardium. The characteristic arteriolar lesions in the heart are concentric intimal hypertrophy and luminal narrowing, patchy contraction band necrosis, loss of cardiac myocytes, and myocardial fibrosis due to microvascular involvement and ischemia-reperfusion injury. Fibrosis of the conduction system is also common, especially at the sinoatrial node. The frequency of epicardial atherosclerotic coronary artery disease may be increased in SSc compared to the general population, similar to other systemic inflammatory diseases. Pericardial involvement with chronic inflammatory infiltrates and fibrinous exudates is common and is sometimes associated with pericardial effusions.

PATHOLOGY IN OTHER ORGANS

Synovitis of the hands may occur in SSc; with disease progression, the synovium becomes fibrotic, and in contrast to rheumatoid disease, pannus formation or bone resorption (distinct from acro-osteolysis) is uncommon. Fibrosis of tendon sheaths and fascia, sometimes accompanied by calcifications, produces palpable and sometimes audible tendon friction rubs. Inflammation and, in later stages, atrophy and fibrosis of skeletal muscles are common findings and are similar to those in polymyositis. Fibrosis of the thyroid and of the minor salivary glands may be seen and underlie hypothyroidism and the sicca syndrome. Placentas from SSc pregnancies show decidual vasculopathy, which is associated with poor perinatal outcomes and fetal death.

TABLE 372-5 Frequency of Clinical Organ Involvement in Limited Cutaneous and Diffuse Cutaneous Systemic Sclerosis (SSc)

CLINICAL FEATURES	LIMITED CUTANEOUS SSc (%)	DIFFUSE CUTANEOUS SSc (%)
Skin involvement	90[a]	100
Raynaud's phenomenon	99	98
Ischemic digital ulcers	50	25
Esophageal involvement	90	80
Interstitial lung disease	35	65
Pulmonary arterial hypertension	15	15
Myopathy	11	23
Clinical cardiac involvement	9	12
Scleroderma renal crisis	2	10-15
Calcinosis cutis	30	50

[a]Approximately 10% of SSc patients have SSc sine scleroderma.

CLINICAL FEATURES

OVERVIEW

SSc is truly a systemic disease that can affect virtually any organ (Fig 372-1 and **Table 372-5**). Although a dichotomous stratification of patients into diffuse and limited cutaneous subsets (Table 372-2) is useful and used widely in clinical practice, SSc is in fact far more complex, and multiple distinct clusters or endophenotypes of SSc with characteristic manifestations and trajectories and outcomes can be recognized within each subset. Unique endophenotypes are associated with autoantibodies with distinct and mutually exclusive specificities (Table 372-4). Moreover, patients with "overlap" have typical features of SSc coexisting with clinical and laboratory evidence of another autoimmune disease, most commonly polymyositis, Sjögren's syndrome, polyarthritis, autoimmune liver disease, or SLE.

INITIAL CLINICAL PRESENTATION

Characteristic initial presentation is quite different in patients with the diffuse (dcSSc) versus limited (lcSSc) cutaneous forms of the disease. In dcSSc, the interval between Raynaud's phenomenon and subsequent onset of other disease manifestations is typically brief (weeks to months). Soft tissue swelling, puffy fingers, and pruritus are signs of the early inflammatory "edematous" phase. The fingers, distal limbs, and face are usually affected first. Diffuse hyperpigmentation of the skin, carpal tunnel syndrome, arthralgias, muscle weakness, fatigue, and decreased joint mobility are common. During the ensuing weeks to months, the inflammatory edematous phase evolves into the "fibrotic" phase, with skin induration associated with hair loss, reduced production of skin oils, and decline in sweating capacity. Progressive flexion contractures of the fingers ensue. The wrists, elbows, knees, and ankles become stiff due to fibrosis of the supporting joint structures. While proximally advancing skin involvement is the most visible manifestation of early dcSSc, important and clinically silent internal organ involvement can occur during this stage. The initial 4 years from disease onset is the period of most rapidly evolving and potentially irreversible lung and renal damage. If organ failure does not occur during this phase of dcSSc, the systemic process may plateau and stabilize. Increasingly recognized is an early stage of the disease, termed *very early diagnosis of SSc* (VEDOSS). These patients have puffy fingers, Raynaud's phenomenon, and SSc-specific autoantibodies and generally show progression to frank disease.

Compared to dcSSc, the course of lcSSc tends to be more indolent. The interval between onset of Raynaud's phenomenon and disease manifestations such as gastroesophageal reflux disease (GERD), cutaneous telangiectasia, ischemic digital ulcers, or soft tissue calcifications can be as long as years. Scleroderma renal crisis, significant ILD, and tendon friction rubs occur rarely in lcSSc, whereas PAH and overlap with keratoconjunctivitis sicca, polyarthritis, cutaneous vasculitis, and biliary cirrhosis can develop, even many years after disease onset.

ORGAN INVOLVEMENT

RAYNAUD'S PHENOMENON

Raynaud's phenomenon (also called secondary Raynaud's), the most frequent extracutaneous complication of SSc, is characterized by episodic vasoconstriction in the fingers and toes, sometimes also affecting the tip of the nose and earlobes. These attacks are typically self-limited and fully reversible, can be triggered by a decrease in temperature as well as emotional stress and vibration, and commonly start with pallor of the fingers, followed by cyanosis of variable duration. Hyperemia ensues spontaneously or with rewarming of the digit. The characteristic temporal progression of the three-color phases reflects the underlying vasoconstriction in arteriovenous anastomoses involved in thermoregulation, followed by ischemia and reperfusion. It is important to note that up to 5% of the general population has Raynaud's phenomenon. Recent GWAS revealed a robust link of Raynaud's with the *ADRA2A* gene, implicating deregulated α-adrenergic signaling in pathogenesis. Secondary Raynaud's occurs in SSc and other connective tissue diseases, as well as hematologic and endocrine conditions and occupational disorders, and can complicate treatment with beta blockers and anticancer drugs such as cisplatin and bleomycin. Distinguishing primary Raynaud's disease from secondary Raynaud's phenomenon can present a diagnostic challenge. Raynaud's disease is supported by the following: absence of an underlying cause; a family history of Raynaud's phenomenon; absence of digital tissue necrosis or ulceration; and a negative ANA test. Secondary Raynaud's phenomenon tends to occur at an older age, is more severe (episodes more frequent, prolonged, and painful), and is frequently complicated by ischemic digital ulcers and loss of digits **(Fig. 372-6)**.

Nailfold capillaroscopy using a low-power stereoscopic microscope or ophthalmoscope permits visualization of nailbed cutaneous capillaries under immersion oil **(Fig. 372-7)**. Raynaud's disease is associated with evenly spaced parallel vascular loops, whereas in secondary Raynaud's phenomenon, nailfold capillaries are distorted with widened and irregular loops, dilated lumen, microhemorrhages, and areas of vascular "dropout." Thus, nailfold capillaroscopy can be helpful for both differentiating primary from secondary Raynaud's phenomenon and for establishing the early diagnosis of SSc.

SKIN FEATURES

Bilateral symmetrical skin thickening is the hallmark that distinguishes SSc from other connective tissue diseases. Skin involvement starts in the fingers and characteristically advances from distal to proximal extremities in an ascending fashion. Some patients note diffuse tanning in the absence of sun exposure as a very early manifestation. In dark-skinned individuals, vitiligo-like hypopigmentation may occur. Pigment loss sparing the perifollicular areas gives rise to a "salt-and-pepper" appearance of the skin, most prominently on the scalp, upper back, and chest. Dermal sclerosis obliterating hair follicles, sweat glands, and eccrine and sebaceous glands causes hair loss, decreased sweating, and xerosis and itching in affected areas of the skin. Transverse creases on the dorsum of the fingers disappear **(Fig. 372-8)**. Fixed flexion contractures of the fingers cause reduced hand mobility and lead to muscle atrophy. Skin and subjacent tendon fibrosis accounts for fixed contractures of the wrists, elbows, and knees. Thick ridges at the neck due to firm adherence of skin to the underlying platysma muscle interfere with neck extension.

Patients with established SSc may show a characteristic "mauskopf" facial appearance with taut and shiny skin and occasionally an expressionless facies due to reduced mobility of the eyelids, cheeks, and mouth. Thinning of the lips with accentuation of the central incisor teeth and prominent perioral radial furrowing (rhytides) complete the picture. Reduced oral aperture (microstomia) interferes with eating and oral hygiene. The nose assumes a pinched, beak-like appearance. In late-stage disease, the skin becomes thin and atrophic and is firmly bound to the subcutaneous fat (tethering). Dilated skin capillaries 2–20 mm in diameter (telangiectasia), reminiscent of hereditary hemorrhagic telangiectasia, are frequently on the face, hands, lips, and oral

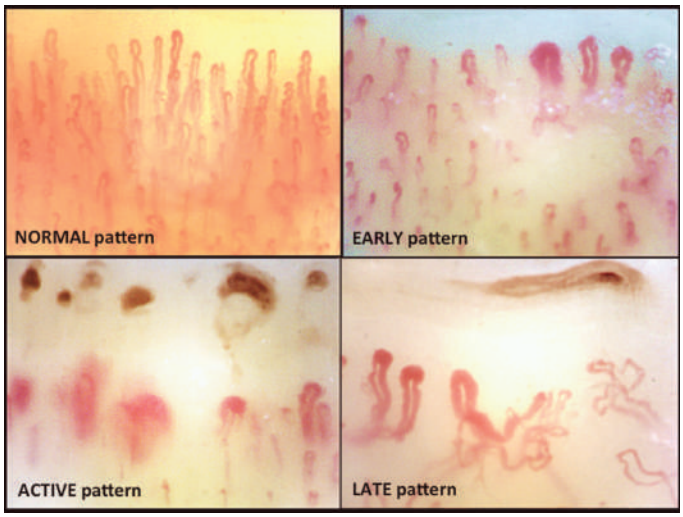

FIGURE 372-7 Systemic sclerosis–associated nailfold capillary alterations. In healthy subjects (normal pattern), note regularly arrayed and uniform-size "hairpin" microvessels. In early pattern, note dilations and symmetrically increased microvessels (giant capillaries). In active pattern, note giant capillaries, collapse with microhemorrhages, and loss of capillaries. In late pattern, note massive loss of capillaries, fibrosis, and neoangiogenesis with secondary dilations (nailfold videocapillaroscopy; magnification 220×). *(Courtesy Professor Maurizio Cutolo, University of Genoa, Italy.)*

B

FIGURE 372-9 Cutaneous vascular changes in systemic sclerosis. ***A.*** Vascular changes at the finger nailfold in a patient with limited cutaneous systemic sclerosis (lcSSc). ***B.*** Telangiectasia on the face.

mucosa **(Fig. 372-9)**. The number of telangiectasias correlates with the severity of microvascular disease, including PAH. Breakdown of atrophic skin leads to chronic ulcerations at the extensor surfaces of the proximal interphalangeal joints, the volar pads of the fingertips, and bony prominences such as elbows and malleoli. Ulcers are often painful, heal slowly, and become secondarily infected, resulting in osteomyelitis. Healing of ischemic fingertip ulcerations leaves characteristic fixed digital "pits." Loss of soft tissue at the fingertips due to ischemia may be associated with striking resorption of the terminal phalanges (acro-osteolysis) **(Fig. 372-10)**.

Dystrophic calcifications in the skin and subcutaneous and soft tissues (calcinosis cutis) in the presence of normal serum calcium and phosphate levels occur in up to 40% of patients, most commonly in those with long-standing anti-centromere antibody–positive lcSSc. Calcific deposits, composed of calcium hydroxyapatite crystals, vary in size from tiny punctate lesions to large conglomerate masses and can be readily visualized on plain radiographs or dual-energy computed tomography (CT) imaging. These deposits occur when calcium precipitates in tissue damaged by inflammation, hypoxia, or local trauma. Common locations include the finger pads, palms, extensor surfaces of the forearms, and the olecranon and prepatellar bursae **(Fig. 372-11)**. Large calcific deposits can cause pain and nerve compression and may ulcerate through the overlying skin with drainage of chalky white material and secondary infections. Paraspinal sheet calcifications may cause neurologic complications.

PULMONARY FEATURES

The two principal forms of lung involvement in SSc, ILD and pulmonary vascular disease, are frequent and together account for a majority

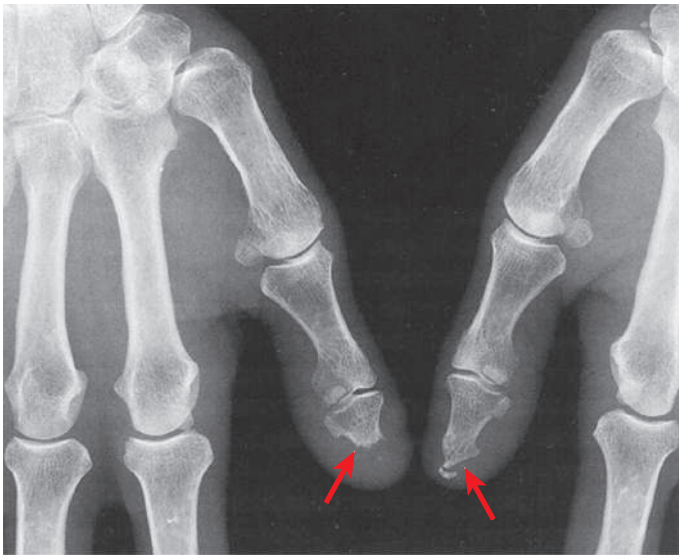

FIGURE 372-10 Acro-osteolysis. Note dissolution of distal terminal phalanges *(arrows)*. Acro-osteolysis is associated with digital ischemia and is seen in patients with long-standing limited cutaneous systemic sclerosis (lcSSc) and Raynaud's phenomenon.

of SSc-related deaths. Survival is particularly poor in SSc patients with concurrent presence of these two processes. Less common pulmonary complications of SSc include aspiration pneumonitis associated with chronic gastroesophageal reflux, pulmonary hemorrhage due to endobronchial telangiectasia, obliterative bronchiolitis, pleural reactions, restrictive physiology due to chest wall fibrosis, spontaneous pneumothorax, and drug-induced lung toxicity. The incidence of lung cancer is increased in SSc.

Interstitial Lung Disease While evidence of ILD can be found in up to 65% of SSc patients by high-resolution CT (HRCT), clinically significant ILD develops in 16–43%; the frequency varies depending on the detection method used. Risk factors for significant ILD include male sex, African-American race, diffuse skin involvement, severe gastroesophageal reflux, and presence of topoisomerase I autoantibodies, whereas SSc patients who are anti-centromere antibody–positive have a lower risk of ILD. Additional risk factors for significant ILD include low forced vital capacity (FVC) or single-breath diffusing capacity of the lung for carbon monoxide (D_{LCO}) at initial presentation. Esophageal dilatation with chronic acid reflux, common in SSc, causes recurrent microaspiration, which is a risk factor for development and progression of ILD. The most rapid progression in ILD generally occurs early in the disease course (within the first 3–5 years), when the FVC can decline by 30% per year. In contrast, new offset of ILD is rare in SSc patients with long-standing disease.

Pulmonary involvement may remain asymptomatic until it is advanced. The most common presenting respiratory symptoms—exertional dyspnea, fatigue, and reduced exercise tolerance—are subtle and slowly progressive. A chronic dry cough may be present. Physical examination may reveal fine inspiratory "Velcro" crackles at the lung bases. Pulmonary function testing (PFT) is relatively insensitive for detecting early pulmonary involvement, although it is central for monitoring its course. In patients with established SSc-ILD, PFT typically shows a restrictive ventilatory defect (FVC <70% predicted and/or forced expiratory volume in 1 s [FEV_1]/FVC ratio >0.8 and reduced total lung capacity [TLC] and D_{LCO}). A reduction in D_{LCO} that is significantly out of proportion to the reduction in lung volumes should raise suspicion for pulmonary vascular disease but may also be due to anemia. Oxygen desaturation with exercise is common.

Chest radiography can be used to rule out infection and other causes of respiratory symptoms in SSc, but compared to HRCT, it is relatively insensitive for detection of early ILD. Characteristic imaging findings include bilateral lower lobe subpleural reticular linear opacities and ground-glass opacifications with an apicobasal gradient,

even in asymptomatic patients with normal PFTs **(Fig. 372-12)**. Additional HRCT findings include mediastinal lymphadenopathy, pulmonary nodules, traction bronchiectasis, and uncommonly, honeycomb changes. The extent of interstitial changes on chest HRCT at baseline is a predictor of ILD progression and mortality. While bronchoalveolar lavage (BAL) can demonstrate inflammatory cells in the lower respiratory tract and may be useful for ruling out tuberculosis and other infections, it has limited utility for SSc diagnosis or for identifying reversible alveolitis. Surgical lung biopsy in SSc is indicated only in patients with atypical findings on chest imaging. The histologic pattern on lung biopsy may predict the risk of progression of ILD, with the NSIP pattern having a better prognosis than UIP.

Pulmonary Arterial Hypertension (PAH) PAH results from vascular remodeling of small (<500 μm) pulmonary arteries. PAH develops in 8–12% of patients with SSc as a late complication and can be an isolated abnormality or associated with ILD. PAH is defined as a mean pulmonary artery pressure (mPAP) >20 mmHg with a pulmonary capillary wedge pressure ≤15 mmHg and pulmonary vascular resistance >2.0 Wood units. The natural history of SSc-associated PAH is variable but often follows a progressive course leading to right heart failure. The 3-year survival of SSc patients with untreated PAH is <50%. Risk factors include limited cutaneous disease, older age at disease onset, high numbers of cutaneous telangiectasia, and antibodies to centromere, U3-RNP (fibrillarin), and B23. Mutations in the *BMPR2* gene implicated in idiopathic PAH are not associated with SSc-PAH.

In SSc, PAH is often asymptomatic in early stages. Patients present with exertional dyspnea and reduced exercise capacity. With progression, angina, near-syncope, and symptoms and signs of right-sided heart failure appear. Physical examination may show tachypnea, a loud pulmonic component of the S_2 heart sound, pulmonic/tricuspid regurgitation murmur, palpable right ventricular heave, elevated jugular venous pressure, and dependent edema. Doppler echocardiography is a noninvasive screening method for estimating the pulmonary arterial pressure. In light of the poor prognosis of untreated PAH and better therapeutic response in patients with early diagnosis, SSc patients should be screened for PAH at initial evaluation and annually thereafter. Estimated pulmonary artery systolic pressure >40 mmHg at rest or tricuspid regurgitation jet velocities >3 m/s suggest PAH. PFT may show a reduced DL_{CO} in isolation or out of proportion with the severity of restriction. Because echocardiography can over- or underestimate pulmonary artery pressures, cardiac catheterization is required to confirm the diagnosis of suspected PAH; assess its severity, including the degree of right heart dysfunction; rule out venoocclusive disease and other cardiac (postcapillary) causes of pulmonary hypertension; and provide prognostic parameters. Distinguishing PAH in SSc patients from pulmonary hypertension secondary to pulmonary fibrosis and hypoxia can be difficult. Serum levels of N-terminal pro-brain natriuretic peptide (NT-proBNP) correlate with the presence and severity of PAH, as well as survival. While NT-proBNP can be useful in PAH screening and in monitoring the response to treatment, elevated levels are not specific for PAH and also occur in other forms of right and left heart disease. Despite more favorable hemodynamics of SSc-associated PAH, its prognosis is worse, and treatment response poorer, than idiopathic PAH. This is most likely due to frequent concurrence of ILD and cardiac involvement in SSc patients.

GASTROINTESTINAL INVOLVEMENT

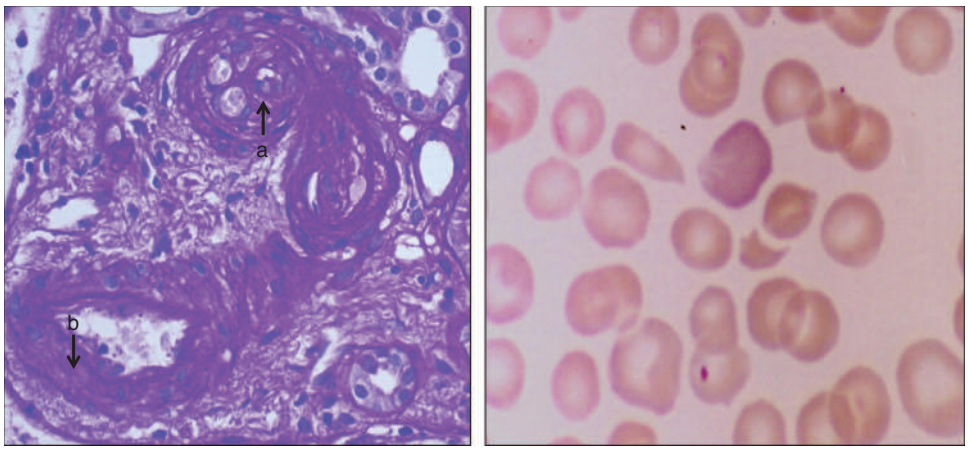
Variable involvement of the gastrointestinal (GI) tract, which can affect any level, is the most common internal organ manifestation of

TABLE 372-6 Prominent Gastrointestinal Manifestations of Systemic Sclerosis (SSc) and Their Management

SITE IN GASTROINTESTINAL TRACT	PRINCIPAL MANIFESTATION	MANAGEMENT
Oropharynx	Diminished oral aperture Dry mouth Periodontitis, gingivitis Swallowing	Periodontal care Artificial saliva Swallowing therapy
Esophagus	Reflux Dysphagia Strictures Barrett's metaplasia	Lifestyle modifications, Prokinetic drugs Proton pump inhibitors Endoscopic procedures
Stomach	Gastroparesis Gastric antral vascular ectasia (GAVE; watermelon stomach)	Prokinetic agents Endoscopic laser cryotherapy
Small and large intestines	Bacterial overgrowth (small intestinal bacterial overgrowth) Diarrhea/constipation Pseudo-obstruction Pneumatosis intestinalis Malabsorption Colonic pseudo-diverticula	Laxatives Prokinetic agents Rotating antibiotics Octreotide Parenteral nutritional support
Anorectum	Sphincter incompetence	Biofeedback, sacral nerve stimulation, surgery

SSc, seen in up to 90% of SSc patients with both limited and diffuse cutaneous disease (Table 372-6). Severe GI tract involvement is associated with male sex and specific autoantibodies. Pathologic findings of GI involvement in SSc include fibrosis, smooth-muscle atrophy, and obliterative small-vessel vasculopathy throughout the length of the GI tract. Together, they have a major impact on quality of life, malnutrition, and mortality.

Upper GI Tract Involvement Decreased oral aperture interferes with regular dental hygiene. Loss of periodontal ligament attaching teeth to the alveolar bone leads to teeth loosening. Additional oropharyngeal manifestations due to a combination of xerostomia, shortened frenulum, and resorption of the mandibular condyles cause much distress. Most SSc patients show symptoms of GERD: heartburn, regurgitation, and dysphagia, due to a combination of reduced lower esophageal sphincter pressure resulting in reflux, impaired esophageal clearance of refluxed gastric contents due to diminished motility, and delayed gastric emptying. Calcium channel antagonists and phosphodiesterase inhibitors commonly used to treat Raynaud's phenomenon in SSc can further aggravate reflux. Esophageal manometry shows abnormal motility in most patients, even in the absence of symptoms. Common extraesophageal GERD manifestations in SSc include hoarseness, cough, and chronic or recurrent microaspiration, which can aggravate underlying ILD. Characteristic chest CT findings include dilated patulous esophagus with intraluminal air. Esophageal dilation is associated with the severity of interstitial lung disease. Endoscopy may be indicated in patients with dysphagia in order to rule out opportunistic infections with *Candida*, herpes virus, and cytomegalovirus. Severe erosive esophagitis may be found in patients with minimal symptoms. Esophageal strictures and Barrett's esophagus may complicate chronic GERD in SSc patients. Because Barrett's metaplasia is associated with increased risk of adenocarcinoma, these patients require regular surveillance endoscopy with biopsy.



Gastroparesis with early satiety, abdominal distention, and aggravated reflux symptoms is common. Barium contrast studies are neither sensitive nor specific for evaluation of gastric involvement in SSc. Gastric antral vascular ectasia (GAVE) in the antrum may occur. These subepithelial lesions, reflecting the widespread small-vessel vasculopathy of SSc, are called "watermelon stomach" due to their endoscopic appearance. GAVE may present with acute life-threatening or recurrent episodes of GI bleeding, resulting in chronic unexplained iron-deficiency anemia. Patients with SSc show increased prevalence of *Helicobacter pylori* infection in the stomach.

Lower GI Tract and Anorectal Involvement Weight loss and malnutrition due to a combination of impaired intestinal motility, malabsorption, and chronic diarrhea secondary to bacterial overgrowth are common. Fat and protein malabsorption as well as vitamin B_{12} and vitamin D deficiency ensue and may be further exacerbated by pancreatic insufficiency. Disturbed intestinal motor function associated with delayed colonic transit may present with intestinal pseudo-obstruction. Patients present with acute abdominal pain, nausea, and vomiting, and radiographic studies show acute intestinal obstruction. A major diagnostic challenge is differentiating pseudo-obstruction, which often responds to supportive care and intravenous nutritional supplementation, from mechanical obstruction. Colonic involvement in SSc may cause constipation, occasionally complicated by sigmoid volvulus. Anorectal dysfunction commonly presents with fecal incontinence. GI bleeding can result from telangiectasia and rectal prolapse. In late-stage SSc, wide-mouth sacculations or diverticula occur in the colon and occasionally cause perforation and bleeding. An unusual radiologic finding is pneumatosis cystoides intestinalis, which is due to air trapping in the bowel wall that may rarely rupture and cause benign pneumoperitoneum. Studies of the fecal microbiota in SSc show a reduction in protective butyrate-producing bacteria, potentially promoting a proinflammatory intestinal microenvironment. Although the liver is rarely affected in patients with SSc, primary biliary cirrhosis may occur, particularly in patients with limited cutaneous disease.

RENAL INVOLVEMENT: SCLERODERMA RENAL CRISIS

Scleroderma renal crisis presents with accelerated hypertension accompanied by acute kidney injury and progressive failure. This acute life-threatening complication occurs in <15% of SSc patients, almost always within 4 years of disease onset. Scleroderma renal crisis can occasionally even be the presenting manifestation of SSc. While short-term survival in scleroderma renal crisis was <10% prior to the advent of angiotensin-converting enzyme (ACE) inhibitors, outcomes for this serous complication have shown great improvement. The pathogenesis involves obliterative vasculopathy of the renal arcuate and interlobular arteries, with consequent intravascular hemolysis (Fig. 372-13). Progressive reduction in renal blood flow, aggravated by vasospasm, leads to increased juxtaglomerular renin secretion and angiotensin II generation, with further renal vasoconstriction resulting in a vicious cycle that culminates in accelerated hypertension. Risk factors for scleroderma renal crisis include African-American race, male sex, and diffuse or progressive skin involvement. Up to 50% of patients with scleroderma renal crisis have antibodies to anti-RNA polymerase III, whereas patients with anti-centromere antibodies appear protected. Palpable tendon friction rubs, pericardial effusion, new unexplained anemia, and thrombocytopenia may be harbingers of impending scleroderma renal crisis. High-risk patients with early-stage SSc should monitor their blood pressure daily. Because glucocorticoid use is associated with scleroderma renal crisis, prednisone in high-risk SSc patients should be taken only when absolutely required and at low doses (<10 mg/d).

Patients with scleroderma renal crisis characteristically present with accelerated hypertension (generally >150/90 mmHg) and progressive oliguric renal insufficiency. However, ~10% of patients present with blood pressure in the normal range. Normotensive renal crisis is generally associated with a poor outcome. Headache, blurred vision, congestive heart failure, and pulmonary edema may accompany elevation of blood pressure. Moderate thrombocytopenia and microangiopathic hemolysis with fragmented red blood cells can be seen, and urinalysis typically shows mild proteinuria, granular casts, and microscopic hematuria. Progressive oliguric renal failure over several days generally follows. Scleroderma renal crisis is sometimes initially misdiagnosed

A B

FIGURE 372-13 Pathologic findings in scleroderma renal crisis. ***A.*** Kidney biopsy demonstrating intimal proliferation *(arrows)* and myxoid changes in medium-sized renal arteries. ***B.*** Fragmentation of circulating red blood cells due to intravascular hemolysis. *(Courtesy of Drs. Edward Stern and Christopher Denton, Royal Free Hospital, London, UK.)*

as thrombotic thrombocytopenic purpura (TTP) or other forms of thrombotic microangiopathy. In such cases, renal biopsy and determination of serum von Willebrand factor–cleaving protease activity may be of benefit. The presence of oliguria or a creatinine >3 mg/dL at initial presentation predicts poor outcome (permanent hemodialysis and mortality), as do vascular thrombosis and glomerular ischemic collapse on renal biopsy.

CARDIAC INVOLVEMENT

Although it is often silent, cardiac involvement is detected in 10–50% of SSc patients screened with sensitive diagnostic tools. Clinical cardiac involvement is more frequent in dcSSc than in lcSSc and may be primary or secondary to PAH, ILD, or renal involvement. Cardiac involvement in SSc is associated with poor outcomes. The endocardium, myocardium, and pericardium may each be affected separately or together. Pericardial involvement is manifested as pericarditis, pericardial effusions, constrictive pericarditis, and rarely, cardiac tamponade. Conduction system fibrosis is common and may be silent or manifested by heart block. Other arrhythmias include premature ventricular contractions, atrial fibrillation, and supraventricular tachycardia. Microvascular involvement, recurrent vasospasm, and ischemia-reperfusion injury contribute to patchy myocardial fibrosis, and the resulting systolic or diastolic left ventricular dysfunction may progress to overt heart failure. Acute or subacute myocarditis leading to left ventricular dysfunction may occur, best diagnosed by cardiac magnetic resonance imaging or endomyocardial biopsy. While conventional echocardiography has low sensitivity for detecting preclinical heart involvement in SSc, newer modalities such as tissue Doppler echocardiography (TDE), cardiac magnetic resonance imaging (cMRI), and nuclear imaging (single photon emission CT [SPECT]) reveal a high prevalence of abnormal myocardial function or perfusion. The serum levels of NT-proBNP, a ventricular hormone elevated in SSc-PAH, may also have utility as markers of primary cardiac involvement.

MUSCULOSKELETAL COMPLICATIONS

Musculoskeletal complications are commonly seen in SSc. Carpal tunnel syndrome may be a presenting disease manifestation, and generalized arthralgia and stiffness are prominent in early disease. Mobility of both small and large joints is progressively impaired, and fixed contractures at the proximal interphalangeal joints and wrists ensue. Large joint contractures occur in patients with dcSSc and are frequently accompanied by tendon friction rubs. These are characterized by coarse leathery crepitation heard or palpated upon passive joint movement and are caused by fibrosis and adhesion of the tendon sheaths and fascial planes at the affected joint. The presence of tendon friction rubs is associated with increased risk for renal and cardiac complications and reduced survival. Synovitis seen on ultrasound or MRI is common; occasional SSc patients develop erosive polyarthritis in the hands, and some may have a seropositive rheumatoid arthritis overlap. Muscle weakness is common and multifactorial; deconditioning, disuse atrophy, malnutrition, inflammation, and fibrosis may all contribute. A chronic noninflammatory form of myopathy characterized by atrophy and fibrosis with mildly elevated muscle enzymes occurs in late-stage SSc. Bone resorption in the terminal phalanges, possibly reflecting recurrent ischemia, underlies the characteristic loss of the distal tufts (acro-osteolysis) seen on plain radiographs (Fig. 372-5). Resorption of the mandibular condyles can lead to bite difficulties. Osteolysis can also affect the ribs and distal clavicles.

LESS RECOGNIZED DISEASE MANIFESTATIONS

Dry eyes and dry mouth (sicca complex) are common in SSc. Biopsy of the minor salivary glands in these cases shows fibrosis rather than focal lymphocytic infiltration characteristic of primary Sjögren's syndrome **(Chap. 373)**. Hypothyroidism resulting from Graves or Hashimoto disease is common, particularly in lcSSc, and may be underrecognized. Whereas the central nervous system is generally spared in SSc, unilateral or bilateral sensory trigeminal neuropathy can occur. Erectile dysfunction is a frequent and occasionally initial disease manifestation. Inability to attain or maintain penile erection is due to vascular insufficiency and fibrosis of corporeal smooth muscle and responds poorly to medical therapy. Sexual performance is also adversely affected in women. While fertility is not impaired in SSc, pregnancy is associated with higher risk of adverse fetal outcomes. Furthermore, cardiopulmonary involvement may worsen during pregnancy, and new onset of scleroderma renal crisis has been described.

Cancer Epidemiologic studies indicate an increased cancer risk in patients with SSc. Lung cancer and esophageal adenocarcinoma typically occur in the setting of long-standing ILD or GERD and may be linked to chronic inflammation and maladaptive repair. In contrast, breast, lung, and ovarian carcinomas and lymphomas tend to occur in close temporal association with the onset of SSc, particularly in patients who are positive for autoantibodies to RNA polymerase III. In this scenario, SSc is thought to represent a paraneoplastic syndrome that is triggered by the antitumor immune response.

LABORATORY EVALUATION AND BIOMARKERS

Mild microcytic anemia is frequent and may indicate recurrent GI bleeding caused by GAVE or chronic esophagitis. Macrocytic anemia may be caused by folate and vitamin B_{12} deficiency due to small-bowel bacterial overgrowth and malabsorption or by drugs such as methotrexate. Microangiopathic hemolytic anemia caused by mechanical fragmentation of red blood cells during their passage through microvessels coated with fibrin or platelet thrombi is a hallmark of scleroderma renal crisis. Elevation of C-reactive protein (CRP) in SSc is indicative of higher risk of progressive fibrosis and mortality. Similarly, an elevated serum level of IL-6 is associated with worse outcomes. The erythrocyte sedimentation rate (ESR) is generally normal in SSc; an elevation may signal coexisting myositis or malignancy.

Circulating antinuclear autoantibodies are detected in almost all patients with SSc. Anti-topoisomerase I (Scl-70) and anti-centromere antibodies are mutually exclusive and highly specific for SSc. Topoisomerase I antibodies are associated with increased risk of ILD and poor outcomes. Anti-centromere antibodies are associated with PAH, but only infrequently with significant cardiac, pulmonary, or renal involvement. Nucleolar immunofluorescence pattern may indicate antibodies to U3-RNP (fibrillarin), Th/To, or PM/Scl, whereas speckled immunofluorescence indicates antibodies to RNA polymerase III,

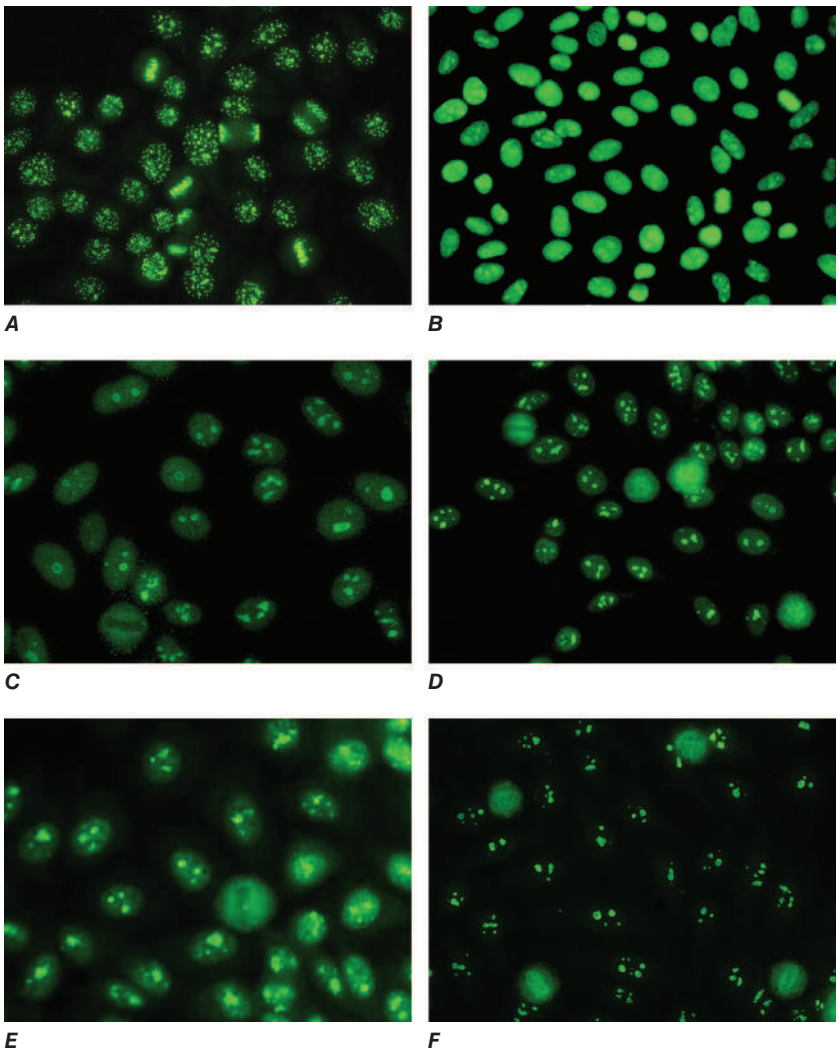


FIGURE 372-14 Systemic sclerosis (SSc)-associated autoantibodies: immunofluorescence. Indirect immunofluorescence of SSc serum samples using HEp-2 substrate. Representative images showing ***(A)*** anti-centromere; ***(B)*** anti-Scl-70/topoisomerase I; ***(C)*** anti-PM/Scl; ***(D)*** anti-Th/To; ***(E)*** anti-RNA polymerase III; and ***(F)*** anti-fibrillarin/U3RNP antibodies. Variations in immunostaining are clues to autoantibody specificity, but immunoassays with purified autoantigens are needed to confirm antigen specificity. *(Courtesy of Marvin Fritzler and Susan Copple, Inova Diagnostics Inc., San Diego, CA.)*

associated with increased risk of scleroderma renal crisis and malignancy (Fig. 372-14).

DIAGNOSIS, STAGING, AND MONITORING

The diagnosis of SSc is made primarily on clinical grounds and is generally straightforward in patients with established disease. Diagnostic criteria developed for classification are >90% specific and sensitive for SSc. The presence of skin induration with a characteristic symmetric distribution pattern associated with typical visceral organ manifestations establishes the diagnosis of SSc with a high degree of certainty. In lcSSc, a history of Raynaud's phenomenon and GERD symptoms, coupled with sclerodactyly and nailfold capillary changes, often in combinations with cutaneous telangiectasia and calcinosis cutis, helps to establish the diagnosis. Primary Raynaud's disease is a benign condition that must be differentiated from early or limited SSc. Nailfold microscopy can be particularly helpful in this situation, because in contrast to SSc, nailfold capillaries are normal. Diagnosing SSc at an early stage may be a particular challenge. In dcSSc, initial symptoms are often nonspecific, Raynaud's phenomenon may be absent, and physical examination may show only upper extremity edema and puffy fingers. Early-stage SSc might therefore occasionally be misdiagnosed as arthritis, SLE, myositis, or, most commonly, undifferentiated connective tissue disease leading to delays in diagnosis. Within weeks to months, Raynaud's phenomenon and advancing skin induration appear. Detection of SSc-specific autoantibodies provides a high degree of diagnostic certainty. Raynaud's phenomenon with fingertip ulcerations or other evidence of digital ischemia, coupled with telangiectasia, distal esophageal dysmotility, unexplained ILD or PAH, or accelerated hypertension with renal failure in the absence of clinically evident skin induration, suggests the diagnosis of SSc sine scleroderma. Patients with a new diagnosis of SSc should be screened for ILD, followed by regular pulmonary monitoring for several years (Fig. 372-15).

MANAGEMENT OF SYSTEMIC SCLEROSIS

OVERVIEW: GENERAL PRINCIPLES

To date, few therapies have been shown to significantly alter the natural history of SSc. In contrast, a variety of interventions are effective in alleviating symptoms, slowing progression of the cumulative organ damage, and reducing disability. Moreover, a significant decrease in disease-related mortality has been noted during the past 25 years. In light of the marked heterogeneity in disease manifestations, course, and outcomes, optimized care for patients with SSc requires a thoughtful "precision medicine" approach that is tailored specifically to each individual patient's unique needs.

The following general principles should guide management of patients with SSc (Table 372-7): prompt and accurate diagnosis; disease subclassification and risk stratification based on clinical, radiologic, and laboratory evaluation, including autoantibody profiles and prognostic and predictive biomarkers; early recognition of organ-based complications and careful assessment of their extent, severity, and likelihood of deterioration; regular monitoring for disease progression, new complications,

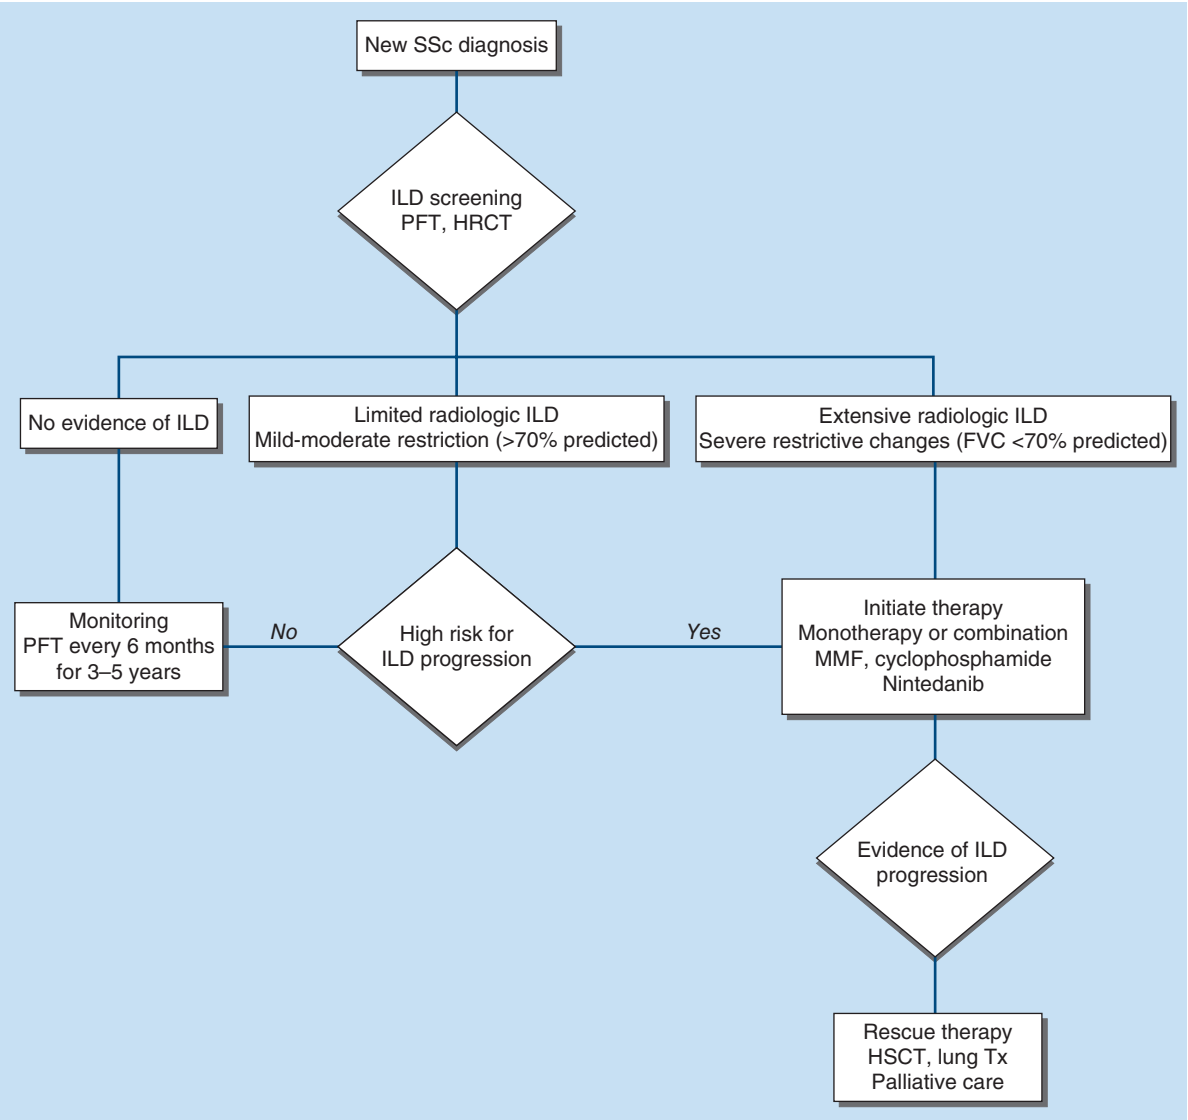

FIGURE 372-15 Algorithm for screening, monitoring, and treatment of systemic sclerosis (SSc)-associated interstitial lung disease (ILD). FVC, forced vital capacity; HRCT, high-resolution computed tomography; HSCT, hematopoietic stem cell transplantation; MMF, mycophenolate mofetil; PFT, pulmonary function testing; Tx, transplantation. *(Adapted from A Perelas et al: Lancet Respir Med 8:304, 2020.)*

and response to and side effects of therapy; adjusting therapy; and patient education. To minimize the risk of irreversible organ damage, management should be proactive, with regular screening and initiation of appropriate intervention at the earliest possible opportunity. In light of the complex and multisystemic nature of SSc, a team-oriented management approach integrating appropriate specialists should be pursued. Patients should be encouraged to become familiar with potential complications and empowered to partner with their treating physicians. This requires a long-term relationship between patient and physician, with ongoing counseling, encouragement, and two-way dialogue.

DISEASE-MODIFYING THERAPIES: IMMUNOMODULATORY AGENTS

Immunomodulatory agents commonly used in other autoimmune diseases have generally shown modest or no benefit in SSc. Glucocorticoids alleviate stiffness and aching in early inflammatory-stage dcSSc but do not influence the progression of skin or internal organ involvement. Since their use is associated with an increased risk of scleroderma renal crisis, glucocorticoids should be given only when absolutely necessary, at the lowest dose possible, and for brief periods only.

TABLE 372-7 Key Principles in Management

- Establish early and accurate diagnosis.
- Detect and evaluate internal organ involvement.
- Define clinical disease stage and activity.
- Tailor individualized therapy to each patient's unique needs.
- Assess treatment response, and adjust therapy as needed; monitor for disease activity, progression, and new complications.

Cyclophosphamide has been extensively studied in light of its efficacy in the treatment of vasculitis **(Chap. 375)**, SLE **(Chap. 368)**, and other autoimmune diseases **(Chap. 367)**. Both oral and intravenous cyclophosphamide have been shown to reduce the progression of SSc-associated ILD, with stabilization and, less commonly modest improvement, of pulmonary function, HRCT findings, respiratory symptoms, and skin induration. These benefits need to be balanced against cyclophosphamide's potential toxicity, including bone marrow suppression, opportunistic infections, hemorrhagic cystitis and bladder cancer, premature ovarian failure, and late secondary malignancies.

Methotrexate had only modest effect on SSc skin involvement in small studies. Mycophenolate mofetil, a prodrug of mycophenolic acid, is an inhibitor of inosine monophosphate dehydrogenase, which impairs B- and T-cell proliferation. Mycophenolate was evaluated in both open-label and randomized controlled trials. Both skin induration and ILD improved in patients treated with mycophenolate mofetil, and the drug was well tolerated. Tocilizumab, a monoclonal antibody that blocks IL-6 receptor signaling, also showed some benefit on both skin and lung involvement in randomized SSc trials. Tocilizumab was

well tolerated and has a role in the treatment of SSc-associated ILD in relatively early disease. Open-label studies and small clinical trials support the use of rituximab, a monoclonal antibody directed against CD20 that depletes peripheral B cells but spares plasma cells and hematopoietic stem cells. Other treatments occasionally used include extracorporeal photopheresis, IV immunoglobulin, and abatacept, a fusion protein that inhibits T-cell co-stimulation and function. The use of cyclosporine, azathioprine, hydroxychloroquine, thalidomide, and rapamycin for SSc therapy is currently not well supported by the literature. Intensive immune ablation using high-dose chemotherapy, followed by autologous hematopoietic stem cell reconstitution therapy (HSCT), was associated with durable remission and improved long-term survival in multiple randomized clinical trials. Currently, HSCT is indicated for selected patients with severe SSc but carries the risk of treatment-related morbidity and mortality, as well as significant cost. Cellular therapies and CD19-targeting CAR-T immunotherapies for SSc are still in early stages of development but show promise for inducing sustained disease remission.

Antifibrotic Therapy Because tissue fibrosis underlies organ damage in SSc, drugs that interfere with the fibrotic process represent a rational therapeutic approach. In older retrospective studies, D-penicillamine was shown to stabilize skin induration, prevent new internal organ involvement, and improve survival. However, a randomized controlled clinical trial in early active SSc found no difference in the extent of skin involvement between patients treated with standard-dose (750 mg/d) or very-low-dose (125 mg every other day) D-penicillamine. Clinical trials show benefit of the tyrosine kinase inhibitor nintedanib, used alone or in combination with mycophenolate, in patients with SSc-ILD, with significant slowing of lung function decline, although no significant benefit on skin involvement.

Vascular Therapy The goal of Raynaud's therapy is to control episodes, prevent and enhance the healing of ischemic complications, and slow the progression of obliterative vasculopathy. Patients should dress warmly, minimize cold exposure, and avoid drugs that precipitate or exacerbate vasospastic episodes. Extended-release dihydropyridine calcium channel blockers such as amlodipine and diltiazem ameliorate Raynaud's phenomenon, but their use is often limited by side effects (palpitations, dependent edema, worsening gastroesophageal reflux). While ACE inhibitors do not reduce the frequency or severity of episodes, angiotensin II receptor blockers such as losartan are effective and well tolerated. Patients with Raynaud's phenomenon unresponsive to these therapies may require the addition of α_1-adrenergic receptor blockers (e.g., prazosin), 5-phosphodiesterase inhibitors (e.g., sildenafil), topical nitroglycerine, and intermittent IV infusions of prostaglandins. Low-dose aspirin and dipyridamole prevent platelet aggregation and may have a role as adjunctive agents. In patients with ischemic digital tip ulcerations, the endothelin-1 receptor antagonist bosentan reduces the risk of new ulcers. Digital sympathectomy and intradigital injections of botulinum type A (Botox) may be considered in patients with severe ongoing ischemia. Empirical long-term therapy with statins and antioxidants may retard the progression of vascular damage and obliteration. There is limited evidence-based information for the treatment of cardiac complications of SSc, which should be guided by specialists experienced in their diagnosis and management. While selective beta blockers such as metoprolol can precipitate vasospasm, nondihydropyridine calcium channel blockers can be used for rate control in atrial arrhythmias, and nonselective alpha/beta blockers such as carvedilol can be used for improving myocardial perfusion and left ventricular systolic function.

TREATMENT

TREATMENT OF SSc-ASSOCIATED INTERSTITIAL LUNG DISEASE

ILD remains a leading cause of death in patients with SSc. The radiographic extent of ILD on HRCT and the FVC at initial evaluation, along with decline in FVC during the preceding 12-month period, are helpful in identifying patients with likely progression. Additionally, male sex, older age at initial presentation, anti-topoisomerase I positivity, progressive skin involvement, and myocardial disease may be risk factors for ILD progression. Patients at high risk for ILD should, in addition to baseline screening HRCT, be monitored by performing PFTs every 3–6 months (Fig. 372-15); serial HRCT imaging is not recommended. Cyclophosphamide, given as monthly IV infusions or orally for 6–12 months, and mycophenolate mofetil both slow the decline in lung function and improve respiratory symptoms. As cyclophosphamide is associated with more frequent side effects, mycophenolate mofetil is generally preferred. In patients who show ILD progression despite immunotherapy, the antifibrotic drug nintedanib might be added. The optimal duration of nintedanib for SSc-associated ILD is currently under investigation. In patients who show continued progression of ILD despite medical therapy, lung transplantation might be considered as a life-prolonging procedure, although significant GERD contributing to organ rejection is a concern in SSc. Recurrence of SSc-ILD in transplanted lung allografts has not been reported.

TREATMENT OF GASTROINTESTINAL COMPLICATIONS

Because oral problems including decreased oral aperture, decreased saliva production, gum recession, periodontal disease, and teeth loss are common, regular dental care is recommended. Gastroesophageal reflux is very common in SSc and may be present even in the absence of GERD symptoms. Patients should be instructed to elevate the head of the bed, eat frequent small meals, and avoid alcohol, caffeine, and known reflux exacerbants or meals before bedtime. Proton pump inhibitors to reduce acid reflux may need to be given in relatively high doses. Prokinetic agents such as erythromycin (a motilin agonist), prucalopride, and domperidone may help in SSc, but are frequently associated with side effects. Botulinum toxin injection sometimes ameliorates impaired gastric emptying. Surgical antireflux procedures such as Nissen fundoplication can result in secondary achalasia and generally should be avoided. Episodic bleeding from gastric antral vascular ectasia (watermelon stomach) may be treated with endoscopic laser or argon plasma photocoagulation, although it commonly recurs. In some patients, enteral feeding and/or decompression via percutaneous gastrostomy or jejunostomy may become necessary. Small intestinal bacterial overgrowth secondary to gut dysmotility causes abdominal bloating and diarrhea and may lead to malabsorption and severe malnutrition. Short courses of rotating broad-spectrum antibiotics such as metronidazole, erythromycin, and rifaximin can eradicate bacterial overgrowth. Small-bowel hypomotility may respond to octreotide, but pseudo-obstruction is difficult to treat. Fecal incontinence, a frequent but underreported complication, may respond to antidiarrheal medication, biofeedback, sphincter augmentation, and sacral neuromodulation. Potential malnutrition should be routinely assessed.

TREATMENT OF PULMONARY ARTERIAL HYPERTENSION

In SSc, PAH carries an extremely poor prognosis and accounts for 30% of deaths. Because PAH is asymptomatic until advanced, patients with SSc should be screened at initial evaluation and yearly thereafter. Treatment is generally started with an oral endothelin-1 receptor antagonist such as bosentan or a phosphodiesterase-5 inhibitor such as sildenafil. Recently, the soluble guanylate cyclase stimulator riociguat, which acts by increasing the production of nitric oxide, and the selective IP prostacyclin receptor agonist selexipag were shown to improve PAH symptoms and survival. Patients may also require diuretics and digoxin. If hypoxemia is documented, supplemental oxygen should be prescribed in order to avoid secondary pulmonary vasoconstriction. Prostacyclin analogues such as epoprostenol or treprostinil can be given by continuous IV or SC infusion or via intermittent nebulized inhalations. Combination therapy with different classes of agents acting additively or synergistically is often necessary. Lung transplantation remains an option for selected SSc patients with PAH who fail

medical therapy, and 2-year survival rates (64%) are comparable to those of idiopathic ILD or PAH.

TREATMENT OF RENAL CRISIS

Scleroderma renal crisis represents a medical emergency. Since its outcome is largely determined by the extent of renal damage at the time that aggressive therapy is initiated, prompt recognition of impending or early scleroderma renal crisis is essential, and efforts should be made to avoid its occurrence. High-risk SSc patients (early disease, extensive and progressive skin involvement, tendon friction rubs, and anti-RNA polymerase III antibodies) should be instructed to monitor their blood pressure daily and report significant alterations immediately. Potentially nephrotoxic drugs should be avoided, and glucocorticoids should be used only when absolutely necessary and at low doses. Patients presenting with scleroderma renal crisis should be immediately hospitalized. Once other causes of acute renal disease are excluded, treatment should be started promptly with titration of short-acting ACE inhibitors, with the goal of rapid normalization of the blood pressure. In patients with persistent hypertension, addition of angiotensin II receptor blockers, calcium channel blockers, endothelin-1 receptor blockers, prostacyclins, and direct renin inhibitors should be considered. In light of evidence for intrarenal complement pathway activation in some patients with scleroderma renal crisis, addition of eculizumab to ACE inhibitors may be considered. Up to two-thirds of patients with scleroderma renal crisis necessitate dialysis. Substantial renal recovery can occur following an episode of scleroderma renal crisis, and in 30–50% of patients, renal replacement therapy can be ultimately discontinued. Kidney transplantation is appropriate for patients unable to discontinue dialysis after 2 years. Survival of transplanted SSc patients is comparable to that of other diseases, and recurrence of renal crisis is rare.

SKIN CARE

Because involvement of the skin in SSc is never life-threatening and stabilizes and may even regress spontaneously, disease management should not be dictated by its cutaneous manifestations. The inflammatory symptoms of early skin involvement can be controlled with antihistamines and short-term use of low-dose glucocorticoids (<5 mg/d of prednisone). Cyclophosphamide and methotrexate have modest effects on skin induration. Because the skin is dry, the use of hydrophilic ointments and bath oils is encouraged, and regular skin massage is helpful. Telangiectasia, which present a cosmetic problem, especially on the face, can be treated with pulsed dye laser. Ischemic digital ulcerations should be protected by occlusive dressing to promote healing and prevent infection. Infected skin ulcers are treated with topical antibiotics and surgical debridement. While no therapy has been shown to be effective in preventing soft tissue calcific depositions or promoting their dissolution, reports support the use of minocycline, as well as bisphosphonates and topical, intralesional, or IV sodium thiosulfate (STS). Additional approaches include carbon dioxide laser treatment, extracorporeal shock-wave lithotripsy, and surgical high-speed microdrilling.

TREATMENT OF MUSCULOSKELETAL COMPLICATIONS

Arthralgia and joint stiffness are very common and distressing manifestations in early-stage disease. Short courses of nonsteroidal anti-inflammatory agents, methotrexate, and hydroxychloroquine and cautious use of low-dose glucocorticoids may alleviate symptoms. Physical and occupational therapy can be effective for preventing loss of musculoskeletal function and joint contractures and should be initiated early.

COURSE

The natural history of SSc is highly variable and difficult to predict, especially in early stages of the disease. Patients with dcSSc tend to have a more rapidly progressive course and worse prognosis than those with lcSSc. Inflammatory symptoms of early dcSSc, such as fatigue, edema, joint pain, and pruritus, subside, and skin thickening reaches a plateau at 2–4 years after disease onset. It is during the early edematous/inflammatory stage that life-threatening visceral organ involvement may develop. While existing visceral organ involvement, such as ILD, may progress even after skin involvement peaks, new organ involvement is rare. Scleroderma renal crisis generally occurs within the first 4 years of disease. In late-stage disease (>6 years), the skin is usually soft and atrophic. Skin regression characteristically occurs in an order that is the reverse of initial involvement, with softening on the trunks followed by proximal and finally distal extremities; however, sclerodactyly and fixed finger contractures generally persist. Relapse or recurrence of skin thickening after peak skin involvement has been reached is uncommon. Patients with lcSSc follow a clinical course that is markedly different than that of dcSSc. Raynaud's phenomenon typically precedes other disease manifestations by years or even decades, and visceral organ complications such as PAH generally develop late and progress slowly.

PROGNOSIS

SSc confers a substantial increase in the risk of premature death. Age- and gender-adjusted mortality rates are fivefold to eightfold higher compared to the general population, and more than half of all patients with SSc die from their disease. In one population-based study of SSc, the median survival was 11 years. In patients with dcSSc, 5- and 10-year survival rates are 70 and 55%, respectively, whereas in patients with lcSSc, 5- and 10-year survival rates are 90 and 75%, respectively. The prognosis correlates with the extent of skin involvement, which itself is a surrogate for visceral organ involvement. Major causes of death are PAH, pulmonary fibrosis, GI involvement, and cardiac disease. Scleroderma renal crisis is associated with a 30% 3-year mortality. Lung cancer and excess cardiovascular deaths also contribute to increased mortality. Markers of poor prognosis include male gender, African ancestry, older age at disease onset, extensive skin thickening with truncal involvement, palpable tendon friction rubs, and evidence of significant or progressive visceral organ involvement. Laboratory predictors of increased mortality at initial evaluation include an elevated ESR, anemia, proteinuria, and anti–topoisomerase I antibodies. In one study, SSc patients with extensive skin involvement, lung vital capacity <55% predicted, significant GI involvement (pseudo-obstruction or malabsorption), clinical cardiac involvement, or scleroderma renal crisis had a 9-year survival <40%. The severity of PAH predicts mortality, and patients with mean pulmonary arterial pressure ≥45 mmHg on cardiac catheterization had a 33% 3-year survival. The advent of ACE inhibitors for scleroderma renal crisis had a dramatic impact on survival, increasing from <10% survival at 1 year in the pre–ACE inhibitor era to >70% 3-year survival at the present time. Moreover, 10-year survival in SSc has improved from <60% in the 1970s to >66–78% in the 1990s, a trend that reflects both earlier detection and better management of complications.

LOCALIZED SCLERODERMA

The term *scleroderma* describes a group of localized skin disorders (Table 372-1). These occur more commonly in children than in adults and, in marked contrast to SSc, are generally not complicated by Raynaud's phenomenon or significant internal organ involvement. Morphea presents as solitary or multiple circular patches of thick skin or, rarely, as widespread induration (generalized or pansclerotic morphea); the fingers are generally spared. Linear scleroderma may affect subcutaneous tissues, leading to fibrosis and atrophy of supporting structures, tendons, muscle, and even bone. In children, the growth of affected long bones can be slowed. When linear scleroderma crosses large joints, significant contractures can develop.

MIXED CONNECTIVE TISSUE DISEASE
