SLD is commonly, but not invariably, associated with a developmental history of problems in speech and language, attention, and motor skills. Moreover, SLD commonly, but not invariably, co-occurs with other neurodevelopmental (e.g., Communication Disorders, ADHD) and mental health disorders (e.g., Anxiety and Mood Disorders). These associated problems are clinically important because the diagnosis of SLD cannot be confirmed until the child has started school and been exposed to formal academic instruction, but Communication Disorders in particular are likely to be apparent and diagnosed earlier and so indicate a risk for later SLD. Likewise, a developmental and family

Telegram: @medical_k

www.konkur.in

history of SLD may indicate a risk for later anxiety and mood disorders in adolescence and adulthood.

Speech and Language Impairments. Oral language constitutes an essential foundation for abilities in written language. Thus, it is not surprising that a developmental history of Communication Disorders (Speech Sound Disorder, Specific Language Impairments (SLI), alone or in combination) in preschool years is a common precursor of SLD, particularly for poor skills in reading words and reading comprehension, spelling, arithmetic fact retrieval, and calculation. Speech sound disorder, defined as problems in producing sounds in one's language accurately and intelligibly, whereas language impairments refer to problems in developing the structural aspects of language, such as grammar (syntax) and vocabulary (semantics). For example, one longitudinal study of a community-based sample of children identified with pervasive speech/language disorders in kindergarten found an estimated three- to sixfold greater risk for SLD (all manifestations alone or in combination) in young adulthood compared to typically developing youngsters. Moreover, according to a recent population-based study, the cumulative risk of SLD in written language by age 19 is about 64% in youngsters with speech/language impairments compared to 18% in those without.

Attention-Deficit/Hyperactivity Disorder. Epidemiologic and clinical studies indicate that the overlap between SLD and ADHD is greater than expected by chance alone. For example, around 20% to 45% of children with ADHD also meet diagnostic criteria for SLD, but the strongest link appears to be between the inattention dimension of ADHD and SLD, particularly SLD in reading and writing. Inattention in the classroom (even at subclinical levels), as rated by teachers, is a robust predictor of concurrent and subsequent poor academic outcomes, as well as a poor response to evidence-based academic intervention. Importantly, there is little robust evidence that medication treatment for ADHD (including stimulant and nonstimulant medications) has any substantial effect on SLD, despite its positive effects on the behavioral symptoms of ADHD and

Telegram: @medical_k

www.konkur.in

academic productivity (i.e., completing more arithmetic problems in a specified time frame). By contrast, preliminary evidence suggests that intensive educational intervention may improve (but not normalize) the behavioral problems. The clinical implications of these findings are that assessment for SLD should include assessment for ADHD and vice versa: Youngsters with SLD who have coexisting inattention or ADHD require multimodal intervention, including intensive educational intervention, since medication for ADHD will not address the SLD and intervention for SLD will be less effective if the inattention remains unaddressed.

Emotional Problems, Anxiety and Mood Disorders, Suicide Risk. Individuals with SLD are highly likely to manifest concurrent social, emotional, and mental health problems. For example, they are only too aware of their academic difficulties, leading to low self-esteem and these negative self-perceptions are very difficult to change and contribute to their problems in social and academic functioning. Avoidance of or reluctance to engage in activities requiring academic skills is common in children, adolescents, and adults. Also, recent meta-analyses confirm that the majority of youngsters with SLD (about 70%) have higher rates of anxiety and depressive symptoms compared to non-SLD peers. Episodes of severe anxiety or anxiety disorders (including somatic complaints or panic attacks) are common across the lifespan and accompany both the circumscribed and broader expression of learning difficulties. Moreover, SLD is associated with an increased risk for suicidal ideation and suicide attempts in children, adolescents, and adults. The co-occurrence of internalizing symptoms and disorders is clinically significant, whereas SLD is treated primarily in the field of education; thus, these internalizing symptoms often remain unaddressed. Thus psychiatrists and other mental health practitioners play an important role in identifying, monitoring, and treating concurrent internalizing problems.

Criteria for Diagnosis

Telegram: @medical_k

www.konkur.in

There are no biomarkers to date for SLD. Thus, SLD is a clinical diagnosis, which is best made by an experienced clinician, based on a comprehensive assessment with careful clinical synthesis of information from multiple sources, including developmental, medical, educational, and family history; school reports; teacher observations, including response to classroom instruction and other intervention provided at school; as well as direct standardized psychometric assessment of the individual's academic skills—including reading (accuracy, fluency, comprehension), spelling, written expression, and arithmetic (number sense, counting, algorithmic computation). The DSM-5 diagnostic criteria for SLD are presented in Table 40–3.

Telegram: @medical_k

www.konkur.in

Table 40–3.
DSM-5 Diagnostic Criteria for Specific Learning Disorder, With ICD-9-CM Codes (ICD-10 Codes Are Shown Parenthetically)

Telegram: @medical_k

www.konkur.in

Diagnostic Criteria

A. Difficulties learning and using academic skills, as indicated by the presence of at least one of the following symptoms that have persisted for at least 6 months, despite the provision of intervention that targets those difficulties:
   1. Inaccurate or slow and effortful word reading (e.g., reads single words aloud incorrectly or slowly and hesitantly, frequently guesses words, difficulties sounding out words)
   2. Difficulty understanding the meaning of what is read (e.g., may read text accurately but not understand the sequence, relationships, inferences, or deeper meanings of what is read)
   3. Difficulties with spelling (e.g., may add, omit, or substitute vowels or consonants)
   4. Difficulties with written expression (e.g., makes multiple grammatical or punctuation errors within sentences; employs poor paragraph organization; written expression of ideas lacks clarity)
   5. Difficulties mastering number sense, number facts, or calculation (e.g., poor understanding of numbers, their magnitude, and relationships; counts on fingers to add single-digit numbers instead of recalling the math fact like peers; gets lost in the midst of arithmetic computation and may switch procedures)
   6. Difficulties with mathematical reasoning (e.g., severe difficulty applying mathematical concepts, facts, or procedures to solve quantitative problems)

B. The affected academic skills are substantially and quantifiably below those expected for the individual's chronologic age and cause significant interference with academic or occupational performance, or activities of daily living, as confirmed by individually administered standardized achievement measures and comprehensive clinical assessment. For individuals aged 17 years and older, a documented history of impairing learning difficulties may be substituted for the standardized assessment

Telegram: @medical_k

www.konkur.in

C. The learning difficulties begin during school-age years but may not become fully manifest until the demands for those affected academic skills exceed the individual's limited capacities (e.g., as in timed tests, reading or writing lengthy complex reports for a tight deadline, excessively heavy academic loads)

D. The learning difficulties are not better accounted for by Intellectual Disabilities, uncorrected visual or auditory acuity, other mental or neurologic disorders, psychosocial adversity, lack of proficiency in the language of academic instruction, or inadequate educational instruction.

Note: The four diagnostic criteria are to be met based on a clinical synthesis of the individual's history (developmental, medical, family, educational), school reports, and psychoeducational assessment.

Coding Note: Specify all academic domains and subskills that are impaired. When more than one domain is impaired, each one should be coded individually according to the following specifiers.

Specify if:

315.00 (F81.0) With impairment in reading:

Word reading accuracy

Reading rate or fluency

Reading comprehension

Note: *Dyslexia* is an alternative term used to refer to a pattern of learning difficulties characterized by problems with accurate or fluent word recognition, poor decoding, and poor spelling abilities. If dyslexia is used to specify this particular pattern of difficulties, it is important also to specify any additional difficulties that are present, such as difficulties with reading comprehension or math reasoning.

315.2 (F81.81) With impairment in written expression:

Spelling accuracy

Grammar and punctuation accuracy

Clarity or organization of written expression

315.1 (F81.2) With impairment in mathematics:

Telegram: @medical_k

www.konkur.in

Number sense

Memorization of arithmetic facts

Accurate or fluent calculation

Accurate math reasoning

Note: *Dyscalculia* is an alternative term used to refer to a pattern of difficulties characterized by problems processing numerical information, learning arithmetic facts, and performing accurate or fluent calculations. If dyscalculia is used to specify this particular pattern of mathematic difficulties, it is important to also specify any additional difficulties that are present, such as difficulties with math reasoning or word reasoning accuracy.

Specify current severity:

Mild: Some difficulties learning skills in one or two academic domains, but may be of mild enough severity that the individual may be able to compensate or function well when provided with appropriate accommodations or support services, especially during the school years.

Moderate: Marked difficulties learning skills in one or more academic domains, so that the individual is unlikely to become proficient without some intervals of intensive and specialized teaching during the school years. Some accommodations or supportive services at least part of the day at school, workplace, or at home may be needed to complete activities accurately and efficiently.

Severe: Severe difficulties learning skills, affecting several academic domains, so that the individual is unlikely to learn those skills without ongoing intensive individualized and specialized teaching for most of the school years. Even with an array of appropriate accommodations or services at home, school, or workplace, the individual may not be able to complete all activities efficiently.

www.konkur.in

This diagnostic category is indicated by using one overarching term, “Specific Learning Disorder,” which incorporates difficulties in learning academic skills, such as reading, writing, and mathematics, which were classified as separate disorders in previous versions of DSM and in ICD-10. The generic term reflects the evidence from behavior–genetic studies showing that learning difficulties in the various academic domains share genetic variance and from clinical and epidemiologic studies that individuals showing a deficit in one academic domain frequently show deficits in other domains as well, although deficits isolated to one academic domain may occur. Using this overarching term, diagnosticians can then specify the details of the areas of learning difficulty and their severity as manifest at the time of assessment.

The manifestation of learning difficulties *at the time of assessment* is coded by adding *Specifiers* to the generic diagnosis of SLD to provide more precise information about the domains that are affected. Specifiers are deficits in reading, deficits in writing, deficits in mathematics, each of which can be further specified by detailed descriptions (e.g., SLD with impairment in reading [currently manifests as problems in word reading accuracy, reading fluency, and comprehension] and impairment in mathematics [currently manifests as problems with memorization of math facts, as well as in accuracy of calculation]). Use of the terms “dyslexia” and “dyscalculia” to refer to problems in learning to read or do arithmetic, respectively, is permitted according to clinician and patient preference, but detailed coding of the manifestation of SLD should still be completed. Severity ratings (mild, moderate, severe), which reflect the dimensional nature of SLD, permit further description by considering the range of learning difficulties and impairments, as well as the likely need for accommodations and support to best promote ongoing learning. DSM-5 specifies a set of four diagnostic criteria, all of which must be met to confirm a clinical diagnosis of SLD.

Criterion A. This criterion lists a range of observable descriptive behaviors or symptoms (Criterion A1 to A6, Table 40–3) which may be observed, probed during the clinical assessment, and confirmed

Telegram: @medical_k

www.konkur.in

by evidence from the school reports, teacher observations or ratings, previous psychoeducational assessment reports, and current performance scores on standardized achievement tests. At least one of these symptoms must be present. Moreover, Criterion A also requires evidence that the symptoms have persisted for at least 6 months despite the provision of intervention that targets each of the affected academic domains. For children, the term "*persistent*" is confirmed by the evidence of restricted progress in mastering the affected academic skill, over at least 6 months, despite the provision of intervention that targets that affected skill. For older adolescents and adults, persistent difficulties refer to ongoing difficulties with literacy or numeracy skills that first manifest during the school years, as confirmed by school reports, evaluated portfolios of past and current work, or previous assessments.

The term "*intervention*" refers to extra help at school or home, small group or individualized instruction, using any instructional approaches available at the school that focus on the affected skill. DSM-5 does not require the provision of intensive evidence-based (research-based) intervention—as specified by a current educational model in the United States (Response-to-Intervention [RTI]). RTI is a multitiered approach to academic and behavioral intervention designed to provide early, systematic, and appropriately intensive assistance to children who are at risk or already underperforming academically or behaviorally, compared to grade-appropriate standards. To date, the RTI approach, while laudable in its goals, not only lacks a strong evidence base but also is not consistently available within the United States and is rarely available outside of the United States.

Criterion B. This comprises two components: (i) academic achievement that is well below average and (ii) impairment resulting from the learning difficulties. In terms of low academic achievement, the DSM-5 applies the "average-person standard" that has been applied in disability discrimination laws for years. An individual's scores on standardized, individually administered, culturally sensitive academic achievement tests are compared to the population mean

Telegram: @medical_k

www.konkur.in

for chronologic age, not to IQ or to achievement scores of subsets of the population, such as peers attending university, medical, or law school. Examples of commonly used standard achievement tests are shown in Table 40–4.

DSM-5 does not specify what cut-off scores to use for determining low academic achievement within the diagnostic criterion itself, but provides guidelines within the text. One suggested guideline for below-average academic performance is to require evidence that scores on standardized academic achievement tests fall at least 1.5 standard deviations below the general population mean for age: This cut-off score is equivalent to a standard score >78 or >7th percentile. Standardized tests vary in the number and composition of items relevant to age, as well as in the particular aspect of reading, arithmetic, spelling, and written expression. Moreover, it is important to recall that standardized testing occurs in rather artificial situations (quiet space, minimal noise or other distractions, use of a standardized procedure that often precludes repetition of a question by the examiner), and performance may be influenced by factors other than academic skill level, such as motivation and effort, familiarity with the testing situation, anxiety, hunger, and sleep status, etc. Thus, greater diagnostic certainty is established by the evidence of low scores on more than one test or subtest.

A second guideline suggests that more lenient cut-off scores may be used (1.0 to 1.5 standard deviations below mean for age) when supported by other converging evidence of learning difficulties, such as academic history, other test scores, school reports, teacher observations, etc.

For individuals aged 17 and older, a documented history of long-standing and impairing learning difficulties (based on self-reported history of difficulties learning to read, spell, do arithmetic or written work; previous standardized testing; school reports; previous systematic clinical assessments for SLD) may be substituted for the standardized assessment. The goal of this substitution is to avoid the time and expense needed for unnecessary repeated standardized assessments, based on the evidence that childhood-onset SLD typically persists into adulthood.

Telegram: @medical_k

www.konkur.in

Identification of SLD in individuals in postsecondary education poses challenges. DSM-5 does not preclude the possibility that an individual with high IQ, giftedness, or attending postsecondary education may have SLD. Evidence required for greater diagnostic certainty in this situation includes previous or current reports (from school, significant others), self-reported history of marked learning difficulties, a manifestation of self-report of an extraordinary effort required or dependence on the provision of support and accommodations needed to attain/maintain performance; previously evaluated portfolios of academic work; previous clinical assessments indicating SLD; family history of SLD; or current evidence of low academic scores (e.g., below the population mean for age). Extensive testing is rarely required: Research evidence indicates that tests of fluent word reading, reading comprehension, word spelling, number sense, and fluency of arithmetic computation suffice.

In the absence of available culturally appropriate and normed standardized academic achievement tests (as occurs in many low- to middle-income countries or non–English-speaking countries), converging evidence of markedly low academic performance must be derived from careful clinical review of scores on locally available tests, school reports, and clinical assessment. (See Tables 40–1 to 40–4 for a description of commonly used tests.)

Table 40–4.
Examples of Commonly Used Standardized Tests of Reading, Written Expression, Arithmetic, and Related Skills

Telegram: @medical_k

www.konkur.in

Name of Standardized Test	Reading Skills
Comprehensive Test of Phonologic Processing (CTOPP); standardized. Ages: 5 years to young adulthood	Basic reading skills (e.g., phonologic awareness, phonologic coding, working memory, rapid naming)
Woodcock Johnson-III Achievement battery	Letter–word identification, word attack, and reading fluency reading comprehension
Test of Word Reading Efficiency (TOWRE); Ages: 5 years to young adulthood	Single-word reading efficiency (e.g., speedy and accurate naming of single words and pseudowords)
Gray Oral Reading Test; Nelson–Denny Reading Test; Gray Silent Reading Test	Reading fluency and comprehension (e.g., rate of reading connected text for meaning)
	Written Expression Skills
Wechsler Individual Achievement Test (WIAT-II) Ages: 5–19 years	Spelling, written expression
Test of Written Language (TOWL; 3rd edition) Ages: 7.5–17.9 years	1. Elicited writing, including vocabulary, spelling, capitalization and punctuation, logical sentences, and sentence combining 2. Spontaneous writing combining
Test of Early Written Language (TEWL; 2nd edition) Ages: 3–11 years	Basic, global, and contextual writing
Test of Written Spelling (TOWS;	Spelling of phonetically regular

Telegram: @medical_k

www.konkur.in

4th edition) Ages 6–18 years	and nonregular words
Woodcock–Johnson Psychoeducational Battery Ages: 5 years–adult	Dictation, proofing, writing fluency, writing samples
	Mathematics Skills
Woodcock–Johnson Achievement Battery-III	Math fluency, calculation, quantitative concepts, applied problems
Test of Early Mathematical Abilities—3rd edition Age: 3–0 to 8–11	Numbering skills, number-comparison facility, numeral literacy, mastery of number facts, calculation skills, and understanding of concepts
Test of Mathematical Abilities Age: 8–0 to 18–11	Mathematical symbols and concepts; computation; mathematics in everyday life; word problems; attitude toward math
Teacher Academic Attainment Scale (TAAS)	Subjective rating scale of student academic achievement (7 items)
Math Anxiety Questionnaire	Math anxiety
Abbreviated Math Anxiety Scale	1. Learning anxiety: anxiety related to learning math 2. Testing: anxiety related to being tested in math
Subjective Numeracy Scale	Subjective rating of one's health numeracy
Test of Functional Health Literacy in Adults (s-TOFHLA)	Objective measure of health literacy
Rapid Estimate of	Objective measure of health

Telegram: @medical_k

www.konkur.in

Moreover, Criterion B emphasizes impairment, in requiring that the learning difficulties cause significant impairment in academic, occupational, social functioning, or in activities in daily living that requires academic skills. Thus, low academic scores per se are not sufficient to meet the specifications of Criterion B: Evidence of associated impairment is required. This component is in line with the standard of the U.S. “Americans with Disabilities Act (ADA)” for determining a disability.

Criterion C. This third criterion requires evidence that the symptoms of SLD manifest in the school years—most reliably interpreted as during the elementary (primary) school years. Symptoms of SLD may manifest in preschool years, but a diagnosis cannot be confirmed until the individual has received formal instruction in the core academic skills. However, a diagnosis of SLD can be made for the first time in adolescence or adulthood. This is because the manifest learning difficulties may have been overlooked, not assessed, or attributed solely to concurrent emotional behavioral difficulties. Also, some individuals (particularly those with higher adaptive and intellectual functioning, or in highly supportive environments) may have coped with the demands for the core academic skills during the school years, albeit by putting forth extraordinary effort, or by using compensatory skills, that no longer suffice in later years, when high demands on accurate and fluent academic skills (e.g., reading or writing lengthy complex reports for a tight deadline, excessively heavy academic or occupational loads) start to exceed the individual’s limited capacities and compensatory mechanisms. In such cases, greater diagnostic certainty is established by converging evidence from comprehensive clinical assessment, and the ability to rule out loss of previously acquired academic skills as a result of a major medical event or condition.

Telegram: @medical_k

www.konkur.in

Criterion D. The fourth criterion refers to a range of exclusionary conditions. These include intellectual disability, other major mental or neurologic conditions, uncorrected visual or auditory acuity, severe psychosocial adversity, lack of proficiency in the language of instruction (for adults, lack of proficiency in the language of the workplace or social community), lack of or inadequate educational instruction, as may occur for children excluded from education for various reasons (e.g., because they are girls; living in war zones, no schools, no teachers, etc.). These exclusionary criteria are evaluated by means of a comprehensive clinical assessment.

As of 2012, UNICEF reports that about 58 million children are excluded from primary school education and 63 million from lower secondary school education (http://www.uis.unesco.org/Education/Pages/out-of-school-children.aspx). Certainly, it makes no sense to make a diagnosis of SLD in immigrant children who previously have been excluded from education. The issue of excluding from the SLD category those children whose low academic scores may be due to instructional factors (inadequate instruction; a limited opportunity to learn) is important but has been challenging for clinicians to operationalize. One component of Criterion A attempts to address this challenge by requiring evidence that symptoms of learning difficulties have persisted for at least 6 months despite the provision of intervention that targets the affected academic skills. As noted previously, the RTI approach was not adopted by DSM-5 due to insufficient evidence, and lack of universal availability of RTI approaches. However, in many countries, the quality of teacher training has improved over recent years (especially in teaching children to read), affording some assurance that a student's limited progress is not due to inadequate instruction, so SLD is a possibility.

Identification of SLD in individuals whose first language (mother tongue) differs from the language of instruction is challenging. Greater diagnostic certainty is accorded by evidence of the following: The individual has a history of language delay or disability in the native language; the individual has had difficulty developing literacy or numeracy skills in the native language (assuming adequate

Telegram: @medical_k

www.konkur.in

instruction in the native language); there is a family history of SLD in parents, siblings, or other close relatives, the individual is not making adequate progress over 6 months compared to other nonnative speakers, despite the provision of targeted intervention.

Does Information from Tests of Intellectual Capacity or Cognitive Processing Assist in the Diagnosis of SLD or Guide Educational Treatment?

Intelligence testing (and IQ profiling using various subtests) with the requirement for a significant discrepancy between intellectual and academic achievement has been the primary and often sole criterion for the diagnosis of SLD in previous versions of the DSM, continues to be used internationally to determine eligibility for special education services and accommodations, and figures strongly in the understanding of SLD by various stakeholder groups (e.g., teachers, psychologists, parents and parent organizations, lobby groups and researchers). Moreover, this “discrepancy” model has become ingrained in clinical training and practice, despite the several decades of research evidence against its validity for diagnosis or utility in guiding educational instruction. For example, discrepancy scores are unreliable, and children with learning difficulties who do and do not meet the IQ-achievement discrepancy do not differ in symptomatology, associated cognitive deficits, or response to intervention. In other words, the purported differences between those with discrepant and nondiscrepant IQ-achievement scores have not proven to be clinically or educationally meaningful. Thus, a measure of intelligence is not required for a diagnosis of SLD (unless there are concerns about the individual’s intellectual ability and adaptive behavior).

Accordingly, based on the available scientific evidence, DSM-5 eliminated the requirement for a significant discrepancy between the IQ score and an achievement score for the diagnosis of SLD. The DSM-5 does not prohibit the inclusion of intellectual assessment in the diagnostic assessment of SLD. Occasionally, information from an IQ test might be helpful in changing a teacher or parent’s overall

Telegram: @medical_k

www.konkur.in

view of the child and their misunderstanding of the child's intellectual ability. However, when formulating a diagnosis of SLD, clinicians should also keep in mind the DSM-5 changes to the conceptualization and criteria for Intellectual Disability: Specifically, poor adaptive and intellectual functioning, with the latter suggested by IQ score less than 70 ± 5 standard points. This means that individuals with an IQ score of greater than 70 ± 5 standard points and adequate adaptive functioning could potentially—but not necessarily—meet the criteria for SLD since the differential diagnosis of Intellectual Disability can be ruled out.

In recent years, testing of cognitive processes (e.g., phonologic processing, rapid automatized naming, auditory and visual processing, processing speed) and executive functions (e.g., working memory, inhibitory control, cognitive flexibility, sustained attention) has been incorporated increasingly in assessment for SLD, in addition to IQ testing. The goal of such testing is to document patterns of cognitive strengths and weaknesses to inform the development of differentiated and more effective educational instruction and intervention. However, it is unclear whether the relationship between SLD and these processes or executive functions is causal or correlational. There is little or no robust evidence that training these cognitive processes and executive functions will boost academic learning particularly in students with SLD. Also, recent meta-analyses conclude that effect sizes of the magnitude of the relationship between children's cognitive characteristics and response to intervention were small and unable to improve clinical prediction from measures of academic skills per se. Moreover, there is little evidence that cognitive profiles are valuable for planning intervention (i.e., little evidence for Aptitude X Treatment interactions). Thus current recommendations are for assessment and intervention for SLD to focus on educational rather than cognitive factors—a position that is understandably threatening to clinicians and other professionals trained in the psychometric tradition and who might lack expertise in curricular and pedagogical practices. Hence the DSM-5 criterion B does require the use of

Telegram: @medical_k

www.konkur.in

individually administered standardized tests of academic achievement in reading, writing, and arithmetic, where possible.

DIFFERENTIAL DIAGNOSIS

SLD can be distinguished from normal variation (individual differences) in learning academic skills due to other internal and external factors by the severity of the learning difficulties, the specificity of the difficulties in the presence of intact intellectual abilities, and their persistence in the presence of adequate educational opportunity and receipt of the same instruction as the peer group, targeted home or school-based intervention, competency in the language of instruction (even when different from one's mother tongue).

A diagnosis of SLD is not usually made before the child is about 7 years old because evidence of failure to learn to read, write, or do arithmetic is required. Difficulties in learning foundational academic skills may occur for a variety of reasons (e.g., lack of adequate exposure to print, limited education) and are associated with numerous mental health conditions, including mental retardation, developmental coordination disorder, communication disorders, ADHD, conduct disorder, hearing or visual problems, and prematurity. The most common distinguishing feature of SLD in reading is a persistent impairment in phonologic processing and spelling; that of SLD in mathematics is a persistent impairment in number facts. In a child with visual or hearing deficits, the learning problems must be in excess of the difficulty typically associated with these sensory disorders. In a child with learning difficulties in the presence of low intellectual abilities (i.e., an IQ score of 70 ± 5), it is important to assess adaptive behavior to be able to rule out Intellectual Disabilities.

SLD is distinct from Intellectual Disabilities: Individuals diagnosed with intellectual disability have reduced cognitive capacity that has a global impact on learning and adaptive functioning in everyday life. By contrast, individuals with a diagnosis of SLD have at least average intellectual capacity but exhibit significant difficulties in one

Telegram: @medical_k

www.konkur.in

or more *academic* areas, while coping well or even excelling in other areas of academic, sporting, or artistic achievement. Moreover, SLD is distinguished from “learning difficulties,” which is a broader term that encompasses difficulties learning as a consequence of a range of causes, including intellectual disabilities, physical or sensory deficits (e.g., hearing or visual impairments), emotional or behavioral difficulties, inadequate environmental experiences, or appropriate educational opportunities.

SLD in Reading, Mathematics, or Written Expression is frequently associated with ADHD, and a concurrent diagnosis is not only permissible but is also essential. An explicit statement should be made concerning the presence of both clinical conditions to ensure that the child can access relevant and effective interventions. Moreover, even if the individual does not meet the full criteria for ADHD but does manifest persistent symptoms of inattention (particularly in the school setting), clinicians should report these problems, given the increased risk conferred for poor response to intervention if inattention is not targeted in the treatment plan.

It might be possible to determine inadequate instruction as the primary explanation for reading problems through detailed interview with parents and teachers. Probes for the number of schools attended, absenteeism (voluntary due to illness or vacation; required due to class or school suspensions and expulsions), and type of reading instruction provided at the school(s) in the primary grades may be informative. However, differential diagnosis may be complicated by parental history or current manifestation of SLD, given that parents with SLD would be less likely to be able to provide the necessary early reading or numerical experiences for the child.

COURSE AND PROGNOSIS

Converging evidence indicates that SLD is persistent and does not remit with increasing age in the absence of effective intervention. SLD tends to be a persistent and chronic condition that remains with the individual his or her entire life, albeit with developmental changes in its manifestation.

Telegram: @medical_k

www.konkur.in

Onset, recognition, and diagnosis of SLD usually occurs during the first few years of elementary school when children are expected to learn to read, write, spell, and do basic arithmetic. Precursor signs (e.g., delayed onset of talking; difficulties with counting or rhyming; problems with fine motor skills required for writing) commonly occur in preschool years before the start of formal schooling. Moreover, preschoolers with poor phonologic short-term memory (STM) skills and specific language impairment (SLI) are highly likely to meet diagnostic criteria for SLD in reading at school age. However, referral and formal diagnosis rarely occurs until a couple of years later in second grade, when the children have failed to respond to formal classroom instruction in reading.

SLD in elementary school–aged children (grades 1 to 3) typically manifests first as marked difficulty learning to connect letters with the sounds they make (particularly in English-speaking children), to recognize and read common one-syllable words (e.g., mat, top) or common but irregularly spelled words (e.g., said, two). Reading aloud is slow, inaccurate, and effortful. Some children may also (or instead) show problems in learning to count, remember math facts, and perform simple single-digit arithmetic. Recent evidence suggested that it is possible to estimate an individual child's risk for SLD in reading at school age from the following factors measured in preschool years (age 3.5 years): Familial history of reading problems, poor grammar and speech articulation, poor letter and object naming speeds, and poor phonologic awareness.

In the middle grades (grades 4 to 6), children with SLD may not only continue to show problems with word reading and basic number sense but also may manifest problems with spelling, writing, and understanding word problems in mathematics. Others may gradually be able to sound out words, but their reading is slow and effortful, they have difficulty understanding what they have just read, and also problems start to manifest in their written work (e.g., poor spelling, poor punctuation, words left out of sentences, short, disconnected sentences, illegible and disorganized writing). Some youngsters continue to count on their fingers since they cannot remember math

Telegram: @medical_k

www.konkur.in

facts. It is not uncommon, even at this young age, for children to dread going to school or to try to avoid reading, writing, or arithmetic.

By adolescence, some youngsters may show improved word recognition and the ability to sound out words, but reading remains slow and effortful, often with poor comprehension, and so they cannot keep up with the increasing demands for reading complex material. They often need to reread material to get even the main point and have great difficulty making inferences from written text. Written work is markedly impoverished: numerous spelling errors, illegible writing, with poor sentence, and paragraph structure. Those who showed problems in basic number sense at a younger age may use long and inefficient strategies to work out even simple arithmetic, such as “7 × 8” (e.g., draw 8 groups of 7 items, and then counting all of the items). Ongoing dread of and failure in school may result in high-school dropout, anxiety, and depression.

A longitudinal investigation of a 1990 U.S. cohort of children reveals that individuals with SLD in word reading (a.k.a., dyslexia) show an achievement gap in reading that is discernible upon school entry in grade 1 (about age 6) and that persists throughout childhood and adolescence. A more recent study by Shaywitz et al., in 2015, examined 414 students from the Connecticut Longitudinal Study to determine if differences between dyslexic and typical readers in their reading scores and verbal IQ are evident as early as first grade, as well as whether the trajectory of these differences is seen throughout adolescence. The study found that a significant achievement gap was evident as early as first grade, and the gap persisted into middle and high school. It remains unknown whether early reading intervention (i.e., kindergarten, grade 1) will eliminate the observed persistent difference in growth trajectories in reading. Likewise, a longitudinal investigation of a large sample of kindergarten children recruited from 1998 to 1999 and followed through 8th grade revealed that children with SLD in mathematics enter kindergarten with lower skill levels, and the achievement gap persists through grade 8.

Young adults with persistent problems in both reading accuracy and fluency appear to develop compensatory mechanisms to cope with reading, such as greater reliance on memory-based rather than

Telegram: @medical_k

www.konkur.in

analytic strategies to assist in word identification. By adulthood, many individuals try to hide the fact that they cannot read, spell, or do arithmetic by avoiding both leisure and work-related activities that require these skills, or use alternative approaches to access print (e.g., text-to-speech or speech-to-text software, audiobooks, audiovisual media).

The clinical course of SLD is often complicated further by comorbidity with other mental health problems, such as ADHD or conduct disorder, as well as with low self-esteem, anxiety, depression, and increased risk for suicidal ideation and suicide attempts. The causal relationships between SLD and the various comorbid disorders are unknown and longitudinal epidemiologic studies suggest that the relationships are complex.

On a more positive note, a recent study reported that adults with SLD in reading (a.k.a., “dyslexia”) are overrepresented among entrepreneurs and manifest higher levels of visual problem-solving skills compared to peers with average reading abilities. This subgroup of individuals attributed their success to an admixture of high self-motivation, educational accommodations, and a supportive social network, particularly parents.

Juan P, a 20-year-old Hispanic college student, presented at the primary care clinic in his home city, with complaints of increasing problems sleeping, inability to concentrate or manage his college schedule, failing some courses, and feeling “down” most days. Clinical history indicated a normal birth, slowness in learning to talk, childhood problems with concentration, hyperactivity and angry outbursts, as well as struggles learning to read, at school. Family history was positive for ADHD (older brother) and SLD (father, now deceased, was reported to have had “dyslexia” and dropped out of school early). He had been diagnosed with ADHD, Predominantly Combined Type, at age 9, but did not meet criteria for SLD, since the discrepancy between his intellectual capacity and reading achievement was deemed not to be “substantial” as required by DSM-IV and his local school board.

During the clinical interview, JP reported that since starting college a year ago, he had been unable to remain focused while reading or listening to lectures, felt overwhelmed, and was unable to complete written assignments on time. He complained of feeling restless, agitated, exhausted, and often in a “blue mood.” He denied any substance use or suicidal thoughts. He stopped taking medication for ADHD when he was aged 12 and had not sought registration with Student Disability Services at his college for help with his ADHD because he thought he could get through college by himself. The current psychoeducational assessment confirmed that JP’s reading fluency and comprehension, spelling, and written expression, were substantially and quantifiably below that expected for age and were causing significant impairment.

Diagnostic formulation: *Attention-Deficit/Hyperactivity Disorder*, with predominantly inattentive presentation, of mild to moderate severity; *Specific Learning Disorder*, with impairment in reading (fluency, comprehension) and written expression (spelling, organization of written expression), all currently of moderate

Telegram: @medical_k

www.konkur.in

severity; depressive symptoms but did not meet criteria for a mood disorder.

TREATMENT

Treatment focuses almost exclusively on academic intervention and rarely includes mental health services even though students with SLD experience higher levels of inattention (and ADHD), anxiety, and depression than their non-SLD peers. Moreover, treatment of SLD is typically carried out in education settings or specialized psychology clinics, and so is not the primary responsibility of psychiatrists or primary care providers.

The primary role of medical health care providers is that of coordinator, which, as a first step, includes the provision of psychoeducation about the disorder and its longer-term implications. Thus, physicians need to be able to explain what SLD is and refer parents (or the adult patient) to organizations, websites, or reading materials that will help (see the References for some useful websites). Also, parents may need help in understanding their child's needs and rights under the IDEA, including possible need for accommodations. Given that SLD tends to run in families, physicians may need to modify how any numeric health information is communicated (prevalence rates, risk ratios, dosage, etc.), as well as to check that the individual or caregivers are able to comprehend any relevant printed or website material.

A second critical step is to establish a monitoring plan with the patient and family, to permit early detection and management of commonly associated mental health problems, such as ADHD, anxiety, and depression, as well as to ascertain whether recommended accommodations have been put in place along with intensive, individualized, explicit instruction. Moreover, the need for transitional planning is essential to help individuals with SLD through major developmental and life transitions (e.g., transition from elementary to secondary school; from secondary school to the

Telegram: @medical_k

www.konkur.in

workforce or postsecondary education; marriage, parenthood, etc.) and facilitate access to services.

One of the major problems is that the standard instruction in regular classrooms is too little, too general, and nonsystematic. For example, one large-scale study found that children receiving special education over a 1-year period advanced in reading by only 0.04 standard deviations per year, which means that it would take at least 8 years to raise these students' scores from the 5th to the 9th percentile. By contrast, students with SLD in reading who received 1 to 2 hours daily of intense and focused intervention for a total of 35 to 70 hours of instruction showed dramatic gains in performance on standardized measures of both decoding and comprehension, which were maintained for several years after intervention. The instruction programs were very explicit and visible, conducted in small, interactive groups of children matched for reading abilities, which promoted engaged and repeated reading of connected text presented in a way that controlled task difficulty, and included instruction in basic reading abilities (e.g., teaching phoneme-to-grapheme correspondences), as well as the application of metacognitive strategies for decoding unfamiliar words and comprehending connected text. Of note, preliminary evidence suggests that intense and focused instruction may, in fact, alter the aberrant brain activation profiles observed in children with SLD. Thus, clinicians need to be aware that recommendations for placement in special education may not be sufficient to improve reading or arithmetic skills. Rather, they need to advocate for the provision of intense, focused, and explicit instruction in each of the affected academic domains.

Also, given the importance of literacy and numeracy skills in health, clinicians are advised to screen for and monitor health literacy and numeracy in all patients (and parents of pediatric patients), regardless of their referral problem. Low literacy or numeracy cannot be inferred reliably on the basis of the patient's education level, intelligence, or other observable behaviors. Reliable short screening forms can be used to assess health literacy and

Telegram: @medical_k

www.konkur.in

numeracy in adolescents and adults and to guide health communication.

Developmental Coordination Disorder

VIJAY VISHWANATH, M.D., PH.D., AND WENDY G. MITCHELL, M.D.

Developmental coordination disorder (DCD) is a neuromotor disability emerging in the early developmental period, which can affect both fine and gross motor skills, interfering with daily activities. Children with DCD have a motor performance that is typically slower, less accurate, and more variable than peers of the same age. DCD is estimated to occur in 5% to 6% of children aged 5 to 11 years, and 1.8% of children 7 years of age exhibit severe DCD. DCD affects boys more often than girls; most recent population studies report ratios of male:female of about 2:1. Children exhibiting DCD often show impairment in gross motor skills such as jumping, hopping, and running, fine motor skills, including handwriting, tying their shoelaces, or using utensils, and balance. Motor coordination disorder is comorbid up to 50% of the time with attention-deficit/hyperactivity disorder (ADHD). Other disorders that may co-occur with DCD are communication disorders and specific learning disorders. Delayed motor milestones may be the first sign of DCD in the absence of intellectual disability. Without intervention, DCD often continues to cause impairment throughout childhood and adolescence, leading to significant consequences physically, educationally, socially, and psychiatrically.

Telegram: @medical_k

www.konkur.in

DEFINITION

The essential feature of DCD, according to DSM-5-TR, is impaired motor skills leading to deficits in coordination compared to children of the same chronologic age and intellectual level, interfering with activities of daily living, social activities, and school productivity. Key symptoms are marked delays in achieving motor milestones, such as walking, crawling, and sitting, constantly dropping objects, inability to catch or throw a ball, and poor handwriting. Children with DCD perform motor coordination tasks slower and less accurately than those peers of the same chronologic age and intellectual capacity. Specific manifestations of DCD are detailed in Table 41–1.

HISTORY

In the early 1900s, childhood motor clumsiness was termed *motor deficiency syndrome*. This syndrome was characterized by awkward voluntary actions, excessive tendon reflexes, mild hypertonicity, and neurologic overflow movement. The term *clumsy child syndrome* first appeared in the literature in the 1930s to describe a set of symptoms associated with clumsy motor behaviors of unknown etiology, not associated with a known neurologic disorder. The observation was made that many children with motor coordination difficulties also exhibited ADHD, communication disorders, and specific learning disorders. During the 1940s, remedial programs were established in an attempt to improve academic learning deficits through the treatment of coordination difficulties observed in children.

By the 1960s, *clumsy child syndrome* was officially distinguished from other categories of learning disorders. From this period to the mid-1980s, significant investigations were conducted into perceptual-sensory causes for motor impairments, as well as social and emotional problems associated with such impairments. Children with clumsy behavior were noted to have deficits rather than solely delayed fine and gross motor coordination skills.

Telegram: @medical_k

www.konkur.in

COMPARATIVE NOSOLOGY

Many terms have historically been applied to the description of *clumsiness* in a child. Terms used in the past that overlap with a description of DCD include congenital maladroitness, choreiform syndrome, psychomotor syndrome, developmental apraxia, developmental dyspraxia, congenital clumsiness, developmental agnosia, and developmental dyspraxia–dysgnosia. It is only appropriate to make a diagnosis of DCD after any suspicion of a neurologic disorder is ruled out. In the DSM-5-TR, DCD is not diagnosed if symptoms are attributable to an intellectual developmental disorder or a neurologic condition such as cerebral palsy, muscular dystrophy, or a degenerative disorder. Although currently, this syndrome is still occasionally referred to as clumsy child syndrome, DCD and specific developmental disorder of motor function are more appropriate terms.

Telegram: @medical_k

www.konkur.in

Table 41–1.
Manifestations of Developmental Coordination Disorder

Gross Motor Manifestations
Preschool age
Delays in reaching motor milestones, such as sitting, crawling, and walking
Balance problems: Falling, getting bruised frequently, and poor toddling
Abnormal gait
Knocking over objects, bumping into things, and destructiveness
Primary-school age
Difficulty with riding bikes, skipping, hopping, running, jumping, and doing somersaults
Awkward or abnormal gait
Older
Poor at sports, throwing, catching, kicking, and hitting a ball
Fine Motor Manifestations
Preschool age
Difficulty learning dressing skills (tying, fastening, zipping, and buttoning)
Difficulty learning feeding skills (handling knife, fork, or spoon)
Primary-school age
Difficulty assembling jigsaw pieces, using scissors, building with blocks, drawing, or tracing
Older
Difficulty with grooming (putting on makeup, blow-drying hair, and doing nails)
Messy or illegible writing
Difficulty using hand tools, sewing, and playing piano

DCD was included as a diagnosis in DSM-III-R and appears in essentially the same form in DSM-5-TR. The tenth edition of the *International Statistical Classification of Diseases and Related*

Telegram: @medical_k

www.konkur.in

Health Problems (ICD-10) also includes the disorder, but the slightly more formalized definition requires an intelligence quotient of at least 70 and performance at least two standard deviations below the mean on a standardized test of motor coordination. In 1994, an international consensus meeting held in London, Ontario, agreed on the term DCD to describe children with a heterogeneous set of motor impairments that caused impairment in performing motor tasks compared to same-age peers. ICD-11 updated the disorder in by listing five essential criteria that more closely align with the DSM-5-TR criteria.

Although DSM-5-TR and ICD-10 and 11 view the disorder as a unitary undifferentiated syndrome, several investigators have suggested that there may actually be several distinct subtypes. Supporting that view is the individual variation in symptomatology, only some of which is clearly age-related. One recent attempt was to reclassify DCD proposed subtypes, such as ataxic syndrome (marked by unsteadiness and mild tremors), hypotonic syndrome (characterized by below-average resting muscle tone), tension syndrome (manifested by constant and excessively high levels of muscle tone), dyspraxic syndrome (identified by the inability to link a series of submovements necessary to execute smooth motor movements), manual–graphic syndromes (two separate manual syndromes, one marked by inadequate dexterity but adequate ability to reproduce written symbols and the other characterized by adequate dexterity but inability to reproduce written symbols accurately using fine motor movements), visual-perceptual clumsiness (ranging from ocular-motor problems involving inefficient movement of eye muscles to severe retinal deterioration), and mixed syndromes (a combination of symptoms already presented under the aegis of the previous six classifications). It is always important to keep in mind that significant ataxia, hypotonia, or any asymmetry between left- and right-side muscle function may be an indicator of a neurologic disorder and requires a neurologic assessment.

EPIDEMIOLOGY

Telegram: @medical_k

www.konkur.in

The prevalence of DCD has been estimated to be approximately 5% to 6% among school-aged children. DCD has been noted in Europe, Asia, Africa, Australia, and North America. Clinical studies of children with DCD have historically found greater rates in boys than girls, of up to 7:1. More recent population studies have found less disparity, and report rates of approximately 2:1, male to female.

ETIOLOGY

A meta-analysis of performance deficits in DCD by Wilson and colleagues (2013) found that several clusters of deficits in learning motor skills emerged, suggesting that brain networks including parietocerebellar and cerebellar regions are involved. The clusters of motor skills dysfunction include “internal modeling of action” (predictive control of motor skills), rhythmic coordination and timing of motor movements, executive function, and dynamic control of posture and gait. The result of insufficient internal models, due to deficits in neural pathways in DCD leads to a lack of fluency and efficiency in coordinated movement. That is, the sequence of a complex motor movement in children with DCD is not properly or efficiently ordered, leading to awkward motions. Poor ability to coordinate a sequence of motor movements in DCD may be attributable to dysfunction in the corticocerebellar brain region. In terms of executive function deficits, impaired attention, working memory, and inhibition may contribute to poor action planning, and exacerbate overall poor motor coordination. The exact etiology of DCD is not yet clear; however, it is likely to include heritable factors, with potential prenatal and prenatal-developmental contributions. There is much heterogeneity in the expression of DCD. Motor control is dependent on numerous skills, including perception of objects in space, regulation of muscle activity, and balance. Children with DCD appear to be less proficient and less consistent in regulating muscle activity in heterogeneous ways. Some children with DCD are poor in manual skills, while exhibiting proficiency in balance, and for others, the opposite is true.

Telegram: @medical_k

www.konkur.in

DCD and ADHD

Epidemiologic surveys have documented the comorbid occurrence of DCD in 30% to 50% of children diagnosed with ADHD. A study of children comorbid for ADHD and DCD in the Netherlands by Fliers et al., in 2007 confirmed previous research demonstrating a consistent increased risk of each of these disorders based on the presence of the other one. This study also investigated the association between the various types of motor coordination problems and inattentive versus hyperactive or impulsive subtypes of ADHD. In this study, data suggested that inattentive rather than hyperactive or impulsive symptoms were related to higher measures of motor coordination symptoms on the Developmental Coordination Disorder Questionnaire (DCD-Q) that was filled out by parents. This finding lends support for hypotheses that deficits in information processing are contributing problems underlying both ADHD and DCD. Although parents report that motor coordination problems often diminish with age, half of adolescents comorbid for ADHD and DCD continue to be impaired by coordination problems. One possible commonality between DCD and ADHD is a deficit in cerebellar activity. The coexistence of DCD and ADHD may reflect a shared heritable disturbance of the dopamine pathway. These two disorders may also share dysfunction in the basal ganglia and the prefrontal cortex.

DCD and Premature Birth

Evidence indicates biologic and cognitive-developmental correlates of DCD. The biologic-organic factors associated with the disorder include various birth and perinatal problems, such as low birth weight, prematurity, hypoxia, and neonatal malnutrition. A study by Marlow and colleagues investigated motor and “executive” cognitive function in 241 children who were born severely prematurely, at less than or equal to 25 complete weeks of gestation. These children were assessed at a median age of 6 years and compared with 160 classmates born at full term. Children underwent assessment of cognitive and neuromotor skills, including the Kaufman Assessment Battery for Children (K-ABC) and the NEPSY (a teacher-based

Telegram: @medical_k

www.konkur.in

assessment of academic achievement). Motor function was assessed by clinicians using the following items from the Movement Assessment Battery for Children (MABC): Heel-toe walking (15 steps), 1-leg balance (more than 20 seconds), and time to post 12 coins. Results from this study indicate that compared to classmates, children born severely prematurely and in the absence of cerebral palsy exhibited a high prevalence of impairment in gross motor function at early school age, in addition to impaired visual–spatial, perceptual-motor attention, and executive function. In each of the above impairments in motor skills or executive functions, at least half of the deficits were not accounted for by limitation of the overall cognitive score. Thus, motor and executive function disturbances in extremely prematurely born children are not due to compromised intellectual function but are more specifically associated with perceptual deficits. Children who were born extremely prematurely were observed to need more time for tasks compared to full-term classmates, and they were noted to have greater difficulty inhibiting associated movements and maintaining a secure postural basis during activities. As many as 7% of extremely prematurely born children were unable to balance on one leg for 20 seconds (compared to 1% of classmates). This study showed that extremely prematurely born children did not differ significantly from classmates on observed off-task motor behavior (17% vs. 25%), mirror movements (32% vs. 46%), and overflow movements (45% vs. 69%). Some investigators have postulated a continuum of reproductive casualty. There are also suggestions of incomplete cerebral dominance or lateralization, neurochemical abnormalities in the brain, and structural lesions in the parietal lobes.

DCD and Speech-Language Comorbidities

DCD frequently occurs concurrently with speech–language disorders and specific learning disorders, including reading disorders and dyslexia. A study showed that more than half of children with severe dyslexia exhibited motor coordination impairments severe enough to warrant intervention. Reading disorders, dyslexia, and speech and

Telegram: @medical_k

www.konkur.in

language disorders have been hypothesized to be associated with cerebellar involvement, as has DCD. One longitudinal study of children with language impairments revealed a continuing correlation between peg-moving performance and language performance. Another study found that fine motor skills, response speed, and upper limb speed were associated with language disturbances, whereas gross motor coordination and visual–motor control were not. Furthermore, evidence indicates that articulation problems are related to motor impairment, although the motor impairment is not necessarily dyspraxia.

DIAGNOSIS AND CLINICAL FEATURES

In 2012, The European Academy of Childhood Disability (EACD) published an interdisciplinary clinical guideline for the assessment, diagnosis, and treatment of children with DCD. These guidelines were subsequently revisited in 2019 to publish the international clinical practice recommendations on the definition, diagnosis, assessment, intervention, and psychosocial aspects of DCD. The essential feature of DCD is poor skill in daily motor activities for a given child's age and intellectual level. Impairments may be observed in gross motor activities, such as running, kicking, or catching a ball, as well as in fine motor coordination, resulting in poor ability to write letters neatly, to drink from a cup, or to use a knife and fork well. Children with DCD exhibit a heterogeneous pattern of impairments and thus function more competently in some motor task areas than others.

The current proposed criteria for diagnosis of DCD per the 2019 international clinical practice recommendations by EACD is similar to the DSM-5-TR diagnostic criteria for DCD (Table 41–2). Careful history-taking (preferably from parents, collateral sources other than parents, and the children themselves), problem-oriented clinical observation, and examination are essential to support the identification of the four diagnostic criteria. However, the recommended order of criteria application to arrive at the final accurate diagnosis of DCD involves first considering the age and

Telegram: @medical_k

www.konkur.in

medical history of the patient (criterion C), then ruling out other medical conditions (criterion D), analyzing the impact on activities and academic achievement (criterion B), and finally, quantification of motor impairment (criterion A). Due to the large variability of motor abilities in normal development, a formal diagnosis of DCD under the age of 5 years is only initiated by motor assessment in case of severe impairment and is usually confirmed by a second motor assessment at least 3 months apart.

Table 41–2.
DSM-5-TR Diagnostic Criteria for Developmental Coordination Disorder

A. The acquisition and execution of coordinated motor skills is substantially below that expected given the individual's chronological age and opportunity for skill learning and use. Difficulties are manifested as clumsiness (e.g., dropping or bumping into objects) as well as slowness and inaccuracy of performance of motor skills (e.g., catching an object, using scissors or cutlery, handwriting, riding a bike, or participating in sports).
B. The motor skills deficit in Criterion A significantly and persistently interferes with activities of daily living appropriate to chronological age (e.g., self-care and self-maintenance) and impacts academic/school productivity, prevocational and vocational activities, leisure, and play.
C. Onset of symptoms is in the early developmental period.
D. The motor skills deficits are not better explained by intellectual developmental disorder (intellectual disability) or visual impairment and are not attributable to a neurological condition affecting movement (e.g., cerebral palsy, muscular dystrophy, degenerative disorder).

Assessment Instruments for DCD

The Developmental Coordination Disorder Questionnaire. The DCD-Q is a 17-item parent questionnaire developed in Canada and validated to identify motor coordination problems in children aged 5–15 years by Wilson et al. (2000). For each item, parents rate the degree of coordination in their child compared to others of the same age on a 5-point scale. By adding the scores for each item, a total DCD-Q score can be calculated. In the study validating this instrument for young children, a score of less than or equal to 53 (15th percentile) was used as the criterion for DCD. The 17 items on the DCD-Q are:

1. Throw ball
2. Catch ball
3. Hit ball
4. Jump over
5. Run and stop
6. Plan activity
7. Writing speed
8. Writing legibly
9. Pencil pressure
10. Cutting
11. Team sports
12. Avoids sports
13. Rides bicycle
14. Learns skills
15. Clumsy
16. Awkward
17. Fatigues easily

The Movement Assessment Battery for Children. The MABC-second edition, was introduced by Barnett, Henderson, and Sugden in 2007 and provided an indication of gross and fine motor skills for children 4 years to 16 years of age. The MABC has two parts: a

Telegram: @medical_k

www.konkur.in

checklist and a performance test. On the MABC checklist, teachers rate the motor performance of children on 48 items reflecting everyday activities in the lives of children from 4 to 12 years. The checklist is divided into 4 sections, with 12 items in each section. On the performance test, there are four age-related item sets, each consisting of eight items that measure manual dexterity, ball skills, and static and dynamic balance. The checklist is a reliable instrument within sections and overall. Since the nature and severity of problems in DCD are very broad, an instrument meant to screen children with DCD must be able to measure a wide variety of motor skills.

Bruininks–Oseretsky Test of Motor Proficiency for Identifying Children with Motor Impairment. The Bruininks–Oseretsky Test of Motor Proficiency (BOTMP) assesses motor skills in children from 4½ to 14½ years old and provides a comprehensive index of motor proficiency as well as individual measures of gross and fine motor skills. In addition to the long form (LF), there is also a short form (SF), which consists of 14 items from the LF that have been validated. A recent study of the BOTMP in the assessment of preschoolers investigated the correlation between the LF and the SF of the instrument. Although the correlation between the two forms was high, short-form total scores were found to be significantly higher than long-form scores, identifying fewer children as having a motor impairment. Therefore, although the LF has been validated for young children, the SF is questionable in its ability to identify motor impairment in very young children.

Additional tests include the Frostig Movement Skills Test Battery, the Slosson Drawing Coordination Test, the Southern California Sensory Integration Test, and the Stott Test of Motor Impairment, which provide a comparative measure of a child's abilities.

CLINICAL FEATURES OF DCD

Symptoms of DCD may be broken down into the following categories: dyspraxia, synkinesia, hypotonia, hypertonia, tremors,

Telegram: @medical_k

www.konkur.in

impersistence, and asymmetries. *Dyspraxia* describes a child's difficulty in exhibiting sequenced, coordinated motor movements when presented with an oral request. Movements identified as *synkinesia* are best described as unintentional muscle movements, also termed *motor overflow*. Mirror movements, such as finger twitching on the opposite hand when the child is asked to perform a finger opposition task or facial grimaces when the child is asked to make hand movements, are examples of synkinetic motor actions.

Two categories that describe muscle tone abnormalities are *hypotonia* and *hypertonia*. Hypotonia can be observed in all parts of the body and is characterized by a flaccid or sleepy quality in the child's facial expression and general muscle tone. Children with this condition may exhibit poor posture and obesity. Children with hypotonia often appear to be floppy and weak, but on actual muscle strength testing, they may have normal muscle strength. *Hypertonia* generally describes high levels of muscle tone in a child. For example, a child with hypertonic movement cannot finish drawing a line at a given point, instead overshooting the intended stopping point. Another example is a child who tends to throw a ball too hard and inaccurately at short distances.

The movement category of *tremors* is marked by irregular unsteadiness in motor movements observed in tasks requiring walking, drawing, or both. For example, legibly formed letters might reveal, on closer inspection, rapid tremors in the actual lines themselves. Unsteadiness might be exhibited in the child's gait as high-amplitude fluctuations in leg muscle movement.

The category of *impersistence* refers to the child's inability to sustain and maintain various body postures for reasonable periods of time. Asking a child to stick out their tongue is an example of a task used often to investigate impersistent motor movements. In this example, the clinician would keep track of how long the child could maintain this tongue position.

The final movement category, *asymmetries*, describes motor behaviors that affect only one side of the body. This category includes unusual flexions or muscle weakness, or both, on one side of the body or general muscle weakness in the limbs on one side.

Telegram: @medical_k

www.konkur.in

These asymmetrical muscle movements can be observed by requiring a child to move laterally in a rapid manner ("like a basketball player on defense, not crossing your feet"). If the child executes the movement more fluidly on one side than the other, it might indicate an asymmetry. A child who is observed to have asymmetrical motor movements is likely to be referred for a magnetic resonance imaging (MRI) study to rule out an organic cause for this symptom. If the neurologic workup is negative, then this symptom may be considered part of a DCD.

Specific manifestations vary across individuals; thus, there is no typically clumsy child. In some instances, manifestations may be quite specific; one case report describes a child who could sew and do jigsaw puzzles without difficulty but could not write neatly.

The most common way to identify DCD is through the observation of delays in achieving motor milestones (e.g., sitting, standing, crawling, and walking). Gross motor coordination manifestations may be seen in difficulties with activities such as sitting, walking, running, balancing, throwing, and kicking. Fine motor coordination manifestations may be identified through difficulties in performing tasks, such as using utensils, tying laces, buttoning or zipping clothing, drawing, and, especially, printing or writing. During motor tasks, children with DCD may exhibit overflow movements in unsupported limbs, mirror movements, slight abnormalities of reflex, or poor ability to make movements smooth.

Some manifestations of DCD are age dependent. Young children show symptoms, such as delayed development, in early motor milestones and delayed acquisition of self-help skills, such as self-dressing (i.e., tying ties, fastening snaps, zipping zippers, buttoning, and unbuttoning) or self-feeding (handling a knife, fork, or spoon). Preschool-aged children may also have balance problems, awkward gait, and a history of frequently bumping into objects, falling down, and getting bruised. Problems with balance, hopping, jumping, catching and bouncing a ball, and tracing appear to be among the more common symptoms of school-aged children with DCD. A common sign of DCD among school-aged children is avoidance of

Telegram: @medical_k

www.konkur.in

sports activities because of poor performance or teasing by classmates.

In addition, children with DCD frequently have comorbid communication and learning difficulties. Among the more common of these difficulties are expressive language disorder, mixed receptive–expressive language disorder, phonologic disorder, reading disorder, disorder of written expression, and mathematics disorder.

Secondary complications for children with DCD often involve rejection from peers who are critical of their poor abilities in sports activities and other tasks. Over time, children who are chronically "picked last" for sports teams and who are unable to keep up physically with their peers may become demoralized or depressed. The DSM-5-TR diagnostic criteria for DCD are listed in Table 41–2. The ICD-10 and 11 diagnostic criteria for specific developmental disorder of motor function (ICD-10) and developmental motor coordination disorder (ICD-11) are presented in Table 41–3A and B.

Table 41–3A.
ICD-10 Diagnostic Criteria for Specific Developmental Disorder of Motor Function

A. The score on a standardized test of fine or gross motor coordination is at least two standard deviations below the level expected for the child's chronological age.
B. The disturbance described in Criterion A significantly interferes with academic achievement or with activities of daily living.
C. There is no diagnosable neurological disorder.
D. Most commonly used exclusion clause. IQ is below 70 on an individually administered standardized test.

Differential Diagnosis

Telegram: @medical_k

www.konkur.in

Informal observation by parents, teachers, and clinicians of gross motor coordination (e.g., hopping, jumping, and standing on one foot), fine motor coordination (e.g., finger tapping and shoelace tying), and hand–eye coordination (e.g., catching a ball and copying letters) is the most common initial screen for identification of coordination difficulties. However, given the vast normal variation in motor skills, it is often not easy to make a diagnosis of DCD. When coordination difficulties interfere with academic achievement or activities of daily living, however, formal testing and evaluation of these skills are recommended (Table 41–4).

Ruling Out Neurologic Disorders. Children with developmental motor disorders progress in gross and fine motor milestones, although at a slower rate than peers. They do not regress. Thus, a child who previously walked, ran, and climbed at age-appropriate levels but who no longer does these activities well should be evaluated for neurologic disorders. A child whose balance has deteriorated needs further testing to determine the cause of the change. Similarly, a child whose fine motor development was at the age expectation but who stopped using a hand, switched apparent hand dominance, or lost previous abilities should be assessed for other medical conditions. Even a child whose initial motor landmarks were delayed should be carefully investigated if they lose previously established abilities.

Table 41–3B.
ICD-11 Essential (required) Features for Developmental Motor Coordination Disorder

- Significant delay in the acquisition of gross or fine motor skills and impairment in the execution of coordinated motor skills manifesting as clumsiness, slowness, or inaccuracy of motor performance.
- Coordinated motor skills are markedly below that expected given the individual's chronological age and level of intellectual functioning.
- Onset of coordinated motor skill difficulties occurs during the developmental period and is typically apparent from early childhood.
- Coordinated motor skills difficulties cause significant and persistent limitations in functioning (e.g. in activities of daily living, school work, vocation and leisure activities).
- Difficulties with coordinated motor skills are not solely attributable to a Disease of the Nervous System, Disease of the Musculoskeletal System or Connective Tissue, sensory impairment, and not better explained by a Disorder of Intellectual Development.

- Weakness
- Asymmetry

Family history is important in consideration of neurodegenerative conditions such as spinocerebellar degeneration, Huntington disease, peripheral neuropathies, or other neuromuscular disorders. Further investigation should be pursued even if the positive family history is of onset in adulthood. Many dominantly inherited neurodegenerative conditions show “anticipation,” presenting in subsequent generations at earlier ages, even early childhood.

A physical examination, including a neurologic examination, should be performed. Skin stigmata, for example, may suggest a neurocutaneous syndrome (i.e., multiple café-au-lait spots, axillary or inguinal freckles suggesting neurofibromatosis type I (NF1); hypomelanotic macules, fibrous cephalic plaques, facial angiofibromas suggesting tuberous sclerosis). Excessive diffuse skin pigmentation, particularly in non–sun-exposed areas, is a clue to possible corticotropin excess, seen in boys in the early phases of adrenoleukodystrophy, at a time when the only other complaints may be loss of adept motor skills and behavior problems. Dysmorphic features, even subtle, may suggest an etiology. The presence of scoliosis, a dimple, bulge, or hair tuft over the spine, or limb asymmetries may suggest that the motor findings are due to a structural spinal cord abnormality. Examination of the ocular fundi is sometimes challenging in small children but is particularly important if loss of motor milestones is accompanied by other symptoms such as headache or vomiting.

Telegram: @medical_k

www.konkur.in

Screening evaluation of cranial nerve function in young children is most easily assessed by observation of eye movements, facial movements, listening to the quality of speech, and watching the child swallow. For example, a child who cannot easily swallow water from an open cup or who coughs or gags when doing so may need to have a gag reflex formally tested. The extremities should be evaluated for muscle bulk, tone, and symmetry of length and girth. Asymmetric extremity size suggests either a structural brain or spinal cord lesion. In young children, strength is best assessed by observation of the child performing specific activities, such as rising from the floor, climbing onto a stool, reaching overhead for a toy, jumping, and hopping. Diffuse or symmetric muscle atrophy or weakness may suggest a neuromuscular disorder (i.e., muscular dystrophy, congenital myopathy, and neuropathy), malnutrition, or systemic illness. For example, boys with early manifestations of Duchenne muscular dystrophy may appear motor delayed and maladroit well before there are obvious complaints of weakness. Although testing of tendon reflexes may yield somewhat inconsistent results in young children, consistent asymmetries, the complete absence of reflexes, or frank hyperreflexia, clonus, or extensor plantar responses mandate further investigation. Gait should be observed in multiple ways: Watch the child walking, running, tandem walking, skipping, and walking on heels and toes. In addition to watching the gait pattern, the examiner should pay attention to posture and movement of the upper extremities as the child walks or runs. Abnormalities such as asymmetric arm swing or dystonic posturing of one or both hands are sometimes only appreciated with activity. Balance can be assessed both by watching the child perform ordinary activities, such as rising from the floor, walking, or turning, and by more structured tasks, such as standing on one foot. Frank ataxia, as opposed to immaturity and delay in acquiring skills, should mandate additional investigations. Many different genetic conditions present with truncal ataxia, with or without other deficits. The initial presentation may be relatively subtle. Fine motor abilities can be observed both directly (i.e., finger-to-thumb tap, thumb-to-sequential-finger-tap) and by watching the child during age-appropriate

Telegram: @medical_k

www.konkur.in

activities. For example, watch the child pick up a toy, color, write, use a handheld computer game or tablet-type computer, drink from a cup, or use a spoon. Look for asymmetries, dystonic posturing, or tremor. Look for tremor or dystonic posturing of the outstretched arms.

Poor motor coordination frequently coexists with learning disorders and disruptive behavior disorders, such as ADHD, particularly in children with high levels of impulsivity. A child may meet the criteria for DCD and ADHD. The tendency for children with DCD to be accident-prone, to fall down, to hurt themselves, and to break objects may, at times, be construed as destructiveness. In the school setting, a child's motor difficulty with holding a pencil and writing legibly may result in great frustration for the child and the teacher. For children whose impaired writing ability and poor production are inadvertently interpreted as a lack of motivation, demoralization is common, and an evaluation for special educational services may be warranted. Children with DCD are at higher risk for poor social skills and are often victimized by bullies.

www.konkur.in

Jimmy was referred for evaluation to determine his need for adaptive physical education (PE), age 9 years of age. Jimmy was failing PE, was unable to run a mile, and he could not throw or catch the ball, and was generally slow motorically. His classmates laughed because he looked so “funny” while running, and he always seemed to be getting hit with the ball instead of catching it. Jimmy was always picked last for team sports games and was beginning to be bullied by his classmates for his poor physical skills. Jimmy already had an accommodation for more time on tests due to his previously diagnosed ADHD. He was being treated with Vyvanse, which was working well. A developmental history revealed that Jimmy was born prematurely at 31 weeks, and his motor milestones were all delayed, although speech milestones were right on time. Currently, Jimmy was unable to tie his shoes correctly, and he struggled to handwrite letters correctly, but his parents were hoping that he would outgrow those problems. Upon questioning Jimmy’s current motor skills, it became apparent that not only was he having coordination problems but that he was now being rejected by peers and had become quite socially isolated. At home, Jimmy’s parents had accepted the fact that he was just a clumsy boy and noted that Jimmy constantly spilled his drinks and was awkward when he used a fork. His food often fell off a fork or spoon before it reached his mouth, and he had great difficulty using a knife and a fork. A comprehensive assessment of fine and gross motor skills yielded the following results: Jimmy was able to hop, but he could not skip without briefly stopping after each step. He could stand with both feet together but could not stand on tiptoe. Jimmy held a ball bounced to him at chest level, and he could not catch a ball bounced to him on the ground from a distance of 15 ft. Jimmy’s agility and coordination were measured with the Bruininks–Oseretsky Test of Motor Proficiency (BOTMP), which revealed functioning levels commensurate with those of an average 7-year-old child.

Telegram: @medical_k

www.konkur.in

Jimmy was referred to a neurologist for a comprehensive evaluation to rule out neurologic disorders. On neurologic examination, Jimmy was found to have no signs of a specific neurologic disorder. Neurologic examination was negative for conditions that could account for his poor motor skills. Based on the history and findings on the BOTMP, Jimmy was given a diagnosis of DCD. Jimmy's symptoms included gross and fine motor impairments, poor balance, and mild hypotonia. Based on an individualized educational plan (IEP) meeting with his school, it became evident that Jimmy required an adaptive PE program for DCD and had other specific learning disorders. In addition to his known ADHD, Jimmy was found to have a writing disability. A treatment plan was developed that included twice weekly with an occupational therapist who used perceptual-motor exercises to improve his fine motor skills, particularly targeting writing and the use of utensils. Jimmy was also enrolled in a treatment program using motor imagery training to improve clumsiness and was also referred to a social skills group to help him deal more effectively with his peers.

Jimmy was relieved to be receiving help, especially for his handwriting and PE class, which he had been close to failing. Over a period of 4 months of treatment, Jimmy showed some improvement in the legibility of his handwriting, although he remained a slow writer. He was responsive to the stimulant medication, and his academic achievement improved as his attention span increased. Jimmy was receiving more praise from his teachers than ever before, and his classmates were teasing him less. As he began to feel better about himself, he began to try to play sports informally with his peers, although not competitively. He was given a modified PE program in school, and he was not required to play on teams, but he practiced throwing and catching a ball and was allowed to walk his mile at a slower time. Jimmy continued to exhibit some impairment in fine motor skills over the year, and he was cooperative with the therapeutic interventions, showed some continual improvement, and demonstrated improved peer relationships.

COURSE AND PROGNOSIS

Children with DCD represent a heterogeneous group with a variety of impairments in gross and fine motor behaviors needed for everyday living as well as in static balance. The profile of specific deficits for a given child is individual and has been shown in recent studies to be modified positively by specific motor skills interventions. The outcome of motor coordination disorder is influenced by the severity of the impairment, the age of initiation and duration of therapeutic interventions, and the presence of comorbid disorders. A recent study of preschool children with DCD at 7 to 8 years of age revealed that those children who had significant impairment at 5 years of age continued to show impairment 1.5 years later. Longer-term studies have shown that motor coordination improves over the long term in at least 50% of children when they reach adolescence. A 2-year follow-up study of children of primary school age who had failed a motor test battery revealed motor performance that, although improved, was still inferior to that of controls. The children with motor impairments also showed poorer educational performance than controls.

A 10-year follow-up of clumsy children and their age-matched, sex-matched peers was done in children over a period of 8 to 9 years. When first identified, the clumsy children were approximately 6 years of age; at follow-up, they ranged from 15 to 17 years of age. Follow-up testing indicated that the clumsy children were still significantly below the controls in most motor skills (e.g., dexterity, ball skills, balance, cutting with scissors, catching, and walking backward) and in global ratings by physical education teachers. The clumsy adolescents showed higher rates of dysgraphesthesia, dysdiadochokinesia, and motor slowness. In addition, the educational achievements of the clumsy adolescents were significantly poorer, and they had significantly lower perceived social competence than their nonclumsy peers. This finding substantiates reports of continuing secondary problems, including peer problems,

Telegram: @medical_k

www.konkur.in

low self-esteem, and academic struggles in children and adolescents with significant coordination difficulties.

A long-term follow-up of children with DCD and those with ADHD and DCD at 22 years of age suggests that there are psychosocial ramifications into adulthood. Psychosocial adjustment difficulties present in young adults with only DCD and those who were comorbid for ADHD included unemployment, use of substances, continued difficulties with reading, and legal problems.

DCD tends to improve in most individuals over time, and those with more severe impairment at a younger age, as well as those comorbid for additional psychiatric disorders, have the poorest prognoses.

TREATMENT

Interventions for developmental motor coordination can be divided into three major categories: (1) *Task-oriented* approaches such as Neuromotor Task Training (NTT) and Cognitive Orientation to Occupational Performance (CO-OP); (2) *Process-oriented* approaches such as Sensory Integration (SI) and kinesthetic training; and (3) *traditional physical and occupational therapy* such as perceptual-motor training, and a therapist-guided parent or teacher intervention. A meta-analysis of interventions to treat DCD in children by Smits-Engelsman and colleagues (2013) found that the strongest evidence of effective treatment for DCD was for task-oriented approaches and traditional motor training therapies, with process-oriented therapy yielding only weak efficacy.

Task-Oriented Approaches

Task-oriented therapies focus on learning particular motor skills with a focus on the aspects of the movements that pose the greatest difficulties for the child. NTT is a hybrid of practicing specific problematic specific motor skills with the addition of cognitive behavioral strategies to increase motor planning, reduce anxiety, and increase the incentive for trying. CO-OP is another form of task-

Telegram: @medical_k

www.konkur.in

oriented therapy which directs a child to form a mental model of how a particular set of movements will be accomplished and then review with the therapist how well the mental image fits the actual motor task trials. CO-OP consists predominantly of cognitive behavioral problem-solving approaches and utilizes cognitive behavioral strategies proposed by Donald Meichenbaum.

Computer gaming with virtual physical motor tasks has been found to benefit children with DCD, often without explicit instructions or learning. A study of children with DCD playing a computer game designed in which children need to catch a ball virtually on the screen showed that they used visual cues to help them virtually catch the ball without even realizing it. These children were able to improve their computer scores implicitly by practicing the game and making use of a perceptual cue without having to be specifically instructed on how to improve. This has implications for treatment in that in addition to providing direct instruction to children with motor coordination problems, improvement can also occur with practice through environmental cues that are not necessarily identified.

A newer task-oriented strategy is Nintendo Wii Fit Training (Wii training). The Nintendo Wii is a gaming system that combines motion sensor technology in handheld controls, and a balance board provides both aspects of biofeedback and virtual reality to the player. In this way, an interactive video game can serve as a therapeutic tool for motor skills improvement.

A study of 56 children between 6 years and 10 years with DCD compared NTT (n = 37) to Wii training (n = 19) by Ferguson and colleagues. Children in the NTT group were provided two sessions per week (45 to 60 minutes) for 9 weeks in which they played games such as soccer, tag, and netball under the guidance of therapists who facilitated the learning of motor skills, provided positive feedback, and manipulated the environment when necessary. Children in the Wii group participated in 30 minutes of gaming three times a week for 6 weeks under the supervision and guidance of therapists who encouraged, praised, and motivated the children. Games included sports such as cycling, soccer, skateboarding, and skiing. Games required that the children shift their weight from side

Telegram: @medical_k

www.konkur.in

to side and jump over virtual objects, and some games required twisting of arm movements. The results found mean motor performance scores in both groups improved during the course of the study. The NTT group showed greater improvement in overall motor performance, functional strength, and cardiorespiratory fitness, while the Wii group showed significant improvement in anaerobic performance. Thus, this study suggests that both NTT and Wii training can provide valuable therapeutic gains.

Overall recommendations for first-line interventions for children with DCD include task-oriented therapies of various types. Younger children can benefit from NTT for problems such as handwriting, that is, writing letters, even before they learn to read. Older children and those with verbal skills may be able to benefit from CO-OP approaches that incorporate more verbal planning. Nintendo Wii and other gaming interventions can be beneficial for children with DCD of all ages.

Process-Oriented Approaches

There has been only a weak suggestion from studies that process-oriented approaches are effective therapies for DCD. However, they are often used in conjunction with other strategies. Process-oriented interventions aim to target neural structures, such as the cerebellum, for improving balance, or sensory processes, such as proprioception, in children with DCD. Interventions aim to enhance and remediate sensory input processing, for example, sensory integration therapy (SIT). SIT approach was introduced in the work of Ayres in the late 1970s, who focused remediation on enhancing sensory information processing in order to achieve more accurate motor execution. Sensory integration programs are often delivered as a related service to children with DCD under the direction of occupational therapists. These programs prescribe specific physical therapies that attempt to modify the motor and sensory functioning of these children. These therapies are based on the notion that sensory integration disorders interfere with body movements and body awareness. Activities are designed to target the tactile, vestibular,

Telegram: @medical_k

www.konkur.in

and proprioceptive systems. A sensory integration program that addresses disorders affecting the proprioceptive system (bumping into walls and inability to button, skip, or write) might involve using scooter boards to improve balance and body awareness. Multisensory modalities, including visual, auditory, and tactile materials, are utilized in this form of treatment. Motor imagery training for clumsiness in children has received attention recently based on results from controlled investigations of this modality compared to perceptual-motor interventions. One study used a successful motor imagery intervention through CD-ROM, which contained six main training components for children with coordination difficulties. The components included visual imagery exercises involving predictive timing, relaxation, and mental preparation, visual modeling of fundamental motor skills, mental rehearsal of skills from an external perspective, mental rehearsal of skills from an internal perspective, and overt practice. This model of treatment is based on the notion that deficits in a child's ability to internally represent the movement tasks contribute to poor motor coordination. The ability for visual imagery of objects is not typically impaired in children with DCD. The previously mentioned training exercises were designed to improve the timing and accuracy of a given child's ability to visualize motor tasks, as well as to reduce muscle tension while imagining completing the given motor task. Finally, the children were trained to mentally rehearse the task before actually practicing it.

Traditional Physical and Occupational Therapy

Traditional physical and occupational therapies target actual activities of daily function and seek to improve the execution of these motor behaviors. A variety of cognitive-motor approaches have been utilized to improve the planning and execution of motor skills. One cognitive-motor approach to improving functional skills by Sugden and Hendersen has been updated and labeled ecologic intervention, which places emphasis on the actual control of movement and is done in a real-life setting.

Telegram: @medical_k

www.konkur.in

Traditional perceptual-motor training consists of a combination of gross motor, fine motor, and perceptual-motor activities related to a child's actual daily motor tasks, such as hopping, skipping, jumping, climbing and moving through hoops, climbing ladders, and jumping on a trampoline, to practice competency. Specific tasks addressing fine motor skills, for example, handwriting training, includes activities to improve the grip of a pencil, wrist rotation, and posture. The results of the previously mentioned study were extremely notable in that the mental imagery treatment was as efficacious as traditional perceptual-motor training exercises in improving a given child's coordination.

An example of functional skill intervention would be those that address impairment in handwriting. It is estimated that between 10% and 30% of children exhibit persistent impairment in handwriting, a skill that remains a critical means of communication even in the face of the pervasive use of computers. Handwriting impairment is associated with academic skills disorders. Handwriting treatment approaches may include perceptual-motor, visual–motor, motor control, individualized interventions or exercises, and supplementary handwriting instruction. Few controlled studies have examined which techniques are most efficacious, and a survey of 50 pediatric occupational therapists found that 90% of them advocated an eclectic approach to interventions for handwriting improvement. A study of school-based occupational therapy intervention for school-aged children with poor handwriting legibility showed efficacy in improved legibility of letters. Children with handwriting difficulties in this study received direct traditional perceptual instruction on writing letters for approximately 30 minutes per week for approximately 7 months. This consisted of a variety of handwriting interventions, such as using vibration or resistance to writing to increase appropriate grip and writing on a chalkboard or a vertical surface to increase arm strength and stability while writing. At the end of this period, children made significant gains in handwriting legibility compared to a control group that did not receive the intervention. Handwriting speed in the children who received the treatment increased from 32 to 37 letters per minute. Although this was a trend toward speed, this did not

Telegram: @medical_k

www.konkur.in

represent a statistically significant increase in speed. Some students in the treatment group wrote their letters with a greater degree of deliberate care, and although this increased legibility, it may have actually diminished their speed. Overall, the increase in legibility applied to letters more than numbers but did not significantly increase writing speed.

42 Communication

42.1 Language Disorder

Tuana Kant, M.Sc., Emiko Koyama, Ph.D., Mahliqa Ashraf, H.B.Sc., and James L. Kennedy, M.D., F.R.C.P.C., F.R.S.C.

Communication disorders are among the most common problems exhibited by young children. Nonetheless, communication disorders often go unrecognized, particularly when they are comorbid with other emotional or behavioral problems. Thus, child psychiatrists, psychologists, and other clinicians need to be alert to the potentially damaging impact of communication problems on a child's overall well-being. Proficiency in verbal communication is critical to success in virtually all human activities and is therefore a highly valued skill-set in society and evolution. Individuals suffering from communication disorders may be unable to competently participate in everyday interpersonal, learning, and occupational situations. Limited participation in such key life activities may further restrict growth in communication and related domains.

To develop effective communication, children must master (a) language, the conventional code used to express ideas about the world, and (b) speech, the complex and rapid motor movements that translate such ideas into spoken words. Children need to also learn how to use language and speech appropriately in a given social context. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and its text revision (DSM-5-TR) recognize five diagnostic categories for

Telegram: @medical_k

www.konkur.in

communication disorders. One category concerns a disorder in language (language disorder), two categories relate to disorders in speech (speech sound disorder and childhood-onset fluency disorder), one category is associated with language use (social [pragmatic] communication disorder), and the final category covers communication disorder not otherwise specified.

DEFINITION AND COMPARATIVE NOSOLOGY

Individuals with language disorders show persistent impairments in the expression and reception (production and comprehension) of language. These impairments will manifest across different modalities, including speaking, writing, and sign language. The expressive difficulties may include limitations in vocabulary range, sentence complexity, and coherence in discourse. These expressive problems, however, are of less overall concern than the receptive difficulties. Children with receptive problems may manifest deficits in basic auditory processing skills, such as auditory discrimination, detection of rapid sound changes, association of sounds and symbols, and memory for sound sequences. Additionally, they may be slow to learn definitions, especially those that are uncommon or abstract. They may not understand the questions or comments of others and may misinterpret complex directions and explanations. They may have difficulty following conversations or learning from lectures. Because of comprehension failures, individuals with language disorders may give illogic or inappropriate responses. Furthermore, their comprehension problems may go unrecognized and instead may be misattributed to inattention, stubbornness, or other psychological or behavioral problems. Because of these problems, individuals with a language disorder would often have limitations in academic achievement, occupational success, and other social participation.

The definition of language disorder in DSM-5-TR combines elements of both the expressive and mixed receptive-expressive language disorders of the revised fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) and the 11th edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-11). Both the DSM-IV-TR and the ICD-11 conceptualized the expressive and receptive subtypes as being mutually exclusive language disorders characterized by significant language problems, despite normal levels of

Telegram: @medical_k

www.konkur.in

nonverbal intelligence. DSM-IV-TR, however, differentiated between the developmental and acquired subtypes, whereas the ICD-11 only recognizes the developmental type, and acquired language problems such as acquired aphasia with epilepsy are listed under separate categories.

EPIDEMIOLOGY

The prevalence estimates of language disorder differ from roughly 3% to 15%. Receptive problems are thought to be somewhat less common than expressive problems. The variation in prevalence estimates is most likely due to differences in language measures used to define the disorder, the age of the children surveyed, and the nature of the sample tested (community or clinic referred).

Language disorders are more common in boys than in girls. Various studies have yielded sex ratios as high as 5:1 and as low as roughly 2:1.

Familial aggregation is characteristic of language disorders. A variety of methods (aggregation, pedigree, twin, adoption, and linkage studies) have provided clear evidence of genetic influences on language disorder. Complementary work also points to environmental input as a key factor that likely contributes to familial aggregation.

Approximately 10% to 15% of children younger than 3 years of age show delayed onset and slow initial progress in language development. Because of the large range of normal variability in the language production skills of young children, it is not yet clear whether an initial delay consistently warrants a diagnosis of language disorder. The majority (50% to 80%) of these children eventually acquire language skills within the normal range, but some show persistent language difficulties into adulthood. Children who continue to exhibit language problems after age 4 are more likely to experience long-term language deficits which may persist into adulthood, although the specific language profiles may change over time.

ETIOLOGY

There are no known causes for language disorder. Various factors have been shown to correlate with language disorder, but none has yet been established as causal. Language disorder most likely has multiple

Telegram: @medical_k

www.konkur.in

determinants, including various biologic and environmental factors. Different factors or combinations may be implicated in some cases and not others, as suggested by the heterogeneity in the population. At least seven general types of possible causal factors have been investigated: (1) brain abnormalities, (2) genetic factors, (3) environmental influences, (4) neurodevelopmental immaturity, (5) general cognitive factors, (6) specific linguistic factors, and (7) auditory processes. Each of the proposed factors enjoys some empirical support, but none has gained widespread acceptance as a plausible account for all cases of language disorder. Moreover, the factors are not mutually exclusive and may interact in complex ways.

Structural or functional brain abnormalities can now be studied in a sophisticated fashion with advanced neuroimaging techniques. Such abnormalities have long been considered possible causation factors in language disorder, because (1) language characteristics of language disorder resemble those of acquired language disorders that result from known neurologic insults, and (2) children with language disorders show elevated rates of soft neurologic signs (e.g., mixed cerebral dominance, attention problems, or fine motor difficulties). Neuroimaging studies of children with language disorders have demonstrated structural and functional abnormalities, often in brain regions known to be crucial for language processing (e.g., left hemisphere or certain subcortical structures). Nonetheless, many questions remain. Both the language disorder phenotype and the techniques used to examine the brain abnormalities differ greatly among the studies, making it difficult to draw conclusions about how underlying brain abnormalities contribute to the phenotypic language disorder. Furthermore, because of the important role experience holds in brain development, it is not clear whether the observed structural abnormalities are a cause or consequence of a language disorder.

Genetic factors have now been clearly implicated in language disorder, but it is far less clear just what these factors are and how they operate pathologically. Loci on chromosomes 13, 16, and 19 have been tentatively linked to differing aspects of language disorder in several studies. Moreover, 22q11 deletion syndrome and sex chromosomal aneuploidy have also been associated with language disorders. Although these regions are unlikely to be the sole determinants of genetic influences on language, their investigation may yield important insights. For example,

Telegram: @medical_k

www.konkur.in

some recent linkage studies have suggested that chromosome 16q may be associated with phonologic short-term memory and chromosome 19q with expressive language. Work also continues to refine or broaden the language disorder phenotype to accurately identify possible subtypes and modes of transmission. An interesting possibility suggested by several lines of evidence is that autism and language disorder may share some relevant genetic characteristics. Genetic factors may also be important in understanding the origin of the brain abnormalities noted earlier. However, genetic assessments are not yet part of the initial diagnostic techniques for language disorders. With advancements in the field of genetics, further robustical research is needed to implement genetic etiologic analyses in clinical practice during the tests for children presenting with symptoms of language disorders.

Various environmental factors may also be critical, at least in some cases of language disorder. Children from families of low socioeconomic status (SES) are at elevated risk for language disorder. Low SES, in turn, correlates with other known risk factors, such as single-parent family status, large family size, lower parental education, pregnancy and birth complications, lack of appropriate learning materials in the home, abuse and neglect. Children from low SES families are also at risk for malnutrition, other health problems, increased exposure to known toxins (e.g., lead), and limited educational and social opportunities. The amount and quality of linguistic input available to children have also been shown to vary dramatically across families, with some children hearing as few as 700 utterances a day and others as many as 11,000! Furthermore, and not surprisingly, these variations in input were strongly related to language development as measured by standardized tests. In adverse conditions, supportive extended family and neighbors may act as protective factors assisting the children's language development. Further work is needed to clarify whether or how various environmental and input factors may interact with one another and, perhaps, with biologic factors to cause language disorder.

Neurodevelopmental immaturity may also underlie language disorder. Proponents argue that language development of children with language disorder generally follows a normal sequence and course but at a slower rate; that is, it is delayed rather than deviant. Delayed maturation of neural structures or slow myelination of neural pathways might also account for associated characteristics that are common in children with language

Telegram: @medical_k

www.konkur.in

disorder, such as attention and motor problems and other behavioral difficulties. Furthermore, such neurodevelopmental immaturities may occur more often in boys than in girls. A related view is that children with language disorder simply have language skills that fall at the lower end of the normal distribution. When basic yet essential skill sets that allow humans to mingle or operate independently are compromised due to language disorders, the evolutionary advantages humans possess to communicate are decreased, as such, children presenting with a diagnosis would be recognized as disadvantaged.

A variety of general cognitive factors have also been proposed to account for language disorder. Speed of cognitive processing is one such factor. Children with language disorder typically perform slower than their peers without the disorder on a variety of linguistic (e.g., naming or grammatical judgments) and nonlinguistic (e.g., fine motor or visual-spatial) tasks. This slower processing speed might somehow interfere with language learning. Some studies, however, failed to show any significant correlations between processing speed and language achievement. Another potential factor is cognitive flexibility, where children with language disorder may show reduced flexibility in adapting thoughts and behaviors to novel environments. Children with language disorder also show impairments in feedback processing, thus may have reduced feedback-based learning, affecting their overall learning capabilities compared to their peers. Others propose that phonologic working memory, the immediate maintenance and manipulation of verbal information, is a key cognitive factor in language disorder. Children with language disorder show deficits in phonologic working memory, which have been linked to deficits in vocabulary learning and reading proficiency. However, strong causal inferences about the role of phonologic working memory are not yet possible based on the available correlational evidence. Overall, differences in cognitive functions are found in preschoolers with language disorder when compared to preschoolers without, where verbal functions are more varying in children with language disorder.

In contrast to the neurodevelopmental immaturities and general cognitive delay perspectives, that imply that children with language disorder experience an overall delay but nevertheless follow a typical course of language development, some researchers have argued that children with language disorders may show specific lingering deficits in

Telegram: @medical_k

www.konkur.in

certain aspects of language that a young child with otherwise matched language ability may not show. For example, children with language disorders have particular difficulty in learning certain grammatical features (e.g., verb tense markers or pronouns in English) to the extent that their use of these features is poorer than that of younger children at the same milestone of language development. Much-needed cross-linguistic work in languages with varied grammars is helping theorists hone in on the commonalities and differences in the grammatical features that pose particular problems for children with language disorders who are learning different languages. At this point, however, these linguistic theories are primarily descriptive rather than explanatory.

Auditory problems have also been investigated as possible causes of language disorders. One concern is otitis media, an inflammation of the middle ear that results from ear infections or allergies. Otitis media is often accompanied by mild hearing loss, which is usually temporary if the underlying infection is treated. Repeated episodes of otitis media and associated hearing loss are common in young children during the earliest stages of language development. Although otitis media alone is not sufficient to cause language disorder, it may contribute in combination with other risk factors. A second concern centers on the auditory perception of sounds. Many (but not all) children with language disorders have difficulty perceiving small sound differences and rapid auditory transitions, which are aspects of the acoustic signal thought to be important in understanding speech. It has proven difficult, however, to develop convincing theoretical and empirical links between auditory perceptual skills and the various language difficulties shown by children with language disorder.

DIAGNOSIS AND CLINICAL FEATURES

The hallmark of language disorder is impairment in receptive and expressive language development. The rate of language growth is slower in children with language disorder than children with typical language development. The receptive and expressive language characteristics of affected children may be largely similar to those of younger children who are acquiring language in a typical fashion. Certain language features, such as the grammatical marking of tense, aspect, number, gender, or case may be especially difficult for children with language disorders to

Telegram: @medical_k

www.konkur.in

acquire. They may have difficulty learning the correct use of auxiliary or modal verbs (e.g., is, were, could), plurals (e.g., cats, geese), verb tense endings (e.g., -ing, -s, -ed), and pronouns (e.g., he, she, they). Children with language disorder may also demonstrate spelling difficulties where they may have decreased sensitivity to silent letters and make errors or omit silent letters while they are spelling.

Comprehension often varies with the complexity of the language. For example, words for familiar, concrete objects, actions, or relations may be comprehended (e.g., *wagon*, *apple*, *walk*, *give*, *in*, *over*), but those with less familiar, abstract meanings may be unknown (e.g., *neuron*, *freedom*, *receive*, *pretend*, *between*, *when*). Similarly, sentences with simple grammatical forms may be understood (e.g., “The boy is smiling.” “The phone rang.”), whereas those with more complex structures may be misinterpreted (e.g., “The car that rammed the bus was towed to the garage.” “Before she finalized the arrangements, she consulted with her lawyer.”). Complex or lengthy instructions, questions, and explanations may not be comprehended. When children with language disorders misconstrue the language and intentions of others, they may inadvertently make inappropriate responses or comments during conversations. Their comprehension failures may also contribute to confusion or inaccuracy in telling stories, relating events, and giving explanations, problems that may be further exacerbated by their expressive language limitations. When their comprehension difficulties are not recognized, children with language disorders may be mistakenly thought to be inattentive, lazy, or unco-operative.

The specific manifestations of language disorder vary with age. Some children with language disorder eventually acquire language skills within the normal range, but the overall prognosis is poorer for children with severe receptive language problems than for children with just expressive language difficulties. The expressive and receptive features adversely affect personal interactions and academic achievement because the spoken language is poorly expressed and understood.

www.konkur.in

Amy was a sociable, active 5-year-old who was diagnosed with a language disorder. She often played with Lisa, her kindergarten classmate. During pretend play one day, each girl told the story of Little Red Riding Hood to her doll. Lisa's story began: "Little Red Riding Hood was taking a basket of food to her grandmother who was sick. A bad wolf stopped Red Riding Hood in the forest. He tried to get the basket away from her, but she wouldn't give it to him."

By contrast, Amy's story illustrated her marked difficulties in verbal expression: "Riding Hood going to grandma house. Her taking food. Bad wolf in a bed. Riding Hood say, what big ears, grandma? Hear you, dear. What big eyes, grandma? See you, dear. What big mouth, grandma?

Eat you all up!"

Amy's story contained many features characteristic of children with language disorders at her age, including short, incomplete sentences, simple sentence structures, omission of grammatical function words (e.g., is and the), and inflectional endings (e.g., possessive -'s and present tense verb -s), problems in question formation, and incorrect use of pronouns (e.g., her for she).

Nevertheless, Amy performed as well as Lisa did in understanding the details and plot of the Riding Hood tale, as long as she was tested with methods that did not involve verbal responding. Amy also demonstrated adequate comprehension skills in her kindergarten classroom, where she readily followed the teacher's complex, multistep verbal instructions (e.g., "After you write your name in the top left corner of your paper, get your crayons and scissors, put your library books under your chair, and line up at the back of the room.").

Julio was a quiet, sullen 8-year-old whose language problems were no longer obvious in casual, social conversations. His speech now rarely contained the incomplete sentences and grammatical errors that were so evident when he was younger. His expressive problems, however, still surfaced in tasks involving elaborate or abstract uses of language, like those required in much of his third-grade academic work. An example was Julio's explanation of the outcome of a recent science experiment: "The teacher had stuff in some jars. He poured it, and it got pink. The other thing made it white." Although each sentence was grammatical, his explanation as a whole was difficult to follow because key ideas and details were omitted or poorly explained. Julio also showed problems in word finding, that is, in using specific words for the concepts and actions, he was describing. Instead, he relied on vague and nonspecific terms, such as thing, stuff, and got.

In early elementary grades, Julio had kept pace with his classmates in reading, writing, and other academic skills. By third grade, however, the increasing demands for written work began to negatively affect his overall academic standing. His written work was characterized by problems similar to those noted in his oral expression, such as poor organization and lack of specificity. Classmates also began to tease him about his difficulties, and he reacted quite aggressively, sometimes to the point of fighting. Nonetheless, Julio continued to show relatively good comprehension of spoken language, including classroom lectures concerning abstract concepts. He also comprehended sentences that were grammatically and conceptually complex (e.g., "The car the truck hit had hubcaps that were stolen. Had it been possible, she would have notified us by mail or by phone.").

Susan was a pleasant 2-year-old who did not yet use any spoken words. She made her needs known with vocalizations and simple gestures (e.g., showing or pointing) like those typically used by younger children. She seemed to understand the names of a few familiar people and objects (e.g., *mommy*, *daddy*, *cat*, *bottle*, and *cookie*). However, compared to other children her age, she had a small comprehension vocabulary and showed limited understanding of simple verbal directions (e.g., “Get your doll.” “Close your eyes.”). Nonetheless, her hearing was normal, and her motor and play skills were developing as expected for her age. She showed interest in her environment and in the activities of the other children at her daycare.

Telegram: @medical_k

www.konkur.in

Min was a shy, reserved 5-year-old who grew up in a bilingual home. Min's parents and older siblings spoke English and Cantonese proficiently. Her grandparents, who lived in the same house, spoke only Cantonese. Min began to understand and speak both languages much later than her older siblings had. Throughout her preschool years, Min continued to develop slowly in comprehension and production. At the start of kindergarten, Min understood fewer English words for objects, actions, and relations than her classmates did. She showed difficulties in following classroom instructions, particularly those that involved words for concepts of time (e.g., *tomorrow*, *before*, or *day*) and space (e.g., *behind*, *next to*, or *under*). It was also hard for Min to match one of several pictures to a syntactically complex sentence that she had heard (e.g., "It was not the train she was waiting for." "Because he had already completed his work, he was not kept after school."). Min occasionally tried to speak with other children. However, these conversations usually broke down because she misinterpreted what others said or could not express her own thoughts clearly. Consequently, her classmates generally ignored her, preferring instead to play with more verbally competent peers. Min's infrequent interactions further limited her opportunities to learn and practice her already weak language skills. Min also showed limited receptive and expressive skills in Cantonese, as revealed by an assessment conducted with the assistance of a Cantonese interpreter. Nonetheless, her nonverbal cognitive and motor skills were within the normal range for her age. She showed no difficulties in solving spatial, numerical, conceptual, or analogic problems, provided they were presented nonverbally.

www.konkur.in

Fred received a diagnosis of language disorder when he was a preschooler. By 8 years of age, he had also received the comorbid diagnoses of specific learning disorder and attention-deficit/hyperactivity disorder (ADHD). This combination of language, learning, and attention problems made it virtually impossible for Fred to succeed in school. His comprehension and attention difficulties limited his ability to understand and learn important information from classroom instructions, discussions, and lectures. Because the unlearned information was critical to the understanding of future academic lessons, Fred fell further behind his classmates. He was also disadvantaged by the fact that he could read only a few familiar words. This meant that he could not learn other academic information that his classmates acquired by reading textbooks, library books, newspapers, and other written materials. His poor reading ability also limited his opportunities to learn the new vocabulary, complex sentence forms, and sophisticated ideas that other children absorbed from reading. Despite his academic problems, however, Fred continued to show nonverbal intellectual skills within the low normal range, although his scores were somewhat lower than those he had earned as a preschooler.

The disorders of speech, learning, and development may co-occur with language disorder. The two most frequently co-occurring disorders are speech sound disorder and specific learning disorder. Speech sound disorder, which is characterized by difficulty in the correct production of speech sounds, occurs in roughly 40% to 60% of preschoolers with language disorder. Specific learning disorder, especially difficulties in reading, occurs in approximately 50% to 90% of school-aged children with language disorder and most frequently for children with receptive language problems. Difficulties in learning to read may be apparent early or may not surface until later in the learning process when knowledge of sophisticated vocabulary and sentence structures is required to support reading comprehension. Because of this high comorbidity between language disorders and reading problems, some researchers have theorized that language impairment and reading difficulties may be different manifestations of the same underlying problems that manifest themselves at different ages. Following this idea, they suggest that in the

Telegram: @medical_k

www.konkur.in

evaluation of spelling difficulties in language disorders, phonologic representations, morphologic awareness, and reading skills should all be assessed. Genetic studies also suggest that families with a known risk of language disorders also tend to be at higher risk for reading problems and vice versa. However, other researchers suggest that reading and language problems should be considered separate disorders, as children with language problems manifest problems that go beyond phonologic awareness and include syntax and semantics. Future studies in molecular genetics may help clarify this debate. Similarly, children with language disorder have an increased risk of exhibiting mathematics disorder. A few children with language disorders also experience childhood-onset fluency disorder (stuttering) and developmental co-ordination disorder.

The risk for concomitant psychiatric disorders is high for children with language disorder, especially when receptive language is impaired. Estimates vary, but comorbid psychiatric disorders may affect as much as 70% of school-aged children with language disorder who have severe receptive language problems. The most common comorbid condition is ADHD, occurring in 30% to 60% of cases. Internalizing disorders are also noted but not as often as ADHD. Genetic studies show that the co-occurrence of internalizing disorders with language disorder may be due to common genetic influences. Therefore, children with language disorder may be at a higher risk for internalizing disorders if they already have a genetic predisposition for internalizing problems. Boys are at particular risk for externalizing disorders, where genetic influences may also affect this co-occurrence. Behavior difficulties tend to occur most frequently in children who have concomitant language and reading problems. Girls with language disorders may be withdrawn and quiet, making the detection of language disorders more difficult.

Most children with language disorder do not show frank neurologic symptoms (e.g., tremor, paralysis, or seizures). As a group, however, children with language disorders show elevated rates of mild-to-moderate abnormalities (e.g., in reflexes or fine motor function) on careful neurologic examination. They are also more likely than typically developing children to show mild-to-moderate abnormalities in measures of brain function or structure, such as electroencephalographic (EEG) readings, magnetic resonance imaging (MRI) and functional MRI (fMRI) scans, or diffusion tensor imaging (DTI)-derived fractional anisotropy (FA).

Telegram: @medical_k

www.konkur.in

Furthermore, the number of abnormal neurologic signs may be associated with the severity of language difficulties.

With advancing technology, new techniques are being tested to improve the detection and intervention of language disorders. Language disorders may go undiagnosed without proper detection. Automatic speech recognition was tested and showed better accuracy than manual transcribers, providing a promising technique to transcribe sentences and improve the detection of language disorders in school-aged children. Moreover, automated computationally driven techniques in scoring the results from language tasks for children have also been shown to be an effective and accurate method to be used instead of manual entry, which may increase the efficacy and objectivity of measurements. Eye tracking has also shown promising results in detecting early steps of language disorders, where children with language disorder may show slower and atypical verb-based prediction behavior. Overall, researchers suggest that instead of focusing on linguistic measures, analyses of a combination of both linguistic and nonlinguistic features may provide a more accurate detection of a language disorder.

PATHOLOGY AND LABORATORY EXAMINATION

There are no laboratory tests that can provide a diagnosis of language disorder. Neuroimaging techniques, such as MRI and fMRI, sometimes reveal structural or functional brain abnormalities associated with language disorder. There are also new techniques being tested with EEG, where machine learning is being tested to classify infants' neural responses to rhythms in order to identify high-risk children for language disorders. However, such abnormalities have neither been found in all cases nor have their possible etiologic or diagnostic values been determined.

DIFFERENTIAL DIAGNOSIS

Standardized evaluations of expressive and receptive language and nonverbal intellectual functioning are the key elements for differential diagnosis of language disorder. Receptive language testing is particularly important because comprehension deficits may be less obvious than expressive difficulties. Receptive and expressive language performance

Telegram: @medical_k

www.konkur.in

must fall substantially below the range of normal language performance expected for a child's age. In addition, the severity of the receptive and expressive language problems must hinder academic performance or social communication. Speech-language pathologists often use observational techniques and analyses of spontaneous language to assess the functional impact of language difficulties and to complement information obtained from standardized language tests. A thorough functional assessment of language abilities may also be substituted when appropriate standardized tests are not available (e.g., if a child speaks a language for which tests have not yet been developed).

A significant discrepancy between receptive language and nonverbal abilities precludes the alternative diagnoses of selective mutism and intellectual disabilities. In selective mutism, receptive language and nonverbal performances usually are similar in level and markedly higher than expressive language skills. In intellectual disabilities, performance is impaired substantially in all three areas of receptive language, expressive language, and nonverbal abilities relative to age-level expectations.

Deficits in receptive language may also be evident in cases of hearing impairment, environmental deprivation, or autism spectrum disorder. A hearing test should be part of the assessment of all cases of suspected language disorder. Collection of a careful history can usually identify severe environmental deprivation. Observations of disturbed social interaction, limited communicative intent, and unusual repetitive behaviors suggest autism spectrum disorder. A concurrent diagnosis of language disorder may be made when receptive and expressive language deficits exceed those expected for the degree of intellectual disabilities, hearing impairment, or environmental deprivation.

Differential diagnosis requires attention to other comorbidity issues. Speech sound disorder is a possible comorbid diagnosis when difficulties in speech sound production accompany language disorder. School-aged children identified with either language or specific learning disorder should be screened for difficulties in the other area because the two disorders frequently co-occur. Similarly, children with psychiatric diagnoses, particularly ADHD, should be screened for language disorder because it is known that a high proportion of children referred for psychiatric assessment shows previously undetected comorbid language disorders. Moreover, children with receptive and expressive language deficits may show signs of reduced autonomy in their play behaviors, as well as

Telegram: @medical_k

www.konkur.in

reduced eye contact with their parents, which can be monitored even in their prelinguistic skills. Furthermore, sometimes a child shows expressive language that is so difficult to follow and so disorganized that the practitioner questions whether it should be considered disordered thinking as a symptom of schizophrenia.

Illustrative of this concern is the case study presented here with a brief excerpt from a conversation with Max, a highly anxious 9-year-old with language disorder who had just visited the dentist. The stream of language in this case study raises serious concerns about a possible diagnosis of schizophrenia. However, a child with language disorder may produce language this disorganized, especially in situations of heightened anxiety. Diagnosis can usually be clarified by reassessment when the child is less anxious and by careful attention to the presence or absence of comorbid symptoms.

What do you suppose you'd like to do today?

Taking a dentist appointment …

[You're taking a dentist appointment.]

Yeah, he has a little cavity …

[He has a little cavity.]

…and I'm going to take it from him cause he's stuck there he sure doesn't like it but he knows there is too far (mumbled)…

…too far and so he was losing a lot of hair so he needs a new way…sounds like he's bald…so he has everything (mumbling) a guy who's not recep…teaching he will have to it's important like he will or he won't.

Acquired language problems may result from a variety of neurologic insults, including (1) cerebral vascular accidents, such as strokes; (2) infections, such as encephalitis, meningitis, or Zika virus; (3) severe respiratory problems that result in intraventricular hemorrhage or anoxia; (4) near drownings; (5) closed head injuries from falls, motor vehicle accidents, or other blows to the head; (6) open head injuries, such as those from gunshot wounds; (7) toxins, such as lead or household poisons; (8) damage from tumors or radiation treatment; or (9) seizure activity. Landau–Kleffner syndrome (acquired aphasia with epilepsy) is a

Telegram: @medical_k

www.konkur.in

rare condition marked by an abrupt loss of language skills, which is often associated with the onset of seizures or abnormal EEG activity.

Acquired language problems vary considerably in their language symptoms as a function of the nature and severity of the underlying neurologic condition. Acquired disorders also show distinctive language characteristics as well as some features shared with language disorder. For example, closed head injury, which often occurs in motor vehicle accidents or falls, typically are sparing of basic skills in vocabulary and grammar (after initial recovery stages), whereas more complex skills, particularly in discourse, remain markedly impaired. Comprehension for lengthy or complex discourse may be limited. Likewise, expression in discourse may be disrupted by disorganized, tangential, inappropriate, and illogic comments, even if basic vocabulary and sentence structures are used correctly. Communication effectiveness may be further hindered by accompanying deficits in memory, attention, affect, behavior, and motor skills. In return, these problems and deficits in language skills acquired as a result of brain trauma may create additional obstacles in the rehabilitation process for the injury itself.

Landau–Kleffner syndrome also shows a unique pattern. Children with Landau–Kleffner syndrome seem to be developing normally until around the ages of 3 to 7 years, when they start to have trouble with expressive and receptive language for no apparent reason. The decline in language ability may be sudden or gradual. Hearing loss is usually suspected by parents; however, laboratory tests disconfirm this suspicion. In about 80% of children with Landau–Kleffner syndrome, one or more episodes of epileptic seizures occur, typically during sleep. Behavioral problems such as hyperactivity, aggressiveness, or depression may co-occur.

Elliott, 4 years of age, was a cheerful, talkative preschooler who suddenly experienced a series of seizures for no apparent reason. His language skills, which had been excellent, simultaneously showed a precipitous decline. He no longer understood words, commands, and sentences that had posed no difficulty for him before the seizures. He also lost his expressive skills and began using shorter, less sophisticated sentences, which became increasingly incoherent as he omitted or misused important words. He also developed significant memory and attention problems. Nonetheless, he continued to show nonverbal intellectual skills that were grossly within the normal range. Although Elliott's seizures were eventually controlled with medication, he experienced persistent problems in comprehension and production of language, which never fully resolved.

Course and prognosis are also variable for children with acquired language problems. Some spontaneous recovery generally occurs rapidly within days or weeks of the neurologic insult, but additional improvements may show a protracted course over months or even years. Approximately two-thirds of children with acquired disorders eventually recover language functioning that is broadly within the normal range, although subtle deficits may persist. Those who do not attain normal language functioning show persistent language and cognitive deficits of varying severity. Prognosis depends on many factors, including the severity, extent, and location of brain damage, the specific etiology, the age of onset, the extent of preinjury language development, and the existence of other preinjury disorders.

Language disorders also occur in children from diverse linguistic and cultural backgrounds. A difficult diagnostic challenge is to differentiate language errors that are a normal part of acquiring a new language from those that are indicative of a disorder. A valid assessment usually requires the co-operation of a well-trained informant from the same cultural and linguistic background as the child. The informant assists in collecting and interpreting history information, assessing the child's skills in the other language, and discussing assessment results and recommendations with the family.

COURSE AND PROGNOSIS

Telegram: @medical_k

www.konkur.in

Language disorder is characterized by considerable variability in severity, course, and outcome. Individuals who have mild-to-moderate language disorders are less likely to suffer from significant long-term mental health problems than individuals who have severe language disorders. Youngsters with early receptive language delays show higher rates of persisting disorder and less favorable long-term outcomes than those with early expressive-only delays. Some, however, do eventually attain language functioning within the normal range. Better outcomes are generally associated with higher levels of early gestural communication, receptive language, and nonverbal intelligence.

Children with persistent language disorders continue to develop language comprehension and production skills during the preschool and school-aged years. However, the rate of development may be quite slow, causing them to fall further behind peers who are developing language at a normal rate. Overall, the communicative prognosis for children with persistent language disorders continues to be poorer than for those with expressive-only disorders.

Children with language disorders are also at risk for academic problems once they enter school. A negative spiral of poor academic performance, low self-esteem, reduced motivation, and social isolation may stem from the language comprehension difficulties, particularly when they are coupled with attention, reading, or mathematics problems. Fortunately, some progress has been made in using performance on early language-related tasks to predict which kindergarten children may be at risk for later reading difficulties. Moreover, interventions to improve phonologic awareness, a key skill for early reading, have proven successful with children with language disorders, at least in the short term.

Many adolescents and young adults with a history of language disorder continue to show problems in communicative effectiveness, academic performance, and social functioning. These problems may limit vocational choices and social participation. Individuals with language disorder are also at heightened risk of being bullied or victimized in general, including sexual assault or abuse for girls and women. Serious psychiatric problems, such as social anxiety disorder or antisocial personality disorder, may also develop in some individuals. Even though the symptoms of language disorders may improve through development in most children, the internalizing or externalizing behavior problems that co-occur with language disorders may not get better with this improvement.

Telegram: @medical_k

www.konkur.in

The societal consequences are significant, as evidenced by the high rate of language difficulties in adults who live in poverty, commit crimes, incur psychiatric illnesses, and achieve limited literacy.

TREATMENT

Experts disagree about the timing of intervention for language disorder. Some advocate a wait-and-see attitude for young children with early expressive delays (late talkers) because most acquire normal language functioning during the preschool years. They argue that intervention should be provided only to those with persistent expressive delays at 4 or 5 years of age. Others suggest that early intervention might prevent or minimize later language, academic, and behavioral difficulties. Unfortunately, few relevant data are available on the efficacy of early- versus late-language intervention.

Direct and mediated interventions have been shown to promote short-term language growth in children with language disorders. In direct interventions, the primary intervention agent is a professional (usually a speech-language pathologist) who works directly with the child to improve language functioning. In mediated interventions, the primary intervention agents are parents, teachers, or paraprofessionals, who have been taught by the speech-language professional to deliver the intervention to the child. Mediators are encouraged to incorporate language facilitation techniques into daily activities and routines, thereby providing regular, naturalistic opportunities for children to use newly learned language features.

Further research on treatment efficacy is needed to address important outstanding issues. For example, studies are required to assess (1) the ways in which interventions might be tailored to address the specific language needs of individual children, (2) the long-term merits of early intervention for children with expressive delays, (3) the extent to which the benefits of intervention achieved in laboratory studies can also be demonstrated in routine community-based interventions, and (4) what the potential harms of early screening or intervention for language delays may be, including the risk involved in false-positive and false-negative results, labeling, parent and child anxiety, and unnecessary evaluation and intervention. One recent study of routine early interventions suggests that systematic efforts may be required to improve their effectiveness.

Telegram: @medical_k

www.konkur.in

Children with language disorders are generally recommended for intervention to address their receptive and expressive language needs. Various language intervention techniques and programs have been developed, but some have not been rigorously evaluated to demonstrate their efficacy. The available efficacy literature, however, suggests that language intervention can foster short-term progress toward specific communicative goals, a conclusion that extends to various intervention techniques and programs. With advancements in technology, different technologic intervention techniques have been tested to improve the treatment outcome. For children with co-occurring speech sound and language disorders, electropalatography (EPG), a technique that monitors contacts between the tongue and hard palate, has been shown to be effective in improving regular speech and language therapy outcomes. Another method that is being developed with advancing technology is a speech and language guidance program as an application for smartphones and tablets, where parents and children have an opportunity to benefit from language therapy remotely with lower costs. Unfortunately, there has been limited study thus far on the possible long-term benefits of language intervention in limiting or reversing the negative impacts of language disorder on linguistic, academic, and psychosocial outcomes.

Interventionists have, however, begun to focus on long-term, broad-based outcomes. Preschoolers with language disorders are receiving interventions designed to promote not only oral language outcomes but also social communication and early literacy skills. Kindergartners with language disorders are being taught certain key prereading skills, which may prevent the early reading failure that is linked to subsequent academic and psychosocial problems. More attention is being given to enabling peers, parents, and teachers to learn methods for fostering frequent, natural, and optimal communicative interactions with children who have language disorders. In schools, there are efforts to co-ordinate the various types of interventions that may be required by a child with a language disorder (e.g., language intervention, special reading help, special education support, or behavioral interventions), as well as to train childcare professionals in delivering group interventions which have been effective in increasing children's phonologic production skills. Even though the parameters for effective dose and intensity of interventions in clinical practice are not yet clearly defined, recent research showed that twice a week may be a more effective method than once a week. Despite some

Telegram: @medical_k

www.konkur.in

initial promising results from these efforts, much remains to be learned concerning optimal goals, techniques, and programs for language intervention.

Language disorders may also necessitate modifications to other interventions that rely heavily on language as a medium (e.g., psychotherapy or cognitive behavioral modification). Comprehension can be facilitated by simplification of vocabulary, sentence structure, questions, and verbal instructions and by repetition of verbal information as required. Compensation for expressive difficulties can be achieved by using nonverbal response modes to supplement verbal responses. Ambiguous or unclear responses should also be clarified. Assessment procedures that depend heavily on language (e.g., projective tests or diagnostic interviews) may require similar modifications.

Overall, people with language disorders are underserved. The discovery and application of better detection and intervention techniques are necessary to provide better care for this population. Raising awareness, providing detection tests in early stages and in-school settings, and better communication with parents and teachers are some ways that can enhance our current level of knowledge and experience with language disorders.

ACKNOWLEDGMENTS

This chapter was written in memory of the late Dr. Joseph H. Beitchman, who continues to inspire us with his dedication, devotion, and extensive research work in childhood language disorders.

42.2 Social (Pragmatic) Communication Disorder

Mirelle Kass, B.A., Young Shin Kim, M.D., M.S., M.P.H., Ph.D., and Bennett L. Leventhal, M.D.

Social (pragmatic) communication disorder (SCD) is a persistent disruption in the communication of social concepts, skills, and intentions. While social communication deficits coexist as a component of multiple disorders, for individuals with SCD, these problems stand alone.

Social pragmatics is derived from the concept of pragmatic language. Language is the full spectrum of expressive and receptive communicative behaviors, including speech, gesture, and other skills. Pragmatics encompasses those behaviors that contribute to implication, relevance, and effectiveness of any form of an individual's communication. In this framework, for effective communication, an individual must follow

Telegram: @medical_k

www.konkur.in

pragmatic language rules to create and transmit any given message. Similarly, individuals must understand pragmatic rules when attempting to interpret receptive communication.

Language pragmatics relate to how context contributes to understanding and meaning in communications, with each component of communication having its own structure and rules. When speech is used, the rules apply to what is being said and how it is being said. The “what” refers to the choice of words, sentence structure, and connections between different elements of content, such as conjunctions and dependent clauses, as well as the use of different types of sentences (statements, questions, etc.). The “how” of speech applies to the rate, rhythm, prosody, volume, tone, and other characteristics of speech production. Pragmatic rules also apply to nonverbal communication, including gesture, body posture, reciprocity, and facial expression. When the pragmatic rules can be correctly and flexibly applied in context, expressive and receptive language can be effective. When they cannot be so applied, individuals have broad difficulties in social intercourse leading to significant problems in adaptation.

SCD is a diagnostic category first introduced in DSM-5. The main characteristic of SCD is the persistent deficit in the social use of expressive and receptive, nonverbal and verbal communication, as well as difficulty using the linguistic context to make inferences and to resolve ambiguities. Symptoms of SCD include deficits in the understanding and the application of social and language rules for verbal and nonverbal communication. Individuals with SCD have difficulty adapting language to the needs of the listener or situation. Similarly, those with SCD have difficulty following the rules of conversations (such as turn taking), storytelling, humor, sarcasm, and other nuanced speech. As a result, individuals with SCD have difficulty communicating and understanding ambiguous and nonliteral language, as well as integrating linguistic context and prior social knowledge.

The elements of SCD overlap with the “A” criterion of DSM-5-TR autism spectrum disorder (ASD). However, SCD is distinct from ASD due to the absence of the DSM-5-TR ASD “B” criterion, “restricted, repetitive patterns of behavior, interests, or activities….” Although SCD can co-occur with other communication disorders, such as language disorder, the social communication and pragmatic deficits for SCD must exceed what

Telegram: @medical_k

www.konkur.in

would be expected from structural language deficits alone. The diagnosis of SCD cannot be made along with the diagnosis of ASD.

HISTORY

While social and language pragmatics have long been a clinical concern for many disorders, SCD was not considered a diagnostic category until the creation of DSM-5. Social communication and pragmatic deficits have been documented in the education and speech and language literature for decades, if not longer. Much of the concern about SCD, and other language disorders, focused on children although it is apparent that SCD and other developmental language disorders (DLDs) persist into adulthood.

Previously, semantic–pragmatic deficits characterized children demonstrating problems with verbosity, word finding, word choice, and poor topic maintenance. A similar term introduced in the late 1980s was "semantic–pragmatic disorder," which was thought to occupy the diagnostic space between ASD and specific language impairment. Both terms reflect the idea that semantic (i.e., the meaning of an expression) and pragmatic (i.e., the use of language in context) difficulties tend to co-occur. In the 1990s, research found that semantic deficits did not necessarily co-occur with pragmatic deficits, and that semantic abilities did not reliably differentiate between typically developing and clinical groups. As a result, the term pragmatic language impairment was coined and appears commonly in the speech and language literature.

While there was much research and clinical progress in understanding etiologic substrates and clinical presentation of autism, as a result of unifying diagnostic criteria between DSM-IV and ICD-10, there was still substantial difficulty distinguishing the subcategories in DSM-IV pervasive developmental disorder (PDD). Research found no etiologic distinctions and a lack of diagnostic reliability with these criteria. In part, this was due to Asperger syndrome becoming a preferred diagnosis for many families because it was associated with much less stigma than the DSM-IV diagnosis of autistic disorder—even today, some still falsely "blame" parenting failure as a cause of autism.

The addition of SCD to DSM-5 is closely associated with the changes made to the diagnostic criteria concerning ASD. In DSM-IV-TR, PDDs included autistic disorder, Asperger syndrome, and PDD—not otherwise

Telegram: @medical_k

www.konkur.in

specified (PDD-NOS). PDD-NOS was for patients who did not meet the full criteria for either autistic disorder or Asperger syndrome. Children or adults who met one or two of the three major autism criteria showed core deficits in one area, such as social deficits, but did not meet the diagnostic criteria for other symptoms, such as restrictive, stereotypical, and repetitive behaviors, would have been given the diagnosis of PDD-NOS. Research has shown that more than half of the children diagnosed with PDD-NOS were given the diagnosis due to the fewer restrictive and repetitive behaviors they exhibited.

FIGURE 42.2–1. Social (pragmatic) disorder changes from DSM-IV to DSM-5.

With the advent of DSM-5, PDD was abandoned. In part, this was due to the clarification of diagnostic criteria which were reorganized from three (B to D) to two (A and B) main criteria: (A) persistent deficits in social communication and social interaction, and (B) restricted, repetitive patterns of behavior, interests, or activities. Interestingly, most of the previous PDD diagnostic criteria were rearranged and preserved in DSM-5 ASD (Fig. 42.2–1).

These changes caused considerable stress for some individuals and families as they either did not want to be associated with the term “autism” or feared that they might lose access to services. As will be discussed below, no one was “left out”; however, the change in nosology is still disconcerting for some.

Telegram: @medical_k

www.konkur.in

The addition of SCD to DSM-5 was a result of the changes made to the diagnostic criteria to create ASD. In DSM-5, the absence of PDD -NOS and Asperger syndrome meant that there was no longer a place to categorize individuals who only met the DSM-5 ASD “A” criterion (or DSM-IV “D” criterion). Therefore, children or adults who met only the social deficits diagnostic criterion but not the “B” criterion (restrictive, stereotypic, and repetitive behaviors) could not be the new diagnosis: SCD. While there remains a lack of clarity, this diagnosis may allow room for individuals with social interaction deficits and mild or no restrictive and repetitive behaviors. These seeming language disorders remained in the DSM-5 section for neurodevelopmental disorders.

While the diagnosis of SCD may appear to be consistent with the broader concept of pragmatic language impairment, multiple definitions of pragmatic language impairment exist, many of which do not include nonverbal communication. Therefore, further study will be required to determine to what extent SCD is related to the understanding of language pragmatics found in the broader language pragmatics literature.

DIAGNOSTIC FEATURES

SCD is a disruption in the development and use of language pragmatics leading to interference with social functioning (Table 42.2–1).

For this diagnosis, pragmatics refers to the rules that govern social interactions when using both verbal and nonverbal language. It is these rules that allow people to relate to one another reciprocally as well as to create and maintain social transactions. For typically developing children, language pragmatics (initially nonverbal) appear very early and expand rapidly—think of the social smile, visual regard, and pointing as examples. While many think pragmatics are completely intuitive to the typically developing child, it is likely that caregiver reinforcement of these skills increases their quantity, quality, frequency, variability, and utility. In contrast, children with SCD may never exhibit these behaviors, or they are so rare that caregiver reinforcement is not possible. This is rarely a parent/caregiver problem but, rather, a developmental delay or developmental deviation. As a result, children with SCD have early difficulty learning and using even the most basic rules of social communication. While this often begins with delays in nonverbal communication, it generally continues with delays and/or deviations in

Telegram: @medical_k

www.konkur.in

spoken language, when to listen, how to phrase a question, how to stay on topic, and knowing when the talk is over. As a result of deficits in pragmatics, individuals with SCD may struggle to engage in and/or sustain conversations. Problems may include frequent interruptions, monopolizing conversations, lack of reciprocity, failing to effectively communicate wants and/or needs, or not talking at all. Individuals with SCD may also say things that are inappropriate or unrelated to the conversation at hand. Taken together, these communication problems often make it difficult for individuals with SCD to develop and sustain meaningful social relationships and communicate well with others at school or in the workplace. In addition to the language problems, the communication deficits often lead to frustration (with attendant behavior problems), anxiety, and depression. The symptoms of SCD include the following:

1. Problems using nonverbal and verbal language, such as greeting and sharing information, in ways appropriate for the social context.
2. Impairment in changing communication to match the context or the need of the listener, such as speaking differently in the classroom than on the playground or talking to a child than to an adult.
3. Difficulties following social conventions in conversation and story-telling, such as taking turns in conversations, rephrasing when misunderstood, and knowing how to use verbal and nonverbal signals to regulate the interaction.
4. Difficulty making inferences when something is not explicitly stated, and difficulty understanding the meaning of nonliteral or ambiguous language, such as idioms, humor, and metaphors, and when there are multiple meanings depending on the context.

Telegram: @medical_k

www.konkur.in

Table 42.2–1.
DSM-5-TR Criteria for Social (Pragmatic) Communication Disorder

A. Persistent difficulties in the social use of verbal and nonverbal communication as manifested by all of the following:
   1. Deficits in using communication for social purposes, such as greeting and sharing information, in a manner that is appropriate for the social context.
   2. Impairment of the ability to change communication to match context or the needs of the listener, such as speaking differently in a classroom than on a playground, talking differently to a child than to an adult, and avoiding use of overly formal language.
   3. Difficulties following rules for conversation and storytelling, such as taking turns in conversation, rephrasing when misunderstood, and knowing how to use verbal and nonverbal signals to regulate interaction.
   4. Difficulties understanding what is not explicitly stated (e.g., making inferences) and nonliteral or ambiguous meanings of language (e.g., idioms, humor, metaphors, multiple meanings that depend on the context for interpretation).

B. The deficits result in functional limitations in effective communication, social participation, social relationships, academic achievement, or occupational performance, individually or in combination.

C. The onset of the symptoms is in the early developmental period (but deficits may not become fully manifest until social communication demands exceed limited capacities).

D. The symptoms are not attributable to another medical or neurological condition or to low abilities in the domains of word structure and grammar, and are not better explained by autism spectrum disorder, intellectual developmental disorder (intellectual disability), global developmental delay, or another mental disorder.

The communication problems facing individuals with SCD often impair effective communication overall, as well as social participation, academic achievement, and/or occupational performance. The many difficulties with social interactions begin early in life, although the extent of the

Telegram: @medical_k

www.konkur.in

impairments may not become fully apparent until social communication requirements become more demanding in the preschool or school-age period.

DSM-5-TR criteria require that the symptoms of SCD are not attributable to another psychiatric, other medical disorder, or neurologic conditions, including, but not limited to intellectual disability, global developmental delay, ASD, or any other mental disorders. The deficit in social communication should not be solely attributable to problems in the mechanics of language, as is the case for individuals with language disorder.

Individuals with SCD may show little interest in social interactions. This may appear to be similar to those with ASD. Individuals with SCD may have difficulty adapting language to different listeners (e.g., talking the same way to an adult and to a child) and to different situations (e.g., talking the same way in a classroom as on the playground). They may have trouble making inferences and/or understanding abstractions or implied thoughts or ideas, while they may be readily able to understand that which is stated explicitly. They may not give necessary information when they are speaking to an unfamiliar person, making it difficult to contextualize their utterances. A significant challenge is having difficulty properly gaining the attention of others to make a request or initiate a conversation. People with SCD are often quite literal in their use and understanding of words. This extends to understanding nuanced language and behavior, making inferences with incomplete information, and noticing social subtleties and social cues. As a result, they have difficulty understanding sarcasm, riddles, and humor, and they have trouble telling even the simplest jokes. Some, but not all, individuals with SCD have difficulty understanding nonverbal communication, including gestures, facial expressions, and body posture, in some cases in spite of more than ample vocabulary. It is important to remember that SCD is both an expressive and receptive communication disorder.

Some children with SCD may also have trouble with reading comprehension, despite having reasonably well-developed phonemic awareness and the ability to read well phonetically—they can read it, but they don’t understand what they have read. These reading issues may not be noticed until midelementary school or later.

It has been suggested that SCD rarely occurs by itself. Language disorder is the most commonly occurring disorder associated with SCD.

Telegram: @medical_k

www.konkur.in

SCD was found to be more common in eighth-grade children with a history of DLD, especially when deficits in pragmatics and structural language occur simultaneously. Having a language disorder of this type during kindergarten was found to increase the risk for SCD during adolescence. However, it was not predictive when “pragmatic and social skills were disproportionately lower than structural language abilities,” according to Ellis Weismer.

Attention-deficit hyperactivity disorder (ADHD) is a common comorbidity associated with SCD. The hyperactivity and inattention problems can aggravate the problems of pragmatic competence. In addition, a lack of social pragmatic skills may lead to children becoming frustrated and having behavior problems.

The following vignettes illustrate SCD in youth with deficits in receptive and expressive nonverbal communication, along with relatively intact structural language.

J is a 6-year-old boy with an age-appropriate vocabulary who often makes comments that are completely out of context. He makes unusual associations with words or phrases and then perseverates on the association. In a similar way, he responds inappropriately to questions from his peers. Taken together, this leads to great difficulty playing with other children. For example, in the midst of playing a game with peers, J said: “What a lovely bouquet.” which he then repeated several times, leaving his peers perplexed. They tried to reengage J, who then just wandered away, repeating the phrase. J’s articulation is clear, and he is able to speak in grammatically correct sentences. He is disappointed and sad because he cannot play with his peers but has little understanding of why.

Telegram: @medical_k

www.konkur.in

N is a 17-year-old youth who is often physically bullied by other youth. He is frequently the object of teasing because he is prone to misinterpret the intentions of others and is easily provoked. He has a history of misjudging jokes and even the positive intentions of others. When he speaks, he has virtually no facial expression and very few gestures. He has difficulty initiating and maintaining friendships. He seeks friendships with individuals 4 years older than he but generally does better with children who are much younger. Irrespective of the age group, he has difficulties in social situations. He is aware of this and wants to change so that he can have friends. He plans to follow his therapist's recommendation to avoid the "mean kids" but is not always sure how to tell who they are. He has no repetitive, restricted interests or behaviors, and his cognitive ability is in the "above average" range.

Diagnostic assessment tools for SCD remain quite limited. Studies that screen for SCD and related disorders often use the Children's Communication Checklist (CCC). This 70-item parent-report questionnaire screens for pragmatic abilities and skills within the context of their child's overall language skills. The second edition of this questionnaire, the CCC-2, is one of the few validated tools that measure deficits in pragmatic abilities. Translations of this tool exist for 30 different languages, and normative data for the CCC-2 are available for over 1,400 children from the United States and the United Kingdom.

The Test of Pragmatic Language (TOPL) measures a few characteristics of pragmatic communication, including audience, topic, visual, gestural cues, physical setting, purpose, and abstraction in children between the ages of 6 and 18. The Comprehensive Assessment of Spoken Language measures expressive language skills, such as idiomatic language, nonliteral language, and pragmatic judgment, in children and adolescents between the ages of 3 and 21. However, these instruments are nonideal for diagnostic purposes due to their dichotomous scoring systems, according to Swineford et al. The Pragmatic Rating Scale measures 19 behaviors related to pragmatics, all of which are included in the SCD criteria. This measure includes a 15-minute conversation, derived from the Autism Diagnostic Observation Schedule (ADOS), that is scored from "normal behavior to strikingly abnormal

Telegram: @medical_k

www.konkur.in

behavior." The Pragmatic Protocol is used for children at a minimum age of 5 and involves a 15-minute observation period in which unstructured conversation occurs. Although the material of these instruments is relevant to SCD, there is a lack of validity and reliability data for either tool.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of SCD can be complex as it must take into consideration the relationship between SCD and psychiatric disorders, especially ASD, intellectual disability, ADHD, and language disorder. Social communication or pragmatic language deficits are common among children referred for psychiatric or psychological assessment. Similarly, comorbidity rates are especially high for children with language disorder, including ADHD, conduct disorder, and traumatic brain injury. Differential diagnosis is especially challenging due to the overlap in symptoms among various psychiatric disorders and the lack of well-validated assessment tools with high levels of reliability. When the DSM-5 was applied to reassess 80 children with DSM-IV-TR PDD diagnoses, 6 children were found to meet SCD criteria, and another 9 children did not meet DSM-5 ASD criteria. Furthermore, six subjects diagnosed with either Asperger disorder, ASD, or PDD-NOS were found to meet DSM-5 criteria for SCD. A study by Mandy et al. (2017) found that their entire sample of 801 children with ASD satisfied criterion B for SCD, and 600 of them also met all four symptom types of criterion A; only 2 of these children did not meet any symptoms of SCD criterion A.

Social communication is one of the two core deficits of ASD. Children with ASD may show adequate structural language abilities yet still have difficulty with pragmatic language, such as pedantic or overly formal speech, verbosity, and reciprocal conversations. For children with ASD, these pragmatic language and social communication difficulties are accompanied by fundamental social deficits, along with restricted interests and repetitive behaviors. The past and/or present symptoms of clinically significant specialized interests and restricted, repetitive behaviors help differentiate ASD from SCD.

Because a diagnosis of ASD can be given to individuals with just a history of fixed interests and repetitive behaviors, individuals who only show significant social and pragmatic language deficits but no present

Telegram: @medical_k

www.konkur.in

behavioral patterns characteristic of ASD may still be given a diagnosis of ASD. Complicating the differential diagnosis further, stereotyped language, which was previously considered to be a symptom of pragmatic language impairment, is now considered part of the repetitive and restrictive behaviors required for giving a diagnosis of ASD. Finally, some children may show an increase in repetitive behaviors and specialized interests as they grow older, further complicating the differential diagnosis.

When considering a primary language disorder as part of the differential diagnosis, usually children with language disorder show deficits in word knowledge, grammar, and discourse. Discourse includes conversational exchange (reciprocity); narrative deficits in these areas tend to be manifest in social communication problems. However, for children with primary language disorders, social and pragmatic language deficits are thought to be a result of, or secondary to, the structural language impairment. Therefore, a clear relationship between language function and measures of social deficits often supports a diagnosis of language disorder. Other language dysfunction, such as limited vocabulary, prosodic abnormalities, articulation problems, receptive language deficits, and reading problems, increase the likelihood of a language disorder diagnosis.

Some studies have shown group differences in symptom profiles of social communication and pragmatic deficits, and making a differential diagnosis based solely on the basis of social communication, and pragmatic deficits can prove to be challenging. For example, children with Williams syndrome have large vocabularies and are hyperverbal while having fewer problems with stereotyped language, nonverbal communication, social relations, and coherence when compared to children with ASD. An observational study comparing children with SCD and children with language disorder has found that, as a group, children with SCD tend to have more problems with turn taking in conversations, provide no response or inappropriate responses to the communication at hand, and make little use of nonverbal signals when compared to children with language disorder. Much more work is necessary to establish an appropriate level of sensitivity and specificity when assessing social and pragmatic language profiles for the purpose of differential diagnosis, as well as establishing risk factors associated with different clinical populations.

Telegram: @medical_k

www.konkur.in

Some have suggested an overlap between SCD symptoms and those in social anxiety disorder. This is due to the apparent uneasiness in social situations in both disorders. However, the time for the onset of symptoms helps differentiate between these two disorders. Children with social anxiety disorder have typically developing social communication skills yet do not utilize them in some settings due to anxiety associated with social interactions. Children with SCD, on the other hand, have early onset of symptoms and usually never had effective social communication.

Although there are no diagnostic tools that specifically screen for SCD according to DSM-5 criteria, some assessment tools have been able to differentiate these diagnoses, according to Yuan and Dollaghan. A study by Morales-Hidalgo et al. identified the ADI-R, the ADOS-2, and a newly developed assessment, the EDUTEA, as three tools that appropriately differentiate ASD/SCD diagnoses from ADHD diagnoses. (The EDUTEA is an 11-item instrument with two factors: social communication impairments and restricted behavior patterns.) High reliability was found for both factors (.93–.95), along with high sensitivity (87.0%) and specificity (91.2%). In addition, the EDUTEA demonstrated sufficient ability to differentiate ASD/SCD diagnoses from ADHD diagnoses, as exemplified by a high sensitivity (83%), specificity (73%), and AUC score (.78).

ETIOLOGY

There is no published systematic research on the etiology of SCD, including examining the heritability and environmental factors associated with SCD using the DSM-5 criteria. The relatively recent labeling of this disorder means that there are few studies examining the familial aggregation and genetic factors associated with SCD. Although the etiology of SCD remains unknown, in the absence of evidence, theories abound.

There is accumulating evidence suggesting that a family history of ASD, language disorder, or specific learning disorder may increase the risk of having social communication and pragmatic language deficits. Many studies are emerging, supporting correlations of impairments in pragmatic language with common gene variants. Duplications at 19p13.12p12 on the short arm of chromosome 19 were identified in a male adult who presented with SCD and intellectual deficits, suggesting that this variant

Telegram: @medical_k

www.konkur.in

may contribute risk for SCD. In addition, the MET promoter variant rs1858830 C from the receptor tyrosine kinase has been found to be associated with difficulties in social communication in a sample of 748 individuals with ASD from 367 families. However, these genetic variants are not specific to pragmatic language impairments; they are associated with other neurodevelopmental and psychiatric disorders, including ASD, intellectual disorders, and language disorders.

Social inference theory suggests that individuals with SCD, much like individuals with ASD, may have deficits in social cognition, especially in theory of mind (ToM), the ability to make inferences about the mental state of others and use that information to understand and predict their intentions and behaviors. Some have suggested that ToM is an essential precursor for the development of social communication. However, it is equally possible that understanding the mental states of others develops as a result of social communication.

The weak central coherence theory posits that social communication deficits may be associated with a more general processing problem of integrating disparate sources of information into a coherent whole that then allows for specific transactions. This theory suggests that social communication deficits occur due to social communication problems, narrowly focusing on inappropriate or less crucial aspects of the communication while ignoring the bigger picture, which, in turn, makes it difficult for them to use linguistic and social context to derive meaning.

The executive dysfunction theory by Vengas and Davidson suggests that individuals with pragmatic language and communication deficits have a general issue with executive functioning. Executive functions are associated with (but not limited to) activity in the prefrontal cortex, which is associated with high-level cognitive functioning impulse control, behavior monitoring, the flexibility of thinking, abstract thinking, concept formation, problem solving, and planning. The executive dysfunction theory helps explain the great heterogeneity in pragmatic language difficulties experienced by individuals with social and pragmatic difficulties. Executive dysfunction has been implicated in multiple psychiatric disorders, such as ASD and ADHD, each of which is associated with pragmatic deficits.

At this point, there is simply not enough research to support any etiologic substrate of SCD or other social communication or pragmatic language deficits among individuals with SCD.

www.konkur.in

EPIDEMIOLOGY

There are no reliable prevalence estimates for SCD. It remains unclear as to whether demographic factors such as age, gender, and socioeconomic backgrounds correlate with SCD prevalence estimates. Out of 1,081 children and adolescents seen in a social communication clinic in England, only 8% met SCD criteria, suggesting that the prevalence of this disorder remains very low. A study in the United Kingdom found that 22% of the children attending a language clinic had pragmatic language impairment. However, due to the differences in diagnostic criteria, it is unclear what percentage of these children will also meet the diagnostic criteria for SCD.

Deficits in pragmatic language have been reported without the presence of social deficits or repetitive activities and behaviors. Another estimate showed that over 50% of the children who were given the diagnosis of PDD-NOS had early onset of social communication deficits. In a study of 94 children with PDD-NOS diagnoses, social communication deficits were significantly more present in the children who had comorbid psychiatric diagnoses when compared to those without comorbid disorders. However, none of the above studies used the DSM-5 criteria for SCD; therefore, prevalence is likely to differ from that of SCD.

Table 42.2–2.
Prevalence Estimates: DSM-IV PDD, DSM-5 ASD, DSM-5 SCD

	% DSM-IV PDD	% DSM-5 ASD	% DSM-5 SCD	% DSM-5 ASD + SCD

A field trial comparing the prevalence of ASD using the DSM-5 criteria and PDD using the DSM-IV criteria showed a decrease in the prevalence of ASD in one site. Nevertheless, when the prevalence of ASD was combined with the prevalence of SCD, the prevalence was not

Telegram: @medical_k

www.konkur.in

significantly different from that of DSM-IV PDD. This suggests that the decrease, if any, in the estimated prevalence of ASD may be accounted for by the inclusion of DSM-5 SCD.

In a total population sample from Korea, Kim et al. initially diagnosed the children using DSM-IV criteria. They were subsequently rediagnosed using DSM-5 criteria. They found that the population prevalence of SCD was 0.49%. In addition, they reported that of the 1.00% previously diagnosed with PDD-NOS, 0.32% met the criteria for SCD, while of the 0.60% diagnosed with Asperger syndrome, 0.05 met criteria for SCD (0.55% met ASD criteria) (Table 42.2–2).

DEVELOPMENT AND COURSE

The diagnostic category of SCD is so recent that there are not sufficient longitudinal studies to give a clear picture of the development of SCD.

The diagnosis of SCD is difficult prior to the development of speech as a tool for complex social interactions between the ages of 3 and 5. However, for those children who are speaking by age 2 and those children with limited social reciprocity, SCD should be a part of the differential diagnosis during evaluations. By 4 or 5 years old, most children should have developed sufficient social communication and language skills. Those who have not done so should undergo thorough evaluations with consideration of SCD as a diagnosis, among other NDDs. While most cases are evident early in childhood, some milder forms of SCD may escape detection until adolescence, when the social communication and language demands intensify. Although SCD requires relatively intact structural language and impaired social communication, there is great heterogeneity in the severity and patterns of symptom manifestation among those who are diagnosed with SCD. One study found that 64 out of 66 children who had been previously diagnosed with DSM-IV PDD-NOS had “one distinct symptom pattern, namely social impairments without significant repetitive and stereotyped behaviors.” As a group, children with ASD tend to have more severe social communication and pragmatic language deficits than children with SCD. Children with language disorder, in turn, tend to show milder symptoms of social and pragmatic language deficits than children with SCD.

With no epidemiologic longitudinal follow-up studies, it is difficult to describe the long-term outcome of SCD. Given the heterogeneity of

Telegram: @medical_k

www.konkur.in

symptoms, it is likely that outcomes will differ greatly. Clinical experience suggests that some children with social and pragmatic skills deficits improve considerably over the course of development while others have persistent social communication skills deficits extending into adulthood.

In general, studies suggest that children with pragmatic language difficulties tend to perform better in academics when compared to children with structural language problems. In addition, children with social communication deficits may also struggle with written expression and reading comprehension. Gilmour et al. found that deficits in pragmatic language skills were frequently observed in children who were persistently disruptive in school settings. There is some evidence suggesting that pragmatic language difficulties in elementary school years may be associated with emotional and behavioral difficulties, higher rates of referral for psychiatric and psychological assessments, and longer duration attending special education.

Social communication problems rarely occur in the absence of other psychiatric disorders. Comorbid disorders, as well as other risk factors, are likely to affect the developmental course and prognosis of SCD.

TREATMENT

Social (pragmatic) deficits rarely occur without other cooccurring behavioral or emotional difficulties. These behavioral and emotional problems may serve as risk factors for further social communication difficulties, and social difficulties, in turn, may accentuate the cooccurring behavioral and emotional problems.

Since SCD is relatively uncommon and only recently recognized as a separate clinical disorder, diagnosis-specific treatments are not readily available. However, this is not unusual and represents the situation for most neurodevelopmental disorders for which most treatments are directed at specific symptoms rather than the diagnosis. As a result, in the current clinical context, the clinician should consider any treatments that are focused on improving social as well as social pragmatic language functions.

One randomized controlled trial examined the social outcomes of children with social communication deficits (both with symptoms of SCD and ASD) who received intensive, individualized, multifaceted interventions as compared to children who received treatment as usual.

Telegram: @medical_k

www.konkur.in

The intervention focused on developing (1) social interaction skills and social understanding, (2) verbal and nonverbal pragmatic skills, and (3) language processing skills. The children received up to 20 sessions from specialized speech–language professionals and trained assistants. The children who received the experimental intervention showed significant improvement in blind ratings of communication skills, teacher ratings of learning behaviors, and parental ratings of social and pragmatic skills. There were, however, no significant changes in the standardized assessment measures of social communication, which may be due to the lack of sensitivity of these measures to detect change.

Several treatment options have been proposed for children with social communication and pragmatic language difficulties who also present behavioral/emotional problems. Several behavioral interventions and cognitive behavioral treatment programs have been proposed, involving multiple collaborators, including speech–language therapists, mental health professionals, family members, teachers, and peers. Irrespective of who implements the treatment, significantly greater improvements have been observed in children who begin treatment early, with maximum benefits occurring in children who begin between the ages of 3 to 4.

The Social Communication Intervention Programme (SCIP) is a manualized, theoretically driven intervention for children with difficulties in social communication. In one study of school children with difficulties related to pragmatics and social communication, SCIP was more effective in addressing pragmatic competence as well as modifications in social communication and language skills; however, no improvements in language functioning were observed. A more recent SCIP feasibility study found that all 15 school-aged children made significant progress according to the practitioner ratings; parent report suggests that 1 of the 15 children did not make progress.

Functional communication training is a behavioral technique that has been used to treat problem behaviors associated with communication problems. After a functional analysis is conducted to identify the environmental triggers that evoke the problematic behavior, a targeted behavioral reinforcement intervention is initiated. Usually, the intervention focuses on increasing socially acceptable communicative responses and behaviors in a variety of social contexts.

Cognitive behavioral therapy (CBT) may also be useful, especially in the presence of anxiety and mood symptoms or specific comorbidity that

Telegram: @medical_k

www.konkur.in

is amenable to CBT.

Didactic training in social skills on its own has yielded few meaningful social changes. This is likely because individuals with SCD do not generally have impaired knowledge of social norms and appropriate behaviors. Interventions targeting underlying deficits, developing strategies to minimize distracting information, or making explicit important verbal and nonverbal cues may be more beneficial.

A social cognitive reinforcement program has been developed for children with SCD. This intervention has three components: executive function training, social cognition training, and communication skills training. It is divided into three steps: introduction (session 1), development (sessions 2 to 7), and conclusion (session 8). Twenty-two children with SCD participated in a comparison study between this intervention and a typical social skills training program. The children who engaged in the social cognitive reinforcement program improved significantly in multiple areas: nonverbal communication, self-assertion, comprehension, and self-control, as demonstrated by notable improvements measured by the Reading the Mind in the Eyes Test, the Children's Color Trails Test, a picture arrangement task, and a picture completion task. Furthermore, at the 3-month follow-up, significant improvements in executive functioning, pragmatic communication, and social skills were observed in the children who participated in the social cognitive reinforcement program, suggesting that a multicomponent intervention may be the most ideal treatment program for children with SCD.

SUMMARY

SCD is a recent addition to psychiatric nosology. While the clinical presentation is characterized by considerable heterogeneity, SCD represents a fundamental deficit in the ability to use language pragmatics to fully engage in adaptive, reciprocal social interactions. SCD is a relatively rare condition with a prevalence in the range of 0.5%. SCD appears to have an onset in early childhood, and, for many, it likely has a chronic course extending through the lifespan. The etiology of SCD is unknown, and, to date, there are no diagnosis-specific treatments. However, symptom-directed interventions appear to show considerable promise.

42.3 Speech Sound Disorder

EMIKO KOYAMA, PH.D., MAHLIQA ASHRAF, H.B.SC., TUANA KANT, M.SC., AND JAMES L. KENNEDY, M.D., F.R.C.P.C., F.R.S.C.

Speech sound disorder is the most common communication disorder in childhood. Children with speech sound disorder do not correctly produce the speech sounds that are expected for their age, developmental stage, and dialect. Sounds may be omitted (e.g., saying *hou* for *house*), substituted for other sounds (e.g., saying *yewo* for *yellow*), or distorted because they are produced in an atypical way (e.g., saying /sh/ with too much air escaping from the sides of the mouth). Often, the speech sound errors occur in systematic patterns. For example, consonants that should involve a steady airflow instead may have an interrupted airflow (e.g., *bacuum* for *vacuum*), or consonants that should appear at the end of words may instead be omitted (e.g., *be* for *bed*). In severe cases of speech sound disorder, speech may be completely incomprehensible to others.

Linguistic and motor learning, as well as their integration and coordination, are essential for speech-sound development. Linguistic learning presumably involves the gradual and implicit acquisition of a complex rule system that underlies the representation, perception, and production of speech. Children acquire knowledge about the individual speech sounds that comprise a particular language and their permissible contrasts and combinations. Children also induce the regularities governing syllable and word stress and the intonation patterns (melody) of speech.

Speech sound development also involves considerable motor learning. Speech production entails the quick, accurate, and coordinated actions of the many muscles that support breathing, voicing, and articulation of speech sounds. Major articulators that shape speech sounds include the tongue, lips, upper teeth, the gum behind the upper teeth (alveolar ridge), the hard and soft palates, the uvula, the pharynx, and the glottis (the opening between the vocal cords). Eventually, most adults learn to control the complex coordination of these fine motor activities well enough to

Telegram: @medical_k

www.konkur.in

enable the production of intelligible speech at rates as high as 250 words per minute.

Children with speech sound disorder generally develop speech sounds in a typical sequence but with a delayed onset and slow rate of growth. Early words generally include consonant sounds designated as the *early eight* (/m/, /b/, /y/, /n/, /w/, /d/, /p/, and /h/), which are also commonly used during the babbling stage from about 6 months of age. As development continues, the *middle eight* consonant sounds (/t/, /ng/, /k/, /g/, /f/, /v/, /ch/, and /j/) are mastered gradually, followed by the *late eight* (/sh/, /th/ [two variants], /s/, /z/, /l/, /r/, and /zh/). Children may not achieve full mastery of the late eight consonant sounds until 7 or 8 years of age. Throughout the course of typical development, children may produce speech sounds incorrectly and inconsistently.

Word formation normally proceeds in a systematic fashion. The first words that children use generally produce consist of simple sequences of consonants (C) and vowels (V) that comprise syllables of the forms CV (e.g., bye), VC (e.g., up), or CVC (e.g., dog) and short repetitive sequences of the form CVCV (e.g., dada). More complex syllable and word shapes are gradually mastered, such as those with multiple, nonrepetitive syllables and consonant cluster sequences, such as /thr-/, /kl-/, /-rst/, or /-nt/. Vowels are generally thought to be acquired early, and most studies suggest that vowel production is relatively accurate by 2 years of age. As such, numerous vowel errors made beyond age 2 years may be early warning signs of impaired speech.

Speech sound errors may also be described in terms of phonologic processes or rules that encompass a pattern of errors. For example, young children often use a phonologic process of final consonant deletion in which they regularly omit consonants at the end of words. This deletion process is often used by young children but may usually disappear from their speech by 3 years of age. Similarly, there are other common processes that gradually disappear during normal development, including reduplication (repetition of a syllable to form a multisyllabic word, e.g., *bahbah* for *bottle*), unstressed syllable deletion (omission of a syllable that is not stressed, e.g., *nana* for *banana*), stopping (use of an interrupted airflow for sounds that should have a continuous airflow, e.g., *tee* for *see*), consonant harmony (e.g., using a sound similar to one that occurs elsewhere in a word, e.g., *tat* for *cat*), and consonant cluster reduction (omitting or simplifying sounds in a consonant cluster, e.g., *top* for *stop*).

Telegram: @medical_k

www.konkur.in

These phonologic processes all occur regularly in the speech of young children, but all are usually overcome before 5 years of age.

Even if a child mispronounces words, it may not affect the overall comprehension of the child's utterances. If a child's spoken word or phrase cannot be understood, the child's speech is said to be *unintelligible*. Intelligibility is influenced not only by the produced speech sounds but also by other factors, such as pragmatic context and the complexity of the sentence. In normal speech development, roughly half of children's speech is considered intelligible at about 2 years of age, roughly 75% is intelligible by 3 years of age, and by age 4 years, nearly all of the child's spoken language becomes intelligible. If less than two-thirds of the child's utterances are intelligible by age 4, clinical attention may be warranted.

COMPARATIVE NOSOLOGY

Speech sound disorder in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders, Text Revision* (DSM-5-TR) largely corresponds to phonological disorder in the revised fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR). The designation of *speech sound disorder* is typically reserved for speech sound problems with no known cause, which are thought to reflect difficulties in learning the regularities of phonology (the sound system of a language). Speech sound disorder may also be designated when causes are known (e.g., hearing impairment), but the speech impairment exceeds what is expected given the known cause. The 10th edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) provides the category of *specific speech articulation disorder* for speech problems of unknown etiology and designates a different category for speech impairment arising from sensory, structural, or neurologic conditions. The 11th edition of the ICD includes *developmental speech sound disorder*, which has similar criteria to DSM. In the research literature, terms such as (developmental) phonological disorder, (functional) articulation disorder, developmental verbal dyspraxia, and childhood apraxia of speech are commonly used in association with speech sound disorder.

EPIDEMIOLOGY

Telegram: @medical_k

www.konkur.in

The prevalence of speech sound disorder is around 5% to 10% in preschoolers, 3% in 6- to 7-year-old children, and 0.5% in 17-year-old children. Estimates, however, vary widely in the research literature, reflecting the diverse criteria and samples that have been used across studies. Slightly more than half show problems only in speech sound production; the remainder also have language difficulties. Overall, speech sound disorder occurs far more frequently than speech impairment with known structural or neurologic origins.

The literature consistently shows that speech sound disorder occurs more often in boys. Estimates for sex ratios are as high as 4:1 and as low as 1.5:1. Speech sound disorder also shows high rates of familial aggregation. Approximately 20% to 40% of children with speech sound disorder have at least one immediate family member who is also affected. There is evidence in favor of genetic contributions to familial aggregation, but environmental factors may also play a role. Familial risk factors such as low maternal education have also been identified as potential risk factors.

ETIOLOGY

The majority of children with speech sound disorder has no known cause. Proposals regarding causation typically focus on many of the same factors considered as possible causes for language disorders, including subtle brain abnormalities, genetic influences, environmental factors, neurodevelopmental immaturity, linguistic factors, and auditory processes. In addition, speech motor control and speech mechanism factors have also been entertained as possible causes.

Speech sound disorder most likely has multiple causal determinants. Although some evidence supports each proposed determinant, no single one is implicated in all cases of speech sound disorder. The idea that brain abnormalities may be responsible for speech sound disorders is supported primarily by indirect evidence, which includes reports of associated soft neurologic signs at higher than normal rates and findings of structural or functional brain abnormalities in children with related disorders, such as language disorder and reading disorder. The evidence in support of genetic factors comes from a variety of methods, including pedigree, twin, adoption, and linkage studies. Recent studies have found susceptibility of speech sound disorder genes in chromosomes 3, 6, and

Telegram: @medical_k

www.konkur.in

15, which are also thought to be candidate regions for dyslexia. One of the genes that have been extensively associated with speech problems is the *FOXP2* gene on chromosome 7. Children with changes or mutations on the *FOXP2* gene may experience difficulties producing sequences of speech sounds and may also experience delays in language, social, and motor development. The prevalence of *FOXP2*-related speech problems is estimated to be relatively rare, affecting 1 to 2 in 1,000 people. The advancement of work on genetic influences will probably stimulate corresponding advances in the understanding of environmental determinants. At present, however, no conclusive evidence links specific environmental factors to speech sound disorders, although it is reasonable to assume that such factors contribute in as-yet unspecified ways.

Neurodevelopmental immaturity is suggested by the fact that children with speech sound disorder usually follow the same sequence in speech sound development as children without the disorder, albeit at a slower rate. Additional indirect support comes from findings of soft neurologic signs and subtle deficits in motor skills. Children with speech sound disorders may also have linguistic deficits that interfere with efficient learning of the regularities of phonology (e.g., permissible sounds, combinations, or positions of occurrence) from the available language input. Difficulties with auditory discrimination and perception or temporary hearing loss may also contribute to some cases of speech sound disorder. Children with speech sound disorder also show elevated rates of subtle abnormalities in the structure and function of the speech mechanism, but it is not yet known whether these abnormalities are causes or just correlates of the disorder.

DIAGNOSIS AND CLINICAL FEATURES

A diagnosis of speech sound disorder is given when a person experiences persistent difficulties in speech sound production due to different degrees of impairment in phonologic knowledge and coordination of movements involved in speech. The onset of speech sound problems is during childhood. The speech sound production is impaired for what is expected based on the speaker's age and dialect and cannot be attributed to medical or neurologic conditions such as cerebral palsy, cleft palate, traumatic brain injury, or hearing impairment. A further criterion is that the

Telegram: @medical_k

www.konkur.in

speech sound difficulties must interfere with social communication, academic achievement, or occupational success. Speech sound disorder ranges in severity from mild, in which errors occur on one or two sounds and speech intelligibility is hardly affected, to severe, in which errors occur on most sounds and speech intelligibility is significantly impaired.

A delayed onset and slow rate of speech sound development are typical of most children with speech sound disorders. However, the course and sequence of development usually resemble those of typically developing children. Simple syllable and word shapes are gradually elaborated to include more complex shapes. The rate of acquisition may be slow but usually follow the typical sequence, with the early eight consonant sounds usually developing first, followed by the middle eight, and then the late eight consonant sounds. The errors in speech sound production resemble those that occur in normal development, but the relative distribution of omissions, substitutions, and distortions may be somewhat different. Children with speech sound disorder generally use phonologic processes that also occur in normal development but may use these processes well beyond the age at which they normally disappear. Children with speech sound disorder also sometimes use unusual or idiosyncratic phonologic processes that are not observed in normal development.

Ramon was a talkative, likable 3 year old with virtually unintelligible speech, despite his normal hearing and language comprehension skills. Ramon's level of expressive language development could not be determined because his speech was so difficult to understand. The rhythm and melody of his speech, however, suggested that he was trying to produce multiword utterances, as would be expected at his age. Ramon produced only a few vowels (/ee/, /ah/, and /oo/), some early developing consonants (/m/, /n/, /d/, /t/, /p/, /b/, /h/, and /w/), and limited syllable shapes (V, CV, and CVCV). This reduced sound repertoire made many of his spoken words indistinguishable from one another (e.g., he said *bahbah* for *bottle*, *baby*, and *bubble*, and he used *nee* for *knee*, *need*, and *Anita* [his sister]). Moreover, he consistently omitted consonant sounds at the end of words and in consonant cluster sequences (e.g., /tr-/, /st-/, /-nt/, and /-mp/). On occasion, Ramon reacted with frustration and tantrums to his difficulties in making his needs understood.

Telegram: @medical_k

www.konkur.in

Kent was a pleasant, cooperative 5-year-old boy who had been diagnosed with a speech sound disorder when he was a preschooler. His hearing and language comprehension skills were within normal limits. However, he showed some mild expressive language problems in the use of certain grammatical features (e.g., pronouns, auxiliary verbs, and past-tense word endings) and in the formulation of complex sentences. He correctly produced all vowel sounds and most of the early-developing consonants but was inconsistent in his attempts to produce later-developing consonants (e.g., /r/, /l/, /s/, /z/, /sh/, /th/, and /ch/). Sometimes, he omitted them; sometimes, he substituted other sounds for them (e.g., /w/ for /r/ or /f/ for /th/); occasionally, he even produced them correctly. Kent had particular problems in correctly producing consonant cluster sequences and multisyllabic words. Cluster sequences had omitted or incorrect sounds (e.g., *blue* might be produced as *bue* or *bwue*, and *hearts* might be said as *hots* or *hars*). Multisyllabic words had syllables omitted (e.g., *efant* for *elephant* and *getti* for *spaghetti*) and sounds mispronounced or even transposed (e.g., *aminal* for *animal* and *lemon* for *melon*). Strangers were unable to understand approximately 80% of Kent's speech. Fortunately, Kent often spoke more slowly and clearly than usual when he was asked to repeat something, as he often was.

Natasha was a shy, reserved 8-year-old girl with a history of significant speech delay. During her preschool and early school years, she overcame many of her earlier speech errors. A few late-developing sounds (/r/, /l/, and /th/), however, continued to pose a challenge for her. Natasha often substituted /f/ or /d/ for /th/ and produced /w/ for /r/ and /l/. Overall, her speech was easily understood despite these minor errors. Nonetheless, she was often reluctant to speak in front of others because of the teasing she received from her classmates about her speech.

Other language, learning, and developmental disorders may co-occur with speech sound disorder. Language disorder, especially deficits in expressive language, frequently co-occurs with speech sound disorder. Children who have both speech sound disorder and language disorder are

Telegram: @medical_k

www.konkur.in

at increased risk for other problems, such as reading, spelling, and other learning problems, attention deficit hyperactivity disorder (ADHD), and developmental coordination disorder. Children with isolated speech sound disorders are at a relatively small risk for severe academic, behavioral, or psychiatric disorders. If a speech sound disorder persists into adulthood, it may contribute to social anxiety disorder.

PATHOLOGY AND LABORATORY EXAMINATION

There are no laboratory tests that can provide a diagnosis of speech sound disorder. When necessary, specific laboratory tests may help identify and document an underlying neurologic condition that is responsible for apraxia or dysarthria.

DIFFERENTIAL DIAGNOSIS

The most important task in the diagnosis of speech sound disorder is to judge if speech sound production is inappropriate for the age and dialect of the speaker. The judgment may be challenging because the speech of children with speech sound disorder often resembles that of younger children who are developing normally. The same speech errors that may indicate disorder in a 6-year-old child may also indicate typical development in a 4-year-old child. Thus, it is critical to carefully compare a particular child's pattern of speech sound errors to the normal patterns of speech sound development in children.

One must also carefully consider the dialect spoken by the child. Sound differences that may be quite acceptable in one dialect may suggest disorder in another. For example, the production of *caht* for *cart* is acceptable for speakers from Boston but not for those from most other parts of North America.

One of the challenges facing clinicians is how to diagnose speech sound disorders in bilingual children. Depending on such factors as the child's first language background and the timing of acquisition of the second language, even typically developing bilingual children may exhibit more frequent and atypical phonologic error patterns compared to their same-age monolingual peers. Research is needed to establish the typical and atypical speech patterns of children acquiring a second language. Meanwhile, an assessment of speech sound production skills in English

Telegram: @medical_k

www.konkur.in

and the child's other language, accompanied by a careful history, may lead to a correct diagnosis.

The diagnostic assessment should also include a hearing test and an oral examination. The hearing test identifies temporary or permanent hearing difficulties that may require medical or other interventions to enhance the prognosis for the development of understandable speech. The results from the oral examination may help clarify whether the speech sound production problems are developmental, structural, or neurologic in origin. For example, children with neurologic conditions may be slow or inaccurate in performing various speech and nonspeech movements (e.g., sequencing syllables, as in *putuku*; protruding the tongue; or rounding the lips) or may show signs of muscle weakness or paralysis. Drooling, feeding, or swallowing problems suggestive of dysarthria, may also be observed or reported in the history. During the oral examination, the diagnostician may also identify structural abnormalities in the mouth, such as tumors or submucous clefts of the palate, which may need to be considered in the overall management of the child.

Selective mutism is an anxiety disorder that is characterized by the consistent failure to speak in specific social settings. Children with speech sound disorder may not speak due to embarrassment about their speech impairments. However, children with selective mutism typically exhibit normal speech in settings where they feel "safe," such as with family or close friends.

Screening for possible co-occurring communication disorders is also important for children diagnosed with speech sound disorders. When an intellectual developmental disorder is suspected, a cognitive assessment may help confirm or rule out this diagnosis. In cases in which speech difficulties are in excess of those expected for a particular degree of intellectual disability, a diagnosis of co-occurring speech sound disorder may be made.

A practitioner should make a referral to a speech–language pathologist for assessment of speech sound production skills when (1) a 2 year old uses little or no speech, (2) a 3 year old is poorly understood by familiar members of the family, (3) a 4 year old is poorly understood by peers and strangers, (4) a child of any age seems to be withdrawing from social interactions as a result of teasing or frustration associated with speech difficulties, (5) a parent or teacher is concerned about a child's speech, or (6) a child (or adult) experiences a sudden deterioration in speech

Telegram: @medical_k

www.konkur.in

production skills. The last may be the first warning sign of a developing neurologic condition and, therefore, also warrants referral for neurologic examination.

COURSE AND PROGNOSIS

Diagnosis may occur as early as 2 years of age in severe cases of speech sound disorder, which may be accompanied by co-occurring language involvement. However, diagnosis around 4 years of age is more usual. Speech sound disorders show considerable variability in severity, course, and outcome. In approximately 75% of mild-to-moderate cases, speech sound production skills normalize by 6 years of age, with or without intervention. Thus far, no specific predictors of normalization have been identified among the various speech, hearing, oral, cognitive, linguistic, or psychosocial variables that have been investigated. For children whose speech has not normalized by 6 years of age, speech sound development proceeds in spurts and plateaus until 8 or 9 years of age. If normalized speech has not been achieved by then, residual articulation problems often persist into adulthood unless successfully treated. These residual errors usually involve distortions of later-developing sounds, such as /l/, /r/, /s/, /z/, /sh/, /ch/, and /th/. Specifically, distortions of the sounds /s/, /z/, /sh/, and /ch/ are termed *lisps*. Residual errors often have little effect on speech intelligibility but may influence others to erroneously perceive a speaker as lazy, immature, or of low intelligence.

Children with mild-to-moderate speech sound disorders are at relatively little risk for adverse long-term outcomes. Although speech typically normalizes by 8 to 9 years of age, subtle deficits in the speed and accuracy of articulation during complex speech tasks (e.g., rapid pronunciation of multisyllabic words) may remain detectable into adulthood but have little functional impact. Overall, language, cognitive, academic, psychosocial, and psychiatric outcomes are usually within the normal range for adults with a history of mild-to-moderate speech sound disorder.

Children with severe speech sound disorders that persist to school age are at a greater risk for poor outcomes. They may not develop adequate phonologic awareness skills (perception, identification, and mental manipulation of speech sounds), which, in turn, may lead to problems in learning to read and spell. Parents and teachers should carefully monitor

Telegram: @medical_k

www.konkur.in

the reading and spelling development of school-aged children with severe, persistent speech sound problems. If required, reading and spelling performance can then be fostered through explicit instruction in phonologic awareness. It is not yet clear whether severe speech sound disorders are associated with an increased risk for adverse psychosocial or psychiatric outcomes.

Children with co-occurring language disorders are, however, known to have elevated risk for adverse long-term outcomes in communicative, academic, psychosocial, or psychiatric functioning. Those with receptive difficulties are at the greatest risk.

TREATMENT

Treatment is typically recommended for children with moderate-to-severe speech sound disorders. A speech–language pathologist may provide the treatment directly to the child or indirectly through paraprofessionals, parents, teachers, peers, or other volunteers who are taught how to provide treatment for the child. Although there are many intervention techniques, styles, and programs that have been advocated, two main approaches to treatment are discernible.

The *traditional approach* is typically used with children who produce substitution or distortion errors for just a few sounds. In this approach, the child participates in activities that highlight the auditory and motor characteristics of a particular sound. The child then practices the production of the sound while the clinician provides feedback and cues concerning the correct placement and movement of the articulators. Treatment is discontinued once the child produces the new sound accurately in spontaneous speech.

A *phonologic approach* is usually chosen for children with patterns of multiple speech sound errors that are described by phonologic processes (e.g., final consonant deletion or consonant cluster reduction). In this approach, the child participates in activities that demonstrate the communicative value of correctly using certain classes of sounds, such as final consonants or consonant clusters. The child then practices the production of various final consonants or clusters in meaningful communicative situations until the targeted groups of sounds are incorporated into the child's phonologic system. Treatment is discontinued

Telegram: @medical_k

www.konkur.in

once the child uses the new classes of sounds correctly and consistently in everyday speech.

Traditional and phonologic approaches have proven effective in accelerating the rate of speech sound development. However, not all variations of these approaches have yet been subjected to rigorous investigations of their efficacy. Additional research is also needed to compare the relative merits of various techniques for children with different profiles of speech errors, although some work of this nature has begun to appear in the literature. Overall, treatment success depends on whether the new speech skills become established as automatic patterns of production. A key factor in achieving this goal may be the extent to which a child or adolescent is motivated to change existing speech patterns.

In addition to speech sound intervention, children with co-occurring language disorder may need interventions to promote language or fluency. Few studies have systematically evaluated the efficacy of such joint interventions. It is possible that speech production gains may occur as an additional benefit of language intervention that did not focus specifically on speech sound production.

ACKNOWLEDGMENTS

This chapter was written in memory of the late Dr. Joseph H. Beitchman, who continues to inspire us with his dedication, devotion, and extensive research work in childhood language disorders.

42.4 Stuttering

Emiko Koyama, Ph.D., Mahliqa Ashraf, H.B.SC., James L. Kennedy, M.D., F.R.C.P.C., F.R.S.C., and Tuana Kant, M.Sc.

Stuttering is a condition in which the flow of speech or fluency is disrupted by involuntary speech–motor events. Stuttering may include a variety of specific dysfluency types, such as sound and syllable repetitions, sound prolongations, dysrhythmic phonations, and complete blocking or unusual pauses between sounds and syllables of words. More severe forms of stuttering are frequently accompanied by a variety of struggle behaviors, commonly referred to as *accessory*, or *secondary*, characteristics of the disorder. These struggle behaviors may be observed at the respiratory, phonatory, or articulatory level of the speech mechanism and may manifest themselves in disordered breathing, glottal fry (abnormal voice quality), lip pursing, and tongue clicking. Additional behaviors, such as eye blinks, facial grimacing, head jerks, and abnormal body movements, may be observed before or during instances of disrupted speech. In addition to the core and secondary physical symptoms of stuttering, the intended communication is often further altered or distorted by linguistic avoidance due to anticipatory sound or word fears. Linguistic avoidance is a commonly observed feature of stuttering, which results in word

Telegram: @medical_k

www.konkur.in

substitution and circumlocution as the individual approaches the feared sound or word during the communicative attempt. Furthermore, it has been reported that varying levels of both utterance length and temporal complexity function to modulate stuttering frequency in adult stuttering speakers. Similarly, situational avoidance is often characteristic of chronic stuttering, and the type of communicative situation often influences the amount and severity of stuttering. Stuttering patterns are extremely variable, ranging from mild, occasional dysfluencies in speech to severe stuttering that renders communication all but impossible for the affected individual and often results in serious psychological difficulty and social withdrawal. Moreover, the person who stutters may exhibit widely fluctuating periods and severity of dysfluency within the course of a day, depending on the communicative situation, anxiety level, fatigue level, and other associated variables, making stuttering a multifactorial disorder. It is to be noted that stuttering severity is not solely a measure of the frequency of observed stuttering but is usually a function of the communicative hardship it places on the speaker. In other words, an individual employed in an office setting who exhibits a stuttering rate of 15% may feel less handicapped than an airline pilot who is 4% dysfluent, but whose fluent communication is critical. Most recently, treatment efficacy studies of stuttering have begun to utilize measures of functional communication and quality of life to supplement traditional data gathered from counts of stuttering frequency.

HISTORY AND COMPARATIVE NOSOLOGY

Psychiatric syndromes can be defined from the point of view of the observer or the patient. Depressed individuals may not look depressed, but if they report subjective symptoms sufficient to meet criteria, a diagnosis of a depressive disorder can be made. Likewise, stuttering can be defined from the point of view of the listener or the speaker. The speaker's sense of subjective distress or loss of control of their speech apparatus reflects an approach to nosology that focuses on the speaker's experience. The *Diagnostic and Statistical Manual of Mental Disorders* (DSM) focuses on the observer's point of view—that is, on the observable behaviors that are impinging on the patient's quality of life.

In both DSM-III and DSM-III-R, stuttering was placed in the category of disorders usually first evident in infancy, childhood, or adolescence. In

Telegram: @medical_k

www.konkur.in

both of these systems, stuttering was coded on axis I, along with clinical psychiatric syndromes. This remains controversial as stuttering is not commonly viewed as a psychiatric disorder among speech–language professionals, and speech–language pathologists have argued that stuttering should not be included in DSM at all.

In DSM-IV-TR, stuttering is categorized as a communication disorder. This is consistent with the speech–language pathology classification, in which all speech and language disorders are kept within the same category. However, it remains to be shown that it belongs in this category; aside from the similarity of causing communicative difficulties, stuttering may pathologically differ from the other communication disorders in this category. The 10th revision of the *International Statistical Classification of Disease and Related Health Problems* (ICD-10) separates stuttering (stammering) from the speech and language disorders and places it in the category of other behavioral and emotional disorders with onset occurring in childhood and adolescence. The diagnostic criteria in ICD-10 are similar to the DSM-IV-TR diagnostic criteria, but a few differences are notable such as the removal of age-dependent criteria in DSM-IV-TR.

DSM-IV-TR requires that the disorder interferes with academic or occupational achievement or social communication for a diagnosis, whereas the ICD-10 diagnosis applies only if it is severe enough to cause notable disturbances in fluency. ICD-10 requires a minimum duration of 3 months of consistent symptomology; DSM-IV-TR has no duration criterion. DSM-IV-TR further specifies that the disturbance must exceed what is appropriate for the individual's age, and, if a speech–motor or sensory deficit is present, the speech difficulties must exceed those usually associated with these problems. ICD-10 has an additional category for cluttering, which is not accorded separate status in DSM-IV-TR.

In DSM-5 and its text revision (DSM-5-TR), stuttering is rephrased as childhood-onset fluency disorder (stuttering) and categorized within the communication disorders. Stuttering is defined by regular uncontrolled disturbances in the normal fluency and patterning of speech that are inappropriate for the individual's age and language skills, persist over time, and are characterized by frequent and marked occurrences of one (or more) of the following: phoneme and syllable repetition, with prolonged vowels and consonants, aberrant interjections and pauses between words and syllables, abrupt pauses in speech, linguistic avoidance of words that

Telegram: @medical_k

www.konkur.in

triggers stuttering, words produced with excessive physical strain, and monosyllabic repetitions (e.g., “I-I-I see him”).

DSM-5 and DSM-5-TR removed the use of interjectional phrases such as “um,” “ah,” and “you know” as part of the diagnostic definition of stuttering. DSM-5-TR also states the disturbance should not be attributable to a speech–motor or sensory deficit, dysfluency associated with a neurologic insult (stroke or hemorrhage), another medical condition (neurogenic stuttering), or better explained by another mental disorder.

The 11th revision of the *International Statistical Classification of Disease and Related Health Problems* (ICD-11) also contains the diagnosis of developmental speech fluency disorder, with similar criteria to the DSM-5-TR.

With onset in early developmental periods, these disturbances facilitate the comorbid development of social anxiety when speaking, which results in limitations to effective communication, social participation, or academic, or occupational performance, individually or in any combination. DSM-5 included the presence of social anxiety or situational avoidance as part of the diagnostic criteria for stuttering.

EPIDEMIOLOGY

Surveys conducted chiefly in the United States and Europe indicate that the prevalence of stuttering in the general population is approximately 1%. Although data regarding incidence vary widely, most specialists would agree that the likelihood of an individual ever exhibiting some form of stuttering is between 3% and 4%. Of those who begin to stutter, the majority, around 80%, stop by adulthood. The estimated percentages of spontaneous recovery in stuttering, again, vary widely because of differing definitions of stuttering and normal nonfluency, age groups studied, and data collection techniques. Several studies have estimated spontaneous recovery to be as high as 80%. Stuttering is more prevalent among boys than girls, with the ratio of boys to girls among U.S. schoolchildren being between 3:1 and 5:1. Current studies have challenged the above estimates of prevalence, incidence, and gender ratios. Among other factors, it has been postulated that most of the risk for stuttering onset is over by age 5. Even in its earliest stages, stuttering has been shown to be both qualitatively as well as quantitatively different from normal dysfluency.

Telegram: @medical_k

www.konkur.in

A high familial incidence is indicated by the presence of stuttering among the relatives of approximately 50% of individuals who stutter. In addition, a high degree of concordance of stuttering exists in identical twins. Individuals who stutter appear to have normal developmental histories, except for speech and language. Numerous studies have demonstrated that young stuttering children are somewhat delayed in early language and articulation development; however, studies of older stuttering children appear to demonstrate that language skills are once again age appropriate. With regard to personality and social and emotional adjustment, children who stutter are often regarded by their parents or primary caregivers as nervous and prone to specific fears. They are often described as overly sensitive to their environment. Adults who stutter tend to be somewhat more anxious and emotionally reactive than their nonstuttering peers. For the most part, studies relating intellectual ability to stuttering are inconclusive; however, there is a significantly higher prevalence of stuttering in the developmentally delayed population.

ETIOLOGY

There has been growing agreement among researchers and clinicians that stuttering is a multifactorial disorder. Specifying the level of causation can facilitate understanding the etiology of stuttering.

The first of these levels pertains to underlying causation, which refers to the genetic, neurophysiologic, and psychological factors that may predispose a child to fluency disruption. Research in these areas has been rather cyclic since the 1940s, and various models implicating psychological, learning, and neurophysiologic variables in stuttering have been presented.

One early psychoanalytic theory of stuttering postulated that disrupted speech represents part of the individual's psychological history, such as disturbed or traumatic early parent–child interaction. Empirical support for this psychoanalytic model is largely lacking, and studies investigating personality factors associated with stuttering have not revealed anything suggesting emotional disturbance or neurosis as a possible cause.

Later psychological models of stuttering have drawn on the principles of classical and operant conditioning to explain stuttering. Several behaviorally oriented researchers offered a model of operant conditioning

Telegram: @medical_k

www.konkur.in

in which the early dysfluencies of the child were subject to an intermittent schedule of reinforcement, resulting in incipient stuttering. The two-factor theory of stuttering posited that dysfluency resulting from negative emotions becomes associated with speech-related stimuli through a process of pairing, or conditioning, as explained by classical conditioning. The individual's response to the fluency failure, the repetitions, sound prolongations, and attempts to terminate the instance of disruption are instrumentally conditioned.

Perhaps the best-known psychological theory of stuttering is the diagnosogenic (semantogenic) model as proposed in the 1940s. This theory postulates that stuttering is caused by parents' diagnoses of the developing child's normal dysfluencies as stuttering, particularly if the child is also socially sensitive. One of the stronger observations used to support the diagnosogenic theory was that of American Indian tribes of which ones lacking a specific word for stuttering in their tribal language had lower rates of stuttering in their overall population, relative to tribes that did. The underlying fundamentals of this correlation reason that if a child with normal dysfluency is subject to a premature diagnosis of stuttering, they would have a mental block preventing them from realizing their potential. However, there is an understanding that specific vocabulary is not necessary for the sake of communication, which leaves this theory under skepticism as it is still very much possible a child is reprehended and stigmatized for their normal dysfluency.

The large proportion of stuttering individuals who have relatives with a similar speech disorder and the high concordance for stuttering in identical twins have long suggested that biologic inheritance plays some part in stuttering. Current models of genetic transmission that can account for familial patterns of stuttering provide strong evidence for the biologic inheritance of stuttering. Moreover, research utilizing the most current genotyping technologies has confirmed the evidence for a strong genetic factor in stuttering. However, these genetic models point to a complex interaction between heredity and environment. Most recent studies have pointed out several possible specific candidate genes. However, it is too early to declare that specific genes underlying stuttering in the general population have, in fact, been identified. Moreover, at this point in time, it remains unclear as to which specific combinations of motor, linguistic, temperament, or other aspects of speech are being transmitted.

www.konkur.in

The theory of cerebral dominance, proposed in the late 1920s, was one of the earliest neurophysiologic models used to explain the cause of stuttering. This theory postulated that stuttering resulted from the lack of an appropriately developed hemispheric dominance of speech and language function.

The theory of incomplete or atypical cerebral lateralization for speech has received varying amounts of support, but not until relatively recently did advances in electrophysiologic techniques and brain imaging begin to yield more reliable data on cortical and subcortical processing of speech in stuttering. Much of the earlier research into the nature of these hypothesized brain processes was based largely on the use of behavioral observations and electromyographic measures. Relevant observations included the effects of delayed auditory feedback on the speech fluency of nonstuttering and stuttering speakers, differences in dichotic listening and dual-task interference performance between stuttering and nonstuttering speakers, and articulatory discoordination and oral kinesthetic deficiencies in stuttering individuals. These observations, among others, represented indirect evidence of differences in neural processing between stuttering and nonstuttering individuals.

Most recently, several brain-imaging techniques used to measure regional cerebral blood flow and oxygen consumption have been applied to the investigation of stuttering. Data from these initial studies using single-photon emission computed tomography (SPECT) and positron emission tomography (PET) point to differential activation patterns in stuttering individuals during both oral and silent reading and even immediately after treatment for stuttering. Findings from these studies have reported a general overactivation in several regions of cortical and subcortical motor networks in individuals who stutter. Recent functional imaging studies have reported increased activation in the right frontal-lateral cortex and the medial-anterior cingulate during both silent and oral reading in stuttering individuals. Moreover, the neural activation in stuttering adults is characterized by a generalized bilateral recruitment of cortical and subcortical neural resources involved in both language formulation and speech production, whereas this activation is lateralized for nonstuttering individuals.

Data coming from studies investigating the effects of behavioral treatment seem to suggest that treatment initially results in an increase in recruitment of resources, including cerebellar activity, after an intensive 3-

Telegram: @medical_k

www.konkur.in

week treatment period, followed by a significant reduction in the overall amount of activation after 1 year. At the 1-year mark, the overall activation pattern observed in the stuttering speakers is very similar to that observed in the normally fluent speakers. This finding has been interpreted as signaling increased automaticity in the application of learned speech–motor skills.

A recent study attempted to establish whether decreased functional connectivity between speech-related cortical areas was the structural basis for stuttering. The investigation reported that stuttering subjects showed disturbed patterns of activation in the premotor and motor cortices, particularly below the regions that represent the laryngeal and tongue in the left sensorimotor cortex. Further evidence pointing to anomalous anatomical cortical structures in stuttering has been reported in a study using volumetric MRI scans. The study found that anomalous anatomical configurations of perisylvian cortical speech–language areas are more common in adults with stuttering. In addition to several other findings, the authors report that both the right and left planum temporale were significantly larger in the stuttering subjects compared to the controls, and planar asymmetry was reduced, implicating speech and language nonlaterality. The authors point out that the left planum temporale is composed of auditory association cortex, which is important in the higher-order processing of linguistic information and is structurally larger than its homologous counterpart in healthy adults, thus the resulting leftward asymmetry. Researchers have speculated that the left planum temporale may be the neuroanatomical substrate for language, and there is some evidence of a relationship between planar asymmetry and language laterality. Additional structural anomalies have been reported in recent studies examining the neuroanatomical differences in speech-related cortex between stuttering and nonstuttering individuals using voxel-based morphometry. Results revealed significant differences in localized gray and white matter densities of left and right hemisphere regions involved in auditory processing and speech production.

The past decade has seen exponential growth in the number of peer-reviewed articles investigating both functional and structural brain differences in stuttering individuals. While there appears to be much in the way of unclear or conflicting evidence, there have been some consistent findings.

Telegram: @medical_k

www.konkur.in

First, several studies have demonstrated that people who stutter demonstrate greater activity in the right hemisphere cortex (gray matter) than nonstuttering individuals. Such overactivation is observed particularly in an area of the right frontal lobe, which is homologous to Broca's area of the left hemisphere. Structural studies have further demonstrated that white matter differences between stuttering and fluent speakers, located primarily in the right primary auditory and frontal cortices, were observed contralateral to the gray matter differences (Fig. 42.4–1). This finding implies that stuttering individuals have decreased functional connectivity between perisylvian areas responsible for hearing speech and producing verbal motor movements, to which the brain tries to overcompensate by contralaterally increasing the formation of white matter tracts. In a recent study of stuttering children, reduced gray matter volumes in the bilateral-inferior frontal gyri and left putamen were observed. These stuttering children also demonstrated increased gray matter volumes in the right ventral premotor and superior-temporal gyri relative to fluent children. These findings are interpreted as reflecting developmental factors resulting in a deficit in speech–motor learning. A number of studies have also reported that stuttering subjects show significantly increased activation in the cerebellum, which is critical for integrating sensory and motor functions early in the acquisition of fine motor skills. In addition, studies have shown decreased corpus callosum tract volume, which communicates information between the right- and left-brain hemispheres, including the finer details of language production, such as tone, humor, irony, and emotions.

FIGURE 42.4–1. Illustrative drawing of the brain anatomy in a coronal slice. The *highlighted regions* show the significant anatomical changes in stuttering children when compared to nonstuttering children.

A second etiologic level of stuttering involves the precipitating causes—that is, when, where, and under what conditions stuttering is most likely to occur. At this level, the concern is with the loci of stuttering and the specific speaking situations impacting fluency. Linguistic factors associated with stuttering have led some theorists to view it as a higher-level cognitive dysfunction. The vast majority of stuttering occurs on the initial sounds of words or syllables. Fluency-facilitating conditions include choral reading, repeated reading of the same material, whispering, and

Telegram: @medical_k

www.konkur.in

speaking under conditions of altered auditory feedback or masking noise. Based on these and other phenomenologic features of stuttering, new theories have implicated higher-level linguistic processes as the fundamental causal elements for speech disruption in stuttering. These processes involve the planning or adjustments of linguistic plans via internal monitoring loops. One such theory, the covert repair hypothesis, emphasizes the role of internal monitoring in detecting and correcting phonologic errors in speech planning and production. The theory suggests that the unintended side effects of these elaborate models of internal speech monitoring and repair create internally conflicting conditions, which are, in part, responsible for the dysfluency in both normal and stuttering speech. The brain's executive section favors the abrupt interruption of normal articulation when there are word-finding or grammatical errors.

A third level of causation and an area of active investigation concerns the motor speech and vocal tract dynamics that are characteristic of stuttering. The vocal tract events generating disrupted speech patterns have been the focal point of much of the physiologic research on stuttering since the early 1980s. It is reasoned that increased knowledge of vocal tract events and the component behaviors of stuttering will ultimately have a direct impact on the diagnostic assessment, measurement, and therapeutic modification of these behaviors. Much information is available on the respiratory, laryngeal, and articulatory dynamics of stuttering. Physiologic studies indicating differences between stutterers and nonstutterers are closely scrutinized because they may, in fact, be dealing only with peripheral events surrounding stuttering, not with underlying causation. The above argument notwithstanding, individuals who stutter, as a group, exhibit relatively longer laryngeal, respiratory, and articulatory reaction times. It has been speculated that the speech–motor systems of people who stutter are limited in their skill or ability to prepare and perform the motor actions that are required to implement the various demands imposed by linguistic, cognitive, emotional, and motor aspects of speech. Additional evidence for this argument comes from within the stuttering patient population, which generally shows boys produce articulations with slower reaction times and diminished amplitude than girls. This observation is upheld by statistical evidence that boys are also five times more likely to be diagnosed with stuttering, providing further evidence that such seemingly peripheral observations may be a potential

Telegram: @medical_k

www.konkur.in

point of the target for both diagnostic measures and therapeutic modifications such as surgical intervention.

The final level of causation involves the environmental factors associated with the onset and development of stuttering. Much information has been collected on the personality traits of young children who stutter and their parents, as well as the psychodynamic, sociologic, and conditioning factors influencing stuttering and their interaction with linguistic development. Considerable inconsistency exists in data obtained from research on the personality of stutterers. There is little (if any) conclusive evidence that stutterers, as a group, exhibit a definable character structure or predictable set of personality traits. This inconsistency is further evidenced in a series of recent articles investigating temperament, emotional regulation, and emotional reactivity in young children who stutter. Some of these studies suggest that greater emotional reactivity experienced by preschool children who stutter, together with their relative inability to regulate their emotions and control their attention, may lead to fluency breakdown. Other studies have been unable to distinguish between the children who stutter and those who do not on these variables. Moreover, there appears to be much overlap in overall adjustment profiles between stutterers and nonstutterers, with lower social adjustment and self-esteem scores characterizing individuals who stutter. However, these traits are more appropriately explained as a product of affect and personality as opposed to the underlying cause of stuttering itself in these individuals.

DIAGNOSIS AND CLINICAL FEATURES

Stuttering is typically characterized by involuntary disruptions in the fluency of verbal expression. These disruptions may be audible or silent and are usually characterized by repetitions or prolongations of sounds or syllables, tense pauses, or the complete cessation or blocking of speech sounds.

Accessory or secondary features frequently accompany instances of stuttering. These secondary behaviors involve both the speech mechanism and related or unrelated body structures. Such behaviors may include eye blinks, facial grimacing, lip and tongue tremors, tics, vocal fry, head jerks, abnormal movements of the limbs, and breathing irregularities. Linguistic and situational avoidance behavior is often observable with

Telegram: @medical_k

www.konkur.in

confirmed stuttering. The affected speaker will often scan the intended utterance to predict stuttering and then attempt to avoid such disruption by substituting words, revising phrases, circumlocutions, or stopping the entire communicative process. Situational avoidance is often reported, such as speaking in front of a group or on the telephone. Most adult stutterers report specific sounds, words, or situations that increase stuttering. Most of this information comes from studies carried out on chronic adult stutterers. Children who stutter have not been studied extensively, but it is generally accepted by clinicians that stuttering in its earlier forms is more often restricted to simpler types of dysfluency, such as repetitions and prolongations, and less often involves the more severe struggle and avoidance behaviors. Definitions of *stuttering* vary widely and are usually based on listeners' observations of the disrupted speech pattern. However, some authors emphasize that the affected individual's sensations of the stuttering moment are crucial to any complete definition. Many forms of stuttering are so subtle that they are undetectable by the listener and are only perceived by the speaker.

Although stuttering varies markedly in terms of frequency and severity, both within and among individuals who stutter, some fairly predictable events or situations are commonly observed that either facilitate fluency or result in a deterioration of the stuttering (e.g., choral reading, singing, whispering, speaking in the presence of masking noise or under conditions of delayed auditory feedback, speaking when alone). Conditions commonly observed to increase stuttering include talking on the telephone, talking to groups, making introductions and saying one's own name, talking to authority figures, and attempting to communicate during stressful situations such as job interviews or formal presentations.

Although severe forms of stuttering are most often observed in adults, children and adolescents can be similarly affected. Stuttering can have a significant impact on the individual's quality of life, causing significant social, emotional, educational, and vocational problems. Preschool and young school-aged stutterers frequently develop social and school-related anxiety. In fact, school children who stutter have a sixfold increase in their likelihood of having a diagnosable social or general anxiety disorder, as compared to a nonstuttering child. The adolescent who stutters tends to withdraw from normal social interaction. The young adult stutterer often reports feelings of restricted academic and career choices and often forgoes the opportunity to develop specific talents and career paths.

www.konkur.in

Adam was a pleasant and likable 8-year-old boy in the second grade. He had a younger brother and older sister whose speech developed normally. Adam's speech was also developing normally until around the age of 3½, at which time he began to show numerous repetitions of words, syllables, and sounds. Adam's pediatrician felt that the dysfluent speech was only a phase that Adam would soon outgrow. Adam's speech progressively worsened, and he began to show signs of struggle as he tried to force his words out on increasingly frequent occasions. The family remained convinced that the physician's predictions would, in fact, be borne out and that Adam would eventually grow out of the problem. By the time Adam was in the second grade, his speech was characterized by severe stuttering, taking the form of silent blocks lasting up to 20 seconds. These blocks were associated with generalized upper body tension and breathing abnormality just prior to the instance of disruption. In addition to being visibly frustrated by his inability to communicate at school and with his friends, Adam became withdrawn and socially isolated. He would not participate in class and would often refuse to go to school if he knew that he would be called on during a certain activity. Adam's mother also reported that there had been several instances of bullying and teasing by two of Adam's classmates. On several occasions, Adam returned home from school crying because of the remarks made concerning his speech. At this point, Adam's mother consented to have the school speech–language pathologist perform a full assessment and begin therapy sessions in order to provide Adam with the relief and support that he had been lacking.

The case study of Adam illustrates two commonly observed scenarios with regard to children's early speech development. First, childhood dysfluent speech patterns are often mistakenly interpreted as normal developmental phenomena. Although it is true that many young children will pass through periods of disrupted speech patterns and will spontaneously recover from these, a significant minority, estimated as high as 30%, of these children will continue to exhibit disrupted speech patterns, and if left unattended, they will develop confirmed stuttering. Recent studies point to the importance of early clinical intervention and, at the very least, referral for assessment by a speech–language pathologist

Telegram: @medical_k

www.konkur.in

to determine whether treatment is indicated. The case study highlights a second frequently observed social impact on children who stutter: teasing and bullying. Recent studies have demonstrated that more than 80% of children who stutter have, at some point, experienced bullying, usually in the form of teasing or name-calling. Children who stutter will often experience feelings of shame and reduced self-esteem as they are identified by their peers as different and vulnerable. They will often be excluded from their peer group activities and become increasingly withdrawn and socially isolated. Because they feel inadequate as communicators, these feelings of inadequacy quite often evolve into generalized feelings of low self-worth and esteem.

www.konkur.in

Susan is a 28-year-old bilingual speaker of English and Bengali. At the time of her assessment, her speech was characterized by severe amounts of hard glottal attacks, sound prolongations, and laryngeal blocks. Secondary behaviors observed included eye blinks and lip tremor. She reported that she regularly used avoidance strategies such as starters, fillers, and word switching to avoid stuttering in public whenever possible. Susan also reported that she avoided speaking with unfamiliar listeners and speaking in group situations. Susan reported that she had participated in treatment at the ages of 8 and 10 with some success in structured settings, but her gains had been difficult to maintain.

Based on her assessment, it was recommended that she participate in an adult group intensive treatment program focusing on fluency-shaping strategies. Susan was judged to be an excellent candidate for this model of treatment based on the following criteria: First, she demonstrated through her assessment interview and reading sample that she possessed the intellectual capacity to manage the rigorous demands of the intensive nature of the program. Second, she demonstrated through her oral mechanical examination and trial therapy probe that she was capable of managing the physical demands of altering her motor movement patterns. Third, she evidenced the emotional readiness to benefit from group therapy and to address the cognitive restructuring requirements of the program. Fourth, she evidenced a high level of motivation to successfully complete treatment and participate in a long-term maintenance program.

Susan's treatment program included 3 weeks of daily clinic sessions lasting for close to 5 hours per day. She further dedicated between 2 and 4 hours to the completion of home assignments each evening.

In addition to successfully acquiring the motor skills required for fluent speech, Susan responded well to the cognitive restructuring goals of the program. She took to heart the suggestion that optimal success in treatment cannot be achieved without a genuine acceptance of one's self as a person who stutters. She gained a level of comfort and openness about stuttering by completing a number of assignments that required her to practice with a variety of partners outside the group. This afforded her the opportunity to discuss her

Telegram: @medical_k

www.konkur.in

speech condition and therapy program with a number of family members, friends, and coworkers.

Susan is currently in the maintenance phase of her treatment program. She has taken many positive steps to create a lifestyle that supports her goal of long-term fluency maintenance. Susan carefully completes her daily schedule of maintenance practice. When she neglects her practice, she realizes the negative effect on her speech but manages these ups and downs with a positive attitude. She thoughtfully selects short-term goals at each follow-up meeting that will support her long-term goal of successful maintenance. Most recently, she revealed that she had been accepted to a graduate program in speech–language pathology.

DIFFERENTIAL DIAGNOSIS

The ability to produce fluent speech is a skill that develops as the young child grows, and it depends on such factors as motor coordination, timing, linguistic, and cognitive development, as well as emotional development and maturity. Fluent speech production results when the motor skills to produce a desired message occur sequentially and synchronously in a smooth manner. This requires a fully developed system composed of respiratory, phonatory, resonatory, and articulatory components acting interdependently to produce fluent speech. Given that these systems are not fully developed at 3 or 4 years of age, preschool children quite commonly exhibit dysfluency in speech during their communication efforts. The factors that distinguish normal nonfluency from incipient stuttering involve both the type and frequency of the observed disrupted speech patterns. Children who stutter exhibit predominantly part-word repetitions, voiced or unvoiced sound prolongations, and broken or fragmented words, whereas the normally nonfluent child is more likely to demonstrate whole word and phrase repetitions, revisions, and end syllable prolongations. Several researchers have emphasized the degree of speech fragmentation as the distinguishing factor between stuttering and normal nonfluency. The child who is developing normal speech patterns usually does not evidence more than 10% of any type of dysfluency in speech, whereas the stuttering child often exhibits higher amounts of speech disruption. Another distinguishing factor is the presence or absence of struggle during speech attempts. The stuttering

Telegram: @medical_k

www.konkur.in

child exhibits difficulty in initiating or maintaining proper breath flow or voicing during speech attempts. The normally developing child is more likely to produce easy, effortless speech with continuous, uninterrupted breathing, even if it is intermittently marked by repetitions of whole words or phrases. As such, a caregiver is in a key position to differentiate whether the child's stuttering requires clinical attention or the child is undergoing a phase of dysfluency.

The discussion thus far has centered on developmental stuttering, the disorder of fluency most commonly observed in children and adults. It should be noted that there are other types of speech dysfluencies that may be observed in clinic populations, two of which will be mentioned here.

Acquired neurogenic stuttering is a condition that can appear for the first time in adulthood and is usually associated with a variety of temporary, progressive, and nonprogressive neurologic disorders, such as traumatic brain injuries, strokes, and extrapyramidal diseases. In addition to adult cases of neurogenic stuttering, there have also been reports in which childhood stuttering worsened or reappeared with the onset of the neurologic disorder. Several features of neurogenic stuttering help to distinguish it from developmental stuttering: general adversities from the problem but no apparent anxiety, instances of dysfluency occurring in any part of the utterance, lack of secondary behavioral symptoms, stuttering on small grammatical words and substantive words with approximately equal frequency, and reduced variability of stuttering across different communicative situations.

Cluttering is another disorder characterized by rapid speech, reduced intelligibility, and frequent telescoping of words under the DSM-5. Cluttering is often marked by grammatical and syntactic errors and is not typically associated with any specific sound or word fears or difficulty maintaining breathing levels when producing sentences. Cluttering has often been associated with a central language imbalance, with some authors suggesting that cluttering exists when an individual presents with one or more impairments in each of five broad communicative dimensions reflecting cognitive, linguistic, pragmatic, speech, and motor abilities. Some of the features differentiating cluttering from stuttering are self-monitoring and general awareness. Whereas people with developmental stuttering are usually hypersensitive to the sound of their own speech, the person who clutters is often only vaguely conscious of their aberrant

Telegram: @medical_k

www.konkur.in

speech pattern and inconsistencies, let alone the existence of their speech disorder. Cluttering patients are often met with poor prognosis, largely as a consequence of the individual's denial to seek medical help for a condition they are seldom aware of.

COURSE AND PROGNOSIS

The onset of stuttering can occur anytime between the ages of 2 and 7, peaking at approximately age 4. Most of the risk for the onset of stuttering is usually negated by the age of 6. The stuttering fluctuates in severity initially, as every patient has a unique course of development. Initially, days or weeks may go by with little or no speech difficulty, only to be followed by a sharp increase in the amount and type of stuttering behavior, and this may be dependent on environmental triggers. Despite fluctuations in severity, young children who begin to demonstrate signs of true stuttering do not continue to be dysfluent in the same manner they began. As children begin to demonstrate more struggle and fragmentation of words and syllables, the stuttering pattern becomes more complex. If these children are left unattended, their stuttering episodes slowly become more concrete and chronic, proving more difficult, but still possible, to treat with speech therapy. In its most advanced form, speech disruptions are accompanied by secondary behaviors such as those previously described. Complete recovery from stuttering is rare after puberty. As many as 80% of stuttering children experience spontaneous recovery, with girls more likely to become spontaneously fluent than boys. Investigations of prognosis in therapy for the older, confirmed stutterer have focused primarily on the influence of personality factors in treatment; subjects with less favorable speech attitudes were less likely to obtain long-term benefits from behaviorally oriented speech therapy for stuttering.

TREATMENT

The vast majority of treatment techniques for stuttering have been conducted on adults. Speech–language pathologists have traditionally practiced two distinct forms of therapy. The first deals directly with the psychological and cognitive aspects of the problem—that is, the attitudes, feelings, and emotions displayed by the individual who stutters. Treatment

Telegram: @medical_k

www.konkur.in

procedures use various types of psychotherapy directed at self-acceptance, attitude change, and avoidance or anxiety reduction. These therapy sessions aim to reduce feelings associated with the triggering of a stuttering episode. The second major speech therapy approach involves modification of the stuttering response to fluent-sounding speech by the application of systematic steps and rules of speech mechanics. In this framework, therapy procedures attempt to reconstruct the respiratory, phonatory, and articulatory gestures used in speech production, either by stuttering modification or fluency-shaping techniques. Therapy formats for adults who stutter have been intensified, and several major stuttering treatment programs now offer full-time treatment approaches administered in blocks of several weeks. Current research and clinical efforts are directed at the maintenance of fluent speech in the posttreatment environment. A significant number of individuals have been reported to exhibit either partial regression or even total relapse of stuttering without the continued practice of speech skills after treatment.

Varying definitions of stuttering and of successful treatment have largely hindered measures of treatment efficacy. Current therapies report success rates ranging from 60% to more than 90% when the sole dependent variable is self-perceived fluent-sounding speech immediately after treatment. However, thorough treatment outcome measures for stuttering should include three elements: (1) a significant positive change in speech output is produced, (2) the change is generalized across speaking situations, and (3) the change is maintained over time.

Far fewer studies have been done on the effects of speech therapy on young stuttering children. Clinicians tend to be somewhat divided on the issue of direct therapeutic intervention for the preschooler who stutters. Many advocate an indirect approach, incorporating parent counseling and environmental manipulation to treat the dysfluent child. This approach incorporates such techniques as parental modeling of relaxed, unhurried speech, and reduction of communicative stressors in the home environment. A second approach trains parents of very young children to apply behavioral techniques of verbal contingencies to stuttering and to verbally reinforce stutter-free speech in the child's everyday speaking environment. If it is determined that these indirect approaches are not sufficient to fully address the stuttering, direct techniques of speech modification or fluency shaping, such as respiratory control and gentle

Telegram: @medical_k

www.konkur.in

phonatory onsets, are taught in a manner similar to those used with older populations.

Currently, there are no approved medications for stuttering on the market. However, advancements in neuroscience, such as medications that modify the dopamine receptors that reduce stuttering severity, may give patients a unique treatment option, especially for individuals who are unresponsive to traditional treatment methods.

ACKNOWLEDGMENTS

The chapter was written in memory of the late Dr. Joseph H. Beitchman, who continues to inspire us with his dedication, devotion, and extensive research work in childhood language disorders.

42.5 Unspecified Communication Disorder

TIM BRESSMANN, PH.D.

The section on communication disorders in the current fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders, Text Revision* (DSM-5-TR) focuses on developmental speech and language disorders, which is consistent with previous versions. The category unspecified communication disorder is open ended and may capture other notable aspects of a patient's symptomatology as they relate to verbal communication.

This chapter will focus on voice disorders. Beyond the linguistic information that is conveyed through a speaker's speech, the underlying voice quality can add important information about the speaker's emotional and physical status. The patient's voice quality and quantity can be an important clinical sign in the anamnesis of a range of psychiatric conditions, and psychiatric and voice symptoms can sometimes interface in interesting ways. Voice disorders can equally be an outlet or a cause for stress and emotional turmoil. The boundary between structural and functional (psychological) etiologies is often blurred.

The voice is part of the speech production mechanism. Speech is a complex physiologic phenomenon that relies on the coordination of multiple anatomical systems. Airflow from the lungs causes the vocal folds to vibrate periodically, generating a raw voice that is filtered and shaped in the pharynx. The velopharyngeal sphincter functions like a valve that can direct the airflow orally to produce oral speech sounds. If the velum is lowered, speech sounds will be nasal. The movements of the lips, jaw, and tongue create differentiated, linguistically meaningful speech sounds. Accordingly, the subsystems of speech can be broken down as follows: respiration (airflow from the lungs), phonation (sound generation in the larynx), resonance (shaping of the sound quality in the vocal tract), oral–nasal balance (direction of airflow into the oral or nasal direction at the level of the velopharyngeal sphincter), articulation (modulation of the

Telegram: @medical_k

www.konkur.in

sound stream into consonant and vowel sounds with the tongue, jaw, and lips), and suprasegmental (speech rhythm, loudness, and intonation).

DEFINITION

In the DSM-5-TR, unspecified communication disorders are described as "presentations in which symptoms characteristic of communication disorder that cause clinically significant distress or impairment in social, occupational, or other important areas of functioning predominate but do not meet the full criteria for communication disorder or for any of the disorders in the neurodevelopmental disorders diagnostic class." The wording of this descriptor is somewhat unfortunate because it implies that unspecified communication disorders do not reach a threshold of criteria to qualify as proper communication disorders. The DSM-5-TR definition goes on to state that the category is applicable in cases where the clinician chooses not to specify the reason that the criteria for another communication disorder are not met or for situations when there is insufficient information to make a more specific diagnosis.

However, the DSM-5 categories are not comprehensive and detailed enough to capture the full range of communication disorders. While this is reasonable because the DSM-5 focuses on psychiatric conditions, speech–language pathologists may feel that this leaves the manual at an uncomfortable halfway point. Many pediatric communication disorders are included with a fair level of detail, while other important and frequent acquired communication disorders such as aphasia (acquired language disorder), dysarthria (neurogenic motor speech disorder), as well as structurally related speech disorders related to head and neck cancer, to name but a few, are omitted in the DSM-5. The clinician may make a diagnosis of an unspecified communication disorder not because of insufficient information but simply because of a lack of a more appropriate diagnostic category.

Examples of disorders that lend themselves to the diagnosis of unspecified communication disorder include voice disorders but also structurally related disorders such as oncologic pathologies (laryngectomy or glossectomy). Because the latter occur only rarely during childhood and are rather self-evidently related to surgical resections, this section is focused on voice disorders.

Telegram: @medical_k

www.konkur.in

Voices are as varied, individual, and recognizable as human faces. What is considered acceptable as normal voice quality, loudness, and pitch may vary markedly between languages or in different cultures. The clinician will therefore try to determine whether a client's voice is appropriate (rather than "normal") with regard to the speaker's physical makeup, culture, and language. A voice may be considered disordered when the speaker experiences marked functional limitations, such as a voice that does not project well or gives out. The vocal quality may attract negative attention and may be perceived as unpleasant by the speaker or the environment. Speaking may be uncomfortable or painful.

HISTORY

The beginnings of modern vocology date to the late 19th century. Much of the research during this time was conducted by singing teachers who were interested in the physiology of the anatomical structures they were trying to educate in their students. The early 20th century saw a rapid improvement in laryngeal imaging methods and a more thorough understanding of the vocal mechanism. During this time, researchers also observed that many voice disorders are the result of chronic hyperfunctional misuse and that the voice can be a target of psychosomatic processes. These findings roughly coincided with the development of early psychoanalysis. As a result, functional voice disorders were often interpreted as a manifestation of a suppressed personal conflict, resulting in a conversion dysphonia. In recent decades, voice scientists and speech–language pathologists have begun to differentiate more carefully between true psychogenic dysphonias and functional voice disorders that are related to excessive muscle tension. Patients with muscle tension dysphonia will experience voice problems chiefly because of poor musculoskeletal alignment. Muscle tension dysphonia can often be treated on its own merit so that a psychodynamic interpretation of the disorder is no longer regarded as necessary or helpful in every case.

COMPARATIVE NOSOLOGY

Human communication disorders are as complex and as varied as psychiatric conditions. The DSM-5 continues to recognize the relevance of

Telegram: @medical_k

www.konkur.in

communication disorders to the psychiatric profession. However, it is neither the aim nor the scope of the DSM-5 to provide the level of detail and differentiation that a speech–language pathologist would bring to the diagnosis and treatment of communication disorders. There are manifold communication disorders that cannot meet the relatively narrow criteria for the types of developmental communication disorders laid out by the DSM-5. Consequently, the DSM-5 category unspecified communication disorder is a diagnostic wild card.

EPIDEMIOLOGY

There are few reliable epidemiologic estimates for the prevalence of voice disorders, and the available figures vary considerably between studies. In part, this is due to uncertainty about the concept of the healthy voice: The acceptability of different vocal qualities and quantities varies considerably in different cultures, languages, and on different socioeconomic levels. Voice quality is an auditory–perceptual impression, so what is considered to be typical or pathologic is very much in the ear of the beholder. The estimated prevalence for pediatric voice disorders ranges from 6% to 23%. The prevalence of adult voice disorders has been estimated between 3% and 10%. The available epidemiologic reports vary in group sizes and compositions as well as in methodology. It is also difficult to estimate how many of the speakers who have been identified as having a pathologic voice quality will require treatment. The need for behavioral, surgical, or pharmaceutical intervention can probably be estimated to be closer to the lower, more conservative end of the prevalence estimates.

The occurrence of voice disorders varies across the lifespan. In children, boys tend to have more voice disorders, probably due to more aggressive vocal behavior and boisterous vocal play. By adolescence, the prevalence is roughly balanced between the sexes. In adults, voice disorders are more frequent among men than women. However, women seek help more often and sooner than men. The highest prevalence of voice disorders in adults is found in the age group of 45 to 64 years. Overall, most voice disorders are benign in nature (vocal nodules, polyps, edemas, and functional dysphonias).

ETIOLOGY

Telegram: @medical_k

www.konkur.in

The precise etiology of a voice disorder is often difficult to determine and needs to be evaluated based on the nature of the pathology, the patterns of voice use, the emotional and physical states, and the underlying or accompanying medical conditions of the individual patient. Sudden onsets tend to denote acute processes, which are mostly reversible, and slow progressive onsets tend to denote longer-standing vocal trauma or degeneration that may require more comprehensive behavioral interventions, often in combination with phonosurgery.

Voice disorders are characterized by deterioration in vocal quality and quantity. A lesion on the free margin of the vocal fold results in incomplete vocal fold closure and a breathy, rough, or hoarse voice quality with a decreased loudness and pitch range. A referral to the otolaryngologist is necessary if a persistent change in vocal quality and quantity is observed. The otolaryngologic examination should always comprise a visual inspection of the larynx in order to rule out potential malignant lesions, such as squamous cell carcinoma.

Voice disorders can be congenital or acquired. The relatively rare congenital disorders of the larynx include conditions such as laryngomalacia (softness of the cartilages of the larynx and the epiglottis), subglottal stenosis (laryngeal webbing between the vocal folds), and rare laryngeal clefts. The immediate concern in infants with these pathologies is to keep the airway patent and ensure the patient can breathe.

Most voice disorders are acquired. Acquired voice disorders present as a hen-or-egg problem: It is difficult to determine whether abusive vocal behavior has led to a vocal pathology or whether a pre-existing pathology has triggered a vicious cycle of maladaptive behavior. Consequently, voice therapy and vocal re-education are paramount in all vocal pathologies.

In both children and adolescents, acquired voice disorders can be caused by a number of factors. The most important factor that causes injury to the vocal folds is vocal misuse (vocal hyperfunction) through excessive yelling, singing, talking, aggressive vocal play, or abusive body-focused repetitive behaviors such as excessive throat clearing. Voice disorders related to vocal misuse are often labeled as hyperfunctional voice disorders. Acute and traumatic vocal misuse can lead to lesions in the vocal fold, such as acute inflammatory (usually bilateral) vocal nodules, acute vocal fold polyps, or acute vocal hemorrhage. If these conditions are the consequence of a singular event (e.g., a spectator

Telegram: @medical_k

www.konkur.in

sports event), they are usually easily reversible by vocal rest and vocal hygiene. Protracted vocal misuse may require more comprehensive behavioral and possibly surgical interventions.

Long-standing voice misuse may result in chronic, fibrotic vocal nodules or chronic, indurated polyps. The delicate and supple superficial layer of the vocal fold (Reinke space) is particularly prone to irritation and swelling, resulting in chronic inflammatory edema of the vocal folds (Reinke edema, chronic laryngitis, polypoid degeneration). Granulomas or contact ulcers on the arytenoid cartilages may be a consequence of low-pitched, strained phonation, sometimes in combination with gastroesophageal reflux. Many of these pathologies will be accompanied by excessive muscle tension, which is often visible and palpable in the extrinsic strap muscles of the larynx. This tension leads to an elevated position of the larynx during phonation. Muscle tension dysphonia can be a symptom that accompanies an organic pathology, or it can be a voice disorder by itself.

Excessive muscle tension is also often found in psychogenic dysphonias. Patients with psychogenic voice disorders can present with severe dysphonia or even complete aphonia (loss of voice), although the larynx is free of any visible pathology. The symptoms of psychogenic dysphonias can be variable: Patients may claim a total loss of voice and present with only whispered or breathy phonation or they may present with an excessively rough and hoarse voice quality, often accompanied by pain and discomfort when speaking. In some psychogenic dysphonias, the ventricular folds (false folds) are adducted together with the true vocal folds. The ventricular folds are situated above the true vocal folds. This mixed glottal–ventricular phonation can be visualized endoscopically and results in rough, low-pitched voice quality (comparable to the singing technique used by Louis Armstrong). The onset of psychogenic dysphonias is mostly sudden, sometimes related to a bout of cold or laryngitis in combination with a high level of life stress or emotional upheaval. According to reports, patients with psychogenic dysphonias are predominantly female, but men and children may also be affected.

A specific psychogenic dysphonia that begins in adolescence (but sometimes extends into adulthood if left untreated) is puberphonia, in which the prepuberty pitch and voice quality are retained by the patient. The result is an age-inappropriate high-pitched voice. It is more obvious in men than in women since the male voice drops about an octave (12 semitones) in puberty, compared with about a terce (3 semitones) in

Telegram: @medical_k

www.konkur.in

females. A puberphonic voice disorder is called postmutational falsetto in men and juvenile voice in women. It is idiopathic but may be associated with resistance to adolescence and adulthood or a feminine self-identification (in men). It is often possible to elicit a more physiologic pitch from these speakers during nonspeech maneuvers such as coughing, throat clearing, and laughing. The discrepancy between the pitch of the speaking voice and during nonspeech tasks can be an indicator of psychogenic dysphonia or of postmutational falsetto.

The complete refusal to vocalize or speak is called selective mutism. This disorder is predominately observed in younger children. These children first achieve the regular milestones in speech and language development but, at some point, refuse to speak because of emotional or psychosocial distress. Most children with selective mutism limit their interaction to a small number of immediate family members with whom they have close relationships. The incidence of prolonged mutism (i.e., longer than 6 months) has been estimated at less than 1 child in 1,000. Girls are more prone to this disorder than boys. The DSM-5 classifies selective mutism as an anxiety disorder.

A disorder that is difficult to categorize in children as well as in adults is idiopathic paradoxical vocal fold movement. This disorder also goes by vocal cord dysfunction or exercise-induced laryngeal obstruction. Patients with this disorder are still frequently misdiagnosed with either asthma or with a panic disorder. The patients experience spontaneous respiratory distress, often related to strenuous physical activity, in a fashion that is similar to an asthma attack. However, no swelling of the bronchi and the trachea occurs in an episode of idiopathic vocal fold movement. The patient experiences isolated involuntary laryngospasms, resulting in complete closure of the vocal folds. Consequently, asthma medication will not provide the necessary relief. Instead, this disorder responds well to behavioral therapy and specific breathing exercises to open the vocal folds.

Viral infection with the human papillomavirus can affect the respiratory tract in children and adults and lead to multiple lesions. In order to prevent the spreading of papillomatosis into the trachea and lungs, the lesions are surgically removed. Since papilloma lesions tend to recur, multiple rounds of surgery may be required. Although this treatment is effective for viral infection, it may result in severe scarring of the larynx and the vocal folds. An incomplete or irregular vocal fold closure with a hoarse and breathy

Telegram: @medical_k

www.konkur.in

voice may result. While this condition is initially organic, the disease and its often-lengthy course of treatment can have significant downstream effects on the patient's psychosocial well-being and quality of life.

Neurogenic voice disorders are related to lesions or degenerative processes in the nervous system. Peripheral vocal fold paralysis can be caused by strokes, degenerative disorders, mechanical or surgical trauma, or viral infections. The peripheral paralysis can be uni- or bilateral, and the location of the lesion along the nerve will determine the position of the affected vocal fold and the consequences for breathing, swallowing, and speech. Lesions in the central nervous system have a more generalized impact on the whole speech motor system on all levels: respiration, phonation, resonance, articulation, and prosody. Depending on the localization of the lesion along the central motor pathways, a spastic, hyperkinetic, hypokinetic, ataxic, or pseudobulbar movement disorder will result. The associated motor speech disorders are labeled accordingly (as spastic, hyperkinetic, and so forth dysarthrias) and are thought to roughly reflect the nature of the underlying movement disorder. Apraxia of speech is a motor speech disorder that is characterized by deficits in muscle coordination and sequencing of speech gestures. This also affects the coordination of the laryngeal voicing and devoicing for voiced and unvoiced speech sounds (e.g., to differentiate /f/ and /v/).

Spasmodic dysphonia is an insidious neurogenic voice disorder that is believed to be a focal dystonia (like torticollis or blepharospasm), possibly caused by small lesions in the basal ganglia. In spasmodic dysphonia, phonation is interrupted by adductor (adductor spasmodic dysphonia) or abductor spasms (abductor spasmodic dysphonia). The voice quality in spasmodic dysphonia is unsteady and often effortful, marked by a chaotic pattern of vocal fold adduction and abduction. Visceral voice production during coughing or throat clearing is often unimpaired. However, during conscious, purposeful speech, the spasms become obvious. Spasmodic dysphonia is very rare in children and adolescents, but occasional cases have been reported. Diagnostically, it can be a challenge to differentiate spasmodic dysphonia from other disorders, such as psychogenic dysphonia or idiopathic paradoxical vocal fold motion.

A number of factors may aggravate or precipitate voice disorders, such as insufficient hydration, other medications, and gastroesophageal reflux. The vocal folds can be dehydrated by insufficient intake of fluids, active and passive smoking, or exposure to irritating or toxic chemical fumes in

Telegram: @medical_k

www.konkur.in

the work or home environment. Severe dehydration makes the vocal folds less flexible and more vulnerable to mechanical trauma caused by loud singing, shouting, aggressive throat clearing, and so forth. Medications can also contribute to vocal fold dehydration. Bronchodilators can influence airflow and air passage. Diuretics, corticosteroids, and decongestants can reduce the fluid level in the vocal fold. Antihistamines, antitussives, and antirefluxiva can reduce pharyngeal and laryngeal secretions. Long-term hormonal therapies (especially with testosterone) can change the vocal fold structure and permanently lower the pitch. A number of psychotropic drugs can cause xerostomia and have dehydrating effects on the vocal folds, including tetracyclic, tricyclic, antipsychotic, and anxiolytic drugs. Usually, the level of oral secretions is a good predictor of the laryngeal secretions and the lubrication of the vocal folds. If marked xerostomia is observed, the patient should be counseled about hydration by a speech–language pathologist before they develop voice problems. Finally, acid reflux from the esophagus can lead to esophagitis (gastroesophageal reflux disease, GERD) with ulcerations or granulomas on the posterior aspect of the vocal folds or the arytenoid cartilages and a resulting voice disorder. Reflux esophagitis with irritation of the larynx may also be the result of self-induced vomiting in bulimic patients. While the most acute symptoms of gastroesophageal reflux are typically observed at night when the patient is lying flat, a subgroup of patients with voice disorders report voice symptoms and pain while awake and upright. A common descriptor for this variety of reflux is laryngopharyngeal reflux.

The perceived subjective impairment resulting from a voice disorder is highly variable across patients. In the extreme, voice disorders may cause anxiety and depression and may impact the patient's work and social interactions. Anxiety about the restitution of the premorbid voice quality is usually highest among professional voice users, such as singers and actors. Professional voice users are often very emotional about even minor changes in their vocal quality and range. Voice problems in professional voice users may sometimes be related to unrealistic or unhealthy artistic demands on the voice, such as prolonged singing or shouting with a deliberately rough and loud voice. In this sense, the vocal folds of a professional voice user are like the knees of a professional basketball player: Irrespective of talent, the body has individual physiologic limits for every organ. Some rock music singers have

Telegram: @medical_k

www.konkur.in

seemingly endless vocal stamina and never sustain a vocal injury, even though they misuse their vocal folds every night on stage. Other singers hit the physiologic limits of their larynx a lot sooner, despite a correct singing technique.

A population with unique voice therapy needs is transgender patients who strive to adjust their voice quality and speech. For the transgender patient's satisfaction with the treatment outcomes and quality of life, the voice change can be more relevant than the physical appearance. Therefore, it is important to ensure that the patient is referred to a speech–language pathologist who is competent in voice therapy for this group. In female-to-male transgender patients, male hormone therapy will lead to a thickening of the vocal folds, which will lower the speaking pitch. However, the vocal tract size will still be female, and the patient may have to work with a speech–language pathologist on developing masculine speaking mannerisms. The transition is often more difficult for a male-to-female transgender patient. The patient must learn to raise the speaking pitch and develop more feminine speaking habits. The larger male vocal tract size can make it more difficult for male-to-female transgender patients to project a female vocal image. Transgender patients can differ in their ambitions as well as their abilities to change their vocal gender as perceived by others, so the patient and the speech–language pathologist have to establish the most efficient strategies to achieve a voice quality that will be comfortable for the patient and effective for their social speech communication.

A final etiology that needs to be mentioned in this section is velocardiofacial syndrome (22q11 microdeletion syndrome). This congenital syndrome is related to a microdeletion on the long arm of chromosome 22 and has highly variable symptoms. As a result, patients are sometimes not identified at birth but only later when symptoms become manifest. Many of the patients show various developmental delays, especially with regard to speech and language development. In childhood, attention deficit hyperactivity disorder, anxiety disorders, phobias, or emotion regulation disorders are considerably more frequent than in the general population. In adulthood, schizophrenia and schizoaffective disorders are frequently observed. As part of the syndrome, many patients present with cleft palate, which leads to hypernasality (too much air and sound emitted through the nose during speech). The cleft palate in this population is often isolated so that it does

Telegram: @medical_k

www.konkur.in

not affect the lip and the alveolar ridge and is not visible in the patient's face. It may even be submucous (concealed under a lining of mucosa) and hidden from a casual oral inspection. Patients with velocardiofacial syndrome are a prime example of the importance of interdisciplinary treatment of complex disorders. The members of the craniofacial treatment team need to be aware of the patient's risk for mental health problems during their lifespan. On the other hand, a psychiatrist who notices hypernasal speech in a patient who has not been followed by a craniofacial team should make the appropriate referral.

DIAGNOSIS AND CLINICAL FEATURES

Any unexplained change in voice quality, especially when it involves hoarseness or pain and persists longer than 2 weeks, should be examined by an otolaryngologist. The diagnosis of voice disorders is based on several diagnostic procedures. One important component is the perceptual evaluation of the voice disorder by an experienced otolaryngologist or speech–language pathologist. This evaluation assesses the patient's voice quality and quantity. Accepted general descriptors of voice quality are breathiness (resulting from incomplete closure or hypoadduction of the vocal folds) and roughness (irregular vocal fold vibration resulting from lesions on the vocal fold or hyperadduction of the vocal folds). Hoarseness is defined as a mixture of roughness and breathiness. Vocal quantity can be described in terms of the pitch and dynamic range of the voice. If the pitch is inappropriate, a speaker's voice is too high or too low for their age, maturation, and sex. If the dynamic range is inappropriate, a patient may speak too loudly or too softly or may have difficulties raising their voice. Associated perceptual assessments concern the patient's oral–nasal balance, which may make speech sound hyper- or hyponasal or may add a nasal twang quality. It should be noted that hyper- or hyponasality are not voice disorders per se. Finally, suprasegmental features of speech (prosody, speech melody) are assessed. Pathologic prosodic patterns include monotonous, unmodulated voice versus exaggerated inflections, excessively slow or fast speech, and inappropriate or uneconomical breaks for inhalation during speech. Quantitative instrumental measures of voice quality, voice range, or airflow can supplement the perceptual diagnosis. This is combined with a detailed interview that assesses voice usage and

Telegram: @medical_k

www.konkur.in

medical history together with health practices, social and occupational circumstances, and psychological well-being. In pediatric patients, developmental and family information need to be considered.

PATHOLOGY AND LABORATORY EXAMINATION

Most lesions of the vocal folds are benign and do not require detailed histologic analysis. However, suspicious lesions should be biopsied and analyzed in order to rule out malignancies. The malignant laryngeal tumors are usually of the squamous cell carcinoma type. Irrespective of the clinical presentation of the voice disorder, the vocal folds should always be examined visually by an experienced otolaryngologist in order to correctly assess or rule out any organic causes of the problem. This can be done with a simple mirror examination, but ideally, a flexible endoscopy or a videostroboscopy should be performed. The videostroboscopic examination allows the physician to slow down the display of the vocal fold motion so that the patterns of vocal fold vibration can be observed. High-speed video kymography allows filming the vocal fold motion in real time, with a temporal resolution of several thousand exposures per second. Although a complete and comprehensive assessment of a patient's vocal structures can be crucial to determining the correct treatment, otolaryngologists may sometimes contend with only superficial investigations, especially of pediatric clients. Malignancies of the pediatric larynx are extremely rare, while on the other hand, a videostroboscopic examination of a small child can be very tedious. However, this wait-and-see attitude may sometimes delay appropriate treatment. Voice disorders in pediatric and adolescent populations should be taken just as seriously as adult voice disorders.

DIFFERENTIAL DIAGNOSIS

Today, most voice centers use videostroboscopy or flexible endoscopy. With these methods, organic voice disorders can be readily detected. However, the challenge in voice diagnosis is to identify the behavioral components of the voice disorder. In particular, the differential diagnosis between hyperfunctional voice disorders and psychogenic voice disorders can often be difficult for otolaryngologists and speech–language pathologists. As a result, the necessary referral to psychiatric services

Telegram: @medical_k

www.konkur.in

may be delayed. Psychogenic voice disorders often have a characteristic onset. They come about suddenly, sometimes related to a minor viral infection. The discrepancy between visceral vocalizations, such as yawning, and voice production in speech is often informative. If a normal voice quality can be produced during coughing, throat clearing, humming, yawning, and sighing but not in speech, then it is likely that the patient can be helped back to a normal voice by a short course of voice therapy. After an acceptable voice quality has been restored, the patient should be referred for a psychiatric follow-up. On the other hand, if the patient presents with a total loss of voice but does not cooperate with the therapist's efforts to restore voice production, a different disorder to consider in pediatric patients is selective mutism.

One of the most difficult diagnoses for an otolaryngologist or a speech–language pathologist is spasmodic dysphonia, which is often diagnosed by exclusion of other applicable pathologies. In particular, psychogenic and neurogenic voice disorders must be ruled out. Since not every clinician is aware of spasmodic dysphonia, some patients still undergo prolonged diagnostic and therapeutic odysseys before the correct diagnosis is finally made. The voice breaks in spasmodic dysphonia may sometimes resemble the tonic blocks of a person who stutters. While the onset of spasmodic dysphonia is in adulthood, stuttering begins during childhood. Another difficult diagnosis is that of idiopathic paradoxical vocal fold motion, which can very much resemble an asthmatic attack. However, the airway constriction in these patients will be restricted to the level of the larynx and will not include the bronchi and the trachea. Finally, patients with velocardiofacial (22q11 microdeletion) syndrome may often present with hypernasality as well as a variety of psychiatric disorders throughout their lifespan. Therefore, it is important to ensure that any psychiatric patient with hypernasality of unclear etiology is referred to a craniofacial team for multidisciplinary assessment and genetic testing.

COURSE AND PROGNOSIS

As voice disorders may be caused by many different conditions, there is a high degree of variability in the long-term prognoses and treatment success. Acute organic processes that are associated with a one-time event of vocal trauma usually have a good prognosis. Examples of such pathologies are acute nodules or polyps. Vocal nodules in children are

Telegram: @medical_k

www.konkur.in

sometimes not removed by surgery as the vocal fold expands during puberty, and the nodules tend to resolve spontaneously. Organic pathologies that are related to long-standing vocal misuse will require more comprehensive therapeutic interventions that also address the associated abusive behaviors. Examples of such pathologies are chronic nodules, chronic polyps, and Reinke edema. If there is persistent voice misuse combined with aggravating factors such as smoking or alcohol abuse, the long-term prognosis can be poorer. Lesions such as nodules may recur quickly after a surgical resection if the maladaptive behaviors cannot be modified. Voice disorders with a pronounced psychogenic component should be addressed with a combined effort by the speech–language pathologist and the psychiatrist. Although the voice disorder can usually be managed effectively in speech therapy, the underlying emotional or psychosocial factors that have contributed to the voice disorder have to be evaluated by a psychiatrist.

TREATMENT

Intervention in voice disorders is dependent on the nature of the problem. Organic pathologies are often managed surgically with laser surgery or microsurgery, followed by a course of voice therapy. In functional voice disorders, the speech–language pathologist will counsel the patient about the nature of the disorder and commence a course of vocal re-education aimed at modifying or eliminating vocal misuse. If psychological factors contribute to the genesis or the persistence of the voice disorder, a referral to psychiatric services will be necessary.

There are many different approaches to voice therapy. Most of these fall within five main streams of voice therapy: symptomatic, physiologic, psychogenic, hygienic, and holistic. This distinction is largely academic because the boundaries between the different approaches are blurred. Most voice therapists will move between these different schools of thought and pursue a more personal eclectic approach to achieve optimum outcomes for their patients. *Symptomatic* voice therapy uses interventions and voice exercises that are geared toward the voice symptoms of the individual patient. *Physiologic* voice therapy draws on concepts from physical therapy, such as respiration or posture exercises, to achieve the foundations for physiologic voice production. *Psychogenic* approaches to voice therapy draw on the cognitive behavioral approach to behavior

Telegram: @medical_k

www.konkur.in

modification to change the way in which a patient reacts to life stresses with a change in voice quality. This type of therapy also uses relaxation techniques such as progressive muscle relaxation. *Hygienic* voice therapy is often a supplement rather than a standalone therapy approach. Hygienic voice therapy emphasizes proper hydration and reduction of gastroesophageal reflux. Finally, a number of schools of voice therapy are *holistic* in that they try to achieve goals on multiple levels through a fixed program of exercises. To give just a few examples of such holistic approaches, the *vocal function exercises* treat the vocal muscles like other muscles in the body and provide consist of endurance and stretching exercises to increase the vocal range and stamina. The *accent method* uses a combination of controlled respiration, chanting, and dancing to elicit relaxed phonation. *Resonant voice therapy* aims at maximizing oral resonance and achieving good voice projection through a combined program of vocalizing and increasing self-awareness.

Telegram: @medical_k

www.konkur.in

The voice can be an outlet for psychological stress. While everybody has experienced symptoms such as a shaky voice or a dry mouth when feeling excited or threatened, in some patients with psychogenic voice disorders, more significant somatoform symptoms such as throat pain and globus sensation can occur together with a change in voice quality. These patients need help to find their normal voice again and often require a referral to psychiatric or counseling services to address the issues underlying the psychogenic voice disorder.

On the other hand, it is also easily possible to conjure up voice symptoms with the purpose of malingering. Garth was a boy of 8 years of age with typical speech and language. When the family moved to a new neighborhood, Garth initially found it difficult to settle into his new school. It was during this time that he came down with frequent bouts of throat pain, accompanied by coughing and alarmingly rough and hoarse voice quality. When these episodes occurred, he could stay home and rest. Because of the recurrent and worrisome voice symptoms, the family met with the school speech–language pathologist when Garth was going through another bout. The speech–language pathologist made Garth laugh with a joke and tested a few nonspeech vocalizations, such as yawning and sighing. On all of these nonspeech vocalizations, voice quality was regular. During the conversation, it also became clear that there was a pattern where the throat pain and voice symptoms became worse around the middle of the week but then improved toward the weekend when Garth was able to participate in family activities again. The patient was confronted with this pattern and agreed that he might have overstated the severity of the pain and voice symptoms. After a few sessions with a psychotherapist specializing in pediatrics and with the support of his family, Garth transitioned smoothly into his new school environment.

Telegram: @medical_k

www.konkur.in

Steven was a 17-year-old teenager who was referred to the speech–language pathologist because of his high-pitched voice. Steven had experienced teasing and negative comments about his voice in the classroom and in other social situations. He was very motivated to change the pitch of his voice. The patient was of normal height and built for his age. An otolaryngologic mirror examination had ruled out the presence of a vocal fold web (patients with a laryngeal web often have a high pitch because the vibrating edge of their vocal folds is shorter). Upon palpation, the larynx was normal in size and had a normal movement range when Steven was asked to swallow (laryngeal elevation) and yawn (laryngeal lowering). An acoustic measurement revealed a fundamental frequency of around 230 Hz, which was twice as high as the appropriate pitch for a male speaker. When the patient was asked to throat clear and to hum, the fundamental frequency dropped to an appropriate range. The speech–language pathologist used gentle vocalization exercises such as chanting in combination with manual circumlaryngeal massage in order to help the patient relax his larynx and lower his fundamental frequency. Steven required only six sessions with the speech–language pathologist to change the pitch of his voice. However, he was apprehensive about using the new voice with his classmates at school. He was worried that the change was quite startling and that he would be ridiculed for seeing a speech–language pathologist. Steven decided that he would spend the Christmas holidays with his family and avoid seeing his friends during these days. When he went back to school in the new year, he told his classmates that he had been sick with flu and that the associated cough had done some damage to his voice box, which had changed his voice.

The patient described here was very motivated to change his voice to an age-appropriate pitch. However, some patients may initially resist the speech–language pathologist's efforts. Speaking with a different fundamental frequency changes a physical activity that is deeply ingrained, and that is as difficult to change as one's posture or gait. Patients may sometimes complain that the new way of phonating feels uncomfortable, hurts their larynx, or even affects their breathing. These initial complaints are usually overcome, and postmutational falsetto should be resolved with a short course of voice therapy. The effect on the patient's appearance in social situations can be stark, so

Telegram: @medical_k

www.konkur.in

it is important to help the patient develop strategies to gently introduce the environment to the new voice.

In puberty, the male larynx grows, and the fundamental frequency drops by an octave or 12 semitones. By contrast, the female larynx shows less growth, and the fundamental female frequency only drops three to four semitones. This means that female puberphonia (also called juvenile voice) can be less obvious and more difficult to recognize than the postmutational falsetto of male speakers. As a result, female puberphonia may be overlooked and treatment delayed.

Autism Spectrum Disorders

FRED R. VOLKMAR, M.D., GIACOMO VIVANTI, PH.D., RYAN K. C. YUEN, PH.D., AND KEVIN PELPHREY, PH.D.

OVERVIEW

The spectrum of autism is characterized by severe and persistent problems in social interaction and difficulties with change and unusual responses to the environment consistent with the first description of the condition by Leo Kanner in 1943 (Kanner, 1943). In DSM-5, the term for the prototypic disorder is changed to autism spectrum disorder (ASD), reflecting an awareness of the broader range of difficulties observed. This term is meant to correspond (roughly) to the earlier diagnosis of autistic disorder in DSM-IV, although as discussed subsequently, the concept is somewhat narrower (despite the spectrum name). DSM-5 also includes a new communication disorder—social communication disorder—to encompass problems in social (pragmatic language) communication.

DEFINITION

ASD now encompasses, to varying degrees, the various concepts previously recognized in DSM-IV as part of the overarching pervasive developmental disorder category. In DSM-5, the historically used triad of impairments in social interaction, communication, and repetitive and restricted interests/behaviors was collapsed into two domains: social communication and restricted and repetitive behaviors. The definition

Telegram: @medical_k

www.konkur.in

requires that all four of the social communication criteria be met (see Table 43–1) and at least two of the four restricted interests and repetitive behaviors must be met. Sensory problems are now included in the latter group. These difficulties must be present from early childhood. Given the significant concern that this approach excludes many of the individuals who would have had a diagnosis of some pervasive developmental disorder in DSM-IV, a specific exception is made so that individuals with "well-established" diagnoses of Asperger disorder or pervasive developmental disorder not otherwise specified (PDD-NOS) can keep their label (and thus not be excluded from services). Effectively this solution continues the older DSM-IV system for previously diagnosed cases while creating a new (and somewhat different) one for newly diagnosed cases.

The DSM-5 also provides a series of specifiers, for example, if a known etiologic factor is present. Another change is the inclusion of a descriptor of required levels of support (this is left relatively ambiguous), with a range from levels 1 to 3. Other specifiers can indicate association with intellectual disability and language impairment or catatonia (see Table 43–2).

The changes in DSM-5 have been somewhat controversial. The older DSM-IV system used 12 polythetic criteria grouped in the three traditional areas (impairments in social interaction, communication, and restricted/repetitive interests) and resulted in over 2,000 combinations of criteria that could yield an autism diagnosis while the current approach offers only 12 such possibilities. A substantial body of work now makes it clear that, likely as a result of the way the DSM-5 system was developed, it takes a narrower view of autism. The two groups (in DSM-IV terms) who are at greatest risk of losing a diagnosis are the higher cognitively functioning and the more able younger children. Perhaps 80% of the higher cognitively functioning cases that previously would have had diagnoses of Asperger's or PDD-NOS lose their diagnosis with DSM-5, as do a significant number of more able individuals who previously would have had a diagnosis of autistic disorder.

The more stringent DSM-5 approach basically reflects the fundamental source of the data used, that is, high-quality data from research diagnostic instruments designed to assure consistency in autism diagnosis for cross-site genetic studies. The rationale for the new

Telegram: @medical_k

www.konkur.in

social communication disorder (a communication disorder diagnosis) is murky and the condition does not simply correspond to the older DSM-IV labels of Asperger's or PDD-NOS. The utility of the various proposed modifiers is debated with concern over their reliability given that clinical presentation can dramatically differ depending on observational context.

HISTORY

The first report of autism as a syndrome was provided by Leo Kanner in 1943. He described 11 children who had what he termed autistic disturbances of affective contact. He felt that this difficulty was innate and viewed this, along with insistence on sameness and difficulties with change, as the two essential features of the condition. Kanner noted the stereotyped motor mannerisms of autism and suggested that these were part of the child's difficulties with change and preference for sameness. Although he did not regard communication skill deficits as essential, he did observe that many of his cases never talked, and those who did have speech that was unusual for echolalia (repetitive use of phrases), unusual voice quality and volume, pronoun problems, and general difficulties in social use of language (pragmatics).

In giving autism a greater historical context, it should be noted that cases of autism had been noted before Kanner's report, for example, possible reports of some "feral" children as well as case reports from state training schools in the United States in the 1800s. His description also gave some false leads relative to confusion of the condition with schizophrenia (the use of the word autism—previously used to describe self-centered thinking in schizophrenia), a lack of apparent associated medical conditions, a tendency for parents to be well educated and successful, and the impression that the children did not have associated intellectual disability, given that on some of the nonverbal parts of IQ tests they did well. Even with these caveats, however, Kanner's phenomenologically based description remains classic.

A year after Kanner's report, Hans Asperger, a Viennese medical student, reported on a group of boys with a condition he termed "autistichen psychopathen" (probably best translated as autistic personality disorder). This group of boys had major social difficulties (hence the word autism as also used by Kanner) but good verbal

Telegram: @medical_k

www.konkur.in

language abilities, remarkable circumscribed interests that were all encompassing, and motor difficulties. The latter features were an area of difference from Kanner's description. Over time, the validity of the concept he described has been much debated and, although DSM-5 has no longer included it, the previous recognition in DSM-IV led to considerable public awareness and interest and an increase in research. In some ways, one of the most significant aspects of Asperger's work was to make it clear that there was a broader spectrum of autism—that is, consistent with the name change in DSM-5 if not with the definition used. His emphasis on genetic factors (he mentioned that fathers had similar problems) also prefigured the considerable interest in genetics discussed subsequently. Indeed, the recognition of a "broader autism phenotype" (BAP) has been the focus of much interest.

www.konkur.in

Diagnostic Criteria

A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples are illustrative, not exhaustive, see text):
   1. Deficits in social–emotional reciprocity, ranging, for example, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate or respond to social interactions.
   2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication.
   3. Deficits in developing, maintaining, and understanding relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers.

Specify current severity:

Severity is based on social communication impairments and restricted repetitive patterns of behavior (see Table 43–2**).**

B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history (examples are illustrative, not exhaustive; see text):
   1. Stereotyped or repetitive motor movements, use of objects, or speech (e.g., simple motor stereotypies, lining up toys or flipping objects, echolalia, idiosyncratic phrases).
   2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns or verbal–nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat food every day).
   3. Highly restricted, fixated interests that are abnormal in intensity or focus (e.g., strong attachment to or preoccupation with

Telegram: @medical_k

www.konkur.in

unusual objects, excessively circumscribed or perseverative interest).

4. Hyper- or hyporeactivity to sensory input or unusual interests in sensory aspects of the environment (e.g., apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).

Specify current severity:

Severity is based on social communication impairments and restricted, repetitive patterns of behavior (see Table 43–2**).**

C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).

D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.

E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level.

Note: Individuals with a well-established DSM-IV diagnosis of autistic disorder, Asperger disorder, or pervasive developmental disorder not otherwise specified should be given the diagnosis of autism spectrum disorder. Individuals who have marked deficits in social communication, but whose symptoms do not otherwise meet criteria for autism spectrum disorder, should be evaluated for social (pragmatic) communication disorder.

Specify if:

With or without accompanying intellectual impairment

With or without accompanying language impairment

Associated with a known medical or genetic condition or environmental factor (Coding note: Use additional code to identify the associated medical or genetic condition.)

Telegram: @medical_k

www.konkur.in

Associated with another neurodevelopmental, mental, or behavioral disorder (**Coding note:** Use additional code[s] to identify the associated neurodevelopmental, mental, or behavioral disorder[s].)

With catatonia (refer to the criteria for catatonia associated with another mental disorder, for definition) (**Coding note:** Use additional code 293.89 [F06.1] catatonia associated with autism spectrum disorder to indicate the presence of the comorbid catatonia.)

In the years following its first definition, work on autism was limited and hampered by diagnostic confusion. This began to clear as diagnostic guidelines were suggested, as some of the misconceptions of autism were clarified (e.g., that autism could be associated with intellectual deficiency, was seen in all social classes, and was associated with a number of medical conditions, including epilepsy and some genetic conditions). During the 1970s, several lines of evidence converged to show that autism was a strongly genetic and brain-based disorder that responded best to structured teaching. Autism was first recognized officially in 1980 in DSM-III, and research both on biology and treatment expanded dramatically with this recognition.

COMPARATIVE NOSOLOGY

Before DSM-III, autism was regarded as a form of childhood schizophrenia, but during the 1970s, the work of Kolvin, Rutter, and others made it clear that these were actually two very different conditions. This recognition, along with other evidence on the validity of autism, led to its official recognition in DSM-III in 1980. The DSM-III definition was monothetic and heavily influenced by the work of Rutter but unfortunately lacked a developmental orientation (the condition was termed and defined as “infantile autism,” and cases not meeting the strict criteria given, but who once had done so, received a diagnosis of “residual infantile autism”—even though their problems were not particularly residual). In DSM-III-R, a more developmentally polythetic definition of autistic disorder was proposed based, in part, on the work of Lorna Wing. It did a better job in covering the entire range (in age and

Telegram: @medical_k

www.konkur.in

levels of severity) of the condition but there were some difficulties with overdiagnosis, particularly among the more intellectually impaired. By the time of DSM-IV, 10 years of work had accumulated, and the DSM-IV definition, developed in conjunction with ICD-10, included 12 criteria grouped in three sets. This polythetic definition converged with the ICD-10. Also, in DSM-IV, Asperger disorder was first recognized, along with Rett and childhood disintegrative disorder (CDD); in the two latter groups, a marked deterioration of function was observed. For Rett's, the potential for confusion with autism was minimal, but it was felt it needed to be included given its distinctiveness and potential for genetic association (and indeed a specific gene was found to be associated with the condition). The unusual onset of CDD (autism that appeared after some 3 to 4 years or so of normal development) appeared to deserve special recognition; the condition itself had a long history antedating that of autism. In addition, in DSM-IV, and consistent with DSM-III and III-R, a category for cases that did not achieve a specific diagnosis but whose troubles resembled those of autism was included—PDD-NOS; such cases would today be recognized as part of the BAP.

Table 43–2.
Severity Levels for Autism Spectrum Disorder

Telegram: @medical_k

www.konkur.in

Severity Level	Social Communication	Restricted, Repetitive Behaviors
Level 3		
"Requiring very substantial support"	Severe deficits in verbal and nonverbal social communication skills cause severe impairments in functioning, very limited initiation of social interactions, and minimal response to social overtures from others. For example, a person with few words of intelligible speech who rarely initiates interaction and, when they do, makes unusual approaches to meet needs only and responds to only very direct social approaches.	Inflexibility of behavior, extreme difficulty coping with change, or other restricted/repetitive behaviors markedly interfere with functioning in all spheres. Great distress/difficulty changing focus or action.
Level 2		
"Requiring substantial support"	Marked deficits in verbal and nonverbal social communication skills; social impairments apparent even with supports in place;	Inflexibility of behavior, difficulty coping with change, or other restricted/repetitive behaviors appear frequently enough to be obvious to the casual observer and

Telegram: @medical_k

www.konkur.in

	limited initiation of social interactions; and reduced or abnormal responses to social overtures from others. For example, a person who speaks simple sentences, whose interaction is limited to narrow special interests, and who has markedly odd nonverbal communication.	interfere with functioning in a variety of contexts. Distress and/or difficulty changing focus or action.
Level 1		
“Requiring support”	Without supports in place, deficits in social communication cause noticeable impairments. Difficulty initiating social interactions, and clear examples of atypical or unsuccessful response to social overtures of others. May appear to have decreased interest in social interactions. For example, a person who is able to speak in full sentences and engages in	Inflexibility of behavior causes significant interference with functioning in one or more contexts. Difficulty switching between activities. Problems of organization and planning hamper independence.

Telegram: @medical_k

www.konkur.in

	communication but whose to-and-fro conversation with others fails, and whose attempts to make friends are odd and typically unsuccessful.

The definition of Asperger's in DSM-IV was problematic in several ways, and although a major text revision was undertaken in DSM-IV TR, the criteria themselves were unchanged so that divergent views of the concept remained. With DSM-5, it was argued that the presence of these divergent views argued against its inclusion. Unfortunately, this decision occurred even as data were emerging to suggest important differences from autism as well as the need for diagnostic refinement of the concept.

A major shift in focus of research also occurred with growing interest in the earliest manifestation of diagnosis of autism in infants and young children. This interest reflected the growing body of research on infants at risk, that is, siblings, as well as the awareness that earlier and effective treatments could be instituted and lead to better outcomes.

EPIDEMIOLOGY

Prevalence

Various factors complicate the study of the epidemiology of ASD. These include the broad range of syndrome expression, difficulties in case definition and identification, case evaluation, and methods used in surveys. The first studies of epidemiology suggested that autism was rare with a rate of roughly 1 per 2,000. However, changes in definition and study design and methodology have led to marked changes in this estimate. There are now over 60 epidemiologic studies, and current estimates suggest a rate of about 69 per 10,000 (or 1 in about 145 children). Time trends are difficult to study but it does appear that changes in diagnosis, practice, and educational policy (children with ASD often receive the most intensive services) and vastly increased

Telegram: @medical_k

www.konkur.in

public awareness account for some portion of this increase. Indeed around the world, increased rates often are associated with greater service availability and public awareness.

Current work on the issue of a possible true increase in the incidence of ASDs is attempting to control for various methodologic factors and may provide better data with which to address this issue. The impact of the DSM-5 criteria on rates remains to be clarified.

Sex Ratio and Gender Differences

A number of studies, using different approaches in both clinical and epidemiologic samples, have repeatedly observed higher rates of ASD in males than in females, on the order of three to five boys for every girl. This ratio has appeared to be more marked among those who are more cognitively able where rates of male predominance are much higher. Several lines of work raise questions about observed gender rates and differences. There is some suggestion that, among females with "classic" autism, severity is increased, suggesting some possibility that boys may be less vulnerable than girls to the cause/causes of autism. At the other end of functioning, there is also a growing body of work suggesting that factors such as diagnosis camouflaging may lead to underdiagnosis in more able females.

Social Class and Culture

In Kanner's original sample, parents were noted to be highly achieving and of high social status, but it is likely that this sample was biased in terms of case ascertainment. Epidemiologic studies have generally failed to reveal such associations. As noted previously, the label of ASD may be more acceptable to better-informed parents and lead to "diagnostic substitution." Within disadvantaged families, ASD may be underdiagnosed, reflecting lack of awareness and services and, potentially, even problems with diagnostic criteria. Similarly, cultural issues in the diagnosis of autism have also become a concern as efforts have been made to expand detection and treatment into developing countries. These issues may reflect basic problems with criteria and/or the ways they are operationalized in assessment instruments. Autism clearly is seen in all cultures and levels of ability, but cultural factors may play an important role in both diagnosis and treatment.

Telegram: @medical_k

www.konkur.in

ETIOLOGY

Psychosocial Theories

In Kanner's original case series, most parents were remarkably successful, and this led to the notion that perhaps their success might have come at the cost of a lack of interest in the child (there was little awareness of the factors that did, of course, highly bias referral to the one person in the country who was interested in such children). This idea led, particularly in the 1950s and 1960, to notions like that of the "refrigerator" mother who failed to respond to the child and their emotional needs. As a result, often the child was removed to a presumably more neutral hospital setting and psychotherapy was undertaken for all concerned—with little impact. During the 1970s, a growing body of work began to clearly show the superiority of structured teaching and behavioral methods in intervention for children with ASD. Since the 1980s and the official recognition of autism as a distinct diagnostic category, a large body of research has grown on effective intervention in ASD.

More recent psychological theories have been more sophisticated and attempt to address the atypical cognitive and behavioral profiles of individuals with ASD, including the notions of core deficits in theory of mind, weak "central coherence," and executive dysfunction among others. These influential accounts, generated in the 1990s, shared the idea that a single "primary deficit" or "cognitive style" provides a parsimonious explanation for the heterogeneous manifestations observed in ASD. The theory of mind account posits that ASD symptoms originate from a fundamental inability to attribute mental states to others (e.g., inferring that a classmate is searching for a toy in her bag because she *believes* that the toy is there, even if the toy is on the floor). These difficulties hinder the ability to adjust behavior according to the social context, especially when more inferential reasoning is required to understand others' intentions (e.g., interpreting a sarcastic remark, whereby the literal content of a sentence does not match the speaker's intended meaning) and when the knowledge available to the child (e.g., the toy is on the floor) is different from that of others (e.g., the classmate's belief that the toy is in her bag).

Telegram: @medical_k

www.konkur.in

The weak central coherence hypothesis points to a diminished drive to integrate details into coherent wholes as the central feature of ASD. This is reflected in strengths across tasks requiring one to ignore global configurations to focus on specific details (e.g., finding a triangle embedded in a larger meaningful figure) and weaknesses in situations demanding an appreciation of the “big picture” (e.g., disambiguating words that have multiple meanings based on the context, or understanding that a tree decorated with specific lights and ornaments is still a Christmas tree even if the ornaments have different colors compared to the previous year’s Christmas tree).

Finally, the executive dysfunction hypothesis explains the difficulties observed in ASD as resulting from executive function impairments, including difficulties in attention shifting, updating and addition/deletion of information in working memory, inhibition of dominant or prepotent responses, abstraction, and processing of multiple cues—an account based on similarities between the behavior of individuals with ASD and that of patients with executive impairments due to frontal lobe lesions.

Although these accounts have generated a wealth of empirical knowledge on ASD, research has failed to lend unequivocal support to these and other theories positing a single cognitive process/dysfunction at the origin of all ASD manifestations. Core limitations across these accounts include unclear support for the specificity, universality, construct validity, explanatory power, and causal role of proposed “primary” deficits. In addition, explanations based on a “static” and universal cognitive style are challenged by research documenting developmental changes and variable outcomes in the ASD population. Accordingly, more recent theoretical approaches to ASD are less “grand” in scope and focus on developmental paths leading from early risk factors to the variable expressions of ASD symptoms.

Biologic Theories

The importance of biologic factors in pathogenesis was clarified as children with autism/ASD were followed over time. It became clear that they were at high risk for the development of seizures both early in life and again in adolescence (the latter being a very unusual time to develop epilepsy). Similarly, it became clear that with minimal or no effective intervention, children often ended up in the intellectually

Telegram: @medical_k

www.konkur.in

impaired range of development and exhibited various neurobiologic soft signs and biochemical abnormalities, for example, delayed development of hand dominance, persistence of “primitive” (early) childhood reflexes, and high levels of the neurotransmitter serotonin. The study of possible biologic abnormalities in the pathogenesis of autism remains an active area of research and has converged with genetic work, for example, in the study of single-gene models where it is possible to develop animal models most readily.

Genetic Factors

In the late 1970s, twin and then family studies began to demonstrate the central role of genetics in the pathogenesis of ASD. The concordance rate for strictly defined autism in monozygotic twins is about 60%, while the rate for concordance with the BAPs is 80% to 90%. These rates are much higher than dizygotic twin concordance rates. Overall, these and other data suggest that genetic factors account for a more substantial share of the risk for autism than environmental factors, although both sets of factors are seen to contribute substantially to population risk.

Although there has been general agreement on the central role of genetic factors for some decades, the search for specific genes has been a challenge. In recent years, the availability of large data sets, collaborative studies, and advances in genomic technologies have significantly increased knowledge of the genetic architecture of ASD and related conditions.

These studies have produced several important themes. One major area of progress has been via a focus on mutations that are rare in the population, may be new in the individual, and which carry significant biologic effects. These changes lead to single-gene dysfunction as well as larger variations in chromosomal submicroscopic structure copy number variations (CNVs). In addition, there is a substantial body of work that shows considerable evidence that polymorphisms that are frequent in the population (common genetic variants) convey risk, but they only confer a small effect on ASD risk individually. However, the aggregation of these small effects can contribute to a polygenic risk of ASD. The associated variants significantly overlap with those identified in other relevant disorders, such as schizophrenia and major depression. Third, while recent studies have underscored an

Telegram: @medical_k

www.konkur.in

exceptionally high degree of genetic heterogeneity underlying ASD, so far, the genes that have been discovered appear to converge on a much smaller number of biologic processes. To date, multiple studies have highlighted the role of, for example, chromatin modification, synaptic and signaling proteins, and targets of fragile X mental retardation protein (FMRP) as playing important roles in pathophysiology and underscore the importance of midfetal human cortical development. Fourth, there is emerging evidence that rare, de novo variations in the non–protein-coding regions of the genome carry risk for ASD. They include regions that are responsible for regulating brain development and repetitive regions that can interrupt gene functions. Moreover, it has also been repeatedly shown that the identical genetic variation in different individuals may increase the liability (sometimes sex dependent) for a very broad range of neurodevelopmental disorders, ranging from schizophrenia, to epilepsy, intellectual disability, or specific language impairment. These findings raise important questions about the specificity of genetic risks underlying ASD. Finally, while the relative contribution of genes is thought to be quite large, influences other than variation in the DNA sequence are likely to turn out to be important as well, including epigenetic mechanisms and environmental factors. Indeed, one of the most important outcomes of the successful search for ASD relevant factors will be the light it will shed on nongenetic, potentially modifiable risks.

Other Medical Conditions and ASD

ASD has also been associated with many different conditions which have a strong genetic component. Fragile X syndrome (FXS) is one of the best known of these associations. In this condition, the marker X chromosome is noted to be “fragile” when grown in folic acid–deficient media. This mutation usually involves a triplet repeat of cytosine–guanine–guanine in the regulatory domain of the gene *FMR1*, and this mutation may amplify in subsequent generations. Characteristic physical signs include distinctive facial features, enlarged testes, and associations with both intellectual deficiency and ASD. Behavioral problems are often noteworthy. It appears that perhaps 20% to 30% of boys with fragile X will meet criterial for ASD; conversely, about 1% of boys with ASD are found to carry the fragile X mutation. Understanding

Telegram: @medical_k

www.konkur.in

the biology and pathogenesis of this condition has potential implications for understanding the etiology of autism.

The advance in genome sequencing has also allowed discovery of novel conditions that are associated with ASD. This “genotype-first” approach involves a performance of comprehensive phenotyping of individuals identified with mutations in a specific gene through large-scale sequencing. One such example is an overgrowth syndrome that is caused by mutations in the *CHD8*—a gene that is highly expressed in brain during the early prenatal development period. *CHD8* codes for an ATP-dependent chromatin-remodeling factor that binds to beta-catenin and regulates its target genes. Physical signs of the condition related to this gene include macrocephaly, distinct facial features, gastrointestinal issues, sleep problems, and cognitive impairment. It is estimated that over 80% of individuals with *CHD8* mutations meet diagnostic criteria for autism spectrum conditions and that mutations in *CHD8* can be found in 0.35% of individuals with idiopathic ASD. The success of identifying novel conditions for ASD using this “genotype-first” approach will help refine the autism spectrum and allow development of more targeted treatments or interventions for ASD.

Pre-, Peri-, and Neonatal Factors

Several studies have shown increased rates of pre-, peri-, and neonatal complications in children with ASD. Much of the difference relates to the observation that something unusual is noted about the child at birth. The association with intellectual disability and these factors may be much stronger than the risk for ASD. This may reflect the operation of genetic as well as perinatal factors. The genetic predisposition to autism may interact with perinatal factors in producing the syndrome.

Other Etiologies

There has been much speculation on the association with a number of factors, although, to date, these mostly consist of anecdotes or case series rather than well-replicated and controlled scientific data. Potential confounds are often unappreciated, and there has been a tendency for case reports to be overemphasized. An early impression of the association of autism with disorders such as congenital rubella had to be modified as these children seemed to lose “autistic-like” features over

Telegram: @medical_k

www.konkur.in

time. In addition, there is now a greater appreciation of the complexities of diagnosis in what often was a severely disabled population.

Although there is clearly a very strong role for genetic factors in the pathogenesis of autism, there is at least some potential role for environmental factors. However, precise mechanisms remain to be specified, and this is an area of active work.

POSTMORTEM AND NEUROIMAGING STUDIES

Neuroimaging and Brain Development

ASD is a neurodevelopmental condition that emerges early in life. Much has been learned about ASD from postmortem, model systems, and neuroimaging studies over the last few decades. However, of these, magnetic resonance imaging (MRI) studies have provided the greatest contribution to the current understanding of attributes of brain structure and function associated with ASD. This section will review the main themes of this research, focusing on neuroanatomical studies using structural MRI (sMRI) and brain function using task-based (tb-) and resting state (rs-) functional MRI (fMRI).

Brain imaging as a tool and as an approach to understanding brain-based disorders emerged on the research landscape in the 1990s, with the arrival of fMRI to complement sMRI, which became a useful research tool about a decade earlier. Neuroimaging in ASD research, however, did not gain traction until the late 1990s, after which it accelerated rapidly, as it did in all subfields of neuropsychiatry. To date, the dominant research approach has been the case-control design, which considers individuals with ASD as categorically distinct from other groups, including typically developing controls (TDCs). Thus, studies focus on describing how the brain is different in ASD than TDCs, at what ages those differences emerge, and how specific brain features map onto phenotypic elements of ASD, genetic risk variants, and outcome measurements. Recent data, however, demonstrate that ASD is extremely heterogeneous, both in its core features, with severity ranging from the boundary of typical development to profoundly impaired, and with respect to many frequently co-occurring conditions such as intellectual disability, epilepsy, anxiety, and attention deficit hyperactivity disorder (ADHD). This is relevant to understanding the neurobiology of

Telegram: @medical_k

www.konkur.in

ASD research literature, because often studies do not replicate upon follow-up and thus cannot provide reliable information. This is inherent both to the heterogeneity that accompanies the current conceptualization of the essence of ASD, as well as to the practice of publishing results based on inadequate sample size, for example, where case and control groups have less than about 20 to 25 individuals each. Inadequate sample size is an acknowledged problem across all of psychological science because it leads to failed replications, undermining the ability to accumulate a stable base of knowledge. Thus, the review of studies herein is confined to research where there have been several studies arriving at similar conclusions, with a bias away from describing studies based on small samples.

Developmental Neuroanatomy

The observation that individuals with ASD tend to have enlarged heads dates back to the origin of the diagnosis itself. Although subsequent studies of head circumference confirmed this observation, it did not receive much attention until the advent of MRI, which provided the excellent soft tissue contrast needed for more precise quantitation of brain morphology. The first MRI study from the middle of the 1990s found total tissue volume of individuals in the ASD group to be about 6% larger than the control group. Subsequent studies suggested that the size increase includes both gray and white matter. Courchesne and colleagues were the first to report that megalocephaly was observable as young as 2 years of age (but was not present at birth). This has been replicated and extended several times. For instance, Hazlett and colleagues showed that while gray matter volume and cortical surface area are enlarged in ASD, cortical thickness is not, which is an important observation, because it constrains the possible biologic mechanisms that could account for these size differences.

The Infant Brain Imaging Study (IBIS) has brought greater precision to the current understanding of the earliest signs of developmental brain differences in ASD. IBIS is a multisite, national study collecting data prospectively on at-risk baby siblings of youth with ASD, with the first brain MRI between 3 and 6 months of age, repeated at regular intervals up until 24 months of age. Initial IBIS results showed that axonal fibers had a blunted development in ASD between 6 and 24 months of age,

Telegram: @medical_k

www.konkur.in

with results clustering in brain regions implicated by fMRI study as part of the “social brain.” These data suggest that ASD begins to develop neurobiologically before the end of the first year of life in those who go on to a formal diagnosis at older ages (e.g., age 3). This is consistent with emerging data from very careful behavioral testing, which also shows significant deficits in the first year of life for those who go on to develop ASD. Another IBIS study found white matter microstructural abnormalities at 7 months of age in the group who went on to have ASD, in particular in fiber bundles associated with visual orienting and with the ability to disengage attention. These data help pinpoint brain circuits that appear to underlie “sticky attention,” a phenomenon in ASD that causes significant behavioral management issues and undermines learning. Both studies confirm that brain connectivity is an early feature that goes awry in ASD. A third IBIS study has focused more explicitly on how the white matter’s individual axonal fibers are organized in ASD using diffusion tensor imaging (DTI). This study found significant fiber network inefficiencies in the brains of toddlers with ASD at 24 months of age. Thus, a developing theme is that white matter shows aberrant organizational properties in the first year of life, which accentuate with time and subserve core features of ASD.

While most studies have not tried to localize areas of the brain that may be disproportionately enlarged, those that have often find frontal and temporal regions most enlarged. In addition, Munson and colleagues discovered early overgrowth of the amygdala, a structure vital to emotional processing, emotion regulation, and memory, in a sample with an average age of 4 years. Subsequent studies have verified and extended these findings showing associations between degree of overgrowth and severity of clinical symptoms. However, findings are confined to preschool ages, as increases are noted later in childhood and adolescence. Several MRI studies have suggested that the brain’s white matter is disproportionately enlarged in ASD, which is viewed as supportive of more recent conceptualizations of ASD as involving disrupted connectivity. However, not all white matter fiber tracts are enlarged. For example, numerous studies have found decreased cross-sectional width of the corpus callosum. Moreover, there is evidence that later myelinating areas, in particular, contribute the most to the increase in brain volume in ASD relative to typically TDCs (i.e.,

Telegram: @medical_k

www.konkur.in

frontotemporal and frontoparietal regions). Allometric models of cerebral development suggest that doubling the number of neuronal processing units (the gray matter “minicolumn”) supports a fourfold increase in neuronal connectivity, potentially generating a fourfold increase in white matter volume. However, even though white matter enlargement seems a bit disproportionate compared to gray matter enlargement in ASD, it may be that the white matter enlargement is less than would be expected under model assumptions. The implication is that the bigger brains in ASD are actually less well connected than smaller brains among TDCs.

The neurodevelopmental trajectory of ASD was refined by subsequent studies that found that ASD increases in head size were observable only below age 12 years, after which group differences disappeared. This observation has been replicated many times, but the finding is not without opposing results. The single largest and best controlled study to date, albeit on head size (an imperfect proxy for brain size), found significant head circumference enlargement regardless of age. This study is remarkable for its very large sample size (n = 1,889 individuals with ASD from young childhood to young adulthood), and for controlling known confounds such as age, body size, and IQ measurements, as well as familial effects on head size, since both parents and an unaffected sibling were also included in the analyses (total n = 7,225). In summary, the brain growth and volume literature suggests that brain overgrowth begins in the first few years of life in ASD, and that by adolescence, brain size is much more typical. This abnormal pattern of growth across infancy and childhood is presumed to have very important implications for the functional properties of the brain and to likely perturb functional organization of systems that support typical social–emotional and cognitive skills. This atypical growth pattern also provides clues as to the possible cellular–genetic bases of ASD, especially mechanisms that govern neural numbers.

Consistent with this summary, a postmortem study of brains of those with ASD recently pinpointed a possible mechanism for brain volume differences in ASD. This study found good evidence for early deficits in neural pruning in ASD. While relatively small by MRI standards, the 20 brains analyzed (about half with ASD) represent one of the larger published postmortem studies. Samples came from individuals who died

Telegram: @medical_k

www.konkur.in

between 2 and 20 years of age. Synaptic pruning after the first year of life is well known as a normal developmental process, which is presumed to yield improved computational efficiencies. While typical controls lost about 40% of their dendritic spines (that part of a neuron that receives signal transmissions) across the age span, those with ASD lost half that much. The investigators also used a mouse model of ASD to study possible causes of this pruning failure. They found that mTOR, a key protein in brain function and development, was hyperactive, which impaired the ability to prune synapses. Overactivity of the mTOR pathway led to blockage of autophagy processes, reduction in pruning, and resulted in mice with ASD-like social behaviors. Significantly, the investigators were able to correct the pruning deficits and ASD-like behaviors in mice through use of an immunosuppressive drug, rapamycin, which inhibits mTOR activity. While this is unlikely to become a standard treatment in humans, owing to its very serious side effects, mTOR is currently being tested in clinical trials for a special subgroup of ASD (those with tuberous sclerosis), where the risk has been judged appropriate. Finally, the investigators also found proteins that reflect deficient autophagy and synaptic pruning malfunctioning in the human postmortem tissue. Collectively, these data are consistent with growing evidence of neural connectivity abnormalities in ASD, especially regional overconnectivity. Given that a great many of the known ASD genetic risk variants interact with the mTOR pathway, deficits in synaptic pruning provide plausible mechanisms contributing to the development and maintenance of ASD. Lack of pruning would also lead to an abundance of synapses, which would create the opportunity for seizures, a common comorbidity of ASD.

Recently, attention has focused on neuroanatomical changes later in adolescence and adulthood. One particularly relevant study matched a very large number of cases and controls (ages 7 to 25 years) on age, gender, and IQ, and found significant, widely distributed reductions in cortical thickness with age in ASD relative to TDCs. These declines were concentrated in the same areas of the brain shown in other studies as exhibiting hypertrophy early in life—frontal and temporal lobe regions, suggesting a unique inverted U-shaped developmental growth trajectory. Prefrontal cortex and the anterior temporal lobe also showed significantly reduced surface area with age (an age-by-group

Telegram: @medical_k

www.konkur.in

interaction). These results are consistent with several other recent studies that showed accelerating cortical thinning with age, including in the temporal lobe. Collectively, these data raise the concern that there might be undetected declines in cognitive and social–emotional functioning as individuals with ASD move into adulthood.

Functional Neuroimaging

fMRI studies of ASD have painted a complex portrait of differences in brain functioning in ASD. While MRI studies of neuroanatomy focus on measurements of a trait of a person, fMRI study results are influenced both by enduring personal traits (e.g., some people are very good at recognizing faces and others are not) and also mental and emotional states at the time of the assessment. Because the MRI experience can vary between individuals (e.g., stress provoking for some, sleep provoking for others), measurement signal can be influenced by state factors. The signal analyzed from fMRI comes from fluctuations in the magnetic field with different blood oxygen levels that accompany changes in neural activity. While the measurement is in this way indirect, fMRI has advantages over other neuroimaging techniques because of its ability to localize activity very precisely to different parts of the brain, with resolution in most studies of about 3 mm^3 (voxel size). Although this is precise by many standards, it is important to recognize that an average cortical gray matter voxel contains about 630,000 neurons.

fMRI studies can be of different types. Some are task based and have focused hypotheses about regions of the brain (e.g., the amygdala) that are hypo- or hyperactive in ASD. This type of study, based on a specific task (e.g., showing emotionally engaging images vs. neutral images with the participant providing a judgment that is recorded by a button press), has expectations that specific brain “modules” will be differentially engaged and has dominated the literature, particularly the early literature. This approach has been successfully used to test a range of theories about the primary deficits in ASD. The social, communication, and behavioral problems that occur with ASD suggest that the syndrome affects a functionally diverse and widely distributed set of neural systems. At one point or another, disturbance in nearly every neural system in the brain has been proposed to be a fundamental mechanism causing ASD. These theories are typically derived from beliefs about the

Telegram: @medical_k

www.konkur.in

most salient behavioral and psychological features of the disorder, sometimes with explicit consideration of developmental course. For example, those who emphasize difficulty with complex information processing as the principal characteristic of ASD postulate widespread cortical abnormalities sparing early sensory and emotional processes as the neural basis of ASD. Such cortical abnormalities, when present from early in life, would impair learning and contribute to developmental features of ASD. On the other hand, those who focus on the social reward and saliency deficits and their role in social difficulties often highlight the limbic system and reward system circuitry in the pathogenesis of ASD. Less sensitivity to social reinforcement and drive for social engagement would curtail social development. Theory-driven research is able to articulate specific hypotheses and pursue programmatic research that accumulates knowledge across time. Table 43–3 summarizes the knowledge about brain functioning that has been gained with this type of approach. Replicated studies that support a role of specific brain areas whose functions are atypical in ASD are represented in this table.

Table 43–3 reflects the literature and the strong interest in the field in localizing specific functions related to social ability to discrete locations in the brain. Perhaps the best studied process and brain region involves face perception and fusiform gyrus (FFG). The fusiform has a specific role in person identity from visual images. Numerous studies show that it is often underactive in ASD, paralleling difficulties on psychological tests of face recognition. The fusiform is functionally synchronized with the limbic system, and in particular the amygdala. The amygdala, along with the reward system, is believed to play a role in directing a person's attention to socially relevant things in the environment, such as people and their social interactions. Both the amygdala and the reward pathway have been shown to be hypoactive in ASD, though the amygdala's social responsiveness is confounded by its role in signaling anxiety and fear. There has been considerable speculation regarding the relationship between ASD symptoms and a constellation of brain areas referred to as the mirror neuron system (MNS). MNS has proven responsive to both the perception and implementation of specific body movements. The posterior part of the superior temporal sulcus has been highlighted in many fMRI studies of social perception (especially recognizing

Telegram: @medical_k

www.konkur.in

nonverbal cues, such as facial expressions, gestures, and eye gaze direction), as well as part of larger systems for representing the intentions of others (i.e., for generating a theory of mind of others). The hub of theory of mind activity, however, is generally localized to the medial prefrontal cortex. Orbital prefrontal cortex represents the value of experiences and of rewards and as such, it plays a key role in emotional learning.

Table 43–3.
Brain Regions of Potential Importance in ASD

Brain Area	Function
Amygdala	Emotional arousal, emotion perception, and emotional learning
Extended amygdala, ventral striatum, and nucleus accumbens	Social reward circuitry
Fusiform gyrus (especially lateral aspect of the right fusiform)	Face (person) recognition
Posterior, superior temporal sulcus	Interpreting nonverbal communications, action observation, and theory of mind
Orbital prefrontal cortex	Emotional learning
Medial prefrontal cortex	Social cognition (interpreting what others might be thinking and feeling)

In the past decade, there has been increased attention given to task-free fMRI studies, most notably what has been termed resting state (rs-) fMRI (rs-fMRI). With this approach, participants are not required to engage in any specific mental activity. Rather fMRI signal is gathered continuously during a rest period, generally of about 5 minutes long and often with more than one rest session. This approach has been most valuable in the context of functional connectivity studies of brain systems, an approach which examines the cross-correlation of disparate

Telegram: @medical_k

www.konkur.in

regional brain activity fluctuations. In essence, the approach searches for synchronous fMRI activity in order to create networks of regions that appear to be working together in a time-locked fashion. This approach has yielded numerous study findings, but many have not been consistently found across studies, and so confirmation of these findings, therefore, awaits larger studies. Those that are consistent often identify brain system differences associated with ASD that can be supported by lesion studies, or task-based fMRI (e.g., as described in Table 43–3). rs-fMRI is an important component of a major NIH initiative—the Human Connectome Project. This multicenter program of research is collecting imaging data on over 1,500 participants. The Human Connectome and related endeavors will allow connectivity matrices derived from graph theory on resting state and diffusion data from individuals with ASD to be compared to several other groups, including, for example, typical development, Alzheimer, and ADHD. These publicly available resources will generate the large samples needed to make gains in characterizing neural circuits with multimodal imaging in basic cognitive neuroscience and in ASD. This is significant given that other lines of evidence support the general theory of underconnectivity of the brains of individuals with ASD. This approach, along with increased implementation of multimodal imaging studies (where sMRI, fMRI, and other techniques are combined to address hypotheses about the neural architecture of ASD), promises to allow important advances in the understanding of ASD in the coming years.

One of the most relevant components of the Human Connectome Project for understanding ASD involves exploring, in unprecedented detail, how the brain typically grows and connects during childhood and the transition through puberty to adolescence and young adulthood. The Lifespan Human Connectome Project Development (HCP-D) Study is currently enrolling 1,300+ healthy children, adolescents, and young adults (ages 5 to 21) to discover how different parts of a child's brain are connected and how these connections (the "connectome") change as the brain develops. Characterizing brain development in healthy children will also allow us to better understand differences that can occur in children with ASD. Similarly, data collection is now ongoing for a large-scale, two-site longitudinal baby connectome project. The study includes

Telegram: @medical_k

www.konkur.in

500 participants who will be studied with brain imaging and behavioral phenotyping at four to six visits from birth to age 5 years.

These longitudinal, developmental studies are providing the basis for a developmental perspective (i.e., early and longitudinal study of brain and behavioral development) on the cognitive neuroscience of ASD. Such a developmental perspective is crucial for several reasons. First, very little is known about the neural mechanisms supporting cognition in infants and children or about the changes in brain function, connectivity, and temporal dynamics that underlie normative behavioral development. This paucity is unfortunate because this basic knowledge is proving essential to understanding ASD. The developmental connectome studies will document the changes in brain functional connectivity as a function of the infant/child's age and sex and also detect changes in connectome during critical periods of childhood before, during, and after major developmental transitions. The availability of these data points will facilitate efforts to characterize atypical developmental pathways and will advance development of more effective interventions for ASD. Second, neurobiologic markers of developmental processes may prove useful in early identification of infants at risk for developing ASD. To the extent that the projects elucidate developmental trajectories of the neural circuitry supporting pivotal, early developing social abilities, it can inform the design of more effective programs for identifying and remediating risk for difficulties in these areas. It is generally accepted that earlier educational interventions are more effective for treating a variety of symptoms in ASD. Therefore, early identification of children with difficulties in cognition is pivotal to optimizing individual intervention outcomes. Developmental neurobiologic markers for individual differences in cognitive abilities would then not solely be important for improving early identification but also could offer advantages for earlier interventions. Moreover, it could be that a marker would relate to the severity of specific deficits and might help us to better understand the heterogeneity that is characteristic of ASD. With this information, more targeted treatments could be developed on a child-by-child basis and implemented early in ontogeny, which might then guarantee the most effective course of intervention possible, and thus the assessment of individual treatment needs could be far more efficient and standardized. Finally, fMRI (tb- and/or rs-) might actually provide a means to better

Telegram: @medical_k

www.konkur.in

quantify treatment effectiveness and reveal whether behavioral improvements correspond to compensatory changes in brain function or normalization of developmental pathways.

Connectome-Based, Individual Differences and Prediction

The human brain is a complex dynamic system, and it is notoriously difficult to build comprehensive theoretical models for even simple neurobiologic and cognitive processes. While there exists a degree of specialization and modularity in the human cortex, the functionality of a specific cognitive process is often largely distributed across brain networks. This makes distilling an experimental result down to a handful of cortical regions challenging and potentially misleading. With these challenges in mind, the advent of technologies in machine learning from computational sciences and graph theory from mathematics have sparked new modeling approaches in cognitive neuroscience.

One particularly influential modeling approach is the connectome-based predictive model (CPM). CPM leverages robust idiosyncrasies of functional connectivity graphs across individuals to make predictions about those individuals. CPM graphs can be constructed from resting-state functional connectivity data as well as functional connectivity data acquired during cognitive tasks. CPM is particularly suited for individual differences research, as the graphs are highly predictive of an individual's intellectual disability. Irrespective of nuisance artifacts such as head motion or anatomical differences. This will allow the field of ASD neuroimaging research to move beyond case-control studies to fully explore the heterogeneity of ASD. Importantly, CPM predictions remain accurate over multiple scan sessions, and the reliability of the CPM graphs for both rs- and tb-functional connectivity increases monotonically as a function of scan time. Successful analysis frameworks using CPM include predicting an individual's ID, age, attention, and general intelligence, among other features.

The development of artificial intelligence/machine learning–informed techniques like CPM marks a new era in which brain imaging could evolve into an integral part of a translational research chain. Novel behavioral treatment and pharmacotherapies for ASD may be further developed with the tremendous benefit of directly and more precisely assessing impairment and change in targeted neural circuits.

Telegram: @medical_k

www.konkur.in

Neuroimaging-informed, developmentally sensitive biologic markers of underlying latent constructs such as social perception, social motivation, and social learning could be used to tailor an individualized intervention plan from treatment outset, informing decisions related to the selection of a behavioral treatment approach as well as its dose, duration and intensity, and any use of concurrent pharmacotherapy. To illustrate the power of such an approach, we highlight a study that utilized fMRI and a social perception task to predict treatment response in young children with ASD.

Pivotal response treatment (PRT) is an evidence-based treatment for young children with ASD. Extensive research has shown its efficacy in promoting language acquisition and social communication development in young children. While supported by a growing evidence base, PRT does not work for all children (no treatment does), and it is currently difficult for clinicians to predict whether a given child will benefit from PRT (or any other behavioral treatment). Unfortunately, this state of affairs means that a family may spend considerable time and financial resources on treatment that is not effective for their child. Utilizing machine learning and a rigorous cross-validation approach, Yang and colleagues discovered fMRI multivariate pattern analysis (MVPA)-based neurobiomarkers that accurately predict response to PRT at the individual subject level (Fig. 43–1). These neurobiomarkers consist of the pretreatment patterns and levels of activity and connectivity in response to coherent versus scrambled biologic motion in the neural circuits that support social information processing (posterior superior temporal sulcus [pSTS], FFG, amygdala, and inferior parietal lobule [IPL]) and social motivation/reward (orbitofrontal cortex [OFC], insula, putamen, pallidum, and ventral striatum [VES]). In sum, the development of biologic markers of treatment response may pave the way forward for precision medicine approaches in ASD.

Understudied Groups in ASD Neuroimaging

The majority of ASD research has focused on individuals with relatively intact language and cognitive functioning. Those characterized as having “low-functioning ASD,” including minimally verbal individuals, children with regressive trajectories, and those with intellectual disability, have tended to be overlooked. Methodologic and recruitment difficulties

Telegram: @medical_k

www.konkur.in

have played a role in this trend, but a desire to study a “pure” form of ASD, uncomplicated by potentially confounding factors, has likely contributed as well. This gap in the literature is exacerbated in the domain of human neuroimaging, where a high degree of behavioral compliance is often necessary to obtain usable data. We suggest that one of the next frontiers of brain research in ASD lies not so much in the development of new technologies or statistical methods as in increased attention to understudied subpopulations within the spectrum, particularly those with significant cognitive, language, or adaptive deficits. Neuroimaging approaches are a particularly powerful means to parse underlying differences (or similarities) in the biologic bases of varying ASD phenotypes. Expressions of ASD characterized by a more severe phenotype, including ASD with intellectual disability (ASD + ID), ASD with a history of developmental regression (ASD + R), and minimally verbal ASD (ASD + MV) are understudied generally, and especially in the domain of neuroimaging. ASD + MV may display abnormalities in preattentive auditory perceptual processing and structural deficits in brain structures that support expressive language function. In the future, longitudinal assessments and more detailed phenotyping of language profiles are particularly needed with this population. ASD + ID brain research findings have been highly variable. This may be related, in part, to underlying genetic heterogeneity in ASD + ID. Recent developments in imaging genetics of variants linked to ASD + ID (e.g., FMR1, NRXN1, CNTNAP2) suggest that these variants may shape brain structure in predictable but often opposing ways, indicating the need to take genotype into account in future ASD + ID work. ASD + R neuroimaging findings have focused mostly on electroencephalographic (EEG) abnormalities and epilepsy, but do not provide support for the hypothesis that epileptic encephalopathy contributes to the phenotype in the majority of cases; however, there is some suggestion that further exploration of nonepileptiform abnormalities may be worth investigating in some ASD + R cases. In the few MRI studies of ASD + R, there is some suggestion that brain enlargement may also be a worthwhile avenue of exploration. Investigating more extreme expressions of the phenotype may be a productive direction for future research.

NEUROCHEMISTRY

Dating back to 1961, there are several studies that have reported that approximately one-third of children with ASD have increased peripheral levels of the neurotransmitter serotonin. This has been the focus of much research, but the significance of this finding remains unclear, as the finding is not specific to ASD, and the relation of peripheral levels to central levels of serotonin is unclear.

Another line of work has focused on other neurotransmitters such as dopamine. A hyperdopaminergic functioning of the brain might explain the overactivity and stereotyped movements seen in ASD. This would be consistent with the general observation that administration of stimulants, which increase levels of dopamine, sometimes worsens behavioral functioning in ASD. Studies of cerebrospinal fluid (CSF) of dopamine metabolites and catecholamine metabolites have been inconsistent. It is clear that agents that block dopamine receptors are effective in reducing the stereotyped and hyperactive behaviors of many autistic children.

The endogenous opioids have been investigated, given the possibility that these compounds—enkephalins and endorphins—might lead to social withdrawal and unusual sensitivities to the environment. This was the rationale for use of opioid antagonists such as naltrexone in treating children with ASD. Although it does appear that there may be a modest effect of these agents on the high levels of activity and agitation overall, results have been disappointing. More recently, work has centered on the potential use of agents like oxytocin that may impact attachment and social brain systems more directly.

FIGURE 43–1. The top panel illustrates four clusters of brain activity identified using functional magnetic resonance imaging (fMRI) multivariate pattern analysis (MVPA). The bottom panel illustrates how well these neurobiomarkers accurately predict each child's response to pivotal response training (PRT), an evidence-based behavioral intervention for core symptoms of autism. (See eBook for color images.) (Reprinted with permission from Yang D, Pelphrey KA, Sukhodolsky DG, et al. Brain responses to biological motion predict treatment outcome in young children with autism. *Transl Psychiatry*. 2016;6(11):e948. doi: 10.1038/tp.2016.213. Licensed under CC BY 4.0.)

IMMUNE THEORIES OF ASD

There is some work on possible immunologic contributions to autism; for example, maternal antibodies that might impact the fetus in utero. There is no evidence that vaccines cause autism. There is some suggestion that possible pre- and perinatal exposure to inflammation and infection in very young children might be a contributing factor. Epidemiologic studies show that gestational exposure to infection is predictor of ASD. Animal models of maternal immune activation (MIA) have provided strong experimental support for maternal immune dysregulation as a contributor to ASD. While hyperactive immune response can disrupt normal brain maturation and cause behavioral abnormalities later in life, the key molecular and cellular pathways responsible for MIA-induced neurodevelopmental disorders remain to be discovered.

DIAGNOSIS AND CLINICAL FEATURES

The DSM-5 diagnostic approach requires three essential social communicative features and at least two restricted/repetitive features thus mixing the older DSM-III monothetic and the more recent DSM-IV polythetic approaches. Deficits are required in the areas of social interaction across settings in area of social–emotional reciprocity, as well as in nonverbal pragmatic communication. Difficulties in all three features are required. In addition, a minimum of two of four restricted and repetitive behaviors must be observed. These include (1) stereotyped motor mannerisms; (2) restricted interests and insistence on sameness, and problems in dealing with change and overreliance on routine; (3) highly restricted interests that are abnormal in focus or

Telegram: @medical_k

www.konkur.in

intensity; and (4) hypo- or hypersensitivity to sensory input. These difficulties must be present from early childhood and be the source of clinically significant impairment. Various additional codes can be used to denote specific features such as intellectual delay or catatonia. In addition, symptoms cannot be better explained by any intellectual difficulty. Reflecting the concern of individuals losing a diagnosis, those with previously "well-established" DSM-IV diagnoses of autistic disorder, Asperger disorder, or PDD-NOS can retain a diagnosis in DSM-5. For cases in which there are major problems in social communication but who do not meet criteria for autism, the new category of social communication disorder can be considered.

Although DSM-5 gives various specific developmental/behavioral examples, it makes it clear that these are not to be taken as the only examples.

One of the challenges in ASD is the marked range of syndrome expression in ASD over both age and levels of intellectual and communicative ability. For the most cognitively impaired, the person is usually largely or entirely mute and exhibits severe deficits in social interaction. At somewhat higher levels of intellectual ability, there may be more passive interest in social interaction albeit with some spoken language, while the most cognitively able individual with ASD often exhibits eccentric and one-sided social styles. In the latter group, pragmatic language deficits are often striking. This group has been termed "active but odd" and often presents the greatest challenge for the new DSM-5 approach. There is considerable potential for misdiagnosis, particularly for the extremes in age and levels of cognitive functioning. Some older persons slip through the cracks and don't appear for diagnosis until adulthood.

The evaluation of the individual with ASD should include a detailed history, comprehensive medical (including genetic) and developmental examination, and psychological testing. Official practice guidelines for screening, assessment, and treatment are available. Specific tests are noted subsequently.

Age of Onset

Kanner believed initially that autism was congenital, and it does appear that onset is indeed early in life. Figure 43–2 illustrates age of parental

Telegram: @medical_k

www.konkur.in

concern—usually around 12 and 18 months as language fails to develop. Sometimes, parents worry that the child is deaf even though they would respond very dramatically to some environmental sounds. Occasionally, parents will report that the infant is “too good,” making few demands on them and having limited interest in social interaction. Such a situation is in stark contrast to the noteworthy social engagement of the typically developing child who finds in people and particularly the human face some of the most interesting and salient features in the world. At times, parents may report that the child seemed to develop some language but then stopped or lost verbal abilities or development plateaus without further gains. This type of regression/developmental stagnation may be reported in 20% or so of cases. Rarely, a child develops normally for a few years and then loses abilities and an autistic-like presentation develops. In addition to careful developmental history, use of videos or even photographs may be helpful. Cases with marked regression after a considerable period of normal development are rare and had their own category in DSM-IV. In contrast to more classic autism/ASD cases, DSM-IV type Asperger’s may not be picked up until the child enters preschool and social difficulties with peers become striking. In these cases, although language has developed, social pragmatic language use is a source of great difficulty, and intense special interests are common. Many of these cases no longer receive a DSM-5 diagnosis of ASD (unless they already had a “well-established” diagnosis). Table 43–4 summarizes some of the features important in differentiating autism from other disorders in the first years of life.

Telegram: @medical_k

www.konkur.in

FIGURE 43–2. Age of recognition in autism in a series of 174 consecutive cases.

Impairments in Social Communication

The typically developing infant has a quite striking interest in social interaction and the social environment from the time of birth. This interest is an important foundation for development of a host of other abilities, for example, observational learning, joint attention, selective attention, communication, executive functions, and so forth. In contrast, for the infant/young child with ASD, the face and social interaction are of much less interest. The young child with ASD may have trouble engaging in some of the early social games of infancy. Social interest usually does increase in ASD with intervention, but problems in social interaction remain a hallmark of the condition throughout the life span.

Problems in language and more generally in communication are a hallmark of ASD. Language may fail to develop at all, or when it does, various difficulties often emerge. These include tendencies to echo speech (echolalia); this reflects the child's tendency toward a gestalt learning style (learning things in chunks). Other problems may include difficulties with tone of voice, loudness of speech, problems with

Telegram: @medical_k

www.konkur.in

pronouns, and reciprocal language. Very idiosyncratic language may develop, that is, specific words or phrases that only the parents understand. Although the syntax and morphology of language can be relatively spared, acquisition of vocabulary and semantic skills may be delayed and social language (pragmatics) difficulties are particularly challenging. As children become older, irony, sarcasm, and humor may be areas of difficulty.

Although prosody is quickly acquired in typically developing infants, those with autism have major difficulties with it, and intonation can be monotonic, loud, and robot like. Perception of social cues is an area of difficulties, for example, the child may not perceive cues from a conversational partner and engage in a one-sided conversation.

Adapted from Chawarska K, Volkmar FR. Autism in infancy and early childhood. In: Volkmar FR, Klin A, Paul R, Cohen D, eds. *Handbook of Autism and Pervasive Developmental Disorders*. 3rd ed. John Wiley & Sons; 2005:230.

Problems in play are common, particularly with more symbolic–imaginative play. The child with ASD may be more engaged with the taste or smell or feel of play materials or their use for self-stimulatory activity than their intended use.

Restricted Activities and Interests

It is typical for the child with ASD to have problems with change and variation in routine. Attempts to interrupt some activity may lead to catastrophic distress on the part of the child. Parents may note the child's overreliance on routine and their difficulties in dealing with change. Often areas of engagement and interest remain highly restricted, for example, collecting strings and using them for self-stimulation, memorizing numbers, etc. When the younger child with ASD has an attachment object, it often contrasts with that of such objects in the typically developing child in that it may be hard rather than soft and the actual object is less important than the category of objects, for example, any firetruck or train will do. Repetitive and stereotyped movements frequently include toe walking, finger flicking, and body rocking. The child may enjoy spinning objects or may be entranced by repetitive visual displays, for example, of a ceiling fan rotating. Repetitive behaviors, in their more full-blown form, are often among the last to develop in younger children but usually are seen by 3 years of age.

Associated Features

Although initial conceptualizations by Leo Kanner and Hans Asperger highlighted the cognitive potential of individuals with ASD, up to 33% of children on the autism spectrum likely now meet criteria for intellectual disability (IQ ≤ 70), with another 24% in the borderline range (IQ 71 to 85). Intellectual disability appears to be more prevalent in girls than in boys, although it is unclear if this finding reflects a true sex/gender difference or challenges with diagnosing ASD in more cognitively able females.

Telegram: @medical_k

www.konkur.in

Performance in IQ tests in individuals with ASD often reflects an uneven cognitive profile, with peaks and valleys at the subtest level. These include relative strengths in visual–spatial and rote memory tasks and relative weakness in verbal comprehension and abstract reasoning, suggesting a “concrete” cognitive style and difficulties going beyond literal information to infer abstract concepts. However, this pattern might be absent or even reversed across different subgroups, including individuals with higher cognitive and language functioning, who might show superior performance in verbal versus perceptual reasoning. Importantly, cognitive tests standardized on typical populations do not always provide an accurate estimate of intelligence in individuals with ASD, particularly for children with lower verbal skills and compliance, requiring the combination of different sources of information to estimate cognitive functioning in this population. Regardless of IQ level, individuals on the autism spectrum often have difficulties translating their cognitive capacity into real-life competencies, as reflected in their adaptive functioning skills lagging behind mental age. A related phenomenon observed in ASD is the presence of “savant” or “splinter” skills—that is, outstanding competencies above the individual’s general level of ability (e.g., normative reading skills in a child with below-average verbal IQ) and/or above the population norm (e.g., calendar calculation skills that are not normally present in the typical population). These exceptional talents, estimated to be present in 10% to 50% of the ASD population depending on operational criteria, are often not capitalized upon to facilitate adaptive functioning (e.g., using exceptional drawing skills to build a successful career as a graphic designer). Fortunately, the appreciation of the unique talents and assets offered by individuals with ASD in the workplace is increasingly appreciated, offering the potential to reverse this trend.

Developmental accounts of ASD have been propelled by prospective research on children at familial risk for autism, whereby younger siblings of a child with autism are followed from birth to examine antecedents of autism symptoms and diagnosis. One prominent model generated by this literature is that early emerging differences in the social domain, including reduced engagement in social play routines, reduced sharing and responsiveness to emotions, and reduced frequency of spontaneous imitation, reflect a fundamental deficit in social motivation

Telegram: @medical_k

www.konkur.in

or social attention. According to this notion, the difficulties in understanding and relating to the social world in ASD are the downstream outcome of reduced interest in social stimuli during infancy. Evidence in support of this account includes the findings of reduced expressions of pleasure during social interaction, as well as reduced attention toward biologic motion, social scenes, and eye gaze during early development in children with ASD. Early emerging deviations in social attention might constrain engagement in social experiences, thus altering the developmental trajectories of neural specialization and behavioral expertise in the social domain. However, it remains disputed whether this developmental cascade originates from alterations in reflex-like social orienting mechanisms that are present from birth, or later disruptions in the developmental transition from reflexive to volitional attentional social engagement during the first months of life. In addition, the notion of fundamental alterations specific to the social domain has been challenged by findings pointing to widespread network abnormalities that are not specific to the social domain in infants with ASD. Accordingly, it has been proposed that autism symptoms might reflect the downstream consequence of widespread alterations in synaptic processing, possibly disrupting social processing due to the complex and transient nature of social stimuli compared to nonsocial aspects of the environment.

Work using eye-tracking technology has been employed to study aspects of social engagement in a more quantitative way. The study of preferential looking has been extended from adults to very young children. Initial work with adults (see Fig. 43–3) illustrated the marked differences in patterns of looking while viewing social scenes—essentially resulting in difficulties for the person with ASD to fully capture the complexity of the interaction. Other examples include differences in ways biologic motion is perceived. These results highlight the significance of early-onset differences in social information processing on subsequent development.

Currently, no consensus has been established on whether “social-first” or “multiple deficits” models provide the most viable account of the pathways from early alterations to symptom expression in ASD. However, regardless of causal pathways, the notion of early emerging alterations leading to downstream developmental deviations and delays

Telegram: @medical_k

www.konkur.in

has been influential to early diagnosis and intervention, propelling efforts to identify and pre-emptively address early emerging manifestations of ASD before children are fully symptomatic.

Despite the theoretical advances from “static” to developmental models of ASD capable of informing practice, the establishment of a comprehensive, unitary account of ASD is hindered by several conceptual and methodologic challenges. These include the definitional haze around social processes and mechanisms, with unclear overlap and fuzzy boundaries around analogous constructs (e.g., social reciprocity, social orienting, social reward, social motivation, social cognition), and challenges with tying explanations based on cognitive and behavioral processes to molecular mechanisms of typical and atypical development. Accordingly, research efforts are increasingly focused on the interplay between genetic, neural, cognitive, and behavioral processes underlying the development of ASD.

FIGURE 43–3. Eye-tracking data from a typically developing young adult (**top line**) and a young, high-functioning man with autism (**bottom line**). The man with autism focuses almost exclusively on the mouth of the person speaking, avoiding the upper part of the face and not noticing the emotional responses of the listener. (Reprinted with permission from Klin A, Jones W, Schultz R, Volkmar F, Cohen D. Defining and quantifying the social phenotype in autism. *Am J Psychiatry* 2002;159(6):895–908.)

Motor and Sensory Abnormalities. A range of motor abnormalities has been documented in ASD, including delayed walking, abnormalities in gait (e.g., toe walking), posture, balance, and coordination, as well as difficulties in motor imitation and pantomime. In addition, individuals with autism often display motor stereotypies, including repetitive tapping, hand and arm flapping, body rocking, finger flicking, waving in front of the face, rigid tensing of the entire body, as well as atypical patterns of hyper- and/or hypomotor activity. Although these abnormalities are not ASD specific, they are observed more frequently in individuals on the autism spectrum than in other conditions. The developmental course of motor abnormalities in ASD involves early subtle manifestations during the first 2 years of life, followed by increasingly deviant motor trajectories during childhood. Motor abnormalities might decrease in

Telegram: @medical_k

www.konkur.in

adolescence and adulthood, particularly in more cognitively able individuals, although motor clumsiness and awkward postures or movements might be observed throughout the life course and across the spectrum of ASD severity.

While the nature of motor abnormalities in ASD is poorly understood, these appear to be interrelated with the pathognomonic features of ASD. Differences in motor imitation and motor gestures in infants and toddlers have been found to predict diagnostic status and communication outcomes, reflecting an interplay between motor and social dimensions of development in ASD in the first years of life. In addition, motor and social abnormalities might continue to exert reciprocal effects across the lifespan. For example, school-aged children who engage less frequently or less accurately in motor imitation have fewer opportunities to join peers in coordinated activities that facilitate social bonding (e.g., joint drumming, giving “high fives”). Similarly, teenagers with ASD who engage more frequently in solitary versus social activities are less likely to adopt the postures and movement patterns of those surrounding them, resulting in idiosyncratic motor behaviors. In addition, atypical motor development has been linked to arousal abnormalities, rigidity/inflexibility, developmental dyspraxia, functional and anatomical abnormalities, as well as abnormal connectivity in the brain systems underlying motor planning and execution. Individual differences are substantial, suggesting multifactorial and heterogeneous causal paths.

Another feature that has been frequently documented in ASD is an atypical perception of and response to sensory information. Sensory abnormalities encompass a range of phenomena, including seeking of specific sensory stimulations (e.g., deep pressure), unusual sensory interests (e.g., peering at or smelling objects), as well as overreaction and/or underreaction to sensory inputs. For example, a child with ASD might experience certain sounds as being excessively loud or certain textures as being aversive, resulting in idiosyncratic reactions such as covering the ears in response to a vacuum cleaner, refusing foods with specific textures, and defensively avoiding being touched. Conversely, hyporeactivity might result in children not responding to specific sensory stimulations, such as pain, or their name being called, and seeking sensory inputs in idiosyncratic ways, such as rubbing a piece of fabric in their hands, squeezing objects, or staring at the circular motion of

Telegram: @medical_k

www.konkur.in

clothes in a washing machine. Hypo- and hypersensitivity might coexist in the same individual in response to different classes of stimuli and at different points in development. Sensory abnormalities have been observed across the spectrum of ASD severity but appear to be more frequent and/or pronounced in more severely impaired individuals. In addition, atypical sensory responsiveness in ASD has been found to be associated with anxiety, although causal paths are unclear. While these phenomena appear to be more prevalent in ASD compared to other conditions, heterogeneity is substantial, pointing to the importance of individualized intervention strategies.

PHYSICAL CHARACTERISTICS

In ASD, higher rates of minor physical anomalies are observed, for example, ear malformations. These may reflect the embryologic period in which older regions of the brain develop. In general, though, children with autism are described as attractive and without dysmorphic features. Interestingly, a significant number of toddlers with autism develop macrocephaly.

PATHOLOGY AND LABORATORY EXAMINATION

Electroencephalography and Seizure Disorders

Various EEG abnormalities are observed even in the absence of clinical seizures (see Fig. 43–4). This is particularly the case when ASD is associated with intellectual deficiency. The observation of EEG differences in ASD for looking at faces as compared to typical controls has emerged as one potential biomarker of ASD.

As noted previously, seizures can have their onset at any time in the developmental period. Individuals who are more cognitively impaired are likely at greatest risk.

Neuroimaging Studies

As noted previously, a large body of research now exists on the social brain using neuroimaging techniques. At present, in the absence of a

Telegram: @medical_k

www.konkur.in

specific clinical indication, neuroimaging studies are not routinely needed in the usual evaluation of a child with possible ASD.

FIGURE 43–4. Rates of first seizure (incidence rate per 1,000) in samples of individuals with autism. (Data from cases with autism from Volkmar FR, Nelson DS. Seizure disorders in autism. *J Am Acad Child Adolesc Psychiatry*. 1990;29:127–129; and from cases with autism/pervasive developmental disorder from Deykin EY, MacMahon B. The incidence of seizures among children with autistic symptoms. *Am J Psychiatry*. 1979;136:1310–1312; as compared to rates in a normative sample from Cooper JE. Epilepsy in longitudinal survey of 5,000 children. *Br Med J*. 1965;1:1020–1022.)

Laboratory Studies

As indicated by history and examination, various laboratory tests may be relevant as part of the assessment. Screening should be done for frequently associated genetic conditions. Indications are summarized in practice guidelines provided in the reference list and these now identify such factors in between 10% and 20% of cases. EEG is indicated when seizures are suspected. Issues of assessment are addressed in various sets of practice guidelines.

www.konkur.in

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of ASD includes other neurodevelopmental disorders, such as intellectual deficiency or language–communication disorders, as well as primary intellectual deficiency. Visual and hearing difficulties should also be evaluated. Over 40 diagnostic instruments and screeners have been developed, but it must be noted that these do not replace good clinical judgment. These can be based on parent, teacher, or clinical report, or on direct examination. Some of these instruments require extensive training. Selected instruments are summarized in Table 43–5. Some young children do not exhibit all features until around age 3.

For the child with mild to moderate intellectual deficiency (but without ASD), social skills are usually consistent with development in areas of cognition and communication. In individuals with severe and profound retardation, the frequency of both autism and autistic-like behaviors increases but present some diagnostic challenges. Sometimes the presence of isolated stereotyped behavior is mistakenly used as a single factor in diagnosis of autism. At the other end of the IQ range, there can be confusion relative to those personality disorders that involve social isolation.

Aids to memory such as videotapes or baby books may help parents recall important historical information. As noted previously, in a small number of cases, the child may seem to develop normally but then either lose skills or plateau as more typical autistic behaviors develop. Other conditions to consider with a history of loss or developmental stagnation include mutism, Rett syndrome, the DSM-IV CDD, language disorder, schizophrenia, and degenerative central nervous system (CNS) disorders. Severe neglect or deprivation, for example, in some institutional rearing settings, can produce some features suggestive of autism, although usually not all features are present and social difficulties tend to dramatically remit if appropriate care is provided. Childhood-onset schizophrenia is rare before age 5 and indeed before puberty. In addition, the more classical features of schizophrenia are present, albeit in a more developmentally appropriate form. In some instances, the diagnosis can only be clarified with certainty over time.

www.konkur.in

John was the second of two children born to middle-class parents after normal pregnancy, labor, and delivery. As an infant, John appeared undemanding and relatively placid; motor development proceeded appropriately, but language development was delayed. Although his parents indicated that they were first concerned about his development when he was 18 months old and still not speaking, in retrospect, they noted that, in comparison to their previous child, he had seemed relatively uninterested in social interaction and the social games of infancy. Stranger anxiety had never really developed, and John did not exhibit differential attachment behaviors toward his parents. Their pediatrician initially reassured John's parents that he was a "late talker," but they continued to be concerned. Although John seemed to respond to some unusual sounds, the pediatrician obtained a hearing test when John was 24 months old. Levels of hearing appeared adequate for development of speech, and John was referred for developmental evaluation. At 24 months, motor skills were age appropriate, and John exhibited some nonverbal problem–solving skills close to age level. His language and social development, however, were severely delayed, and he was noted to be resistant to changes in routine and unusually sensitive to aspects of the inanimate environment. His play skills were quite limited, and he used play materials in unusual and idiosyncratic ways. His older sister had a history of some learning difficulties, but the family history was otherwise negative. A comprehensive medical evaluation revealed a normal EEG and computed tomography (CT) scan; genetic screening and chromosome analysis were normal, as well.

John was enrolled in a special education program, in which he gradually began to speak. His speech was characterized by echolalia, extreme literalness, a monotonic voice quality, and pronoun reversal. He rarely used language in interaction and remained quite isolated. By school age, John had developed some evidence of differential attachments to family members; he also had developed a number of self-stimulatory behaviors and engaged in occasional periods of headbanging. Extreme sensitivity to change continued. Intelligence testing revealed marked scatter, with a full-scale IQ in the moderate range of intellectual deficiency. As an

Telegram: @medical_k

www.konkur.in

adolescent, John's behavioral functioning deteriorated, and he developed a seizure disorder. Now an adult, he lives in a group home and attends a sheltered workshop. He has a rather passive interactional style but exhibits occasional outbursts of aggression and self-abuse.

COURSE AND PROGNOSIS

Typically, ASD is a disability that is lifelong although with a considerable range in adult functional outcome. Over time, fewer and fewer individuals have needed the considerable interpersonal and familial support observed in the first cohorts of cases. It appears that with earlier and more evidence-based intervention, overall outcome is improving. There are some cases of "optimal outcome" where individuals technically no longer meet full diagnostic criteria (although some interpersonal oddity or other difficulties may remain). Some cases, despite early identification and good intervention, do not do well.

More people with ASD are entering the workforce and attending college but may face their own challenges in these settings. More individuals with ASD are now living independently and some are marrying. Initial outcome studies suggested rates of adult independence at around perhaps 5% of cases; this number has dramatically increased, as has the number of individuals who are living semi-independently. Vocational challenges often remain. Associated mental health issues, for example, anxiety and depression, can be a source of additional difficulty for adults. Even adults with more severe associated intellectual disability can make gains, and longer-term goals here include acquisition of important adaptive skills to maximize self-sufficiency to the degree possible.

Factors associated with better long-term outcome include presence of communicative speech by the age of 5 or and nonverbal IQ above 70. Cognitive ability that is overall within the normal range is a positive prognostic sign. Treatment studies of large groups of younger children will typically show a few children who make very dramatic gains in the first years of life. Several studies have now demonstrated observable brain changes in response to treatment using techniques like EEG or fMRI response to social stimuli.

Telegram: @medical_k

www.konkur.in

During the elementary school years, gains are usually observed in social compliance and communication, particularly if good evidence-based treatments are provided. Kanner was the first to note that, during adolescence, some children make major gains while a somewhat smaller number deteriorate. Sometimes gains in adolescence are associated with a greater interpersonal awareness on the part of the teenager who has a desire to fit in; this both motivates change but also can be a source of anxiety and depression.

TREATMENT

No treatment has unequivocally proven to reverse the core symptoms of ASD. However, numerous interventions for ASD have shown beneficial effects, including improvements in language, communication, cognitive, social, and adaptive functioning. Effective approaches rely on various applications of behavioral, developmental, and special education principles. Given the heterogeneous nature of the autism spectrum, intervention goals must be individualized, using comprehensive evaluation procedures to tailor objectives to the individual's profile of strengths and needs. Treatment goals must be updated periodically based on progress and consideration of evolving age- and context-specific needs and challenges. The intensity and timing of intervention are important factors in shaping outcomes, with children receiving intervention at a younger age and more intensively (i.e., 15+ hours per week), showing better intervention response. However, individuals with ASD benefit from evidence-based intervention at all ages, including adults who did not receive services during childhood.

Many evidence-based practices in ASD use principles and procedures derived from applied behavior analysis (ABA), a discipline focused on the examination and manipulation of the contingencies that create/maintain specific behaviors (e.g., self-aggression in response to specific demands), with the goal of discouraging maladaptive responses and teaching new skills. In the comprehensive ABA-based approach known as Early Intensive Behavioral Intervention (EIBI), the acquisition of new skills is facilitated through a structured learning environment designed to minimize distractions, with targeted skills broken down into discrete behavioral units that are taught in isolation. Stripped-down

Telegram: @medical_k

www.konkur.in

directive instructions are repeated until the child's behavioral response meets a predefined criterion, and correct responses are systematically reinforced, while various error correction procedures are used to discourage incorrect responses.

Other interventions embed ABA principles within naturalistic developmental behavioral approaches. These emphasize the importance of responding to the child's cues, building learning episodes on the child's initiative and choices, establishing emotional attunement and positive relationship between child and adult, and creating learning environments that resemble the "real world" where targeted skills would naturally be utilized. In addition, several intervention practices focus on the importance of environmental accommodations to create "autism-friendly" learning experiences, particularly in educational settings and workplaces. These include arranging spaces and using visual supports that capitalize on the visual processing strengths of those with ASD to facilitate understanding of expectations and communication (e.g., using pictures that illustrate what is expected in a specific space, or how to accomplish a specific task). Relatedly, many intervention programs include the use of visual and/or augmentative approaches to facilitate and teach communication. These include the use of visual cues (e.g., giving a partner a picture of an item in exchange for the actual item) or electronically generated sounds (e.g., pushing a button in a device that "speaks electronically" to request an item) that are designed to address difficulties in understanding language or using speech.

Although these intervention approaches are sometimes depicted as mutually exclusive, they are better characterized as falling along a multidimensional continuum from more structured to more naturalistic, from more adult directed to more child directed, from more focused on changing behavior to more focused on accommodating differences, and from more comprehensive to more targeted on specific skills. A growing body of literature has examined outcomes for different intervention packages along this continuum, identifying several elements that are in common across approaches shown to be effective. These include (1) timeliness (the earlier, the better), (2) intensity, (3) use of manualized and clearly operationalized instructional strategies, (4) focus on the core features of ASD, including sensory issues, as well as functional/adaptive skills, (5) assessment procedures to generate and update individualized

Telegram: @medical_k

www.konkur.in

sets of goals, (6) collection systems to monitor progress and implementation fidelity, (7) involvement of caregivers in establishing treatment goals and delivering intervention, (8) developmental appropriateness and developmental sequencing of goals (i.e., teaching age-appropriate skills and their developmental prerequisites), (9) promoting the individual's active engagement and communicative intent, (10) incorporating intervention strategies and opportunities in everyday routines, (11) thoughtful environmental arrangements (including minimizing distractions/maximizing focus toward salient stimuli), (12) creating predictable and consistent routines and experiences, with a balance between structure and novelty to support flexibility, (13) incorporating the individual's special interests when possible, and provision of reinforcements that are meaningful to the individual, (14) use of task analysis to break down complex functional skills into teachable steps, (15) use of scripts, visual supports, and practice opportunities to remind the individual about the steps involved in the targeted skill (e.g., rehearsing the steps involved in buying groceries through visual scripts and supported role-playing), (16) focus on generalization skills (e.g., using the skills acquired in a therapy sessions at home and school), (17) addressing challenging behaviors through the systematic analysis of their function, and teaching more desirable behavioral alternatives, (18) using prompts to facilitate the individual's response to the instruction, while also fading supports over time to promote autonomy.

Although research has documented the beneficial effects of these practices, there are important gaps that require additional research effort. First, despite the increased number of studies evaluating interventions for younger children, there is limited knowledge on interventions for older individuals, especially those on the most severe end of the spectrum. In addition, most existing literature has tested the efficacy of interventions in the highly resourced context of clinical trials, with more limited knowledge on intervention outcomes when these are transported into community clinical and educational programs.

In addition, although contemporary approaches have shifted away from the use of psychodynamic psychotherapy to address autistic symptoms, cognitive behavioral therapy (CBT) has been shown to effectively address co-occurring anxiety and depression symptoms that

Telegram: @medical_k

www.konkur.in

are common in children and adults with ASD. Several modifications have shown to facilitate the success of CBT for those with ASD, including using visual and multimodal teaching strategies, a focus on explicit problem-solving behaviors, and incorporating special interests into sessions. There may be an increased risk for suicidal ideation and suicide, and clinicians should be alert to this issue.

Psychopharmacology

The core social difficulty of ASD has, so far, proven resistant to treatment, although work is ongoing with agents such as oxytocin (a hormone involved in attachment). Medication can be of significant benefit for other features such as irritability, overactivity, aggression, and self-injury. Since children and adolescents are often enrolled in special educational programs, there may be opportunities to facilitate independent data collection of value in assessment of drug treatments. Potential benefits and side effects should be considered (e.g., with antipsychotic medications), and baseline laboratory studies (e.g., liver, kidney function, ECG, weight, and so forth) should be obtained. Depending on the agent used, it may be important to closely monitor for side effects, for example, tardive dyskinesia.

Antipsychotics. These agents have been extensively studied and, with relatively low doses, they may produce decreased irritability and agitation. This in turn may foster greater engagement in a treatment program. It is important to monitor for side effects. More recently atypical neuroleptics have been utilized. In one large double-blind, placebo-controlled study, risperidone was shown to quickly have a significant benefit in reducing agitation and other problematic behaviors. This and other atypical neuroleptics have now been approved for use in autism.

Selective Serotonin Reuptake Inhibitors. Interest in this group of agents arose given the awareness of higher peripheral serotonin levels in autism as well as in the increased risk for anxiety and depression. Several studies using placebo control methods have shown benefits for repetitive behaviors and impulsive aggression. Some children may have a paradoxical agitation.

Telegram: @medical_k

www.konkur.in

Stimulants. Many school-aged children exhibit significant problems with attention and overactivity that may be responsive to the traditional stimulants and related medications. However, associated side effects, for example, agitation, may be higher than in the general pediatric population.

Other Agents. A number of other agents have been used in ASD. Often data is limited to case reports or open-label studies, and controlled studies are not available. Lithium has occasionally been used, particularly with family history of bipolar illness and clinical presentation suggesting possible bipolar disorder.

Complementary and Alternative Treatments

These are frequently used by parents although, by definition, they lack a strong evidence base. This evidence is based on anecdote and sometimes a case series. One claim was that the gut peptide secretin was suggested to produce marked improvement, but a number of double-blind, controlled studies, did not show benefit over placebo. Parents should be encouraged to pursue proven treatments and avoid those with some risk to the child, either directly due to side effects or more commonly due to lack of participation in effective treatment programs provided in schools. Some resources for parents on these treatments are available (see Volkmar and Wiensser, 2021).

Attention-Deficit Disorders

44.1 Attention-Deficit/Hyperactivity Disorder

Lily T. Hechtman, M.D., F.R.C.P., A.B.P.N., Margaret D. Weiss, M.D., Ph.D., and Philippe Hwang, M.B., B.Ch., B.A.O., M.Sc.

Attention-deficit hyperactivity disorder (ADHD) is the most common childhood behavioral disorder diagnosed in outpatient settings in the United States. It is a chronic disorder that can cause impairment into adolescence and adulthood. In 2007, Polanczyk and colleagues estimated worldwide prevalence of ADHD in children and adolescents to be 5.29% using a comprehensive meta-analysis including hundreds of articles and more than 100,000 patients. Similarly, a meta-analysis from 2012 by Willicut using full DSM-IV diagnostic criteria found the prevalence of ADHD to be 5.9% to 7.1%. The National Survey of Children's Health (NSCH) showed that 9.4% of U.S. school-aged children had been diagnosed with ADHD by 2016. It has been suggested that the increasing rates of diagnosis and treatment may be due to increased awareness and access to care as opposed to an increase in the number of children in the population meeting criteria for ADHD.

Telegram: @medical_k

www.konkur.in

HISTORY

ADHD first was described by George Still in 1902, who wrote about children who were restless, impulsive, and inattentive, with intense affective responses and conduct problems. After the influenza pandemic and the epidemic of encephalitis lethargica from 1919 to 1920, children who survived the flu frequently developed severe behavior problems and are now thought to have suffered organic brain damage. For that reason, the childhood condition was termed “minimal brain damage syndrome,” even though brain damage could not be proven. In the early 1960s, the condition was renamed “minimal brain dysfunction.” Not only did these terms postulate unproven etiologic mechanisms, but they were also stigmatizing. The ninth revision of the *International Classification of Diseases and Related Health Problems* (ICD-9) and the second edition of the DSM adopted the same descriptive term for the condition—hyperkinetic syndrome of childhood. The 1980 version of the American Psychiatric Association (APA) classificatory system, DSM-III, renamed this diagnosis attention-deficit disorder (ADD) due to research suggesting that the main disability was the difficulty of maintaining sustained attention and problems with impulsivity. Much of the diagnostic criteria for ADHD have remained the same between DSM-IV in 1994, the text revision (DSM-IV-TR) in 2000, and the most recent version (DSM-5) released in May 2013.

DIAGNOSIS AND DEFINITION

The fifth edition of the APA’s *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), published in May 2013, describes ADHD under neurodevelopmental disorders as a pattern of inattentive and/or hyperactive–impulsive behavior inconsistent with developmental level which interferes with functioning in social, educational, or work settings. Symptoms are divided into two categories: inattention and hyperactivity/impulsivity. There are five main diagnostic criteria: (1) onset before age 12 years old; (2) duration greater than 6 months; (3) children must have at least six

Telegram: @medical_k

www.konkur.in

symptoms from the inattention and/or hyperactive/impulsive symptom list, while older adolescents and adults must have at least five; (4) several symptoms must be present in two or more settings and interfere with functioning; and (5) symptoms that do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better accounted for by another mental disorder, such as depression. DSM-5 has no exclusion criteria for those with autism spectrum disorder (ASD), allowing both autism and ADHD to be diagnosed simultaneously in the same patient. Possible specifiers for the disorder in DSM-5 include combined presentation (criterion met for both inattention and hyperactivity–impulsivity), predominantly inattentive presentation, or predominantly hyperactive/impulsive presentation. Other specifiers describe current severity of the disorder being mild (few to no symptoms in excess of those required), moderate or severe (many symptoms in excess of those required), or to specify if the disorder is in partial remission (fewer than full criteria met in past 6 months, but still results in impairment).

The inattention symptom criteria list includes the following: (a) often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities; (b) often has difficulty sustaining attention in tasks or play activities; (c) often does not seem to listen when spoken to directly; (d) often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace; (e) often has difficulty organizing tasks and activities; (f) often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort; (g) often loses things necessary for tasks or activities; (h) often easily distracted by extraneous stimuli (or unrelated thoughts for adolescents and adults); and (i) often forgetful in daily activities.

Hyperactivity and impulsivity symptoms criteria include the following: (a) often fidgets with or taps hands or feet or squirms in seat; (b) often leaves seat in situations when remaining seated is expected; (c) often runs about or climbs in situations where it is inappropriate (for older adolescents and adults, feeling restless without the overactivity can apply); (d) often unable to play or engage in leisure activities quietly; (e) often “on the go,” acting as if “driven by

Telegram: @medical_k

www.konkur.in

a motor"; (f) often talks excessively; (g) often blurts out an answer before a question has been completed; (h) often has difficulty waiting their turn; and (i) often interrupts or intrudes on others.

In the DSM-5, enhanced item descriptors were added to diagnostic criteria to demonstrate symptoms across the lifespan. For example, motor hyperactivity appears far less frequently in affected adolescents and adults, who continue to have attentional and organizational problems, poor anger management, job instability, and problems with social relationships and self-esteem. All 18 of the DSM-IV-TR symptoms of ADHD were retained in the DSM-5, but enhanced elaborators of each were added to better describe difficulties experienced by adolescents and adults. For instance, the inattention criteria "often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort" now includes specific examples of this symptom "(preparing reports, completing forms, reviewing lengthy papers)" to be applied to older adolescents and adults in addition to "(schoolwork or homework)," which is primarily specific to children.

COMPARATIVE NOSOLOGY

Previously, ICD-10 criteria differed from DSM-5 criteria significantly, with fewer children diagnosed with ADHD under ICD classification (called "hyperkinetic disorder" [HD]). In ICD-10, if a diagnosis of generalized anxiety or major depression was present, these disorders would be considered primary and HD would be excluded. For example, investigators in the United Kingdom applied an algorithm to the 579 children with DSM-IV ADHD combined subtype who had been recruited into the National Institute of Mental Health (NIMH) Multimodal Treatment Study of Attention Deficit Hyperactivity Disorder (MTA trial) in order to generate an ICD-10 diagnosis of HD. Only 25% of the MTA sample continued to meet the diagnostic criteria for HD in ICD-10.

However, the ICD-11 classification of ADHD is closer to that found in the DSM-5, removing this exclusion criterion. Therefore, the rate of diagnosis may increase following the adoption of the ICD-11 despite

Telegram: @medical_k

www.konkur.in

the incidence remaining unchanged. Both diagnoses are now based on similar structures with presentations that are predominantly inattentive, hyperactive, or combined, and that have been present for over 6 months. The DSM-5 focuses on meeting criteria out of lists of symptoms, whereas the ICD-11 uses more generalized symptoms for each presentation, but both specify that these symptoms must be evident in multiple settings. The ICD-11 specifically describes essential characteristics of the disorder without providing a precise age of onset, duration, or number of symptoms necessary for the diagnosis.

ETIOLOGY

ADHD is a complex disorder of multifactorial etiology, thought to have multiple genetic and environmental variables of small effect acting together to produce vulnerability to ADHD. Although the etiology of ADHD yet has to be determined, there is a growing consensus that the condition involves functional and anatomical dysfunction in the brain's cortico-basal ganglia-thalamo-cortical circuitry. These areas support the regulation of attentional resources, the programming of complex motor behaviors, and the learning of responses to reinforcement. Theories involving these areas have been examined in studies involving neurobiologic studies of healthy humans, humans with ADHD, and animal models.

Genetics

Twin, sibling, adoption, and family studies, all suggest a strong genetic component in the development of hyperactivity, inattention, and impulsivity, with the heritability index estimated to range from 0.6 to 0.98. Heritability estimates include both genetic influences, as well as the effects of gene–environment interaction. ADHD-like behaviors have also been reported in rare genetic disorders such as fragile X syndrome, neurofibromatosis type 1, DiGeorge syndrome, tuberous sclerosis, Turner syndrome, Williams syndrome, Angelman syndrome, and Prader–Willi syndrome.

Telegram: @medical_k

www.konkur.in

Twin Studies. Twin studies suggest that 76% of the variance in the transmission of ADHD is attributable to genetics, making ADHD one of the most heritable psychiatric disorders. Monozygotic twins have been found to be more concordant for ADHD symptoms of hyperactivity, inattention, and impulsivity than are same-sex dizygotic twins. The concordance rate among monozygotic twins ranges from 59% to 92%, whereas the concordance rate in dizygotic twins ranges from 29% to 42%.

Sibling and Half-Sibling Studies. Pettersson and colleagues reported on family data of 4,408,646 full and maternal half-siblings and genetic data of 125,533 cases and 208,215 controls in the Swedish sibling study. The strength of this study was the large sample size, and that psychiatric status was based on clinical diagnosis using standard diagnostic criteria. There was, however, the assumption that siblings and maternal half-siblings lived in the same household and thus shared the same environment. ADHD was one of the eight psychiatric disorders studied and was found to have a heritability estimate of 80%. An earlier sibling study found that 10 of 19 full-sibling pairs were concordant for ADHD, versus 2 of 22 half-sibling pairs; a significant difference supporting the genetic transmission of ADHD in families.

Adoption Studies. Studies have found that the biologic relatives of children with ADHD are more likely to have ADHD themselves. This relationship is not seen in adoptive relatives of children with ADHD. Adoptive relatives of children with ADHD have a risk of ADHD similar to relatives of control children, while the biologic relatives of children with ADHD are more likely to have ADHD or associated disorders. In a study of international adoptees aged 10 to 15 years, Van den Oord and colleagues estimated that genes accounted for 47% of the variance of inattention scores on the Child Behavior Checklist. Eighteen percent of biologic relatives of adopted-away children with ADHD were found to be at risk for the disorder versus 6% of the child's adopted relatives.

Telegram: @medical_k

www.konkur.in

Family Studies. Family studies have shown that first-degree relatives of children with ADHD are two to eight times more likely to have the disorder. First-degree relatives of children with ADHD have a 20% to 25% risk for ADHD, compared with 4% to 5% for relatives of controls. If a parent has ADHD, 50% of their offspring are likely to have that condition. The increased incidence of ADHD is also extended to second-degree relatives.

Mode of Inheritance. Several hypotheses of ADHD's mode of transmission have been advanced. Omenn explored the possibility of sex-linked transmission because of the male preponderance in the condition. Other theories include a polygenetic inheritance model, including those of Morrison and Stewart, but limitations in sample size made this hard to prove. Rhee and colleagues postulated a polygenetic multiple threshold model after analyzing sex differences in an Australian twin and sibling-pair study. However, differences in fit between genetic models were modest, as is true for comparisons of multifactorial and single-gene inheritance. This led to the suggestion that symptoms of ADHD may be caused by several interacting genes of modest effect. This hypothesis is consistent with ADHD's high population prevalence and high concordance in monozygotic twins, but modest recurrence risk for first-degree relatives. However, diagnostic uncertainty impedes progress in developing genetic models of inheritance.

Molecular Genetic Studies. There has been increasing interest in attempting to identify the specific "risk" genes that may be implicated in the development of ADHD. This search has yielded generally inconsistent results due to complexity of the trait and heterogeneity across studies. Candidate genes have been chosen for study based on theoretical considerations related to their function, and the majority of studies have concentrated on dopamine-related genes given the implication of dopamine dysfunction in ADHD. Candidate genes discovered so far are responsible for less than 5% of genetic variation in ADHD.

Telegram: @medical_k

www.konkur.in

The dopamine transporter gene (DAT1) codes for a sodium-dependent dopamine transporter protein that regulates reuptake of dopamine from the synaptic cleft. Cook et al. were the first to show an association between ADHD and DAT1 with 480–base-pair allele. Several studies have indicated that DAT1 might be more strongly associated with the hyperactive/impulsive or combined subtypes of ADHD. Another early gene studied was the dopamine type D2 receptor gene (DRD2). The gene is not specific to ADHD and is not believed to be a primary cause of the disorder. The dopamine-4 receptor seven-repeat allele gene (DRD4) has been linked to novelty seeking and connected to the impulsivity seen in ADHD. DRD4 has also been related to the inattentive subtype of ADHD. The synaptosomal-associated protein 25 gene (SNAP25) codes for a protein involved in neurotransmitter regulation and axonal growth. Researchers have found an association between SNAP25 and sensitivity to methylphenidate (MPH) adverse events in preschoolers with ADHD. Genes that code for dopamine β-hydroxylase (DBH), catechol-O-methyltransferase (COMT), dopamine 5 receptor gene, norepinephrine transporter gene (SLC6A2), serotonin transporter gene (SLC6A4), α-2A adrenergic receptor (ADRA2A), thyroid receptor B gene, androgen receptors, and factors in immune function and regulation have also been reported to correlate with ADHD symptoms. Subsequent studies and meta-analyses have not sufficiently supported the association between ADHD and these genes.

GENOME-WIDE SIGNIFICANT COMMON VARIANTS. Genome-wide association studies (GWAS) scan the entire genome to detect common DNA variants having small etiologic effects. GWAS assay hundreds of thousands or even millions of single nucleotide polymorphisms (SNP). Thus, genome-wide statistical significance must have extremely high “p” values and very large samples. Such a large sample was formed by the consortium of ADHD researchers who carried out a GWAS meta-analysis of 12 studies involving 20,183 people with ADHD and 35,191 children and found 12 independent loci (Demontis et al., 2019) which reached significance. Loci identified

Telegram: @medical_k

www.konkur.in

include loci pertaining to dopamine regulation, educational attainment, and speech and language disorders. The GWAS analyses also showed that much of ADHD's heredity is due to the polygenic effects of many common variants each having a very small effect.

GENOME-WIDE ASSOCIATION STUDIES AND COPY NUMBER VARIANTS. Copy number variants (CNV) of the genome often delete or duplicate a large genome segment spanning part or even the entire gene. They clearly affect gene functioning. Such deletions and duplications are overrepresented in ADHD samples and significant effects have been found for small CNV. It has been shown that CNV affect the metabolism of glutamate receptor genes which may be associated with cognitive and clinical impairments of ADHD. Magnetic resonance spectroscopy showed dysregulation of glutamate–glutamine concentration in ADHD patients. The area of genetics in ADHD is evolving and the picture is far from complete. However, the strong heritability of this condition is clear.

Neuroanatomical Aspects

Investigators have postulated the presence of an anterior attention network for promoting multiple aspects of attention, including focusing, executing, sustaining, and shifting functions. The attention networks are widespread through the cortex of the brain and are closely related to the default mode network described by Castellanos and others. MRI studies suggest that there are structural abnormalities in the brains of children with ADHD, including differences in the frontostriatal areas, temporoparietal lobes, cerebellum, basal ganglia, corpus callosum, amygdala, hippocampus, and thalamus. A meta-analysis of voxel-based morphometric (VBM) studies by Nakao and colleagues of children and adults with ADHD found global reductions in gray matter volumes, especially the right lentiform nucleus extending to the caudate nucleus, with slightly larger gray matter volumes in the left posterior cingulate cortex. These areas were demonstrated to normalize with age as well as with stimulant medication treatment. Developmentally, children with ADHD

Telegram: @medical_k

www.konkur.in

have a 3- to 5-year delay in cortical thickness maturation, particularly in the frontal and temporal brain regions. Diffusion tensor imaging (DTI) studies show white matter tract abnormalities and dysfunctional connectivity in ADHD during rest and while engaging in cognitive tasks.

Recent studies with larger samples by Hoogman et al. found lower surface area values in the frontal, cingulate, and temporal regions, with the largest effect being in total surface area and decreased cortical thickness in the fusiform gyrus and temporal lobes in children with ADHD. Neither surface area nor thickness differences were found in groups of adolescents and adults with ADHD, again suggesting some normalization occurring with age.

In a study using machine learning analysis of MRI data, significant differences were found in children and adults with ADHD compared to controls. However, prediction performance and effect sizes were better for the child versus the adult samples, suggesting greater differences in children versus adults with ADHD.

Deficits in neural activity within frontostriatal and frontoparietal circuits are consistent findings in ADHD. Functional MRI studies using cognitive tasks to target the neural circuits show significantly reduced frontal lobe activity in subjects with ADHD compared to controls. Meta-analysis shows hypoactivation in the frontoparietal and ventral attention networks in children with ADHD, areas that control goal-directed executive processes and decision making. Hart and colleagues found that right dorsolateral prefrontal cortex activation was reduced in medication-naive patients, but normal in long-term stimulant-medicated patients. Electroencephalography (EEG) studies have reported an elevated theta/beta ratio (TBR) in subjects with ADHD versus controls; however, increased theta band activity has also been associated with substance use and bipolar disorder. Recent meta-analysis determined that excess theta and elevated TBR was not a reliable diagnostic measure for ADHD but could have prognostic value for treatment outcome.

Neurotransmitters in ADHD

Telegram: @medical_k

www.konkur.in

The nonspecific catecholamine hypothesis of ADHD posits that the psychophysiology of ADHD symptomatology emerges from an imbalance among various neurotransmitters, including norepinephrine, epinephrine, and dopamine. Human studies investigating the catecholamine hypothesis of ADHD produced conflicting results, possibly due to the difficulty of measuring brain levels of these neurotransmitters in peripherally obtained samples.

Dysfunction in brain norepinephrine systems, particularly a lack of inhibition of locus coeruleus neurons, could explain the inattention, cognitive deficits, and higher levels of gross motor activity seen in children with ADHD. Randomized clinical trials (RCTs) have suggested that the norepinephrine reuptake inhibitors (NRIs), tricyclic antidepressants (TCAs), and atomoxetine (ATX) are effective in reducing ADHD symptoms by restoring a more normal ratio of epinephrine and norepinephrine. Molecular genetic studies have targeted genes that code for dopamine receptors, and positron emission tomography (PET) scans in adults with ADHD have provided imaging data that correlate stimulant-driven increases in dopamine concentration. There is weak evidence for serotonin's role in ADHD. Medications that exclusively affect serotonin function, such as the selective serotonin reuptake inhibitors (SSRIs), have no efficacy in the treatment of children with ADHD. For that reason, serotonin is thought to play a secondary role in the pathology of ADHD.

Recently, the glutamate neurotransmitter system has also been implicated in ADHD. It has been reported that CNV in glutamatergic genes were associated with cognitive and clinical impairments of ADHD. In addition, a pharmacogenomic GWAS study found SNP in glutamate receptor genes (e.g., GRM7) was one of the most significant findings. Thus, the glutamate neurotransmitter system may also have a role in ADHD, and this impact needs to be elucidated.

Environmental Factors

ADHD has been associated with numerous environmental factors, although it is difficult to conclusively determine causality. In utero risk factors that have been associated include prenatal exposure to

Telegram: @medical_k

www.konkur.in

alcohol, nicotine, recreational drugs, glucocorticoids, poor maternal diet, and maternal stress during pregnancy. Perinatal ADHD risks include prematurity, low birth weight, and obstetric complications. ADHD has been associated with childhood illnesses such as meningitis, encephalitis, cardiac disease, thyroid disease, epilepsy, head trauma and concussions, autoimmune and metabolic disorders, and in survivors of pediatric brain tumors. Psychosocial adversity including poverty, childhood maltreatment, negative parenting, family discord, and bullying have all been associated with ADHD. It has been difficult for investigators working with children affected by adversity to determine whether their ADHD symptoms reflect a response to negative parenting, a harsh environment, a genetically influenced biologic problem, or some interaction among these factors.

Dietary Influences. Dietary factors as a cause and possible treatment of ADHD are controversial. There have been reports of a connection between ADHD and nutritional deficiencies of essential fatty acids (omega-3 and omega-6) as well as mineral deficiencies (e.g., zinc, copper, and iron), but the beneficial effects of supplementation are inconclusive. Some studies have indicated that a small subset of children may have sensitivity to certain food additives, excess refined sugar intake, or nutritional deficiencies (such as fatty acids or iron), causing behavioral effects. There has been some previous support for elimination diets to treat ADHD, such as the Feingold (additive and salicylate-free) diet, oligoantigenic (hypoallergenic) diet, and ketogenic diet. However, in 2011, the U.S. Food and Drug Administration (FDA) determined that existing data do not support a causal link between additives and behavioral disturbance in children.

DIAGNOSIS AND CLINICAL FEATURES

The diagnosis of ADHD requires the integration of data from multiple sources, including clinical interview, direct observation, behavioral rating scales, and the subjective observations of parents and teachers. Most children with ADHD are referred for care because of

Telegram: @medical_k

www.konkur.in

impairment in academic, family, and/or peer relationship functioning. Symptoms of impulsivity, overactivity, and inattention drive this impairment across the lifespan.

Clinical Features

DSM-5 Diagnostic Criteria. DSM-5 criteria were outlined previously in this chapter. We will here elaborate on key symptoms and their presentation.

Hyperactivity. Hyperactivity describes the inappropriate excessive motor activity observed in ADHD, including restlessness, fidgeting, and appearing to be “driven by a motor.” These behaviors are often first noticed when the child is a toddler but can be normative before age 4. The level of gross motor activity usually decreases with age, however, the inner sense of restlessness may continue into young adult life. Children with ADHD display sustained levels of high activity in different settings such as home, school, and playgroup. Activity increases occur during sleep as well. Hyperactivity may be absent in novel situations or when the child is engaged in an activity they find particularly engrossing, such as playing video games.

Impulsivity. Impulsive actions occur without forethought about consequences and may be associated with a desire for immediate rewards or to avoid delay. Impulsivity might be seen when the child engages in dangerous activities, yells out in class, or interrupts or intrudes on others during games or conversations. Impulsive behavior might also result in trouble with parents, teachers, or other children, including verbal or physical fights. Children with ADHD can demonstrate overly quick and error-prone performance on standardized tasks. Symptoms of impulsivity can persist into adulthood, even after hyperactive symptoms have diminished.

Attentional Difficulties. Inattention includes difficulty sustaining focus, trouble maintaining organization, and being easily distracted by extraneous stimuli. The symptoms of inattention often become prominent in elementary school, when the child is approximately 8 to

Telegram: @medical_k

www.konkur.in

9 years old, and symptoms can be lifelong. Attentional difficulties are most often seen in routine settings in which the youth with ADHD must sit and carry out tasks that involve repetition under conditions of low levels of reinforcement and external motivation. Sluggish cognitive tempo (SCT) is a type of attentional difficulty that has been closely associated with the inattentive subtype of ADHD. SCT describes a constellation of symptoms such as daydreaming, staring, tendency toward confusion, mental fogginess, sleepiness, apathy, and physical hypoactivity. There is growing evidence suggesting that SCT is a condition distinct from ADHD; however, SCT is currently not considered a separate disorder or diagnostic subtype.

Associated Factors. Children with ADHD might have areas of impairment that are not listed under the DSM-5 symptom criteria covered exactly by the 18 symptom exemplars of hyperactivity, impulsivity, or inattention. Children and adolescents with ADHD often show difficulty with time management and do not develop an internal sense of pace in planning tasks. This poor sense of time leads to problems in estimating the actual difficulty of waiting in line, planning how much time a task requires, or even knowing when to come home when out playing with other children. Children with ADHD often lack persistence and can become bored playing interactive games with peers. They also find it difficult to delay gratification.

Neuropsychological testing and normalized rating scales such as the Behavior Rating Inventory of Executive Function (BRIEF) have found that individuals with ADHD demonstrate impaired executive functioning, including abnormal response inhibition. On any given measure of executive function, less than half of children with ADHD have been found to be impaired. Executive functioning problems also occur in other psychiatric disorders of childhood, such as depression, and are not specific to ADHD. It has been shown that academic functioning is more strongly affected by an impulsive need to get through tests quickly, a deficit closely linked to poor behavioral inhibition, rather than poor executive functioning.

ADHD is often associated with problems in emotion regulation, resulting in temper outbursts, mood lability, and reactivity. Moods can

Telegram: @medical_k

www.konkur.in

change dramatically with no obvious connection with what is going on in the environment. Social skills are often significantly impaired in children with ADHD compared to controls. Individuals with ADHD may have problems accurately interpreting nonverbal social cues and have trouble cooperating with other children and following rules in games. Peers identify these individuals as intrusive, bossy, and insensitive to the needs of others. Children with ADHD often overreact and respond to frustration in social situations which can lead to verbal or physical aggression. This is a strong stimulus for peer rejection, which has been shown to be a reliable long-term negative predictor of development, particularly in adolescence.

MEDICAL AND LABORATORY EXAMINATION

Children with ADHD should be given a medical evaluation, including a thorough history and physical examination, to rule out physical disorders that can mimic the symptoms of ADHD. The medical history should cover the prenatal, perinatal, toddler, and preschool phases of development. Inquiries should be made about pregnancy complications, such as maternal illness (eclampsia, diabetes), maternal smoking, alcohol, or illicit drug use. The perinatal period should identify the presence of labor problems, delivery complications, prematurity, jaundice, and low birth weight. Feeding and sleeping routines during the perinatal and postnatal periods need to be described. Developmental milestones, illnesses, injuries, and symptomatology need to be reviewed. A detailed family, medical, and psychiatric history should be completed.

The medical history should include specific questioning about any past heart disease, syncope, dizziness, chest pain, shortness of breath, or palpitations at rest or exertion in the child. In addition, it is recommended to screen for family cardiovascular history including sudden death, early-onset cardiac disease, arrhythmias, or prolonged QT syndrome. It is also helpful to document a premedication baseline for common side effects such as stomachache, headache, insomnia, or rapid heartbeat.

Telegram: @medical_k

www.konkur.in

The medical examination can identify physical problems that can increase the risk of serious adverse events should a stimulant medication treatment be initiated, including tachycardia, arrhythmia, or abnormalities in blood pressure. Height and weight at baseline should be recorded. Physical examination of a child with ADHD may reveal nonlocalizing neurologic signs, such as poor coordination, dysrhythmias, and overflow movements. Medical problems that might aid in the differential diagnosis, such as petit mal epilepsy, hearing and vision difficulty, thyroid dysfunction, and hypoglycemia, all need to be ruled out. No blood, genetic, or neuroimaging tests are available to diagnose ADHD.

RATING SCALES

Many standardized behavioral rating scales for ADHD have been developed. Rating scales should not be used independently to diagnose ADHD but can be particularly helpful in establishing the presence of core ADHD symptoms in more than one setting. ADHD-specific scales have been found to have greater than 90% sensitivity and specificity if used in the correct population. Clinical advantages of rating scales include the ability to obtain collateral information from different settings and to identify children who require further treatment because, although they are improved, they are not in remission. There are several commonly used rating scales in the public domain to assess for ADHD symptoms. The National Institute of Children's Health Quality (NICHQ) Vanderbilt Assessment scales for parents and teachers are now in their third edition and widely available on the internet (nichq.org), including a scale specific to the preschool population. The Vanderbilt scales also screen for oppositional disorder and conduct disorder (CD), depression, anxiety, school performance, learning, family, and peer relationships, and participation in activities. The Swanson, Nolan, and Pelham (SNAP) scale includes a 26-item form to look at ADHD and oppositional disorder and a 90-item version that includes a broad screen for other disorders and problems and which has been subject to psychometric validation. More recently, The Strengths and Weakness of ADHD-

Telegram: @medical_k

www.konkur.in

Symptoms and Normal Behavior (SWAN) scale was developed to evaluate attention and behavior dimensionally, from below average to far above average. Proprietary scales such as the ADHD RS and Conners must be purchased but have the advantage of being consistent with DSM-5 and including psychometrically validated age and gender scoring paradigms. The Conners scales, now in their fourth edition, include forms specific to preschool, adolescent self-report, and comprehensive screening for a wide range of problems. The Weiss Functional Impairment Rating Scale has a parent and self-report version that evaluates the specific symptom-driven impairments a patient may experience. This is helpful in identifying those areas of functional impairment that may not respond to medication treatment alone and require other targeted interventions.

DIFFERENTIAL DIAGNOSIS

A clinician must make a differential diagnosis when judging whether a patient meets criteria for ADHD. The distinction between differential diagnosis and comorbidity is not well defined in the DSM-5. If the impairing condition is best accounted for by another disorder, that other disorder rules out ADHD. Conditions whose symptoms mimic those of ADHD should be considered and ruled out when possible, with attention to the possibility of either medical or psychiatric comorbid diagnoses.

For example, symptoms of inattention may be present in medical conditions such as hypoglycemia, petit mal epilepsy, substance abuse, sleep apnea, and hypothyroid or hyperthyroid conditions. Disrupted or poor sleep quality may present with tiredness, as well as difficulties with inattention, learning, and impulse regulation. Children undergoing ADHD evaluation should also be screened for clinical signs and symptoms suggestive of sleep apnea mimicking ADHD.

Symptoms of ADHD may also be present in psychiatric illnesses such as anxiety, depression, oppositional defiant disorder (ODD), and early psychosis in adolescents. The symptoms of children with oppositional defiant behavior must be distinguished from the reluctance and resistance that children with ADHD exhibit when they

Telegram: @medical_k

www.konkur.in

avoid effortful mental tasks. For children with intellectual disability, inattention may be a natural accompaniment of the intellectual limitations, so the diagnosis of ADHD should only be applied if that symptom is excessive for the mental age of the child and the impact of intellectual challenges has been ruled out.

Furthermore, children who experience traumatic events (e.g., serious injury, physical/sexual abuse, neglect, violent acts, unexpected death of a loved one, life-threatening disasters, or parental divorce) can develop a stress response that mimics ADHD symptoms, including disorganization, difficulty concentrating, distractibility, and difficulty sleeping.

Symptoms of impulsivity, gross motor hyperactivity, or inattention may also appear during the use of medications, such as the akathisia that accompanies second-generation antipsychotics or from bronchodilators. Such children should not receive a diagnosis of ADHD, but one of other substance-related disorder.

COURSE AND PROGNOSIS

Parents often notice very high levels of gross motor activity when the child with ADHD is a toddler, just when the child has learned to walk independent of the parents' help. However, the energy, oppositionality, and curiosity of toddlers can be confused with the excessive, almost random motion of older children with ADHD, so that one must be cautious when applying the ADHD diagnosis to a preschooler. Usually, the ADHD diagnosis is first applied in primary school, during grades one to six, when adjustment to the sedentary learning style is compromised. School-aged children with ADHD may experience academic failure and peer rejection. Behavior problems at school and at home are not infrequent, with ODD being a common comorbidity.

During childhood, 65% to 75% of children with ADHD have one or more comorbid conditions, which in addition to ODD, can include conduct disorder (CD), anxiety and mood disorders, tics or Tourette syndrome, learning disorders, and autistic spectrum disorders. Many of these comorbidities continue into adolescence.

Telegram: @medical_k

www.konkur.in

In adolescents, the external overactivity lessens but the internal restlessness does not. The adolescent with ADHD continues to have academic and social problems which erode self-esteem and at times promote the gravitation to a negative peer group. Thus, adolescents with ADHD who are untreated, compared to peers with no mental disorder, have a threefold increase in substance use and abuse, more frequent delinquent acts and trouble with the law, and increased rates of car accidents when they begin to drive. Adolescents with ADHD also start sexual intercourse earlier, with a higher number of sexual partners and greater frequency of unprotected sex and corresponding higher rates of sexually transmitted infections and unwanted pregnancy. The rate of depression and anxiety also increases in adolescence because of the many functional problems due to increasing demands and decreasing supports.

Approximately 60% of children with ADHD continue to be impaired well into adult life, with prevalence estimates suggesting that 4% of adults may suffer from ADHD. In adulthood, hyperactivity may be expressed by inner feelings of restlessness, inability to relax and excess talkativeness, fidgeting, and inability to remain seated for long periods of time, for example, in meetings, symposia, or in church. Impulsivity may be expressed in impatience, interrupting others, acting without thinking, and ending or starting ventures on impulse, for example, jobs, relationships, and at times sensation-seeking behavior. Inattention is seen in distractibility, disorganization, chronic lateness, or missing appointments. The distraction and disorganization often result in careless mistakes and forgetfulness. Procrastination is another important problem. Even when things are started, they are often not finished and so deadlines are thus missed.

The inattention and distractibility also make it appear that the adult with ADHD is not interested and not listening to what is being said. This can strain relationships at home and at work. Some adults with ADHD also suffer from labile moods and “short fuses.” These characteristics, coupled with the problems described above, result in more frequent losses of jobs and relationships. The consequences of this are lower job status, lower income, and a sense of underachievement or failure on the part of the adult with ADHD. The

Telegram: @medical_k

www.konkur.in

inattentiveness and impulsivity also increase the likelihood of driving accidents, and infractions or other types of accidents are also more prevalent. In general, adults with ADHD may have an unhealthy lifestyle, with smoking, alcohol and drug abuse, risky sexual behavior, and chronic sleep problems frequently seen.

In adulthood, comorbidity is the rule, with more than 75% of adults with ADHD having at least one comorbid condition. Anxiety, depression, substance use, and some personality disorders are the most common comorbidities. Gambling and other addictions are also frequently seen.

Prospective follow-up has found that age is associated with a decline in symptoms, but less often with full functional remission. Hyperactive and impulsive symptoms tend to decline at a higher rate than inattention symptoms. It should be noted that even though the male/female ratio in children with ADHD can be 3 to 4:1, in adulthood it is 1:1. It is possible that many girls who tend to be less disruptive are not identified or referred in childhood but have significant impairment as adults and seek help then.

TREATMENT OF ADHD

The efficacy of both medication and psychosocial interventions for the treatment of ADHD has been well established. Treatment with ADHD medications reduces educational underachievement, accidental injury, bone fractures, traumatic brain injury, substance use, cigarette smoking, sexually transmitted infections, teenage pregnancy, depression, suicide, and criminal activity. Nonmedication treatments for ADHD are less effective than medication treatments for ADHD symptoms but are frequently useful to help problems that remain after medication has been optimized. The preferences of families and availability of services largely guide the choice of treatment.

Stimulants

Stimulants are considered first-line agents to treat ADHD symptoms based on decades of proven safety and efficacy. Therapeutic effects of stimulants include a decrease in hyperactivity, impulsivity, and

Telegram: @medical_k

www.konkur.in

inattention, as well as improvement in associated behaviors. The two groups of stimulant medication that have received U.S. FDA approval for the treatment of youth with ADHD are MPH and amphetamines (AMP). There are approximately 30 stimulants on the market in the United States, many in both generic and branded versions (see Table 44.1–1 for brands, dose, onset, and duration of action). Stimulants are classified with drugs that can be abused or cause dependency under the category of schedule II–controlled substances by the U.S. Drug Enforcement Agency (DEA) (Table 44.1–1). In choosing between preparations, clinicians need to consider the needed duration of action, flexibility of dosing, time of day of impairment, time of day when maximum drug is released, whether the child can swallow pills, availability, and cost. Whenever possible, single-day dosing is helpful in improving compliance and coverage. Adherence and persistence with stimulant treatment have been problematic and can be managed by addressing efficacy and side effects and frequent follow-up. In addition, direct instruction, use of a pill box, and parental supervision, monitoring, or use of digital interventions can help patients to remember to take their medication.

www.konkur.in

Table 44.1–1. Methylphenidate Formulations

Generic Name	Formulation	Doses	Duration of Action	Comments
Methylphenidate Products				
Short Acting				
Methylphenidate immediate release	Tablet, chewable or solution	5, 10, 20 mg Solution 5 mg/5 mL Solution 10 mg/5 mL Chewable	2–4 hours	
Dexmethylphenidate Immediate release	Tablet	2.5, 5, 10	4–6 hours	
Intermediate Acting				
Modified release methylphenidate	Capsules	10, 20, 30, 40, 50, 60 mg	8–12 hours	Onset of action 1.5 hours
Methylphenidate Extended release	Chewable Extended-release suspension	20, 30, 40 mg 25 mg/5 mL	8–12 hours	
Long Acting				
Methylphenidate multi-layer release	Capsule	10,15, 20, 30, 40, 50, 60 mg	10–12 hours	Beads can be sprinkled
OROS methylphenidate	Capsule	18, 27, 36, 54 mg	10–12 hours	22% release in the morning, 78% release in the afternoon
Dexmethylphenidate extended release	Capsule	5, 10, 15, 20, 25, 30, 35, 40 mg	12–14 hours	Can be sprinkled
Methylphenidate extended release	Oral disintegrating tab Extended-release suspension	8.6, 17.3, 25.9 mg 25	10–12 hours	
Delayed release, extended release methylphenidate	Capsule	20, 40, 60, 80, 100 mg	22 hours	Given at night with delayed release of drug for morning onset of action
Methylphenidate transdermal system	Skin patch	10, 15, 20, 30 mg	Depends on how long patch is on	Onset of action 2 hours after applying patch. Patch must be removed at 9 hours.
Methylphenidate long acting	10, 20, 30, 40 mg		10–12 hours	
Methylphenidate extended release	Extended-release suspension	25 mg/5 mL	10–12 hours	
Methylphenidate multi-layer release	Capsule	25, 35, 45, 55, 70, 85	13–16 hours	Can be sprinkled

Pharmacology and Pharmacokinetics. Psychostimulants increase central nervous system activity in brain regions and increase blood pressure and pulse in the periphery. Although the exact mechanism of action is not completely understood, stimulants increase the concentration of dopamine and norepinephrine in the synaptic cleft. MPH appears to act primarily as a dopamine–norepinephrine reuptake inhibitor, while AMPs block the reuptake of both norepinephrine and dopamine as well as facilitate dopamine release. Some patients respond selectively to either MPH or AMP, with the majority of patients responding to both. AMP products are approximately two times more potent but may have lower tolerability in children. Dextro methylphenidate (d-MPH) is twice as potent as MPH, since it is the d isomer of the racemic mixture. Medication is introduced at a low dose and titrated up to optimize effect and

Telegram: @medical_k

www.konkur.in

minimize side effects. There are wide differences in interindividual dose–response, so each individual needs to be titrated to their own optimal dose, and dose–response needs to be re-evaluated over time. When switching within the same class of stimulants (MPH or AMPs), direct switching is possible. However, when switching from one stimulant class to the other, decreasing the first class before switching to the second is recommended.

Formulations

FORMULATIONS OF METHYLPHENIDATE. Table 44.1–1 summarizes the commonly used short-acting immediate-release preparations (3 to 6 hours), intermediate acting (8 to 10 hours) and long acting (12 to 16 hours) of MPH and AMP drugs, as well as their availability as a tablet, capsule, suspension, chewable, or patch. These options increase the clinician's ability to provide individualized treatment for patients who need a short onset of action, a particular duration of action, patients who cannot swallow pills, patients who need more medication at the end of the day, or patients who wish to take medication in the evening rather than in the morning. These preparations differ in the pharmacologic mechanism they use to extend drug release. These include the osmotic release oral system (OROS) osmotic pump, use of beads with multiple layers, and drugs that combine immediate- and delayed-release beads. There are also differences between various formulations in the amount of drug released at a particular time of day. Choice between formulations depends on the length of time that a child needs medication and what time of day they are most impaired. There are also differences in time to onset of drug action, which is important in timing the early-morning administration of the drug to assure it is active at the time treatment needs to be effective.

Table 44.1–2. Amphetamine Formulations

Amphetamine Products				
Short Acting				
Dextroamphetamine Immediate release	Tablet, solution	2.5, 5.0, 7.5, 10, 15, 20, 30 mg Solution 5 mg/5 mL	4–6 hours	
Mixed amphetamine salts	Tablet	5, 7.5, 10, 12.5, 15, 20, and 30 mg	6–8 hours	
D, L amphetamine 1:1 ratio	Tablet Oral dissolving tablet	5, 10 mg 5, 10, 15, 20 mg	6–8 hours	
Intermediate Acting				
Dextroamphetamine extended release	Capsules	5, 10, 15 mg	4–9 hours	Onset of action 1.5 hours
d, l amphetamine 1:1 ratio	Tablet Oral dissolving tablet	5, 10 mg 5, 10, 15, 20 mg	4–9 hours	
Long Acting				
Mixed amphetamine salts extended release	Capsule Suspension Oral dissolving tablets	5, 10, 15, 20, 25, 30 mg 1.25, 2.5 mg/mL 3.1, 6.3, 9.4, 12.5, 15.7, 18.8	10–12 hours	Beads can be sprinkled
D, L amphetamine 1:1	Oral dissolving tablets	5, 10, 15, 20	10–12 hours	22% release in the morning, 78% release in the afternoon
Lisdexamfetamine	Capsule Chewable tablets	10, 20, 30, 40, 50, 60, 70 mg 10, 20, 30, 40, 50, 60 mg	12–14 hours	Can be dissolved in liquid

FORMULATIONS OF AMPHETAMINE. Table 44.1–2 summarizes the commonly used AMP medication for ADHD. Although absorption of MPH products is generally not affected by foods, some long-duration preparations of dextro amphetamine (d-AMP) show decreased concentrations when taken with high-fat meals. Whereas MPH is metabolized in the gut wall and plasma by esterases, the metabolism of d-AMP and mixed amphetamine salts (MAS) takes place in the liver. Variants in the human CES-1 gene coding for the hydrolyzing enzyme have led to interindividual variations in MPH metabolism and plasma level.

AMP product package inserts approved by the FDA warn that urinary excretion of AMP metabolites can be increased by foods of acidic content (vitamin C and orange juice), thus lowering plasma concentration. Conversely, foods that shift urinary pH higher reduce excretion and thus increase the plasma concentration of d-AMP or MAS.

Efficacy. A systematic and rigorous meta-analysis of randomized, double-blind, controlled medication trials in 10,068 children and adolescents demonstrated large effect sizes for both AMPs and MPH on parent ratings and large effect sizes for MPH on teacher ratings. Intercontinental Medical Statistics (IMS) data (2015) indicates that the

Telegram: @medical_k

www.konkur.in

majority (52%) of children are on MPH products, whereas the majority (76%) of adults are on AMP products. The MTA study found that 77% responded to MPH, and an additional 10% of MPH nonresponders responded to d-AMP. Teacher rating scales showed significant reductions in ADHD symptoms for stimulants compared with placebo, with effect sizes ranging from 0.8 to 1.0 on behavioral measures and an effect size of 0.5 for cognitive measures for those children randomized to active drug. Placebo response rates in controlled studies have ranged from 17% to 40%, and for reasons that are unclear have increased over time. The Preschool ADHD Treatment Study (PATS) determined that preschool-aged children required lower optimal doses of immediate release (IR) MPH, experienced higher rates of adverse events, and had a diminished response as compared to school-aged children. Preschool children also had a slower clearance of the drug.

AMP and MPH both share the ability to reduce gross motor overactivity, increase sustained attention on tasks, and reduce impulsive responses on laboratory measures. Some individuals respond preferentially to MPH, whereas others respond preferentially to AMP. The majority of evidence indicates that MPH and AMP both have large effect sizes.

Cognitive and Behavioral Effects. Greater effects due to stimulants are found to occur in behavioral domains rather than in cognitive areas. Psychostimulant medications have been shown to reduce gross motor overactivity, out-of-seat behavior, calling-out in the classroom, disruptiveness, impulsive behavior, and noncompliance while improving self-perception, academic productivity, peer nominations of the child, and mother–child interaction. Stimulants have been shown to improve vigilance and reaction time, reduce variability, and enhance short-term memory and learning of verbal and nonverbal material in children with ADHD. The MTA Titration Trial showed a linear dose–response curve for behavioral measures between 0.5 and 1.0 mg/kg/day. Recent controlled trials revealed improvements in school-based productivity,

Telegram: @medical_k

www.konkur.in

grade point average, test scores, and reading attendance in children with ADHD consistently treated with stimulants.

Adverse Effects

SHORT-TERM ADVERSE EFFECTS. Common side effects of the stimulant medications include decreased appetite, weight loss, delayed onset of sleep, headaches, stomach aches, and small increases in blood pressure and pulse. Most of the short-term side effects can often be dealt with by changing the time or dose of medication, change in diet, and sleep hygiene with or without use of melatonin to improve sleep-onset latency. Headaches tend to abate with time and stomach aches are decreased if medication is administered on a full stomach. Stimulants can also be associated with psychiatric side effects such as an increase in dysphoria, anxiety, irritability, social withdrawal, being “too quiet,” and emotional dysregulation.

Parents may complain of a worsening of behavior when medication is wearing off, sometimes called rebound. Rebound presents the sudden return of more severe overactivity, impulsivity, and inattention alongside increased irritability and emotional reactivity when medication is wearing off than was present at baseline off medication. Attempts to demonstrate their presence in full-day, laboratory classrooms have been unsuccessful, so these effects may be generated as the child interacts with task demands in their natural environment. Use of stimulants with a longer duration of action or a small booster dose of short-acting stimulant medication before the onset of rebound may be helpful. If these measures are not effective, a small dose of a short-acting α-blocking agent shortly before the onset of rebound can be useful.

Infrequent side effects include tics or the unmasking of Tourette syndrome. If the tics are functionally impairing, treatment with an α-blocker may be helpful.

Rare side effects include paranoia or other psychotic symptoms, priapism, choreiform movements, and self-directed behavior, such as lip licking, nail biting, and rubbing of sores. These problems are first

Telegram: @medical_k

www.konkur.in

treated by discontinuing the medication until the adverse event disappears.

Two large recent studies in children and one in adults found that ADHD medications are not associated with an increased risk of severe cardiovascular events. General cardiac side effects of stimulant drugs are an increase in heart rate of approximately 1 to 2 beats/minute and an increase in systolic and diastolic blood pressure of 3 to 4 mm Hg. Stimulants have not been found to induce clinically significant changes in electrocardiographic parameters. The evidence suggests a potential for severe adverse cardiac events in some children with certain forms of congenital heart disease or arrhythmias. Routine electrocardiograms are not recommended prior to initiating stimulants in the absence of concerning physical examination findings or personal or family cardiac history.

Long-Term Adverse Events

EFFECTS ON GROWTH. The use of stimulants in children has been associated with growth suppression. Two large-scale NIMH-supported RCTs have shown that MPH can reduce the rate of height and weight gains in developing children with ADHD. The reductions in linear growth have been approximately 1 cm in height and 2.5 kg in weight during the first year of treatment with stimulants. Net growth loss in adulthood is greater with consistent than inconsistent use of medication, with a maximum loss of about 1.3 inches. Small, single-site studies are discordant concerning whether psychostimulants suppress human growth hormone (HGH) or affect prolactin levels. Clinicians need to regularly monitor the height and weight of children with ADHD treated with psychostimulant medication. Drug holidays during summer vacations increase the probability of growth rebound and thus may mitigate problems of growth deceleration when it occurs.

SUBSTANCE ABUSE. There is no evidence to suggest that the use of stimulants in young people increases the risk for later substance use disorders (SUDs). A meta-analytic study by Wilens and colleagues

Telegram: @medical_k

www.konkur.in

suggests that stimulant treatment in childhood has a protective effect, bringing the risk down to the level of the general population. Other studies have revealed that stimulant therapy neither increases nor decreases the risk for subsequent SUD in children and adolescents with ADHD. Clinicians should take into consideration if family members are currently abusing prescription medication before prescribing stimulants for ADHD.

Stimulant medication can be misused or diverted for the purpose of academic performance enhancement or euphoric effects, with immediate-release stimulants more often misused compared to extended-release formulations. A systematic review of 21 studies indicated the prevalence of psychostimulant misuse in the year prior to the study ranged from 5% to 9% in grade and high school–aged children and 5% to 35% in college-aged individuals. Close monitoring, pill counts, or switching to long-acting, less easily abused formulations should be tried and, if not successful, nonstimulant medication should be employed by the clinician if misuse or diversion is suspected.

Summary of Stimulant Medication. Continuous treatment of children with ADHD with psychostimulants is both effective and safe over the first 2 years. Long-acting preparations provide the convenience of once-daily dosing, better coverage, and reduced stigma associated with taking medication at school and can decrease the potential for abuse. Short-acting forms are useful for younger children who often require smaller doses than are available in extended-release preparations. Many adverse events can be handled by adjustment of dose and/or the time of administration of the medication. Long-term adverse events such as growth rate suppression concern parents but may be managed by instituting drug holidays to permit growth rebound.

Nonstimulant Medication in the Treatment of Children with ADHD

Whereas psychostimulants constitute the first-line treatment for children with ADHD, other medications need to be used for the

Telegram: @medical_k

www.konkur.in

treatment of patients who do not respond to or cannot tolerate stimulants. Some nonstimulant medications, such as Atomoxetine (ATX) and long-acting clonidine or guanfacine, have been approved by the FDA for the treatment of ADHD in children and adolescents. Advantages of nonstimulant medications include longer duration of action and the absence of psychostimulant effects such as behavioral rebound or delay of sleep onset. These drugs provide a moderate rather than a large effect size of stimulants but, nonetheless, provide clinical benefit.

Atomoxetine. ATX, a norepinephren reuptake inhibitor (NRI), is an approved alternative to stimulants. ATX may be considered in individuals where stimulants have failed or parents have refused stimulant treatment. In particular, for patients who are unable to tolerate stimulants because of worsening anxiety or tics, ATX is a reasonable alternative since it may ameliorate these comorbid conditions. ATX is well absorbed after oral administration and is minimally affected by food. At steady state, ATX provides 24 hours of coverage.

ATX is metabolized by the cytochrome P450 (CYP) 2D6 hepatic enzyme system. A fraction of the population are poor metabolizers of CYP 2D6–metabolized drugs. Such individuals may experience elevated plasma concentrations and extended plasma half-life; therefore, very slow initial titration may be required for all patients to prevent excessive dosing of these patients. Patients taking other medications metabolized by CYP 2D6, such as fluoxetine, paroxetine, and quinidine, might show signs of competitive inhibition, namely increased plasma levels of both ATX and the competing drug.

In order to mitigate side effects and to optimize the dose for individual patients with variable 2D6 activity, patients are usually started at 0.5 mg/kg and titrated up slowly with increases every 1 to 2 weeks up to 1.2 mg/kg. Patients who are slow metabolizers may require lower doses, just as patients who are ultrafast metabolizers may require higher doses. The time to therapeutic effect is in the range of 1 to 4 weeks, with full response at 6 to 12 weeks. Early signs of response in the first month are predictive of response at 3 months,

Telegram: @medical_k

www.konkur.in

which can be helpful in encouraging parents to persist with treatment in the absence of the immediate benefits seen with stimulants.

ATX has been shown to reduce ADHD behaviors in children, adolescents, and adults with a medium effect size of 0.5 to 0.7. Common adverse events associated with ATX involve abdominal discomfort, nausea, decrease in appetite, sedation, daytime sleepiness, headache, dizziness, vertigo, irritability, and mood swings. To minimize the risk of stomach aches, ATX is best taken on a full stomach. Minor increases in blood pressure and pulse have been reported and thus should be regularly monitored. Rare adverse events in youth include priapism, disturbances in sexual functioning, increased suicidality, and liver toxicity. ATX has a black box warning of possible suicidal ideation, although more recent studies have questioned if this is actually a concern. Some patients may also experience adverse psychiatric side effects such as new-onset anger or irritability.

α-Adrenergic Agonists. The α-adrenergic agonist agents were initially approved for the management of hypertension in adults. The long-acting α-adrenergic agents guanfacine ER and clonidine ER have been FDA approved as monotherapy and adjunctive treatment of ADHD in children 6 to 17 years old. The immediate-release clonidine and guanfacine have not been approved to treat ADHD, although they are used as second-line or adjunctive agents. Guanfacine has also been found to be effective as an adjunctive agent in improving response to stimulants, particularly in decreasing blowups. The supposed mechanism of action of the α-adrenergic agents involves stimulating α-receptors in the prefrontal cortex leading to improvement of inattention, impulsivity, and hyperactivity. The α-adrenergic agonists are clearly less efficacious than the psychostimulants, with several meta-analyses suggesting a moderate effect size. However, a small multisite, double-blind, RCT showed that children and adolescents comorbid for ADHD and Tourette syndrome benefited from clonidine alone or in combination with MPH, in both cases significantly better than placebo. Guanfacine has proven

Telegram: @medical_k

www.konkur.in

efficacy in reducing oppositional symptoms in children with comorbid oppositional behaviors and ADHD.

Common side effects of the α-adrenergic agents are sedation, fatigue, somnolence, headache, hypotension, syncope, and bradycardia. Clonidine is very sedating and has been used to treat sleep difficulties of children with ADHD, as well as to offset the delay in sleep onset caused by stimulant medications. Guanfacine is a more selective α-adrenergic agonist and is slightly less sedating than clonidine. The α-adrenergic agonists need to be discontinued very slowly to prevent rebound adrenergic overdrive, with hypertension, agitation, fever, headache, tachycardia, chest pain, sleep disturbance, nausea, and vomiting. Families need to be warned of the potential dangers of sudden discontinuation of this medication, even for holidays or weekends with another parent.

Bupropion. Bupropion is an antidepressant with dopaminergic and noradrenergic properties that has shown modest efficacy in ADHD but is less effective than stimulants or ATX. It is available in extended-release preparations that permit once-daily dosing. Bupropion may be considered as an option for patients presenting with significant depression. Starting dose for young adolescents is 75 mg twice a day to a maximum of 200 to 300 mg/day. The doses can be increased once weekly until improvement is noted. Bupropion usually takes 4 to 6 weeks at a therapeutic dose to show effect. Side effects of bupropion include fatigue, dry mouth, insomnia, headaches, nausea, vomiting, constipation, tremor, and skin rash. Seizures will reliably occur if the adolescent's dose exceeds 400 mg/day. This medication is FDA approved for the treatment of depression and smoking cessation, but not ADHD, in individuals older than 18 years of age. Bupropion is considered a second-line, off-label treatment for ADHD.

Other Alternative Medications. Anticonvulsants, including carbamazepine, lithium, and SSRIs have not been shown to be effective for the treatment of ADHD. Second-generation antipsychotic medications such as risperidone have been shown to be effective for

Telegram: @medical_k

www.konkur.in

the treatment of aggression in children with disruptive behavior disorders, especially when combined with parent training and MPH.

Summary of Medication Treatments

Most children with ADHD respond to stimulant medication with good effect on all the core symptoms, making stimulant treatment the first-line medication treatment. If stimulants are ineffective or poorly tolerated, nonstimulant alternatives such as ATX can be used. Monotherapy with α-adrenergic agents is a third choice because they are less effective. Patients with a suboptimal response to stimulants or inability to tolerate an optimally effective dose may benefit from combination treatment with a stimulant and nonstimulant. Clonidine and guanfacine are sedating and have significant cardiovascular side effects. For all these drugs, careful monitoring and slow, cautious discontinuation are essential.

Treatment of ADHD Comorbidities

Tic Disorder. Stimulants alone or in combination with clonidine, guanfacine, or ATX appear to reduce ADHD symptoms in individuals with both ADHD and Tourette syndrome or tic disorders. Although stimulants have not been shown to worsen tics in most patients with tic disorders, they may exacerbate tics in some individual cases. In these instances, decreasing the dose of stimulants, adding α-agonists, or switching to ATX may be alternative strategies. Habit reversal therapy (HRT) and cognitive behavioral intervention for tics are evidence-based therapies that have been shown to be effective for tics.

Seizure Disorder. Children with seizure disorders may also suffer from ADHD. Although there are concerns about psychostimulants, particularly MPH, lowering the seizure threshold, experiencing a first seizure when starting a psychostimulant is extremely rare. Studies of EEG epileptiform activity, seizure rates, or interactions between antiepileptic drugs (AEDs) and psychostimulants have not shown any additional seizure risk. On the contrary, studies have shown that

Telegram: @medical_k

www.konkur.in

children with ADHD and a seizure disorder that is adequately controlled on antiepileptic medications show reduced ADHD symptoms and no change in seizure frequency.

Aggression, Oppositional Defiant Disorder, and Conduct Disorder. Individuals with ADHD and comorbid aggression, ODD, and/or CD require comprehensive intervention which includes pharmacotherapy and psychosocial treatments. Stimulants have been shown in randomized, controlled trials to improve ADHD, aggression, ODD, and CD symptoms. α-Blockers (guanfacine and clonidine) alone or as adjuncts to stimulants have also been shown to decrease ADHD, aggression, and oppositional symptoms. Stimulants also reduced negative social interactions and covert antisocial behavior (stealing and vandalism but not cheating). However, one cannot solely rely on medication to treat children with ADHD and these comorbid conditions. A comprehensive treatment approach which may include parent training, social skills training, and anger management for the child, as well as an appropriate academic program and support, may also be needed. Adjunctive treatment with α-blockers (guanfacine XR or clonidine) can be helpful in managing extreme explosive outbursts. If these are not effective, replacing these drugs with risperidone or aripiprazole can be useful, although this benefit has to be weighed against the risk of the metabolic effects of the latter drugs. Careful metabolic monitoring is essential. Treating aggression, ODD, and CD early and effectively is critical, as long-term consequences of these disorders include later drug and alcohol abuse and antisocial behavior with involvement of the criminal justice system.

Anxiety Disorder. It had been suggested that children with ADHD and comorbid anxiety may be less responsive to and experience more side effects with stimulant medication. The large multimodal study of ADHD (MTA) did not find this to be the case. However, children with ADHD and anxiety disorder seemed to benefit significantly from psychosocial treatment as well as medication. Thus, for children with ADHD and comorbid anxiety, slow and careful

Telegram: @medical_k

www.konkur.in

titration of stimulant medication for the ADHD symptoms is recommended. Evidence-based psychosocial treatments such as cognitive behavioral therapy (CBT), parent training, and social skills training combined with an appropriate academic program and academic support is suggested. However, should all these measures prove inadequate, SSRIs (fluoxetine or sertraline) to address the anxiety can be added.

Mood Disorder. In community samples, major depressive disorder (MDD) in youth with ADHD is more than five times higher than in youth without ADHD. Depressive disorders in youth with ADHD usually occur several years after the onset of ADHD and may be due to the cumulative effects of ADHD-related impairments and negative environmental circumstances they need to cope with. Youth with depression and ADHD have greater levels of psychosocial impairment than those with either condition alone. For individuals with both disorders, depressions start earlier, last longer, are more likely to recur, and have higher rates of suicides and hospitalizations than those who have depression alone.

A combination of pharmacotherapy and psychosocial interventions is recommended for patients who have both ADHD and major depression. In general, as per the Texas Children's Medication Algorithm Project (CMAP), it is suggested that the clinician begin with the most effective medication for the most impairing condition for the patient. Only after the full effect of this medication is determined for both conditions, should a second medication be added to deal with residual symptoms of the second condition. Thus, in some cases of the combination of ADHD and mood disorders, both stimulants and SSRIs may need to be used.

Psychosocial interventions both for the depression, for example, CBT, and the ADHD, for example, organizational, study skills remediation, and appropriate academic and/or vocational programs, may all be needed.

There has been controversy regarding the comorbidity of ADHD and bipolar disorder. Emotional dysregulation and irritability can be an important source of impairment in children with ADHD, and these

Telegram: @medical_k

www.konkur.in

children may require additional and specialized intervention. DSM-5 introduced the diagnosis of disruptive mood dysregulation disorder (DMDD) to assist clinicians in attempting to characterize children who have chronic and frequent severe temper outbursts, anger, and irritability in multiple settings during latency or adolescence. Classical symptoms of bipolar disorder, such as severe elation of mood, grandiosity, racing thoughts, and hypersexuality, are used to confer the bipolar diagnosis. In these circumstances, the bipolar disorder needs to be stabilized with mood stabilizers and/or antipsychotics before stimulant treatment can be introduced.

Developmental Disorders. ADHD symptoms of inattention and hyperactivity are seen in children with intellectual and developmental delays, Autistic Spectrum Disorders (ASD) or both. Stimulants have been shown to be beneficial in both groups, particularly in those children with IQs greater than 50. MPH has been found to be more effective than placebo in reducing symptoms of ADHD in children with autism, and approximately one-third of children and adolescents with autism are on concomitant stimulant treatment. In the Research Units of Pediatric Psychopharmacology (RUPP) study, 49% of children with autism and ADHD responded to stimulants, with up to 18% unable to tolerate stimulant treatment. A trial of guanfacine found a 45% decrease in behavioral but not cognitive symptoms. ATX has also been found to be effective in the treatment of ADHD in autistic children.

Psychosocial Treatment of Children with ADHD

Psychosocial treatment of children with ADHD refers to nonmedication treatment. This type of treatment includes different modalities such as psychoeducation, academic organization skill teaching and remediation, parent training, behavior modification, CBT, social skills training, and individual therapy. Of these modalities, parent training, intensive behavior modification, social skills training, and academic organizational skills have shown efficacy for children with ADHD in controlled trials. Standardized parent training programs have been evaluated in systematic reviews including parent–child

Telegram: @medical_k

www.konkur.in

interaction therapy, friendship coaching, and the positive parenting program. Children with ADHD may also have difficulties regulating emotions and anger management and would benefit from nonpharmacologic interventions to address these potential problems.

Behavioral interventions are the preferred choice of treatment for preschool children with ADHD and are recommended as adjuncts to medication in school-aged children and adolescents. Parent training and intensive behavioral interventions are based on principles that will enhance parenting techniques. These include parental psychoeducation about the course, risk factors, and long-term outcomes of ADHD, as well as education on and encouragement of the use of strategies that will address behavior both in and outside of the household. Techniques such as token economy, contingency management, setting small achievable goals, checklists, and closer attention to a child's behavior especially when the child is behaving appropriately are encouraged. While the effects on behavior and performance in the classroom have been shown, the effects do not tend to generalize to other settings. In practice, behavioral therapy is often carried out in consultation with parents and teachers to establish ideal in-school and home management. However, published trials tend to rely on parent and teacher ratings of improvement but do not have independent evaluators. There is some evidence in recent reviews that, even with blinded assessments, the effects of behavioral therapy persist for improving parenting and decreasing child conduct problems.

Academic interventions can take several forms to aid the child with ADHD. Organizational skills such as time management education are useful and have been shown to be effective. However, for some children, their academic difficulties may have put them behind their peers, and they might also require some level of academic support or remediation. A diagnosis of ADHD may qualify a child for special education or related services, as well as accommodations in a regular classroom. All these avenues should be explored to best support the child's learning.

Certain alternative interventions including physical activity and mindfulness may be useful supplements in the treatment of ADHD

Telegram: @medical_k

www.konkur.in

but have not yet been rigorously studied. Other interventions such as dietary interventions, neurofeedback/biofeedback, and mineral and vitamin supplementations are still largely unproven. Recent studies suggest some benefit from fish oil.

Practice guidelines published for child and adolescent psychiatrists strongly suggest a combination of behavioral interventions, such as parent training or classroom management, alongside pharmacologic treatment in the management of ADHD. This is especially important due to the potential deficits along multiple axes in ADHD, and this combined multimodal treatment would benefit most the children who are responding only partially to stimulant medication or who exhibit a comorbid psychiatric disorder whose impairment is not responding to the stimulant medication.

SUMMARY AND CONCLUSIONS

ADHD is a prevalent condition that begins in childhood but often continues into adolescence and adulthood. It is accompanied by significant academic, occupational, social, and emotional impairment. The patients with ADHD often have other comorbid conditions. These comorbidities include oppositional defiant, conduct, learning, and anxiety disorders in childhood and anxiety, depression, and substance use and abuse in adolescence and adulthood.

Treatment must focus on both the ADHD and the various comorbidities. Thus, pharmacotherapy and psychosocial treatment as well as appropriate academic programs and support are needed for optimal outcome. It must be stressed that ADHD is a chronic condition for which ongoing long-term monitoring and treatment is required to optimize functioning.

SPECIFIC CASE OF CHILDHOOD ADHD

Telegram: @medical_k

www.konkur.in

Ben is an 8.5-year-old adopted boy who lives with his parents and 11-year-old brother. He attends third-grade regular education in his local public school and received special services including speech, physical, and occupational therapy. Ben had suffered several upper respiratory infections at age 2 years requiring several rounds of antibiotics. Developmentally, some motor delays were reported, with crawling by 1 year and walking by age 2 years. He was speaking one word by his first birthday, but by age 3½ years, his expressive language was behind his peers in fluency. He demonstrated difficulties following multipart directions, even though his hearing tested in the normal range.

Ben has had difficulty with daydreaming and wandering about since kindergarten. His teachers complained that Ben did “not seem to listen,” had “poor concentration,” and was constantly “out of his seat.” Ben had never had close friends and other children seemed to avoid him because he could not stick with an activity for very long and he was always “in their space.” Ben’s adoptive parents were drained from the nightly battles over homework and discouraged by his lack of focus and “spaciness.” His inattention and impulsivity put him in danger and caused injury. He had run into traffic on several occasions, even after being hit by a truck with resulting injuries.

Ben’s parents and his third-grade teachers completed the SNAP rating scale. Clinician assessment revealed seven symptoms of inattention. His mother also endorsed all nine symptoms of hyperactivity/impulsivity. These symptoms were moderately to severely impairing across multiple settings, including school, home, peer relations, personal safety, and during athletics.

Ben was started on extended-release MPH at 18 mg daily, which was later increased to 27 mg daily. His teachers reported improvement in attention and hyperactive behavior at school. Homework was no longer such a struggle, and he was noted to play quietly with his toys in the evenings.

44.2 Adult Manifestations of Attention-Deficit/Hyperactivity Disorder

JAMES J. MCGOUGH, M.D., M.S.

Although attention-deficit/hyperactivity disorder (ADHD) was originally conceptualized as a developmental delay of childhood, it is now recognized as a lifespan neurodevelopmental disorder with widely acknowledged adult manifestations. Longitudinal studies indicate that

Telegram: @medical_k

www.konkur.in

a majority of school-age children diagnosed with ADHD continue to have clinically meaningful symptoms and related impairments as young adults. Community epidemiologic studies suggest that prevalence rates of ADHD among adults are among the highest of all psychiatric disorders. Adults with ADHD have patterns of psychiatric comorbidity and neurocognitive deficits similar to children but suffer from a much broader array of functional impairments. Both structural and functional brain imaging studies demonstrate distinct abnormalities in groups of adults with ADHD compared to those without, and genetics studies conducted in adults have replicated pediatric findings. Adult ADHD is associated with significant medical, occupational, economic, and social impacts and has emerged as a major public health concern.

DEFINITION

ADHD was classified as a Neurodevelopmental Disorder in the 5th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and its text revision (DSM-5-TR), reflecting the disorder's initial emergence in childhood and common co-occurrence with other early-onset brain-based syndromes. In a departure from previous editions, DSM-5 fully acknowledged the persistence of ADHD across the lifespan with modified diagnostic criteria for older adolescents and adults to better reflect developmental changes in symptom sensitivity with increasing age. While criteria in younger patients require evidence of six or more inattentive or hyperactive/impulsive symptoms, this threshold was reduced to five symptoms in either domain for the diagnosis of patients aged 17 years and older. This modification recognized that the population prevalence of ADHD symptoms decreases with increasing age, but adults with as few as four symptoms suffer significant clinical impairments compared with similarly aged peers. As in youth, symptoms must have been present for a minimum of 6 months and exceed what is expected for the patient's expected developmental level. Additionally, there must be some evidence of symptoms prior to age 12 with concomitant functional impairments in multiple life settings, such as home, school,

Telegram: @medical_k

www.konkur.in

work, social relationships, or personal activities. Current symptoms must be associated with a clinically significant level of functional impairment. Symptoms cannot occur exclusively during an episode of schizophrenia or other psychotic illness and cannot be better attributed to other psychiatric conditions such as mood, anxiety, dissociative, or substance use disorders.

DSM-5 eliminated ADHD subtypes. Instead, *specifiers* describe the overall clinical presentation evidenced in the prior 6 months. Adults with at least five symptoms of inattention and hyperactivity/impulsivity exhibit the combined presentation. Those with five or more inattentive but fewer than five hyperactive/impulsive symptoms exhibit the inattentive presentation. Those with a minimum of five hyperactive/impulsive but fewer than five inattentive symptoms exhibit the hyperactive/impulsive presentation.

Other specifiers describe disorder severity. *Mild ADHD* is specified when the minimal number of symptoms required for diagnosis occur and functional difficulties are at the threshold for clinical significance. *Severe ADHD* is specified when there are many symptoms in excess of the required threshold, or in the presence of marked functional difficulties in one or more settings. Moderate ADHD is specified when the number of symptoms and associated degree of impairment falls between “mild” and “severe.”

DSM-5 further permitted the diagnosis of “other specified ADHD” when an individual exhibits significant impairment due to ADHD symptoms but fails to meet full diagnostic criteria. In this instance, the clinician should specify which criteria are not met, for example, “other specified ADHD with insufficient symptom number.” Clinicians may also assign the diagnosis “unspecified ADHD” if they choose not to specify which criteria are lacking.

HISTORY

For the first half of the 20th century, the condition now recognized as ADHD was variably referred to as minimal brain damage (MBD), minimal brain dysfunction, or hyperkinesis. While these terms conveyed some expectation that the disorder arose from underlying

Telegram: @medical_k

www.konkur.in

brain pathology, the syndrome was principally viewed as a developmental delay that was most often outgrown during adolescence. This position was maintained in the second edition of the DSM (DSM-II), published in 1968, which placed the diagnostic category *hyperkinetic reaction of childhood* within the grouping "Behavioral Disorders of Childhood and Adolescence." Unique among editions of the DSM, DSM-II further implied that core features of short attention span, restlessness, and hyperactivity were a reaction to unsupportive environments and/or inadequate parenting.

In the 1970s, concurrent with development of the third edition of the DSM (DSM-III), seminal work by Paul Wender and colleagues at the University of Utah identified a group of adults with persistent childhood ADHD symptoms. Wender asserted that symptoms under consideration for inclusion in the DSM revision were developmentally inappropriate for older patients. He proposed the Wender Utah Criteria for Adult ADHD, empirically derived from extensive experience with older patients, as an alternative to the DSM. Wender Utah Criteria required (1) retrospective diagnosis of childhood ADHD made on the basis of patient interview and, when available, confirmation by a third-party informant; (2) evidence of ongoing impairment in adulthood from hyperactive and impulsive symptoms adulthood; and (3) the presence of additional symptoms felt to be typical of adults with the disorder, including mood lability, irritability, impulsivity, disorganization, and poor stress tolerance. The diagnosis could not be made in patients suffering from severe depression, psychosis, or severe personality disorders.

DSM-III, published in 1980, continued to define attention deficit disorder as a childhood condition. However, with some deference to work by Wender and others, DSM-III allowed the diagnosis of attention deficit disorder, residual type, for adults previously diagnosed as children who had ongoing evidence of some symptoms. This category inherently implied that adults could not meet full diagnostic criteria. Text of the revised third edition (DSM-III-R) allowed that ADHD might continue through adulthood in up to 30% of affected children.

Telegram: @medical_k

www.konkur.in

Throughout the 1980s and 1990s, and in the absence of clearly applicable DSM criteria, Wender Utah Criteria were used widely in clinical practice as well as research studies of adult medication response, brain imaging, and genetics. Concurrently, longitudinal follow-up studies of adults previously diagnosed with childhood hyperactivity reported ADHD persistence in 40% to 60% of cases. These converging lines of evidence influenced subsequent DSM revisions and increased recognition of ADHD in adults. Although Wender Utah Criteria had a tremendous impact in promoting initial acknowledgment and study of adult ADHD, their use was largely abandoned as DSM criteria were increasingly applied outside of pediatric age groups. More recently, building on Wender's contributions, there has been renewed recognition of difficulties related to emotional dysregulation in some adults with ADHD, which, while not diagnostic, predict increased risk for comorbidity and functional disability.

In the 1990s, emerging research and several best-selling lay publications spurred widespread public awareness of adult ADHD. These studies and resultant increases in public demand for clinical services catalyzed growing interest in the phenomenology, causes, and potential treatments of adult ADHD. Nonetheless, although the fourth edition (text revision) of the DSM (DSM-IV-TR) provided further leeway for adult diagnosis, it continued to maintain that ADHD symptoms are typically resolved by late adolescence.

Revisions in DSM-5 incorporated more than two decades of research and clinical experience in adults. Enumerated ADHD symptom criteria remained unchanged from those previously identified in field trials of school-age children, but text clarifications were added to reflect developmental changes in symptom presentation that occur with increasing age. The age of onset criterion from previous editions of the DSM was modified from requiring evidence of symptoms and impairment prior to age 7 to requiring some recognition of symptoms alone prior to age 12. In response to studies that demonstrated declining symptom prevalence rates with increasing age, as well as significant functional impairments seen in adults with as few as four ADHD symptoms,

Telegram: @medical_k

www.konkur.in

DSM-5 required only five symptoms in either the inattentive or hyperactive/impulsive domain for diagnosis in individuals aged 17 and older. Finally, descriptions of typical impairments associated with ADHD were broadened to include the range of difficulties frequently seen in adults, notably problems with work, personal activities, social relationships, and general health maintenance. The text revision of the DSM-5, DSM-5-TR did not many any significant changes to this scheme.

Several birth cohort studies suggested the occurrence of adult-onset ADHD in individuals with no history of childhood symptoms, undermining the conceptualization of the disorder as a chronic neurodevelopmental syndrome emerging before age 12. These studies were largely symptom-based and did not require a demonstration of associated functional impairments. One subsequent investigation found that the failure to detect childhood ADHD was a function of higher IQ and lack of comorbidity. Other studies found that over 95% of supposed adult-onset cases failed to retain the diagnosis after comprehensive examination but instead generally suffered from other psychiatric disorders or functional impairments due to heavy substance use. Current evidence suggests that true adult-onset ADHD occurs rarely or not at all. Further research is necessary to better elucidate this question.

COMPARATIVE NOSOLOGY

The 11th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-11) harmonized with DSM-5-TR in renaming the ICD-10 category of hyperkinetic disorders as ADHD and moving it from the grouping of disruptive behavior to the neurodevelopmental domain. Consistent with DSM-5-TR, ICD-11 required *either* inattentive *or* hyperactive/impulsive symptoms, not both as in previous editions, and allows the use of predominately inattentive, hyperactive/impulsive, or combined presentation specifiers. Unlike DSM-5-TR, ICD-11 does not define a precise age of onset, specific symptom number, or duration. Also, unlike DSM-5-TR, ICD-11 continued to exclude the diagnosis in the presence of autism

Telegram: @medical_k

www.konkur.in

spectrum disorder. ICD-11 is the principal classification system used outside the United States and generally relied upon within the United States for insurance billing purposes.

EPIDEMIOLOGY

Epidemiologic studies demonstrated that ADHD is the most common behavioral disorder of childhood, with prevalence estimates ranging from 5% to 10% of school-age children. Longitudinal studies suggest the persistence of the disorder from childhood to adulthood in approximately 65% of cases. The World Health Organization estimates the prevalence of adult ADHD to be 2.8%. However, there is a wide range of estimates across studies and countries (e.g., 1.1% in South Korea vs. 5.8% in Brazil). Differences in reported prevalence rates are deemed related to methodologic differences between investigations. These converging reports confirm that significant numbers of adults suffer from ADHD and related impairments. Unlike other common psychiatric conditions, such as mood and anxiety disorders that are typically episodic, adults with ADHD are apt to experience chronic and unremitting symptoms that require ongoing management.

ETIOLOGY

ADHD is best viewed as a neurodevelopmental disorder that arises from the interplay of genetic and environmental factors. Similar to studies in youth, meta-analyses suggest heritability estimates in the range of 70% to 80% in adults, with approximately one-third of this risk explained by polygenic effects of common variants with small individual effects. Adult genome-wide association studies (GWAS) identified a similar set of risk loci as seen in studies of youth, supporting the conceptualization of ADHD as a neurodevelopmental disorder with a significant genetic overlap with ADHD in children. Approximately one-third of adults with ADHD have at least one child with the disorder, and similarly, one-third of children with ADHD have at least one affected parent. Ongoing investigations will further

Telegram: @medical_k

www.konkur.in

elucidate the genetic, environmental, and gene-by-environment interactions that affect ADHD risk.

Early structural and functional brain imaging studies in groups of adults with ADHD revealed localized dysfunctions in discrete areas of the prefrontal cortex and basal ganglia, similar to findings in children. Longitudinal imaging studies in youth demonstrated maturational delays in cerebral cortex myelination. Some have suggested that cortical maturation is associated with symptom attenuation in adulthood, whereas ongoing subcortical dysfunction predicts symptom persistence. Newer imaging research has shifted from examining distinct anatomical abnormalities to consideration of impaired functional connectivity in brain regions engaged in executive, attention, reward, and default networks. The heterogeneity of imaging findings reflects clinical heterogeneity, but ongoing research might provide insights into the persistence or desistance of childhood ADHD into adulthood

Meta-analyses suggest adult ADHD persistence in 65% of child cases, with some estimated variability due to differing methodologies. Approximately 15% of children demonstrate full diagnostic criteria as adults; an additional 40% to 60% show partial remission. Risk factors for persistence include the severity of childhood ADHD symptoms, the presence of childhood comorbidity, and parental mental health. There is no apparent impact from individual IQ, socioeconomic status, or quality of the parent–child relationship. Comorbid juvenile conduct disorder is the strongest predictor of severe adult outcomes, including increased risk for substance use disorders, criminality, and early mortality. Some evidence suggests that early and sustained medication treatment of childhood ADHD is associated with decreased risk for substance use disorders as young adults.

DIAGNOSIS AND CLINICAL FEATURES

Although parents and teachers generally serve as primary informants in the assessment of pediatric ADHD, adult patients themselves are usually the primary sources of information in their own assessments. Unfortunately, research showed that young adults are frequently poor

Telegram: @medical_k

www.konkur.in

reporters of ADHD symptoms and associated difficulties, although reliability is much improved when patients reach their late 20s. Studies also revealed that both adults with ADHD and parents of these adult children exhibited poor retrospective recall of problems related to childhood ADHD, often reporting ages of onset up to 4 years later than documented in prospectively collected data. As with children, optimal assessment of adult ADHD depends on the clinical synthesis of all available information, including reports of childhood and current difficulties, symptom reports from parents and significant others, school and occupational reports, and a review of pertinent medical records.

Inattention		Hyperactivity and Impulsivity	
Younger Individuals	**Older Individuals**	**Younger Individuals**	**Older Individuals**
Fail to notice small details, make careless errors	Careless, inaccurate work	Frequently fidget, tap hands or feet, squirm while seated	Often fidgety or restless
Difficulty maintaining attention	Problems staying focused on boring work, mind often wanders, trouble with extensive reading	Frequently get out of seat or have trouble staying seated	Can't sit long at meetings or other activities where seating is required
Seem not to listen even when spoken to directly	Trouble retaining what people say even when addressed directly	Often run or climb at inappropriate times	Often feel internally restless or unsettled
Trouble finishing work or following through on instructions	Sidetracked easily, problems following directions or finishing tasks	Have trouble playing quietly; often too loud	Often louder than necessary or appropriate
Problems with organization	Can't prioritize, procrastinate, messy, miss deadlines, and bill payments	Often "on the go," as if "driven by a motor"	Difficulty unwinding or relaxing; always needing to be busy

Telegram: @medical_k

www.konkur.in

Avoid activities that require sustained concentration	Delay and avoid work and other activities that are boring or repetitive	Get in trouble for excessive talking	Talk too much in social settings, don't tolerate silence
Lose or misplace things frequently	Often misplace things needed at home, work, or other activities	Often blurt out answers before questions are finished	Finish others' sentences or answers before questions are completed
Distracted easily when interrupted	Easily distracted by surrounding noises, interruptions, or extraneous thoughts	Have difficulties when waiting for turn or standing in line	Frustrated when needing to wait
Frequently forgetful	Fail to remember appointments, deadlines, and other obligations	Frequently interrupt or intrude	Interrupt others' conversations and activities, socially intrusive

Data from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. text rev. American Psychiatric Association; 2022.

Consideration of an ADHD diagnosis should be given to any adult with long-standing difficulties from inattention or distractibility. A single DSM symptom, "Is often distracted by extraneous stimuli," correctly differentiated 97% of ADHD-affected adults compared with 98% of community controls. One additional symptom, "Avoids tasks requiring sustained mental effort," correctly identified 89% of ADHD cases when compared with other clinical cases without ADHD.

As with children and adolescents, the diagnosis of ADHD in adults is based on DSM-5-TR criteria. DSM-5-TR acknowledged developmental changes observed in adults by requiring only five

Telegram: @medical_k

www.konkur.in

inattentive and/or hyperactive/impulsive symptoms for diagnosis, compared with six for younger individuals. ADHD symptoms in DSM-5-TR are identical to DSM-IV and were initially derived from field trials conducted in school-age children. However, text descriptions in DSM-5-TR provided adult correlates for these symptoms and allow greater applicability to older patients, as summarized in Table 44.2–1.

Diagnosis is based principally on information derived from a clinical interview with the adult patient. The self-administered Adult ADHD Self Report Screening Scale (ASRS), developed under the auspices of the World Health Organization and calibrated to DSM-5, is easily administered and has high diagnostic sensitivity and specificity. A related semistructured interview, the Adult ADHD Clinical Diagnostic Scale (ACDS), probes retrospective childhood and prior 6-month adult ADHD symptoms. ADHD assessment requires careful consideration of potentially comorbid psychopathology as well as a broad range of functional impairments. Common co-occurring conditions include lifetime histories of disruptive behavior and antisocial activities, nicotine dependence, substance use disorders, anxiety disorders, depression, risky behavior, and poor health maintenance. Typical impairments include difficulties in academic, occupational, social, and family functioning.

Many clinicians remain highly skeptical of the validity of adult ADHD and presume that most adults seek the diagnosis to obtain various academic or occupational accommodations or scheduled medications. ADHD symptoms are easily feigned. Clinicians should be particularly suspicious about adults claiming to suffer severe symptom levels without reasonable evidence of prior functional impairments. Several investigations compared individuals pretending to have ADHD with known adult cases and found that malingerers had atypically high rating scale scores and greater numbers of self-reported ADHD symptoms. This finding contrasts with the anticipated age-related symptom reduction typically seen in the disorder. Similarly, on computerized attention tasks, those feigning ADHD made many more errors in omission and commission than individuals with historically validated cases, suggesting deliberate attempts to perform poorly. Some have proposed that computerized performance

Telegram: @medical_k

www.konkur.in

validity tests or symptom validity tests, such as the Exaggeration Index of the Connors Adult ADHD Rating Scale, aid in recognizing malingering, but evidence supporting this approach remains inconclusive. Clinical corroboration of self-reported ADHD symptoms and expected associated impairments with third-party informants, past records, and an overall life course remains the best approach for establishing the adult diagnosis.

Laboratory Studies

There are insufficient data to support the use of neuropsychological tests, computerized tests of attention (CPTs), or brain imaging modalities in the diagnosis of adult ADHD. Neuropsychiatric testing can be useful in differentiating ADHD from specific learning disabilities and other cognitive impairments, particularly with a predominance of inattentive symptoms or a history of school failure. Nonetheless, neuropsychiatric testing has no demonstrated value in assessing ADHD itself. Easily administered self-report measures, such as the Behavior Rating Inventory of Executive Function (BRIEF), can provide evidence of typical ADHD-related cognitive impairments supportive of the diagnosis but fail to identify deficits in half of the cases. Research studies using electroencephalography (EEG), functional magnetic imaging (fMRI), positron emission tomography (PET), and other imaging modalities reveal distinct features in groups of adults with ADHD compared with nonclinical controls. However, these findings have poor predictive value in assigning diagnoses to individual patients, and no evidence supports their utility in clinical settings. As with children and adolescents, adult ADHD remains a clinical diagnosis derived through careful history taking, adherence to clinical criteria, and differential diagnosis of other psychopathology.

Differential Diagnosis

Clinicians should consider a diagnosis of ADHD in any adult patient complaining of pervasive difficulties with inattention, hyperactivity, or impulsivity. Several ADHD symptoms, such as problems with

Telegram: @medical_k

www.konkur.in

sustained attention, motor restlessness, increased speech, and acting “on the go,” are common in other psychiatric disorders. Clinicians must distinguish ADHD from other psychiatric syndromes while remaining sensitive to a high probability of coexisting psychopathology.

Depressive disorders are differentiated from ADHD in that problems with concentration and motor restlessness occur only during periods of dysphoric mood, anhedonia, or increased irritability. Discrete episodes of somato-vegetative symptoms, such as appetite changes and alterations in sleep patterns, further confirm a depression diagnosis. Patients with both ADHD and depression will report ongoing difficulties with core ADHD symptoms that persist outside of discrete mood episodes. Similarly, patients with bipolar I disorder report racing thoughts, rapid speech, and impulsive behaviors only in the context of sustained periods of elevated or irritable mood. Somewhat more controversial is the overlap of ADHD with hypomania and rapidly cycling bipolar disorder. A clear past history of discrete depressive episodes or strong family history might assist in clarifying the diagnosis, but some patients will meet the criteria for both conditions. Anxiety disorders are distinguished from ADHD by subjective worry that is either generalized and difficult to control or specific to situations or stimuli. Patients with substance use disorders and ADHD should have histories of ADHD symptoms that precede the initiation of substance use. Patients with histories of early school difficulties and childhood conduct disorder are likely to be comorbid for both ADHD and substance use. Adults with ADHD and a childhood history of conduct disorder might also exhibit antisocial personality disorders.

Adults with histories of school difficulties and inattentive symptoms in the absence of hyperactivity or impulsivity should be evaluated for specific learning disabilities or other executive functioning deficits. This generally requires a battery of neurocognitive tests to measure academic aptitude and achievement. Patients with significantly idiosyncratic interests and impaired social functioning might also be diagnosed with an autism spectrum disorder.

Telegram: @medical_k

www.konkur.in

Although considerable research has described considerable psychiatric comorbidity in adults diagnosed with ADHD, far less attention has been paid to the prevalence rates of ADHD co-occurring with other adult psychiatric disorders. Evidence suggests up to 16% of adults currently suffering from major depression, 10% with current anxiety disorders, and up to 25% with current substance use disorders meet ADHD criteria. In view of its high overall adult prevalence and associated developmental risk for comorbid psychopathology, all adult psychiatric assessments should include routine diagnostic consideration of ADHD.

www.konkur.in

A 42-year-old woman was evaluated for complaints of distractibility and general nervousness. The patient had spent the past 16 years at home caring for her children. Her youngest child recently began elementary school, and she obtained part-time work as an assistant manager in a large retail department store. She was excited about the position, particularly the flexible work hours and the opportunity to earn extra income for the family. Nonetheless, she reported particular difficulty remaining focused on her job, had general trouble organizing her time, and was in danger of losing her job due to her failure to meet several deadlines. She was tense, irritable, had trouble relaxing, and described difficulty falling asleep because she was worried about what she needed to do the next day. She complained her “mind goes completely blank” when overstressed. She denied depressed mood, loss of pleasure in her usual activities, change of appetite, or suicidal preoccupations.

The patient reported that she was considered a bright student, particularly in elementary school. She enjoyed school but was generally shy and uncomfortable in unfamiliar social situations. Beginning in middle school and throughout college, she felt increasingly bored, easily distracted, and particularly frustrated with long reading assignments. She graduated with a 3.0-grade point average and subsequently worked for 2 years as a retail clerk. She became pregnant soon after her marriage and left her job to raise her family. She described her marriage as “typical,” generally stable and satisfying, with occasional marital tension due to financial stresses and child-rearing. Her middle child, a 12-year-old boy, had been diagnosed with ADHD, which was successfully managed with stimulant therapy and behavioral techniques learned through parent training.

The patient completed an Adult ADHD Self Report Screening Scale (ASRS), which suggested the presence of a high number of symptoms. An ADHD Rating Scale 5 (ADHD-RS-V) completed by her husband reflected a similar symptom pattern. Clinical synthesis of all available information supported an ADHD

Telegram: @medical_k

www.konkur.in

diagnosis with a retrospectively determined age of onset in middle school, a history of impairment at school, work, and home, and a comorbid diagnosis of generalized anxiety disorder.

The treating clinician outlined several options for medication therapy, specifically an initial stimulant trial with subsequent selective serotonin reuptake inhibitor (SSRI) treatment for residual anxiety versus atomoxetine (Strattera) monotherapy. The patient agreed to a medication trial with the main target symptoms of distractibility, nervousness, and sleep disturbance.

On stable medication, she reported improved focus at work, better general organization, less general anxiety, and improved sleep. She was initially followed with monthly medication visits, which were reduced to visits every 3 months once her clinician deemed her to be stable. After 6 months of medication treatment, the patient was pleased to report that she recently finished reading a novel, her first since college. She resolved her initial difficulties at work and was given a commendable employment evaluation. She was feeling less stressed at home but remained troubled by what she viewed as her inadequacies and inability to manage all her responsibilities. In response, her clinician referred her for a brief course of cognitive-behavioral therapy (CBT) to address residual anxiety symptoms and organizational skills.

COURSE AND PROGNOSIS

The prevalence of ADHD symptoms declines with age. Many children with the combined presentation of ADHD exhibit fewer hyperactive-impulsive symptoms by midadolescence and subsequently exhibit the inattentive presentation as adults. Given the age-related decline of ADHD symptoms in the general population, adults can remain significantly impaired relative to same-age peers with fewer symptoms than are required for diagnosis in childhood. This suggests that reported rates of ADHD remission are more a function of syndrome definition than true syndrome remission. Long-term outcome studies of ADHD-affected children are limited, and there are

Telegram: @medical_k

www.konkur.in

insufficient data to draw conclusions regarding the developmental course of ADHD from early to middle adulthood. Between 25% and 45% of ADHD children do not suffer ADHD-related impairments as adults. Nonetheless, many adults with ADHD continue to struggle with the consequences of the disorder throughout their lives.

Adults with ADHD have significant rates of co-occurring psychopathology and limitations in adaptive functioning when compared with unaffected peers. They exhibit higher rates of childhood conduct disorder, with a subset of these developing antisocial personality disorders. Significantly higher rates of substance use disorders are consistently reported compared with adults without ADHD. There is no clear evidence that adults with ADHD prefer one type of recreational drug compared to another, but those who develop drug dependency have a more difficult time achieving sobriety than individuals without ADHD. Similarly, adults with ADHD initiate nicotine use at earlier ages, demonstrate higher rates of lifetime nicotine addiction, and have more difficulty maintaining smoking cessation efforts. Adults with ADHD suffer high rates of lifetime mood and anxiety disorders. The differential impact of comorbid psychopathology on long-term ADHD outcomes has not been adequately studied.

ADHD confers a significant risk for lifetime functional impairments. Lower self-esteem, poorer lifetime academic achievement, less successful work histories, and more failures in long-term relationships are evident. Adults with ADHD often make poor choices regarding personal health, including participation in high-risk activities, unprotected sex, and unsafe driving. Conversely, some of these succeed in making lifestyle adjustments that minimize evidence of impairment. Individuals find occupations for which they are well suited, can live alone or find suitable close relationships, or can utilize other talents that compensate for ADHD-related difficulties. Additional research is required to identify predictive factors that mitigate these impairments.

Telegram: @medical_k

www.konkur.in

A 26-year-old man was evaluated for severe distractibility after being involved in a minor traffic accident. In early grade school, he had particular difficulties making careless mistakes on tests, forgetting his assignments, and sitting still in class. Although he was considered intelligent, he earned average grades, and he had no college aspirations. After high school, he had several short-term jobs in the construction industry, which were enjoyable because he spent most of his time outdoors. In the past year, he obtained part-time work as a wedding videographer and found himself increasingly interested in making and editing videos.

During his clinical interview, the patient described ongoing difficulties maintaining his attention on uninteresting tasks, easy distractibility, problems with time management, generally feeling restless, and frustration when required to sit for extended periods. He endorsed six inattentive and five hyperactive/impulsive symptoms on a DSM-5-TR ADHD checklist of current symptoms. After a clinical interview, the patient was diagnosed with the combined presentation of adult ADHD.

After discussing the nature of ADHD with his clinician and receiving additional educational materials, the man agreed to a medication trial. A once-daily extended-release preparation of stimulant medication was prescribed in escalating doses over several weeks to determine the optimal dose that maximized symptom reduction and minimized side effects. At his follow-up visit, the patient described robust improvement in his ability to focus and was surprised at his increased motivation to attend to the technical details of video editing. After several months, he enrolled in a community college to pursue formal coursework in video production.

TREATMENT

Good long-term clinical care is contingent on adequate patient education about the nature of the disorder and the effects of treatment. Once a diagnosis is made, clinicians should provide

Telegram: @medical_k

www.konkur.in

sufficient information to assist adult patients in choosing treatment options that meet individual patient needs. Given the degree of misinformation about ADHD from the Internet and other lay sources, patients are well served when clinicians guide them to appropriate reference materials. Many individuals are relieved to understand that they have a biologically based condition that is shared by a significant number of other adults. National organizations such as Children and Adults with ADD (CHADD, www.chadd.org) or the National Alliance for the Mentally Ill (NAMI, www.nami.org) provide access to local support networks and reliable educational materials.

Pharmacotherapy remains a treatment cornerstone. Medications found to be useful in the treatment of childhood ADHD are generally shown to be effective in adults. FDA-approved medications for adult ADHD include both stimulants and nonstimulants. Of the nonstimulants, atomoxetine has the greatest amount of clinical trial evidence supporting its use in adults. Medications commonly used off-label include bupropion, immediate alpha-2-agonists, tricyclic antidepressants, and the wake-promoting agents modafinil and armodafinil. Stimulants are the most frequently prescribed ADHD medications in adults, and their greatest clinical effects are seen with robust dosing. One noteworthy difficulty for adults is the frequent necessity for multiple daily dosing, even with extended-release formulations, in order to provide adequate symptom relief throughout the day. College students, in particular, have irregular daily class schedules and might not be best served with reliance on morning-administered extended-release stimulants. Well-considered use of immediate-release compounds is necessary at times to meet the clinical needs of these patients.

Many clinicians are reluctant to prescribe stimulants based on concerns about abuse, misuse, and illicit diversion. Misuse and diversion of prescribed stimulants among college students are common. In most cases, these medications are used with the expectation of improving academic performance, although there are no data to support this outcome. Approximately 30% of stimulant misuse among college-age students is for recreational purposes, that is, to cause euphoria. Misuse for academic purposes is highest

Telegram: @medical_k

www.konkur.in

among white male students attending academically competitive universities, who are in fraternities, are in academic distress, and with prior histories of conduct-disordered behaviors and recreational drug, alcohol, and nicotine use. Several research reports recommend using prodrug and certain extended-release stimulant formulations, deemed less likely to be used for recreational purposes compared with older immediate-release forms if the clinician is concerned about potential misuse. Nonstimulant medications remain an option in patients at high risk for stimulant abuse or misuse. Proper record keeping and thorough documentation of prescriptions written are essential to good practice. When available, clinicians can verify that patients are not obtaining inappropriate amounts of controlled substances by checking prescription records on government-sponsored databases.

As they move toward independent living outside the structure of high school and their parents' homes, transitional-age youth, that is, those ranging in age from 16 to 26 years, have particular clinical needs. During these years, individuals with ADHD have an increased risk for substance use problems, academic underperformance, occupational failures, and relationship difficulties. Treatment adherence and responsible medication use might also be of concern. In working with this age group, clinicians should be particularly mindful of providing adequate counseling regarding responsible sexual activity, alcohol consumption, recreational drug use, and appropriate medication use.

Although many adults have significant lifetime histories of other psychiatric disorders, there have been few treatment studies for comorbid ADHD. Current evidence suggests that clinicians should first initiate therapy for the condition (i.e., ADHD vs. other psychopathology) that is causing the most distress. One example is sequential pharmacotherapy with either a stimulant or SSRI for co-occurring ADHD and anxiety or depression. A particularly vexing problem is whether stimulant medications should be provided to patients with known histories of substance use disorder. It is essential that physicians maintain proper documentation of patients' diagnostic assessments and prescription medication records. Some clinicians are comfortable initiating ADHD pharmacotherapy in the presence of

Telegram: @medical_k

www.konkur.in

intermittent alcohol or cannabis use but are advised against stimulant pharmacotherapy in those patients with chronic use or the use of other psychoactive agents such as opioids or methamphetamine.

There is growing support for certain nonmedication treatments in adult ADHD. The strongest evidence exists for CBT, which has been administered successfully both in individual and group settings. Well-controlled blinded investigations of omega-3 fatty acid supplementation have also yielded small but significant positive effects on ADHD symptoms. Other nonmedication approaches, such as ADHD coaching, mindfulness training, meditation, yoga, cognitive remediation programs, EEG neurofeedback, and the use of digital technologies such as electronic scheduling and reminder systems, remain popular, despite a lack of sufficient scientific data to support their general use. Individuals are best served when psychosocial interventions are individually tailored to their own specific difficulties. For example, patients who suffer from marital or relationship difficulties might be referred to couples therapy. The emphasis in this treatment should be on the couple's relationship problems, not the individual's ADHD. Parents might benefit from participation in a parenting course, particularly if they themselves have children with ADHD. Insight-oriented psychotherapy might be useful for some patients with significant self-esteem or interpersonal difficulties.

Proper management of adult ADHD is also likely to include appropriate educational planning and consideration of academic and occupational accommodations. Occupational counseling and vocational training can be better options for some individuals than insistence on attending a 4-year college. Adults who attend college should be referred to their school's office for students with disabilities. The Americans with Disabilities Act (ADA) has particular implications for adults with ADHD. Regulations implementing the ADA require that *reasonable* accommodations be made in areas of education and employment for individuals with documented disabilities. Colleges and universities develop their own guidelines for the provision of special accommodations based on Federal mandates. At higher-grade levels and for standardized testing at the college level and beyond, it is generally necessary to conduct formal

Telegram: @medical_k

www.konkur.in

neuropsychological testing to document ADHD-related learning impediments prior to granting accommodations. In occupational settings, the ADA requires that reasonable accommodations be made for persons with disabilities but does not require that anyone be hired for a position who is not otherwise qualified. It is essential that thresholds for disability be determined in reference to population or societal norms and not speculations about the individual's potential capabilities. *Reasonable* accommodations should have minimal impact on employer expectations, job performance, and coworkers.

www.konkur.in

A 19-year-old woman was evaluated at a drug rehabilitation center for methamphetamine dependence. In early grade school, she was extremely hyperactive, reckless, and prone to impulsive judgments. Her father suffered from alcohol dependence and was physically abusive to her and her mother. She began smoking cigarettes at age 11 and using alcohol and marijuana at age 12. At age 13, she was raped by a high school senior whom she had been dating. Two years later, she quit high school and ran away from home. She began smoking crystal methamphetamine the previous year and was court-ordered for drug evaluation after an arrest for prostitution.

A careful history of early school experiences revealed significant problems with distractibility, completing assignments, sitting still in class, and general irritability. On a DSM checklist assessing childhood symptoms, she endorsed six inattentive and eight hyperactive/impulsive symptoms. Currently, she endorsed five inattentive and six hyperactive/impulsive symptoms, general dysphoria, fatigue, anhedonia, and suicidal preoccupation.

The patient enrolled in a long-term, court-funded residential treatment program for drugs and alcohol. After several weeks her mood symptoms diminished, but she continued to suffer from marked inattention, distractibility, and restlessness. After careful consideration, her physician initiated nonstimulant medication treatment for ADHD. At discharge from her residential program, she resolved to stay in outpatient drug treatment and obtain part-time work. At the 1-month follow-up, she described a good response to treatment and had begun studying to obtain a general equivalency diploma (GED). Her physician continued to monitor her on a monthly basis with intermittent, unannounced drug testing to monitor ongoing sobriety.

FUTURE DIRECTIONS

Ongoing advances in neuroscience are apt to increase the acknowledgment of adult ADHD as a biologic syndrome. Changes in

Telegram: @medical_k

www.konkur.in

clinical practice increasingly reflect a shift from viewing adult ADHD as a unique and rare phenomenon to routine consideration of ADHD both alone and as potentially comorbid with other traditional adult psychopathologies. There will be ongoing interest in developing medication treatments with less perceived potential for abuse and longer durations of effects. Concurrently, there will be sustained efforts to develop effective nonmedication therapies. Although revisions made to ADHD criteria for DSM-5 and DSM-5-TR better reflect the developmental aspects of the behavioral phenotype, ongoing research will increasingly focus on the identification and modification of underlying dysregulation in brain neural networks. Such discoveries would raise the possibility of early identification of risks and treatments that target specific dysregulated systems in individual patients.

Disruptive Behavior Disorders in Children and Adolescents

Erin P. Vaughan, M.A., Eva R. Kimonis, Ph.D., M.S., and Paul J. Frick, Ph.D.

Oppositional defiant disorder (ODD) and conduct disorder (CD) are included in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders, Text Revision (DSM-5-TR) in the chapter on disruptive, impulse control, and conduct disorders. The disorders included in this chapter all involve problems with the self-control of emotions or behavior. While many disorders included in the DSM-5-TR also involve problems with emotional and/or behavioral regulation, the disorders listed in this chapter are unique in that the problems in regulation bring the individual into significant conflict with societal norms (CD) or authority figures (ODD) or violate the rights of others (CD). Importantly, the DSM-5-TR and its global public health counterpart, the International Classification of Diseases 11th Revision (ICD-11), recognize the causal heterogeneity involved in the self-control problems of individuals who meet ODD and CD diagnostic criteria. Further, many of the symptoms that define ODD and CD occur to some degree in typically developing individuals, making it important to diagnose these disorders in the context of what is normative for a person's age, gender, and culture, while also considering the degree of impairment that is associated with the symptoms of the disorder.

Considered together, ODD and CD are among the most frequent reasons for children and adolescents to be referred to psychology and psychiatry clinics. This is because these disorders cause significant disruption to those around the child and are associated with a high degree

Telegram: @medical_k

www.konkur.in

of concurrent impairment. Children and adolescents with ODD or CD are at risk for a variety of other mental health problems (e.g., anxiety, depression, substance use), social problems (e.g., peer rejection, conflict with parents, siblings, and teachers), academic problems (e.g., school suspension and dropout), and legal problems (e.g., arrest for illegal behavior). ODD and CD also increase risk for psychiatric disorders, physical health problems (i.e., cardiovascular disease, serious injury, and sexually transmitted diseases), poor educational and occupational adjustment, and legal problems in adulthood. As a result, ODD and CD are associated with higher rates of public expenditure (e.g., mental health treatment, medical treatment, incarceration) than other psychiatric conditions that are common in children and adolescents.

OPPOSITIONAL DEFIANT DISORDER

Definition

The essential features of ODD can be grouped into three symptom clusters: angry/irritable mood, argumentative/defiant behavior, and vindictiveness. Angry and irritable mood involves frequent temper outbursts, especially when the person does not get their way, and a general pattern of being angry, resentful, and easily annoyed. Argumentative and defiant behaviors are expressed by persistent stubbornness and unwillingness to compromise, give in, or negotiate with adults or peers. Defiance may also include deliberate or persistent testing of limits, usually by ignoring requests or commands, arguing, failing to accept blame, and blaming others for misdeeds. Individuals with ODD often do not regard themselves as oppositional or defiant but justify their behavior as a response to unreasonable demands or circumstances. Symptoms generally begin early in life at home in the child's interactions with the parents, other primary caregivers, and siblings. As the disorder progresses and increases in severity, angry/irritable and argumentative/defiant symptoms generalize outside of the home toward teachers or other authority figures at school or in the community. While significant symptoms of ODD at home are predictive of current and future impairment, displaying symptoms outside the home is an important marker for the severity of the disorder.

Given that ODD symptoms can be present to some degree in typically developing individuals, they are considered indicative of a disorder when

Telegram: @medical_k

www.konkur.in

an individual exhibits four of eight possible symptoms over the past 6 months. Behaviors also must be present outside of interactions with siblings. While the required frequency of behaviors is not explicitly stated in symptom definitions (with the exception of vindictiveness, which must occur at least twice in the past 6 months), tentative guidelines are provided to distinguish symptomatic behavior from behavior within normal limits. For younger children (below age 5 years), behaviors should occur most days of the week in order to exceed normal behavior for young children. For individuals over the age of 5 years, behaviors should occur at least once a week. However, there is a degree of flexibility in these guidelines, in order to allow for clinical judgment on what is or is not within the expected range of behaviors for a particular individual based on their developmental level, gender, and culture. Importantly, the behaviors must also be associated with significant distress or impairment within the individual, their social context, or other important areas of functioning.

Disruptive mood dysregulation disorder (DMDD) shares several symptoms in common with ODD, including angry or irritable mood and temper outbursts. In fact, most individuals who meet diagnostic criteria for DMDD also meet criteria for ODD. However, the main differences between ODD and DMDD are in the frequency and intensity of symptoms and the pervasiveness of a negative mood between temper outbursts. That is, individuals with DMDD display more intense mood outbursts and do not have periods of normal mood between angry outbursts (i.e., anger or irritability is present most of the day every day). In individuals who meet diagnostic criteria for both ODD and DMDD, only a diagnosis of DMDD is given.

While ODD includes problems with emotional regulation (e.g., irritability, anger) that increase risk for later emotional disorders, these symptoms are not included in the diagnostic criteria for CD. As a result, when criteria are met for both ODD and CD, both diagnoses can be given. However, symptoms of ODD and CD are highly correlated and are often considered to represent a single dimension of disruptive or externalizing behaviors. In fact, most children who develop CD prior to adolescence begin by showing ODD symptoms, whereas most children with ODD do not go on to develop CD.

History

Telegram: @medical_k

www.konkur.in

ODD first emerged as a diagnosis distinct from CD in DSM-III. Previously, the Group for the Advancement of Psychiatry had suggested the concept of childhood oppositional personality in 1966, emphasizing the symptoms of disobedience and pervasive negativism. Early conceptualizations of ODD emphasized the passive-aggressive nature of the oppositional symptoms. With the introduction of DSM-III in 1980, oppositional disorder was included with explicit behavioral criteria. Subsequent editions of the DSM added a defiant label and expanded the ODD symptom list from two of five possible items (DSM-III) to five of nine possible symptoms (DSM-III-R) and finally to four of eight total symptoms (DSM-IV, DSM-IV-TR, DSM-5, and DSM-5-TR). Although DSM-5 and DSM-5-TR include the same eight ODD symptoms as in DSM-IV-TR, they are newly grouped into three categories (i.e., angry/irritable mood, argumentative/defiant behavior, and vindictiveness) on the basis of factor analytic and longitudinal research showing that these symptoms show distinct patterns of covariation and the different symptom clusters uniquely predict different comorbidities and future problems. Specifically, the angry/irritable dimension is associated with greater emotional disorders, the argumentative/defiant dimension is related to attention-deficit/hyperactivity disorder (ADHD), the vindictive symptom is related to callous-unemotional (CU) traits, and all three dimensions are highly related to CD. Thus, DSM-5-TR conceptualizes ODD as a disorder with both emotional and behavioral dimensions. DSM-5 attempted to provide a more lifespan view of all disorders and, in doing so, eliminated the chapter on disorders first evident in infancy, childhood, or adolescence in which ODD was included in previous editions of the DSM, relocating this disorder to the disruptive, impulse control, and conduct disorders chapter.

Despite ODD being included in recent editions of the DSM, spanning many decades, the disorder has been somewhat controversial for two reasons. First, the oppositional and argumentative behaviors that form the criteria for ODD are commonly displayed in normally developing children, especially at certain developmental periods, such as in the toddler and early preschool years (i.e., the terrible twos) and in adolescence. Second, ODD is frequently comorbid with a host of other disorders and, in fact, is rarely displayed without symptoms of other disorders. As a result of these two issues, there were concerns that ODD over-pathologizes a normative behavior pattern and that, unless accompanied by another disorder (e.g., ADHD, CD), the symptoms of ODD are transient and benign and should

Telegram: @medical_k

www.konkur.in

not be considered as a separate disorder. ODD was ultimately included in the DSM-5, however, based on research showing that its symptoms did predict impairment, even when controlling for comorbid conditions, and clearer guidance was provided on how to differentiate ODD from more normative displays of these behaviors.

Comparative Nosology

The DSM-5-TR and ICD-11 include similar descriptions of ODD. While the 10th edition of the ICD included ODD as a subtype of CD, ODD is classified as a separate disorder in the ICD-11. Similar to DSM-5-TR, ICD-11 defines ODD as a persistent pattern of defiant, disobedient, provocative, or spiteful behavior that is outside the normal range expected based on an individual's age and developmental level. The behaviors must be present outside of interactions with siblings and must cause significant impairment in functioning. The primary difference between the DSM-5-TR and ICD-11 criteria for ODD is their use of specifiers. In ICD-11, ODD is classified with specifiers to designate the presence or absence of chronic irritability-anger and the presence or absence of limited prosocial emotions (LPE). The presence of chronic irritability-anger requires a pervasive angry or irritable mood in addition to frequent temper outbursts, leading the diagnosis of ODD with chronic irritability-anger to strongly resemble DSM-5-TR's diagnosis of DMDD, which is not otherwise represented in ICD-11. The presence of LPE is defined by elevated levels of callous-unemotional (CU) traits. The symptoms for this LPE specifier include a lack of empathy, lack of remorse or guilt, lack of concern over poor performance, limited expression of emotions, and relative indifference to punishment. Although the LPE specifier applies to both ODD and CD diagnoses in ICD-11, it is only used for a diagnosis of CD in DSM-5-TR, excluding the fifth symptom related to indifference to punishment.

Epidemiology

DSM-5-TR cites an average overall prevalence estimate of 3.3% for childhood ODD, which is based on a review of probability estimates from school and community samples worldwide. Interestingly, this overall rate did not differ across countries that varied in their racial and ethnic composition. These prevalence rates were based on studies with children and adolescents, and there have been few studies estimating the

Telegram: @medical_k

www.konkur.in

prevalence of ODD in adults, although it appears much rarer in this age group. ODD is more prevalent in males than females (1.6:1) in middle childhood, but this gender ratio is narrower in preschool children and adolescents. ODD is also more prevalent among children and adolescents from families of low socioeconomic status.

Etiology

One difficulty in interpreting the research on the causes of ODD is that, while the distinction between ODD and CD is made in clinical settings, most research combines symptoms of both disorders when studying risk factors and causal mechanisms. Further, most children who develop CD prior to adolescence show ODD earlier in development and, over time, start displaying the more severe CD symptoms in addition to ODD symptoms. Thus, the causal models developed to explain the development of childhood-onset CD, which are reviewed in the following section, are also relevant for explaining the onset of ODD. A critical piece of information that is currently unknown is what factors lead some children to develop ODD but not to go on to develop CD, and what factors lead other children to progress on to develop more severe CD symptoms.

What is critical to all theories of ODD is that it is a transactional disorder involving both dispositional characteristics of the child and problems in the child's psychosocial context. That is, ODD is related to factors within the child that make them difficult to socialize. As a result, the child evokes negative responses from others in their environment, in particular caregivers and authority figures, which further increases the child's defiant and negative behavior. Consequently, most causal theories for ODD involve gene-by-environment interactions and dynamic, interactive models involving reciprocal interactions between the child and their caregivers over time.

The degree to which ODD symptoms present within typically developing individuals differs across developmental stages, and several ODD behaviors are highly prevalent in 2- to 4-year-olds and adolescents. However, in addition to considering the child's developmental stage when diagnosing ODD, it is also important to consider the developmental processes that contribute to severe and impairing levels of ODD behaviors. For example, the defiance that is somewhat normative during the third and fourth years of life, as a child develops some degree of independence from caregivers, can lead to impairing behavior if it is met

Telegram: @medical_k

www.konkur.in

by harsh and inconsistent responses from parents. Similarly, the questioning of authority that often accompanies identity development in adolescence can lead to severe and impairing behaviors, if supported by a deviant peer group or if the adolescent is not appropriately monitored and supervised by parents or other authority figures.

Biologic Factors. Twin studies estimating the genetic and environmental contributions to oppositional defiant behavior find support for additive genetic, unique environmental, and shared environmental influences for both boys and girls. However, these studies generally find support for a genetic vulnerability to oppositional and defiant behaviors that interacts with the child's environment across development to result in the expression of ODD. This research supports the clinical observation that oppositional and disruptive behaviors frequently cluster in siblings and biologic relatives of a child with ODD.

It is likely that genetic predispositions lead to ODD through the child's temperamental characteristics. Temperament is defined as the child's characteristic style of emotional and behavioral responses in a variety of situations and to a variety of environmental stimuli. Specific temperamental styles can be observed early in life and show a modest persistence over time, often developing into personality traits later in life. A cluster of temperament dimensions described as the "difficult temperament" has been shown to be a risk factor for ODD in children across a number of racial, ethnic, and socioeconomic groups. Although many definitions exist, the difficult temperament is generally characterized by emotional hyper-reactivity (especially through frequent and high-intensity responses of negative emotion), poor behavioral control (e.g., overactivity and difficulty sustaining attention), and low adaptability to new situations. This cluster of temperamental characteristics has been shown to predict a wide range of emotional and behavioral problems, and not only ODD. Whereas a difficult temperament alone is a relatively weak predictor of ODD, it becomes increasingly predictive when combined with various psychosocial stressors.

Psychological Factors. One psychosocial factor that is consistently linked with ODD is harsh, coercive, and inconsistent parenting. However, as noted above, this risk factor is usually considered in causal models along with the child's difficult temperament. An influential theory for the development of ODD that integrates both parenting and the child's

Telegram: @medical_k

www.konkur.in

temperament is Gerald Patterson's coercion theory. Coercion theory applies learning theory, specifically negative reinforcement, to explain how oppositional child behavior develops. A problematic behavior is negatively reinforced when it allows an individual to escape from a noxious, aversive, or unpleasant situation or task. The negative behavior of one member of a parent–child dyad serves to terminate the ongoing negative behavior of the other, thereby negatively reinforcing the first member's original negative behavior. In the case of the child with a difficult temperament who expresses high-intensity negative emotion in response to parental demands (e.g., temper tantrums), this often leads the parent to use increasingly harsh and coercive discipline to change the child's behavior. The child's improved behavior negatively reinforces the parent's use of harsh discipline techniques. However, over time, the child learns that if they increases the negative behavior (e.g., longer and more intense temper tantrums), the parent will back down on their discipline attempts. This process reinforces the child's negative behavior. Thus, the child and parent become entangled in a coercive cycle in which they each use increasingly negative behavior to change the other's behavior. Over time, the child learns that aversive behavior "works" to solve social problems and may begin to generalize their angry and oppositional interpersonal behavior outside of the home to interactions with teachers and other authority figures at school and in the community, as well as to peers.

Sociologic Factors. Ecologic variables, including parental depression and other mental health problems, family discord, family stress, and poverty, are also associated with increased risk of developing ODD. However, these factors appear to have their influence on the development of ODD through their effects on parental discipline. For example, parents living in impoverished living conditions experience a large number of stressors and daily hassles that make it difficult to engage in positive parenting and to set and enforce consistent limits on their children. Similarly, studies of the relation between maternal depression and ODD find that depression in the mother reduces maternal–child interaction quality, making the parent less involved and responsive to their child's needs. Maternal depression can also lead to increases in negative parent–child interactions, including irritability or hostility between the mother and child.

Diagnosis and Clinical Features

Telegram: @medical_k

www.konkur.in

Diagnostic criteria for ODD are listed in Table 45–1. The diagnosis is not limited to a particular age group, but most commonly emerges between the ages of 4 and 8 years old. While studies of ODD in adults are rare, there is evidence that adults can display this disorder as well. Impairment associated with ODD largely depends on the number of settings in which behaviors are present. Problem behaviors are usually first evident at home in relationships with those most familiar to the child. In more severe cases, ODD symptoms may also occur outside of the home, such as in daycare or school settings, usually in situations where authority figures set limits or place demands on the child. Thus, it is particularly important to investigate behavior in school, with friends, and in other settings to determine the degree of ODD severity. In addition, the child with ODD often does not see their behaviors as a problem and commonly places blame on others for any problems. Thus, the clinical evaluation should include multiple reporters including both parents (where applicable) and teachers, in addition to the child. Finally, given that the behavior associated with ODD can be displayed to some degree in typically developing children and adolescents, it is important that the diagnostic process involves some method for comparing the child's level of behavior to what is normative for the child's age, gender, and culture.

www.konkur.in

Jonah is a 7-year-old boy whose mother reports that he has been difficult to control at home since he was a toddler, with his behavior worsening when his younger sister was born. In addition to impulsive and hyperactive behavior, Jonah is often defiant and argumentative with his parents. Requests to clean his room, get ready for school or for bed, or share his toys with his younger sister are met with angry refusals that escalate into temper tantrums. His mother reports that her attempts to discipline him are unsuccessful, and she displays her frustration with his defiance by shouting and making threats that are not enforced. When Jonah began preschool, these negative behaviors began to be present with his teachers and peers as well. According to his second-grade teacher, he does not follow directions in class, blames other students for his mistakes, argues with adults, and loses his temper on a weekly basis. These behaviors have resulted in several discipline notes being sent home, and he has been kicked out of two afterschool programs due to his difficulty following rules and repeated conflicts with teachers and classmates. In addition to impairment at both home and school, reports from Jonah's parents and teacher on standardized rating scales reveal that his behavior is more severe than would be expected for a boy his age (over the 95th percentile compared to age norms). His performance on cognitive and academic testing indicates abilities within the normative range, and his mother reports an unremarkable developmental and medical history.

Telegram: @medical_k

www.konkur.in

Table 45–1.
DSM-5-TR Diagnostic Criteria for Oppositional Defiant Disorder

Telegram: @medical_k

www.konkur.in

A. A pattern of angry/irritable mood, argumentative/defiant behavior, or vindictiveness lasting at least 6 months as evidenced by at least four symptoms from any of the following categories, and exhibited during interaction with at least one individual who is not a sibling.

Angry/Irritable Mood

1. Often loses temper.
2. Is often touchy or easily annoyed.
3. Is often angry and resentful.

Argumentative/Defiant Behavior

4. Often argues with authority figures or, for children and adolescents, with adults.
5. Often actively defies or refuses to comply with requests from authority figures or with rules.
6. Often deliberately annoys others.
7. Often blames others for his or her mistakes or misbehavior.

Vindictiveness

8. Has been spiteful or vindictive at least twice within the past 6 months.

Note: The persistence and frequency of these behaviors should be used to distinguish a behavior that is within normal limits from a behavior that is symptomatic. For children younger than 5 years, the behavior should occur on most days for a period of at least 6 months unless otherwise noted (Criterion A8). For individuals 5 years or older, the behavior should occur at least once per week for at least 6 months unless otherwise noted (Criterion A8). While these frequency criteria provide guidance on a minimum level of frequency to define symptoms, other factors should also be considered, such as whether the frequency and intensity of the behaviors are outside a range that is normative for the individual's developmental level, gender, and culture.

B. The disturbance in behavior is associated with distress in the individual or others in his or her immediate social context (e.g., family, peer group, work colleagues), or it impacts negatively on social, educational, occupational, or other important areas of functioning.

C. The behaviors do not occur exclusively during the course of a psychotic, substance use, depressive, or bipolar disorder. Also, the

Telegram: @medical_k

www.konkur.in

criteria are not met for disruptive mood dysregulation disorder.

Specify current severity:

Mild: Symptoms are confined to only one setting (e.g., at home, at school, at work, with peers).

Moderate: Some symptoms are present in at least two settings.

Severe: Some symptoms are present in three or more settings.

Pathology and Laboratory Examination

No laboratory tests are available for the diagnosis of ODD, and assessments are based largely on clinical examination and history. Several validated rating scales are available to assess oppositional and defiant behaviors. These scales document symptom severity relative to same-age and gender peers. Rating scales may assist in treatment planning by identifying specific targets for interventions and by documenting baseline disorder severity and subsequent response to treatment. Rating scales completed by both parents and teachers can aid in determining if the child's behavior is displayed in multiple situations and settings, and with multiple people. However, the cross-situational pervasiveness of behaviors can also be assessed through the clinical interview. Rating scales to measure the degree of functional impairment caused by symptoms are also available, although this too is often assessable through clinical interviews. Finally, observing parent–child interactions in young children can not only aid in determining the severity of a child's behavior but can also document specific parent–child interactional patterns and parenting practices that serve to maintain the ODD behaviors and could be targeted in treatment.

Differential Diagnosis

Children with ODD often have comorbid diagnoses of ADHD and CD. The behaviors associated with ADHD, especially the problems with impulse control, often lead children to have problems regulating their emotions and behaviors and make them difficult to discipline consistently. The diagnosis of ODD is added to the diagnosis of ADHD when the child shows active defiance and noncompliance that cannot be solely attributed to impulsive

Telegram: @medical_k

www.konkur.in

acts. Over time, the behaviors associated with ODD can develop into the more serious behavior problems associated with CD (e.g., aggression toward people or animals, recurrent destruction of property, covert theft, or deceit). Maintaining the diagnosis of ODD alongside a CD diagnosis may be required to capture the emotional symptoms (e.g., angry/irritable mood) that can be part of ODD but not CD. Defiant and disruptive behaviors may occur after a major stressor such as a traumatic event or the loss of a loved one. If the behavioral disturbance lasts less than 6 months, an adjustment disorder with disturbance in behavior is the more appropriate diagnosis. In individuals with intellectual disability, a diagnosis of ODD is only given if the oppositional behaviors are markedly greater than is commonly observed among individuals of a comparable cognitive level. Irritable, defiant, and oppositional behaviors can be associated with mood and anxiety. However, in most cases of children who meet criteria for ODD, the emotional distress is caused by impairments associated with the child's behavior problems (e.g., disciplinary problems at school, conflict with parents, peers, and teachers). Bipolar disorder presenting in those younger than 18 years can include defiance of authority, oppositionality, and irritability, but the behavior problems are confined to the mood episodes. Also, oppositional behaviors may be a feature of psychotic illness in children and adolescents, but ODD is not diagnosed separately if the ODD symptoms occur only during the course of a psychotic or mood disorder. Refusal to follow the directions of authority figures needs to be distinguished from disorders of hearing and language. Children with hearing loss or receptive language disorders may look oppositional on the basis of a failure to hear or understand spoken commands.

Although DSM-5-TR classifies DMDD as a depressive disorder, DMDD shares several symptoms in common with ODD, including an angry or irritable mood and temper outbursts. The key difference between DMDD and ODD is that, while the angry/irritable mood and temper outburst symptoms of ODD are only required to take place "often" (typically once a week), DMDD requires an angry or irritable mood between temper outbursts that are present most of the day, nearly every day. Temper outbursts in DMDD must also occur three or more times a week on average. Finally, DMDD symptoms must be present for at least 12 months (rather than 6 months for ODD) and in two settings (while ODD symptoms can be present in only one setting for a mild severity). Diagnosis of DMDD

Telegram: @medical_k

www.konkur.in

must also be made between ages 6 and 18, and symptoms must have emerged before age 10, while no such age requirements are needed for ODD. Despite these differences, research suggests that most individuals with DMDD would also meet the criteria for ODD. As such, DMDD can be conceptualized as a severe variant of ODD, with the primary problems being with emotional control rather than behavioral control. Thus, if criteria for both DMDD and ODD are met in an individual, DMDD is diagnosed as the more severe condition, and ODD is not diagnosed.

Comorbid Conditions

ODD often co-occurs with other psychiatric disorders and, in fact, it is rare for a child to show ODD without other comorbid problems. The most common comorbid diagnosis with ODD is ADHD. Studies have shown that 60% to 80% of children with ODD assessed in clinics may also meet criteria for ADHD, and about 50% of children with ADHD will also meet diagnostic criteria for ODD. Approximately 15% to 20% of clinically referred children and adolescents with ODD have comorbid depression, bipolar disorder, anxiety disorders, or language disorders. Concurrent substance abuse is also more common in individuals with ODD, especially teenagers with comorbid ADHD.

Course and Prognosis

The combination of ADHD and ODD confers risk for more problematic outcomes, including progression to CD. Children with an earlier age of onset of ODD (i.e., preschool or early elementary school) are also three times more likely than those with a later age of onset (i.e., later elementary school years or beginning in adolescence) to develop CD. Approximately 30% of children with ODD will eventually develop CD. Although the diagnosis of ODD is relatively stable over time, about two-thirds of children diagnosed with ODD will no longer meet diagnostic criteria within the following 3 years. Just as ODD confers risk for the eventual development of CD, CD confers risk for the development of antisocial personality disorder (ASPD) in adulthood. Longitudinal studies have shown that about 10% of children with ODD will meet diagnostic criteria for ASPD as adults. These are usually the children with ODD that progress to CD. Children with the angry/irritable mood symptoms of ODD are also at risk for developing anxiety and mood disorders later in life. The

Telegram: @medical_k

www.konkur.in

development of mood disorders in children with ODD often results from the many impairments associated with their behavior problems.

Treatment

Research suggests that treatment of ODD is critical, not only for reducing the impairments associated with the disorder, but also to prevent the later development of CD, ASPD, and anxiety and depressive disorders. Treatment for ODD tends to be most effective when it is implemented early in childhood (i.e., prior to age 9 years). The most successful of these interventions is parent management training (PMT), also called behavioral parent training, which is based on social learning principles. There are several variants of PMT, such as Parent Management Training Oregon Model (PMTO), Parent–Child Interaction Therapy (PCIT), Helping The Noncompliant Child (HNC), Incredible Years, And Triple P, that have been successfully utilized in clinic, home, school, and online delivery settings and implemented with families in individual and group formats. There is recent evidence to support the effectiveness of various forms of self-administered PMT as well, including interventions provided via books, video, internet, and smartphone applications.

Although many different types of PMT exist, the underlying rationale for all programs is based on the general view that child oppositional problem behaviors are inadvertently learned, developed, and sustained in the home by chronic and maladaptive parent–child interactions. The goals of PMT programs are to teach parents how to develop and implement structured contingency management programs and to use more effective discipline strategies (e.g., increase consistency with and use of a variety of approaches). Roughly half of PMT programs examined in a meta-analysis were found to also integrate a positive parent–child relationship-building component (e.g., to increase parental warmth, sensitivity, and responsiveness). Several of these programs are implemented in two phases. The first phase focuses on improving the quality of the parent–child relationship by teaching parents how to interact with their child in a positive and responsive manner, how to use positive reinforcement to encourage compliant and prosocial behavior, and how to reduce coercive parent–child interactions using selective attention. The second phase focuses on teaching parents how to give clear and effective instructions to their children and to use consistent and noncorporal punishments, such as time-out, to decrease noncompliant, attention-seeking, and other

Telegram: @medical_k

www.konkur.in

negative behavior. In many PMT programs, therapists model the skills for the parent during treatment sessions, in addition to providing didactic instruction and discussion. Some PMT programs involve real-time coaching of the parent during interactions with the child to practice the skills taught. Most PMT programs also rely on regular home practice assignments and exercises to support learning of parenting skills.

When the child with ODD has comorbid ADHD, which, as noted previously, is quite common, ODD symptoms often respond to psychopharmacological intervention with stimulant medications. However, there is little scientific evidence to suggest that ODD responds directly to medications when it is not accompanied by ADHD.

CONDUCT DISORDER

Definition

The essential characteristic of CD is a repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are repeatedly violated beginning in childhood or adolescence. These behaviors fall into four main groupings: aggression toward people or animals, destruction of property, deceitfulness or theft, and serious rule violations. To meet criteria for a diagnosis of CD, at least 3 of 15 criterion behaviors must be present during the past 12 months, with at least one behavior present in the past 6 months (see Table 45–2). The disturbance in behavior must also cause clinically significant impairment in social, academic, or occupational functioning. However, the level of severity of CD can vary greatly, from relatively mild lying and stealing to severe aggression involving serious harm to others involving a weapon or forced sexual activity. Severity is classified as mild, moderate, or severe based on the number of symptoms and the degree of harm to others caused by the symptoms. Except for requiring that the criteria for adult ASPD are not present if the individual is aged 18 years or more, there are no exclusionary criteria. Thus, individuals with any other diagnosable disorder, such as post-traumatic stress disorder (PTSD), depression, bipolar disorder, or schizophrenia can be additionally diagnosed with CD, if their behavior over the past year meets criteria.

Telegram: @medical_k

www.konkur.in

Table 45–2.
DSM-5-TR Diagnostic Criteria for Conduct Disorder

Telegram: @medical_k

www.konkur.in

A. A repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated, as manifested by the presence of at least three of the following 15 criteria in the past 12 months from any of the categories below, with at least one criterion present in the past 6 months.

Aggression to People and Animals

1. Often bullies, threatens, or intimidates others.
2. Often initiates physical fights.
3. Has used a weapon that can cause serious physical harm to others (e.g., a bat, brick, broken bottle, knife, gun).
4. Has been physically cruel to people.
5. Has been physically cruel to animals.
6. Has stolen while confronting a victim (e.g., mugging, purse snatching, extortion, armed robbery).
7. Has forced someone into sexual activity.

Destruction of Property

8. Has deliberately engaged in fire setting with the intention of causing serious damage.
9. Has deliberately destroyed others' property (other than by fire setting).

Deceitfulness or Theft

10. Has broken into someone else's house, building, or car.
11. Often lies to obtain goods or favors or to avoid obligations (i.e., "cons" others).
12. Has stolen items of nontrivial value without confronting a victim (e.g., shoplifting, but without breaking and entering; forgery).

Serious Violations of Rules

13. Often stays out at night despite parental prohibitions, beginning before age 13 years.
14. Has run away from home overnight at least twice while living in the parental or parental surrogate home, or once without returning for a lengthy period.
15. Is often truant from school, beginning before age 13 years.

B. The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.

Telegram: @medical_k

www.konkur.in

C. If the individual is age 18 years or older, criteria are not met for antisocial personality disorder.

Specify whether:

Childhood-onset type: Individuals show at least one symptom characteristic of conduct disorder prior to age 10 years.

Adolescent-onset type: Individuals show no symptom characteristic of conduct disorder prior to age 10 years.

Unspecified-onset type: Criteria for a diagnosis of conduct disorder are met, but there is not enough information available to determine whether the onset of the first symptom was before or after age 10 years.

Specify if:

With limited prosocial emotions: To qualify for this specifier, an individual must have displayed at least two of the following characteristics persistently over at least 12 months and in multiple relationships and settings. These characteristics reflect the individual's typical pattern of interpersonal and emotional functioning over this period and not just occasional occurrences in some situations. Thus, to assess the criteria for the specifier, multiple information sources are necessary. In addition to the individual's self-report, it is necessary to consider reports by others who have known the individual for extended periods of time (e.g., parents, teachers, coworkers, extended family members, peers).

Lack of remorse or guilt: Does not feel bad or guilty when he or she does something wrong (exclude remorse when expressed only when caught and/or facing punishment). The individual shows a general lack of concern about the negative consequences of his or her actions. For example, the individual is not remorseful after hurting someone or does not care about the consequences of breaking rules.

Callous-lack of empathy: Disregards and is unconcerned about the feelings of others. The individual is described as cold and uncaring. The individual appears more concerned about the effects of his or her actions on himself or herself, rather than their effects on others, even when they result in substantial harm to others.

Telegram: @medical_k

www.konkur.in

Unconcerned about performance: Does not show concern about poor/problematic performance at school, at work, or in other important activities. The individual does not put forth the effort necessary to perform well, even when expectations are clear, and typically blames others for his or her poor performance.

Shallow or deficient affect: Does not express feelings or show emotions to others, except in ways that seem shallow, insincere, or superficial (e.g., actions contradict the emotion displayed; can turn emotions "on" or "off" quickly) or when emotional expressions are used for gain (e.g., emotions displayed to manipulate or intimidate others).

Specify current severity:

Mild: Few if any conduct problems in excess of those required to make the diagnosis are present, and conduct problems cause relatively minor harm to others (e.g., lying, truancy, staying out after dark without permission, other rule breaking).

Moderate: The number of conduct problems and the effect on others are intermediate between those specified in "mild" and those in "severe" (e.g., stealing without confronting a victim, vandalism).

Severe: Many conduct problems in excess of those required to make the diagnosis are present, or conduct problems cause considerable harm to others (e.g., forced sex, physical cruelty, use of a weapon, stealing while confronting a victim, breaking and entering).

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Text Revision, DSM-V-TR, pp. 530–532 (Copyright © 2022). American Psychiatric Association. All Rights Reserved.

Subtypes and Specifiers of Conduct Disorder

As with all disorders in the category of disruptive, impulse control, and conduct disorders, the behaviors associated with CD can be the result of a number of different factors. In an attempt to acknowledge the heterogeneity inherent in the diagnostic criteria for CD, a number of subtypes are recognized in addition to the severity criteria. DSM-5-TR indicates subtypes for CD based on the age of onset of the symptoms and the presence of LPE. Childhood-onset type refers to the onset of at least one CD symptom prior to the age of 10 years. This distinction is based on a long history of research in both mental health and criminology, showing

Telegram: @medical_k

www.konkur.in

that the age of onset of antisocial behavior has important clinical, etiologic, and prognostic implications. Specifically, research finds that a relatively small group of children (generally boys) with the onset of antisocial behaviors in childhood (as contrasted with onset in adolescence) are more likely to be aggressive and to continue to display problem behaviors, including criminal behavior, into adulthood. Also, compared to the later-onset group, individuals with childhood-onset CD display more neuropsychological deficits, including comorbid sustained attentional deficits, failure to inhibit impulsive responding, chronic learning failure, and academic underachievement.

The second subtype of CD recognized in the DSM-5-TR, the adolescent-onset type, defines individuals for whom all symptoms begin after 10 years of age. The adolescent-onset group typically involves more girls than the childhood-onset subtype and is likely to show aggressive and violent behavior. The adolescent-onset subtype is less likely to show aggressive and violent behavior into adulthood but, importantly, are not completely free of risk for problems as adults. Their antisocial behavior in adolescence can result in continuing problems (e.g., school dropout, substance abuse, and criminal behavior) which can influence their adult adjustment.

It is important to note that while the importance of distinguishing between early and later onset CD has strong research support, the exact age at which to define the subgroups has been debated. Research has used ages ranging from 9 to 14 to make this distinction. Some have also argued that the distinction should be based on pubertal status or made continuously (i.e., the earlier the age of onset, the more severe the CD). The DSM-5-TR also recognizes that pinpointing the age of onset in a person through historical reports can be difficult and, as a result, CD unspecified onset is used when criteria for a diagnosis of CD are satisfied, but the age of onset of the first CD symptoms cannot be reliably determined.

While the distinction between childhood-onset and adolescent-onset CD is included in most recent editions of the DSM, the DSM-5 newly added another specifier to recognize that there can be clinically and etiologically important distinctions within the onset subtypes, particularly within the more severe childhood-onset subtype (DSM-5-TR continued this with identical criteria). Thus, a CD specifier called “with limited prosocial emotions” (LPE), which is defined by the presence of significant and

Telegram: @medical_k

www.konkur.in

pervasive levels of CU traits, was added to the DSM-5. The LPE specifier is defined by the presence of two of the following four symptoms:

- a lack of remorse or guilt,
- callousness/lack of empathy,
- lack of concern about performance in importance activities, and
- shallow or deficient affect.

At least two of these characteristics must be present in multiple relationships and settings for at least 12 months. While this LPE specifier is new to the DSM-5, many of these symptoms were included in the definition of the undersocialized subtype of CD in the DSM-III. These traits are considered the affective components of conscience in developmental research, and the affective components of psychopathy in research with antisocial adults. The basis for adding the LPE specifier to the DSM-5 came from research showing that CU traits predict more aggression and poorer outcomes, even when controlling for the number of CD symptoms and age of onset. Individuals with CD and co-occurring CU traits typically show a childhood onset to their CD symptoms, which are more severe and aggressive, lead to more harm to their victims, and involve aggression that is more likely to be premeditated (i.e., planned) and instrumental (i.e., for gain) than other youth with early-onset CD. In contrast, children with childhood-onset CD who do not show elevated CU traits tend to show aggression that is confined to reactive acts occurring in context of high emotional arousal and in response to real or perceived provocations from others. In addition, although youth with CD and elevated CU traits do respond positively to many evidence-based treatments for CD, they often begin and end treatment with more severe behavior problems.

In addition to these clinically important differences, there are a number of other differences between children with CD with and without elevated CU traits that have implications for etiologic theories. For example, the conduct problems of children with elevated CU traits tend to show stronger influences from heredity. These children also show a number of deficits in how they recognize and react to emotional stimuli, such as showing poor recognition of fearful face stimuli and less emotional reactivity to signs of fear, sadness, and distress in others. In addition, children with CD and elevated CU traits tend to show reduced responses to cues of punishment and lower fear and anxiety relative to other children

Telegram: @medical_k

www.konkur.in

with CD. In contrast, individuals with childhood-onset CD without elevated CU traits often show elevated rates of emotional reactivity, especially to others' distress cues and provocation from others, as well as other signs of difficulty in regulating their emotions and behaviors (e.g., high rates of anger and anxiety). Thus, these two subgroups of children with CD show very different emotional and cognitive correlates that are important to consider in etiologic theories and could also be important for tailoring treatment to the individual needs of individuals with CD.

History

Descriptions of youths with conduct, delinquent, and antisocial symptoms antedate the very existence of the field of child and adolescent psychiatry. As early as 1837, Prichard used the term "moral insanity" to describe young adult patients with recurrent patterns of antisocial behavior who were not overtly psychotic. Benjamin Rush, the father of American psychiatry, described cases exhibiting "innate, preternatural moral depravity" and speculated that these patients had a defect in the "moral faculties of the mind." In the 19th century, scientific thought emphasized the inherent traits and physical defects (i.e., phrenology) that appeared to mark the antisocial individual.

Beginning in the early 20th century, a shift in thinking occurred as clinicians, social workers, pediatricians, welfare workers, and academics began to consider the impact of the environment and adverse individual or social conditions on adolescents who commit crimes. Concern over keeping the youthful offender out of jail, combined with hope that advances in the new psychoanalytic and psychodynamic therapies being introduced into America in the first two decades of the new century might undo the psychological damage that early childhood adverse experiences might cause, lead to new optimism in the treatment of young people with antisocial behaviors. This shift in thinking combined with hope for new treatments led to the beginning of the child guidance movement in the United States with the opening of the Juvenile Psychopathic Institute in Chicago in 1909, and the Judge Baker Clinic in Boston in 1917. The initial purpose of these clinics was to advise the courts on the psychology of juveniles under arrest. In 1923, Karl Menninger brought together a group of psychiatrists concerned with youthful offenders and started the American Orthopsychiatric Association. Thus, psychiatry's concerns for youths with conduct problems and antisocial behaviors have been

Telegram: @medical_k

www.konkur.in

intimately intertwined with shaping psychiatry's own development as a medical discipline over the past 100 years.

CD was first recognized as a mental health disorder in the DSM-II published in 1968. Continuing a focus on adverse experiences, this early definition of CD in the DSM-II was conceptualized as being a reaction to negative environmental factors, and three distinct reactions were described: runaway reaction, undersocialized aggressive reaction, and group delinquent reaction. Thus, from its very first definition in classification systems for mental disorders, there has been recognition that there are multiple distinct subgroups of individuals with CD who can be differentiated by the behaviors they display and the causes leading to these behaviors.

Over the years, the basic definition of CD as behavior in which the rights of others or major age-appropriate norms are violated has not changed much, but the methods for subtyping individuals within this category have been the major source of change in the diagnostic criteria over time. The DSM-III introduced a different method for subtyping individuals with CD according to whether or not they were (a) aggressive and (b) considered "socialized" (e.g., had lasting friendships, felt guilt/remorse). Relative to the socialized subtype, individuals with the undersocialized subtype of CD showed poorer outcomes in adulthood, and several unique neurophysiologic correlates to their CD, such as low serotonin levels and autonomic irregularities. While the undersocialized subgroup was defined by some characteristics shared in common with the DSM-5-TR's LPE specifier (e.g., does not feel guilt or remorse), the undersocialized label created considerable confusion as to its core features and most suitable operationalization. Some definitions focused on the child's ability to form and maintain social relationships, whereas others focused primarily on the context (alone or with a peer group) in which antisocial acts were typically committed. Few definitions focused directly on the LPE themselves.

In an attempt to address this definitional confusion, the next revision of the DSM (i.e., the DSM-III-R) revised how CD was subtyped. The criteria for the undersocialized subtype were changed to focus solely on whether the antisocial acts were committed alone and whether the pattern included aggressive symptoms, both of which were judged to be more easily assessed than the CU features included in the original undersocialized definition. This change was accompanied by relabeling the specifier as

Telegram: @medical_k

www.konkur.in

the solitary-aggressive subtype. The criteria for the second subtype focused solely on whether the antisocial acts were committed with other antisocial peers, and this subtype was assumed to be primarily nonaggressive in nature, leading to its renaming as the group subtype.

In the DSM-IV, these subtypes were replaced by the childhood-onset and adolescent-onset distinction that was retained in the DSM-5. The focus on onset was intended to capture the distinction between early and later onset of antisocial behavior that had been long studied in research on criminal behavior and proven to be important for predicting different outcomes. Also, given that the childhood-onset subtype was more likely to be aggressive, the distinction based on onset was viewed as adequately capturing the distinction between aggressive and nonaggressive subtypes. Since the publication of the DSM-IV, substantial research supported that CU traits could be assessed reliably in children and adolescents and their presence designated a unique group of children, primarily within the childhood-onset category. An estimated 25% to 35% of children and adolescents with childhood-onset CD show elevated CU traits. However, this minority of children with early-onset CD show a more severe, stable, and difficult-to-treat pattern of behavior, as well as distinct risk factors that have led to etiologic theories for different causal pathways leading to CD in those with and without elevated CU traits.

Comparative Nosology

The ICD-11 description of conduct-dissocial disorder strongly resembles diagnostic criteria for CD in DSM-5-TR, describing a persistent pattern of behavior that violates the basic rights of others or major age-appropriate norms, rules, or laws. While previous editions of the ICD classified CD as either CD confined to the family context, undersocialized CD, socialized CD, or ODD, ICD-11 brought its classification more in line with DSM-5. The ICD-11 definition includes specifiers based on the age of onset (childhood or adolescence) and level of prosocial emotions (limited or typical). One difference between the ICD-11 and DSM-5-TR specifier for LPE is that the ICD-11 includes a fifth symptom defined as “insensitivity to punishment.”

Epidemiology

The worldwide prevalence of CD is estimated to be 2% to 2.5%, with about 10% of individuals affected at some point during childhood or

Telegram: @medical_k

www.konkur.in

adolescence. There is little evidence that the prevalence of CD differs by world region, and findings of differences between racial and ethnic groups are mixed and not easily teased apart from socioeconomic factors. The prevalence of CD increases from childhood to adolescence, with the median age of onset of CD in the United States being 11.6 years old. Overall, boys show higher prevalence rates of CD than girls at approximately a 2:1 male-to-female ratio. However, like ODD, the sex ratio for CD varies across development, being narrower in early childhood and adolescence than in middle childhood. This narrowing of the sex difference in adolescence is due largely to the finding that girls typically show an adolescent onset to their CD.

Etiology

The vast body of research on antisocial and aggressive behavior generally or on CD specifically has produced several clear conclusions. First, the development of CD typically results from a host of risk factors in both the child's biologic and genetic background, as well as problems in their social environment. Thus, focusing on any single risk factor or even a single class of risk (e.g., biologic risk, familial risk, neighborhood risk) will likely be inadequate to explain how the vast majority of children and adolescents develop CD. Second, research on CD has clearly documented that children can develop CD through many different causal processes, which is reflected in the multiple subtypes of CD that have been proposed, each of which is associated with at least somewhat distinct risk factors.

Telegram: @medical_k

www.konkur.in

Table 45–3.
A Summary of Risk Factors for Conduct Disorder

General Risk Factors	Risk Factors Unique to Specific Subtypes		
	CU Traits	Childhood-Onset	Adolescent-Onset
Prenatal exposure to toxins and birth complications	Stronger genetic contribution	Stronger evidence for shared and nonshared environmental influences	Low traditionalism
Socioeconomic disadvantage	Structural and functional deficits in amygdala	Frontal lobe dysfunction	High rebelliousness
Physical and sexual abuse and neglect	Insensitivity to punishment	Low executive functioning/verbal IQ	Poor parental monitoring and supervision
Deviant peer affiliation	Low fear and anxiety	Emotional dysregulation, including anxiety	Few bonds with prosocial institutions
Parental depression and substance use	Low reactivity to cues of distress in others	High reactivity to threat and provocation	
Community and media violence	Deviant social goals	Hostile attributional bias	
	Low parental warmth	Harsh and inconsistent parenting	

While research has historically focused on simply uncovering the multitude of dispositional and environmental factors that can place an individual at risk of showing CD symptoms, more recent work is focused on developing theoretical models that can explain both multiple risk factors and the heterogeneity of causal mechanisms. Further, many of

Telegram: @medical_k

www.konkur.in

these theories have attempted to embed this research on CD within research on normal development. That is, current theories of CD not only attempt to describe dispositional risk factors that have been empirically linked to CD, but also propose and test how these risk factors can affect important developmental processes in the child that make them more likely to display antisocial and aggressive behavior. These etiologic theories could have important treatment implications because, even if a child shows a historical risk factor that cannot be changed (e.g., prenatal exposure to toxins), if one can document what effects this exposure has had on the developing child, these effects could be the target of treatment.

This developmental psychopathology approach to explaining the causes of the various subtypes of CD, as defined in the DSM-5-TR, has led to theories specifying very different developmental mechanisms underlying adolescent-onset CD, childhood-onset CD with LPE, and childhood-onset CD without LPE. Adolescent-onset CD is viewed as an exaggeration of the normal process of identity formation, which leads to rebellious behavior as an attempt to establish autonomy and results in the rejection of traditional status hierarchies. This view explains why the CD behavior in this group does not onset until adolescence when this need for autonomy becomes more prominent, and why there is greater desistance from antisocial behavior in adulthood for individuals in this group. While most adolescents show some level of rebellious behavior, only a small minority show CD. The exaggeration of the normal process of rebellion can be due to associations with deviant peers who encourage maladaptive forms of rebellion, poor supervision by adults, a lack of connection to prosocial institutions, or simply a rebellious temperament. In contrast, childhood-onset CD is viewed as more of a characterologic disturbance because these behaviors start earlier in development and persist across multiple developmental stages. However, the different correlates to CD in children with versus without elevated CU traits suggest that the type of disturbance may differ for these groups. Children with elevated CU traits show deficits in how they process emotional stimuli that are evident very early in development, which can make it difficult for them to develop empathy, guilt, and other aspects of conscience. In contrast, children in the childhood-onset group without elevated CU traits show elevated levels of emotional reactivity and cognitive deficits (e.g., lower verbal intelligence and deficits in executive functioning) that can make it difficult for them to learn to regulate their emotions and behaviors.

Telegram: @medical_k

www.konkur.in

Thus, this theoretical model specifies at least three common causal pathways to CD corresponding to the subtypes recognized by the DSM-5-TR, each involving different developmental mechanisms and somewhat different risk factors. This research is summarized in Table 45–3. In the subsequent sections, discussion of the various types of risk factors that have been associated with CD is organized within this framework.

Biologic Factors

HERITABLE FACTORS. Research has long shown that antisocial behavior, aggression, and conduct problems tend to cluster in families. Familial clustering can reflect shared environmental factors (i.e., factors that all siblings in a family share such as socioeconomic status), genetic factors, or the interaction between genetic vulnerability factors and adverse environmental experiences (i.e., gene-by-environment correlations and interactions). However, there is clear evidence from twin and adoption studies that there is a genetic influence on CD. Adoption studies have shown that biologic children of antisocial parents who are adopted away at birth to nonantisocial adoptive parents show elevated rates of CD. Further, twin studies have consistently shown that about 50% of the variance in CD symptoms are due to genetic influence, with the rest accounted for by shared and nonshared environmental influences. Importantly, there appears to be a different pattern of genetic influence across the subtypes of CD. Specifically, children with CD and elevated CU traits show stronger genetic influences compared to other subtypes.

Recent research has focused on gene-by-environment interactive effects in the development of CD. Several of these studies specifically investigate the gene for the enzyme monoamine oxidase type A (MAOA), which is involved in the metabolism of several central nervous system (CNS) monoamine neurotransmitters that are important in the etiology of many psychiatric disorders. Polymorphisms in the MAOA gene explained variance in the eventual development of CD for boys who experienced sexual or physical abuse. That is, abused boys with a gene variant for low MAOA activity were twice as likely to develop CD as those with a gene variant coding for high MAOA activity. In boys without an abuse history, variations in MAOA were unrelated to the eventual development of CD. This research demonstrates the importance of examining both

Telegram: @medical_k

www.konkur.in

environmental risk factors and genetic vulnerability factors, along with their interactions, in order to understand the etiology of CD.

PHYSIOLOGIC FACTORS. CD is associated with a number of physiologic factors related to activation of the autonomic nervous system and how it responds to emotional stimuli. The different developmental pathways to CD are particularly important for interpreting this research because the subtypes of CD can have very different and even opposing patterns of physiologic arousal. Specifically, CD in children with elevated CU traits is associated with reduced physiologic arousal to various emotional stimuli, such as signs of emotional distress in others or cues to punishment. These findings have been consistent across studies using very different measures of physiologic arousal, including the child's self-report of arousal, attentional orienting to pictures of emotional stimuli, skin conductance changes in response to visual or auditory emotional stimuli, changes in startle reflex following exposure to emotional stimuli, and paradigms that measure physiologic and behavioral responses to changes in reward and punishment contingencies. These physiologic correlates to CD in those with elevated CU traits are combined with neuroendocrine and neurocognitive differences that can also reflect emotional underarousal to certain stimuli.

Importantly, not only do children with CD without elevated CU traits not show this same consistent pattern of underarousal as is seen in those with elevated CU traits, but they often show the opposite pattern of arousal by being hyper-reactive to emotional stimuli. This includes emotional reactivity to provocation, which could help to explain the reactive aggression that is often displayed by children in the low CU group. From this research, it is apparent why using the DSM-5-TR LPE specifier to designate those with CD and elevated CU traits from those without elevated CU traits is critical when studying psychophysiological correlates to CD. Since some individuals with CD show overarousal and others show underarousal, grouping them together could lead to the conclusion that arousal plays no role in the development of CD since these two opposing patterns could cancel each other out. Further, these patterns of arousal could be critical for understanding how other correlates can influence the development of CD in children from the two subtype groups. The reduced emotional arousal may make children with elevated CU traits less likely to develop empathy and guilt because they do not

Telegram: @medical_k

www.konkur.in

become aroused to signs of distress in others and therefore are not motivated to avoid hurting others. The lack of response to punishment could also make many forms of discipline less effective for children with elevated CU traits, such that a focus on positive reinforcement becomes more important. In contrast, the overarousal in those without elevated CU traits may make them more likely to evoke reactive and hostile discipline from parents, leading to harsh and coercive interchanges between the parent and child.

NEUROENDOCRINOLOGIC FACTORS. Several studies have examined neuroendocrine risk factors associated with CD subtypes. The hypothalamic–pituitary–adrenal (HPA) axis is a major stress-regulating system in the body, whose final product is the release of cortisol, a stress hormone, into the bloodstream. Cortisol has many effects on biologic arousal systems, preparing the organism to respond to environmental threats. Research has studied basal, diurnal, and stress-reactive levels of cortisol in children and adolescents with CD, with somewhat mixed findings. These inconsistent results may be due to a failure to consider the subtypes of CD. Consistent with other biologic risk factors, there is some support for differences in emotional reactivity by CD subtype, such that those with elevated CU traits tend to show blunted cortisol activity in response to a stressor.

NEUROTRANSMITTER FACTORS. Research identifying specific neurotransmitters in relation to CD has been inconsistent, again possibly due to the failure to consistently consider differences across subtypes. However, three classes of neurotransmitters have been found to be associated with CD. First, there is some support for a relationship between lowered catecholaminergic activity (dopamine and norepinephrine) in the CNS and increased risk for aggressive behavior, ODD, and CD. Second, serotonin is a ubiquitous CNS neurotransmitter that plays an important role in stabilizing information processing in neural systems, resulting in coherent behavioral, emotional, and cognitive outputs. Disturbed serotonin neurotransmission is associated with disinhibited, aggressive, and impulsive behavior in humans, perhaps by increasing sensitivity to cues that elicit irritation and aggression and by diminishing sensitivity to stimuli that signal punishment or consequence for one’s actions. Decreased sensitivity of the serotonin 1A receptor (5-

Telegram: @medical_k

www.konkur.in

HT_{1A}) is associated with increased impulsive aggression, whereas sensitivity of the serotonin 1B receptor gene (5-HT_{1B}) is associated with CU traits in boys. Thus, the exact nature of serotonin involvement in CD may differ depending on the subtype. Third, recent studies have found associations between methylation of specific sites on the oxytocin receptor genes and lower levels of circulating oxytocin in children with elevated CU traits. Oxytocin has been associated with a range of biologic and psychological functions, including greater attention to emotional stimuli.

NEUROANATOMIC FACTORS. Structural MRI studies of children and adolescents with CD or aggressive behavior consistently document reductions in grey matter volume across various cortical (i.e., ventrolateral, medial prefrontal, middle/superior temporal, and anterior insular cortices) and subcortical (i.e., amygdala, caudate, and putamen) regions. The most consistent abnormalities in CD are reduced cortical thickness in the ventromedial prefrontal/orbitofrontal cortex, superior temporal cortex, fusiform gyrus, precentral gyrus, and precuneus. These regions are implicated in moral and affective decision-making, face processing, motor functions, and self-referential processing, respectively. Most structural imaging studies have failed to consider the subtypes of CD. However, there is some evidence of a negative correlation between CU traits and cortical thickness in the right superior temporal cortex and lingual/fusiform gyrus, which are both involved in moral decision-making and face processing.

Functional MRI (fMRI) studies of CD have focused on emotion processing, using tasks involving viewing emotional images, facial expressions, or empathy-eliciting stimuli. These studies have reported lower activation in the dorsal and rostral anterior cingulate cortex (ACC), anterior insula, medial prefrontal cortex, ventral striatum, and amygdala in youth with CD. Reduced neural activity in the amygdala, anterior insula, and ACC have been specifically related to elevated CU traits in children with CD. These regions are implicated in fear conditioning and processing distress and pain cues in others. Few studies have directly compared CD children with and without CU traits on fMRI tasks, but those that have done so have found clear differences in brain activation, similar to those found for measures of physiologic arousal. That is, children with CD and elevated CU traits show reduced emotional reactivity in the amygdala in

Telegram: @medical_k

www.konkur.in

response to distress cues in others, whereas those without elevated CU traits show enhanced arousal in the amygdala.

PRENATAL AND PERINATAL FACTORS. There are a number of prenatal and perinatal risk factors that have been associated with CD, largely through their influence on the CNS of the developing child. Maternal smoking, drinking, drug use, and stress during pregnancy are the most consistently documented prenatal risk factors for CD. Perinatal risk factors for CD include birth complications and malnutrition. Hypoxia during birth can disrupt white matter tracts that have been associated with CD, and malnutrition could contribute to neuronal loss that has been associated with risk for CD.

Psychological Factors

COGNITIVE FACTORS. Some of the biologic factors associated with CD could have effects on the developing child through their influence on the child's cognitive functioning. Lower intelligence, particularly verbal intelligence, and executive functioning deficits, are some of the most frequently studied cognitive correlates of CD, particularly for childhood-onset CD. These cognitive deficits could explain why some children with CD have difficulty anticipating the consequences of their behavior, as well as why CD is often linked to academic difficulties. Some children and adolescents with CD also fail to appropriately attend to and accurately encode social cues from others in the environment. For example, children with CD often attribute hostile intentions to others, even when the expressed cues are neutral and nonthreatening. Such deficits in social cognition are thought to explain the high rate of reactive aggression displayed by some children with CD.

These cognitive deficits seem to be most strongly related to children with CD who do not show CU traits, while children with elevated CU traits show a different set of cognitive deficits. Relative to other youth with CD, children, and adolescents with elevated CU traits display an insensitivity to punishment cues, which includes responding more poorly to punishment cues after a reward dominant response set is primed, responding more poorly to gradual punishment schedules, underestimating the likelihood that they will be punished for misbehavior, and being less sensitive to potential punishment when peers are present. Youth with CD and elevated CU traits are also more likely to view

Telegram: @medical_k

www.konkur.in

aggression as an acceptable means for obtaining goals, blame others for their misbehavior, and emphasize the importance of dominance and revenge in resolving social conflicts.

FAMILY FACTORS. Various forms of parental mental health problems have been associated with CD. As noted above, because antisocial behavior tends to run in families, parents of children with CD often also show antisocial and aggressive behavior. Higher rates of parental substance use and depression are also consistently linked to CD. Some of the most common parenting styles that are associated with CD involve low levels of positive parenting (i.e., infrequent use of positive reinforcement, low parental involvement, and low parental warmth and sensitivity) and high levels of negative parenting (i.e., poor monitoring and supervision of the child, inconsistent discipline, and use of coercive and harsh physical discipline). There is evidence that the link between problematic parenting and CD is bidirectional. That is, negative parenting can lead to increases in CD over time, and CD also evokes increasingly negative and decreasingly positive parenting over time.

Relevant to the subtypes of CD, poor monitoring and supervision are particularly important for adolescent-onset CD, possibly by allowing for greater time to affiliate and be influenced by deviant peers. Harsh and inconsistent discipline appears particularly important to the development of childhood-onset CD without elevated CU traits, by leading to harsh and coercive interactions between parent and child and by not providing the child with appropriate skills to regulate their emotions and behavior. Meanwhile, in those with elevated CU traits, parental warmth appears to be particularly important for the development of CD. Warm and responsive parenting is important to the formation of a secure parent–child attachment, which is disturbed in children with elevated CU traits and is foundational to their ability to form close bonds with others and to attend to and decipher others' emotions.

Childhood physical abuse, sexual abuse, and a history of neglect are associated with an increased risk for the development of a wide variety of mental health problems, including CD. Further, childhood maltreatment could lead to different subtypes of CD through different causal mechanisms. An adolescent who did not have behavior problems as a child may rebel in maladaptive ways to escape abuse in the home, such as dropping out of school, running away from home, and stealing to

Telegram: @medical_k

www.konkur.in

support themselves. Also, physical abuse can lead a child to develop a hostile attributional bias in which they are hypervigilant to threat cues, making them more likely to act in a hostile, angry, and aggressive manner. Finally, chronic abuse and emotional deprivation can desensitize a child to the emotions of others and lead to a CU interpersonal style.

Sociologic Factors

NEIGHBORHOOD AND CULTURAL FACTORS. A number of extrafamilial risk factors have been associated with CD, including living in neighborhoods where the child might be exposed to high rates of community violence. Other societal factors that have been linked to CD are the easy availability of firearms and high levels of exposure to media violence. Further, poverty, low socioeconomic class, unemployment, poor housing, and overcrowded living conditions have all been linked to CD. There is some indication that the effects of socioeconomic deprivation are mediated through their effects on parenting behaviors. That is, parents living in environments with multiple chronic stressors may find it more difficult to provide consistent, warm, and responsive parenting.

PEER FACTORS. A consistent finding from the research is that children with CD are rejected by their peer group. They tend to have fewer friends, are liked less by their peers, and are more likely to be excluded from activities with peers compared to typically developing children. This rejection by peers is not surprising given that children with CD are often aggressive toward others and bully other children. While children with CD are often the instigator of aggression, they are also more likely to be the victim of aggression from others.

Children with and without elevated CU traits both appear to have problems with peers. Specifically, both groups tend to be disliked by a large number of peers. Although children with elevated CU traits are better able to make friends than other children with CD, their friendships tend to be unstable and unsatisfying, and their peers are more likely to describe them as “mean.”

CD is also related to association with deviant peers. Children with CD often have friends who also have behavior problems and engage in antisocial behavior. This association with deviant peers seems to be related to all subtypes of CD. However, while deviant peer affiliation is often considered to be a primary cause of adolescent-onset CD, it is

Telegram: @medical_k

www.konkur.in

thought to be a consequence of rejection by prosocial peers for the childhood-onset CD subtype. Children with elevated CU traits are especially likely to commit antisocial acts with peers. They are also likely to be the leaders of their antisocial peer groups and instigators of antisocial acts.

Diagnosis and Clinical Features

The DSM-5-TR diagnostic criteria for CD are provided in Table 45–2. The assessment of CD involves 3 primary goals:

- determining the presence and severity of the primary symptoms of CD, including their pervasiveness and the degree of harm they cause others;
- determining the presence of key indicators of the distinct developmental pathways to CD (i.e., the age of onset of the first CD symptom and the presence of CU traits); and
- assessing common comorbidities and key risks and maintaining factors that should be the target of treatment.

To assess the primary symptoms of CD, information should be obtained from multiple informants, including the child, their parents, and their teacher. The child's teacher appears to be particularly important for assessing conduct problems in children prior to adolescence. In contrast, self-report becomes increasingly important as the child approaches adolescence, and parents and teachers may be less aware of the adolescent's behavior. Finally, parents are often the best source of information on the timing of symptom onset. The use of standardized rating scales is recommended; these scales are often used to document the severity and pervasiveness of CD symptoms, compare the child's behavior to a normative comparison group, and identify treatment targets. The assessment of CU traits should also be conducted by collecting information from multiple sources. Particular care should be taken to determine if the indicators of CU traits are shown by the child in most situations and with most people rather than occasionally or only in certain relationships and settings. It is important for clinicians to screen for the presence of common comorbid psychiatric conditions such as ADHD, depression, bipolar disorder, substance use disorders, and learning disabilities (e.g., reading, speech, and language delays) that frequently accompany a diagnosis of CD.

Telegram: @medical_k

www.konkur.in

Zach is a 12-year-old boy whose parents sought a psychological evaluation as a result of his continued pattern of severe behavior problems. From a very young age, he has displayed inattention, hyperactivity, and impulsivity, but his parents are more concerned about his defiance and oppositionality, which later progressed to rule-breaking and physical aggression. For example, he once locked his mother out of the house for several hours and then ran away from home overnight. In addition, he has repeatedly destroyed the toys and property of his two siblings, lied to avoid punishment for his behavior, stolen from extended family members, and threatened violence against his mother. At school, his teachers had repeatedly complained about the danger he posed to other students due to his frequent bullying, fighting, and physical cruelty to others, including an incident in fourth grade when he choked another student. Zach's parents and teachers, along with Zach himself, report that he does not feel guilty or apologize when he does something wrong or hurts someone. Instead, he blames others for his behaviors, such as stating that the classmate whom he choked "deserved" it for making a negative remark to him on the playground. He does not appear to care about the feelings of others and does not display empathy toward others. In addition, his emotions often appear shallow or inappropriate, even in distressing situations such as his grandfather passing away. Zach rarely puts forth effort in school or extracurricular activities but manages to do well on exams and earn A and B grades. At age 7, he received a diagnosis of ADHD and was placed on stimulant medication, which improved his inattention and hyperactivity. However, his oppositionality and conduct problems have only worsened since they began around age 5, and his parents do not know how to control him, given that punishment does not appear to help.

Pathology and Laboratory Examination

No laboratory tests are useful or required for making the diagnosis of CD. All individuals meeting diagnostic criteria for CD merit a complete physical examination to rule out any associated physical trauma associated with a high-risk lifestyle. Particular attention should be paid to the possibility of drug abuse and the risk of sexually transmitted diseases. In girls with CD, early-onset sexual activity may lead to the possibility of early pregnancy.

Telegram: @medical_k

www.konkur.in

Due to the association with learning disabilities, psychoeducational testing to assess potential academic difficulties is also necessary.

Differential Diagnosis

Isolated instances of conduct problem behaviors that do not cause substantial daily impairment need to be differentiated from a consistent pattern of rule-breaking and violations of the rights of others that may constitute a disorder. Early-onset CD needs to be differentiated from ADHD, which can be marked by hyperactivity, impulsivity, risk-taking, and problems with affect regulation. CD and ODD share symptoms in common with intermittent explosive disorder (IED) that bring the individual into conflict with adults and authority figures such as teachers and parents. However, IED does not include the nonaggressive features of CD and contains no element of premeditation in order to achieve some contingent goal such as money or social dominance. ODD behaviors do not include overt aggression toward people or animals, destruction of property, or a pattern of theft and deceit. While ODD generally precedes CD in the course of development, many children with ODD do not go on to meet the criteria for CD. When diagnostic criteria are met for both ODD and CD, both diagnoses may be assigned.

Comorbid Conditions

Children and adolescents meeting diagnostic criteria for CD often meet criteria for other psychiatric diagnoses. ADHD frequently co-occurs with CD, particularly childhood-onset CD. Many youths with CD also have internalizing disorders, such as depression and anxiety. These internalizing disorders often onset after the CD, potentially as a result of the impairments caused by the behavior problems, such as conflict with others, disciplinary problems at home and school, or legal problems. Substance use disorders and learning disorders are also common among individuals with CD.

Course and Prognosis

The development and trajectory of CD depend greatly on the different developmental subtypes, and the three common patterns of development are illustrated in Figure 45–1. As noted in the figure, childhood-onset CD is typically preceded by ODD and ADHD in early childhood. For some, CU

Telegram: @medical_k

www.konkur.in

traits will also begin to emerge in early childhood, which can lead the child to show more severe and varied aggression, which includes both reactive and instrumental forms of aggression. Other children in the childhood-onset pathway who do not have elevated CU traits begin showing more severe behavior problems later in childhood. Their behaviors are less likely to be aggressive but, when aggression does occur, it tends to be limited to reactive forms. Research suggests that between 20% and 40% of children who show childhood-onset CD will be arrested or show ASPD as an adult. In addition, about 20% of those in the childhood-onset pathway with elevated CU traits will show significant levels of adult psychopathic traits.

In contrast, individuals who follow the adolescent-onset trajectory do not start showing significant behavior problems until they approach adolescence, at which point they start showing a range of problems involving symptoms of both ODD and CD. Their behavior problems tend not to be aggressive. However, their antisocial behavior can lead them to have problems at school, leading to school dropouts, as well as problems with the law. Their association with deviant peers can also lead to problems with substance abuse, which can continue into adulthood. In adulthood, individuals in the adolescent-onset group are less likely to have legal problems or ASPD compared to those in the childhood-onset group, but they can still have social, occupational, and mental health consequences of their adolescent behavior.

FIGURE 45–1. Three common trajectories of conduct disorder are illustrated over the course of development.

Treatment

Given that most children who develop childhood-onset CD show ADHD and ODD prior to developing CD, successful treatment of these conditions can be considered secondary prevention of CD. Thus, pharmacologic treatment to treat ADHD, such as with CNS stimulants, has also been shown to reduce conduct problems in children with comorbid diagnoses of ADHD and either ODD or CD. Further, the PMT interventions that were described previously in the treatment of ODD are also effective for young children who have begun to show CD. Children with elevated CU traits have typically not responded as well to PMT and other behavioral interventions as other children with CD. Children with CD and elevated CU traits often start and end treatment with more severe behavior problems, despite showing some improvement. These findings have led to attempts to enhance PMT interventions for children with elevated CU traits by targeting their distinct risk factors and needs. These novel treatment targets include: (a) teaching parents how to increase their warm and responsive parenting, (b) emphasizing the use of consistent rewards to encourage positive behavior, including prosocial behavior, over punishment-based parenting strategies such as time-out, and (c) parent–child emotion recognition training. To date, such interventions have shown

Telegram: @medical_k

www.konkur.in

promising results but await randomized controlled trials to better document their effectiveness.

For older children and adolescents with CD, interventions that are multi-component and can be tailored to the unique needs of the youth appear most effective. Such interventions recognize that CD is often caused and maintained by multiple factors, and the causal processes may differ across youths with CD. Further, the subtypes of CD can help to guide these comprehensive and individualized approaches to treatment. For example, interventions that focus on enhancing identity development and increasing contact with prosocial peers, such as mentoring programs or programs that provide structured after-school activities, may be effective for youth with adolescent-onset CD. In contrast, interventions that focus on anger control or on reducing harsh and ineffective parenting may be more effective for children in the childhood-onset group who do not exhibit elevated CU traits but often show problems with emotional regulation and come from families that use dysfunctional parenting practices. Finally, interventions that teach children to pay attention to emotional cues in others, motivate them to change their behavior in ways that capitalize on their self-interest using positive reinforcement over punishment, or focus on increasing parental warmth and responsivity may be more effective for children with elevated CU traits.

Several treatment models have been developed that are designed to provide this comprehensive and individualized approach to treatment. Two of these have proven to be quite effective in treating adolescents with CD in randomized controlled trials. Functional family therapy (FFT) represents a unique integration and extension of family systems and behavioral, cognitive, and affective approaches to treatment. FFT focuses on engaging the adolescent and the family in treatment, developing individualized motivations for change, and adapting its treatment to modify structural and systemic family processes that may be maintaining the youth's problem behaviors. FFT also relies upon a number of proven behavioral principles to treat CD. For example, FFT targets enhancements in communication and mutual problem-solving skills between parents and adolescents, as well as improvements in parental contingency management. Finally, FFT focuses on the generalization of new skills to other settings, such as school or the legal system.

Another comprehensive and individualized treatment model for adolescents with CD is multisystemic therapy (MST). MST was

Telegram: @medical_k

www.konkur.in

specifically developed as a treatment to address the multiple risk factors that can lead to severe antisocial and delinquent behavior in adolescents. As its name implies, MST tries to intervene in multiple systems, familial and extrafamilial (e.g., maladaptive parenting, deviant peer or gang affiliation, poor school achievement), that can influence the adolescent's behavior. Emphasis is placed on making changes in the adolescent's social ecology that will reduce problem behavior and support these changes after treatment ends. Treatment can range substantially across individuals, depending on an initial needs assessment.

As is the case for PMT, both FFT and MST have been proven to reduce behavior problems in youth with elevated CU traits. However, also consistent with the research on PMT, children with CD and CU traits still often leave treatment with more severe behavior problems than other children with CD. Thus, future work should focus on how to enhance these and other comprehensive approaches to treatment to be more effective for the subgroup of youths with CD and CU traits.

FUTURE DIRECTIONS

There have been a number of major advances in our understanding of the causes of ODD and CD, as well as advances in the treatment of these disorders in recent years. These advances have largely been the result of the fact that research has gone beyond simply documenting the many different risk factors that can play a role in the development or maintenance of these disorders. Instead, recent research is trying to determine the most common ways in which these risk factors can negatively impact important developmental processes, leading to behavior that brings the child into conflict with authority (ODD) or to act in a way that violates the rights of others or major age-appropriate norms (CD). This work has helped to delineate several common developmental pathways to ODD and CD that are now reflected in psychiatric diagnosis.

The importance of this approach to research on causal factors is exemplified by work showing that some children with CD show under-reactive responses to emotional stimuli (i.e., those with elevated CU traits), whereas others show hyper-reactive emotional responses (i.e., those without elevated CU traits). Failure to differentiate these subtypes likely is the reason that previous research on the emotional correlates of CD has been inconsistent. It is possible that future research in molecular

Telegram: @medical_k

www.konkur.in

genetics and neuroimaging will result in more consistent findings on the neurocognitive correlates of CD once potential differences across subtypes are consistently tested.

This research on developmental pathways to CD has also aided the development of more effective treatments for CD. Treatments no longer focus on changing a single risk factor in the same way for all children and adolescents with CD. Instead, treatments now focus on targeting multiple risk factors and are tailored to the individual needs of the youth with CD. Interventions are beginning to use research on the developmental pathways to CD to guide these tailored approaches to treatment. A promising direction of future treatment research is adapting evidence-based treatments with enhancements specifically designed to be more effective for children with elevated CU traits, a subgroup who heretofore have not responded as well to traditional treatments.

Feeding and Eating Disorders of Infancy and Early Childhood

IRENE CHATOOR, M.D., AND LOREDANA LUCARELLI, PSY.D.

The term *feeding and eating disorders* describes a variety of conditions including food refusal, food selectivity, eating too little, food avoidance, fear of feeding, pica, and rumination in infancy and early childhood. Particularly, the term *feeding* is commonly used to emphasize the dyadic nature of the "feeding relationship" in infants and young children that involves complex interactions between the child and the parent. During a reciprocal feeding process, optimal parent–child interactions depend on sensitive, responsive parenting as well as the child's ability to clearly communicate hunger and satiety cues. It is estimated that in the general population, 25% to 45% of infants and young children have various feeding and eating problems and that severe disorders associated with poor weight gain occur in 1% to 5% of pediatric hospital admissions and between 4% and 14% in ambulatory care. However, an exact evaluation of the prevalence or incidence rates of feeding and eating disorders, and of particular diagnostic subtypes, has not been published up to now because of the variability of definitions used and the lack of a general diagnostic classification of feeding and disorders shared by clinicians and researchers. Overall, several studies have found that early feeding and eating problems not only cause distress to the

Telegram: @medical_k

www.konkur.in

young child but affect the whole family and often continue into later childhood and adolescence.

DEFINITION

Criteria for Feeding Disorder of Infancy or Early Childhood in DSM-IV have been criticized for being too restrictive and not capturing many young children with feeding difficulties, and an alternative system in DC: 0–3R (2005) has often been used. This system includes six subtypes of feeding behavior disorder proposed by Chatoor. Avoidant/Restrictive Food Intake Disorder (ARFID) in DSM-5 replaced Feeding Disorder of Infancy or Early Childhood in DSM-IV, and more recently, ARFID was introduced in the 11th Revision of the World Health Organization's International Classification for Diseases (ICD-11). ARFID has expanded the earlier, more limited diagnostic criteria by introducing three main categories of feeding/eating problems based on the three subtypes of Feeding Behavior Disorder in DC: 0–3R, and the text addresses the three remaining feeding disorders from DC: 0–3R. In addition, the ARFID criteria can be applied to individuals of all ages, consistent with the recognition of the continuity of psychopathology across the age range from early childhood to adulthood. ARFID is defined as a persistent disturbance in feeding or eating that can result in severe malnutrition, significant weight loss or a failure to gain weight, growth compromise, and/or a marked interference with psychosocial functioning. ARFID provides a diagnostic label for a heterogeneous group of individuals across the age range who engage in avoidant or restrictive eating behaviors without weight or body image concerns. The new criteria of ARFID in DSM-5 and its text revision (DSM-5-TR) describe three variants of an eating or feeding disturbance that is characterized by, for example, apparent lack of interest in eating or food; avoidance based on the sensory characteristics of food; concern about aversive consequences of eating. These new DSM-5 criteria of ARFID with the accompanying text map directly on three of the DC: 0–3R subtypes. The new subtype, "apparent lack of interest in food or eating," has been described in DC: 0–3R as infantile

Telegram: @medical_k

www.konkur.in

anorexia (IA); the second variant, “avoidance based on the sensory characteristics of food,” describes children who select or avoid food in relation to the appearance, taste, texture, smell, or temperature of food and has been defined in DC: 0–3R as Sensory Food Aversions; the third variant “concern about aversive consequences of eating” is described in DC: 0–3R as Feeding Disorder Associated with Insults to the Gastrointestinal Tract and has been described by Chatoor as Post-Traumatic Feeding Disorder (2002).

In addition, in the text, there is allowance to diagnose ARFID in infants and children with the remaining three feeding disorders described in DC: 0–3R, those who have difficulty with state regulation, those who may not engage with the caretaker during feeding, or those whose feeding problems are associated with a medical condition when the disturbance of intake is beyond what can be explained by the physical condition.

To delineate feeding disorders from less severe feeding difficulties, DSM-5-TR expanded the criteria of impairment to affect one or more of four areas of health or functioning:

- Significant weight loss (or failure to achieve expected weight gain or faltering growth in children)
- Significant nutritional deficiency
- Dependence on enteral feedings or oral nutritional supplements
- Marked interference with psychosocial functioning

HISTORY AND COMPARATIVE NOSOLOGY

Prior to the inclusion of the diagnostic category of Feeding Disorder of Infancy or Early Childhood in the DSM-IV, there were no nationally defined criteria for the diagnosis of feeding disorders. In the absence of a recognized standard, different authors have used several labels for feeding problems: picky eaters, choosy eaters, selective eaters, problem eaters, food refusal, feeding resistance, food phobia, food aversion, and dysphagia. However, none of these diagnostic labels has been operationalized. The field of feeding disorders has been further complicated by the fact that feeding disorder and failure to

Telegram: @medical_k

www.konkur.in

thrive (FTT) have been used interchangeably. The term *failure to thrive* refers to inadequate weight gain based on standard growth charts. Historically, FTT has been dichotomized along organic and nonorganic axes. Whereas the former attributes growth failure to a medically diagnosable cause, the latter has commonly been thought to reflect maternal deprivation or neglect. A third category was later added and represents a mixture of organic and environmental etiologic factors of growth failure.

Concerns have been expressed about the usefulness of the label FTT as a "catch-all" diagnosis for all feeding disorders. First, the overlap between FTT and feeding disorders is confusing because not all infants with FTT have feeding disorders, and not all infants with feeding disorders have FTT. Second, Goldbloom pointed out that the term FTT is purely descriptive and does not address the process that caused the infant to grow inadequately. Although many authors agree that FTT should be viewed as a symptom rather than a diagnosis, FTT continues to be used as a diagnostic label, particularly in the pediatric and psychological literature.

As described above, because of the limitations of the diagnostic criteria of Feeding Disorders of Infancy or Early Childhood in DSM-IV, an alternative classification of feeding disorders has been adopted by DC: 0–3R, which served as a template for the new diagnostic category of ARFID in DSM-5 and DSM-5-TR.

The original diagnostic criteria were published by Chatoor in 2002 and were modified with the help of the 2003 Task Force for Research Diagnostic Criteria for Infants and Preschool Children. They were further developed with the help of a work group that was supported by the American Psychiatric Association, and the revised criteria were published in 2007 in *Age and Gender Considerations in Psychiatric Diagnosis.* As explained above, the diagnostic criteria for these six feeding disorder subtypes were also included in the 2005 edition of the *Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood: Revised Edition* (DC: 0–3R).

The six feeding disorder subtypes are as follows: (1) feeding disorder of state regulation, (2) feeding disorder of caregiver–infant

Telegram: @medical_k

www.konkur.in

reciprocity, (3) IA, (4) sensory food aversions, (5) feeding disorder associated with a concurrent medical condition, and (6) feeding disorder associated with insults to the gastrointestinal tract. The first four feeding disorders tend to start during specific developmental periods and are arranged accordingly, whereas post-traumatic feeding disorder and feeding disorder associated with a concurrent medical condition can occur at various stages of the child's development.

Since recently published research on feeding disorders has frequently used the classification in DC: 0–3R, the authors will discuss the various feeding disorders as listed in DSM-5-TR and will use the descriptions of the feeding disorders in DC: 0–3R as subtitles.

SPECIFIC FEEDING DISORDER SUBTYPES

Avoidant/Restrictive Food Intake Disorder

Subtype: apparent lack of interest in eating or food (DSM-5-TR)
Infantile Anorexia (DC: 0–3R)

Diagnosis and Clinical Features. IA is characterized by poor appetite, lack of interest in eating, and poor growth in an otherwise active and playful child. It was first described by Chatoor in the 80s and was adopted in DC: 0–3R (2005) as one of the subtypes of Feeding Behavior Disorder. It usually begins in the first 3 years of life, most commonly between 9 and 18 months of age, when infants learn to walk, begin to talk, and are transitioned to spoon and self-feeding. The children are active and playful and appear to be interested in everything else but food and eating. They resist going into the highchair; they refuse to open their mouth to be fed and throw the food and feeding utensils. The parents become increasingly worried because of the children's poor food intake and growth, and they often resort to distracting, coaxing, and bribing to get the children to eat. Some parents become so anxious that they try to feed the children whenever they are willing to open their

Telegram: @medical_k

www.konkur.in

mouth, and some become so desperate that they resort to force-feeding their children. Maternal worry about the child's underweight mediates and moderates the mother–child feeding interactions and perpetuates the feeding disorder. Consequently, there is increasing conflict between the children and their parents, and mealtimes become miserable for the whole family.

Differential Diagnosis. IA needs to be differentiated from other feeding disorders that are characterized by food refusal. ARFID subtype: "concern about aversive consequences," usually has a more sudden onset of the food refusal following a traumatic event to the oropharynx or gastroesophageal tract, such as choking, severe gagging, or vomiting, or the insertion of feeding or endotracheal tubes. The infant with this feeding disorder may refuse all food, only solid food, or only the bottle, depending on what mode of feeding the infant associates with the traumatic experience(s). Infants with ARFID subtype: "avoidance based on the sensory characteristics of food" or sensory food aversions (DC: 0–3R) consistently refuse specific foods but eat well if offered preferred foods.

Etiology and Course. Toddlers with IA have been found to have a higher level of physiological arousal and more difficulty down-regulating their arousal. This may explain why they have so little awareness of hunger because they seem very excited by their play and enjoy talking, but they have difficulty turning away from these pleasurable activities. Studies from different centers have found significant correlations among difficult child temperament, irregular feeding and sleeping patterns, negative and willful behaviors by the toddlers, and mother–child conflict during feeding. At the same time, mothers' insecure attachment to their parents and mothers' drive for thinness and bulimia, anxiety, and depression also correlated significantly with mother-child conflict during feeding. Finally, mother–child conflict during feeding correlated strongly with the child's weight: the more conflict between mother and child, the lower the child's weight. However, correlations need to be used with caution to explain etiology, although the feeding histories of children

Telegram: @medical_k

www.konkur.in

with IA suggest that the lack of appetite and food refusal by the toddlers evoke severe anxiety and feelings of helplessness in the parents, who then try to engage the children in distractions and do anything to get the children to eat. The more insecure the parents feel, the more they allow the child to control the feeding situation, and the more ineffective the parents become in setting appropriate limits to the child's demanding behaviors. Consequently, parents and children become trapped in maladaptive interactional patterns.

Research further revealed that toddlers with IA, on average, performed in the normal range of cognitive development. However, the Mental Developmental Index (MDI) score of a control group of healthy eaters was 11 points higher than that of the group of toddlers with IA. Further analyses showed that not weight but mother-toddler interactions during feeding and play seemed to contribute significantly to these differences. Mother–toddler conflict and struggle for control during feeding and maternal intrusiveness during play were associated with the lower cognitive performance of the toddlers.

A longitudinal study from Italy by Lucarelli and colleagues of 58 boys and 55 girls with IA who received only minimal intervention at the time of diagnosis revealed some interesting findings. The diagnosis of IA was made by two independent clinicians, and following the publication of DSM-5, the research team clarified that the young patients originally diagnosed with IA and enrolled in this study met the criteria for the ARFID subtype "apparent lack of interest in eating or food." The mothers of the children who were diagnosed with IA were recontacted and invited to take part in a pediatric and psychological assessment at three time points at 5, 7, and 11 years of age. Mothers received some psychoeducation about this specific eating disorder at the time of the diagnosis and during subsequent assessments but did not pursue any specific psychotherapeutic treatment for various reasons: lived or moved to another city, lived in other areas of Italy without appropriate resources, refusal by one or both parents to participate in the study, or precocious termination of treatment. However, the children were followed closely by the pediatricians at the hospital in Rome and in

Telegram: @medical_k

www.konkur.in

their community, and they were periodically called back for subsequent appointments at the hospital in Rome. About 70% of the children with IA seen at follow-ups from 2 to 11 years of age, showed ongoing eating problems and higher scores in anxiety, moodiness, aggressive behaviors, and somatic complaints when compared to the controls. These longitudinal data also showed significant correlations between continuing maternal eating and psychopathology, especially depression and anxiety, and internalizing problems of the children. At 11 years of age, the girls' emotional/behavioral problems and their mothers' psychopathology and disturbed eating attitudes were more severe than that of the boys and their mothers. These results demonstrated a significant effect of sex–namely that at the age of 11 years, especially the girls and their mothers demonstrated increased eating pathology and associated psychopathological symptoms. Further longitudinal research is necessary to better understand how these children will negotiate adolescence. It raises the question of whether these children will develop a fear of becoming fat and transition to the full picture of anorexia nervosa or other restrictive eating disorders during the critical developmental period of adolescence, which represents a peak period for the onset of eating disorders, especially in girls. Overall, this study on the natural course of IA highlights the importance of early diagnosis and specific interventions for children diagnosed with IA.

A follow-up study of 20 children at 6 months to 2 years at the time of diagnosis, who had completed a specific treatment described later, demonstrated that 17 children had changed considerably. The conflict in the parent–child relationship over the child's food intake was resolved. The children had learned to recognize hunger and increased their food intake, which led to weight gain and improved growth. However, the parents reported that many of the children continued to lose their appetite when they were excited, if they had houseguests, if they had a birthday party, or if they traveled. Once they calmed themselves, they would regain their appetite and usually make up for the lost meals. There were three children who continued to struggle with their parents over their poor eating. In two cases,

Telegram: @medical_k

www.konkur.in

day care seemed to be too stimulating to allow these children to relax enough for eating. In the third case, the home situation was very overcrowded and disorganized.

Clinical experience suggests that older children who have been untreated and who present for the first time with the diagnosis of IA during school age are usually thin and short for their age. However, their head size and their intellectual development appear to be normal for their chronologic age. This was confirmed in a follow-up study by Chatoor and colleagues of children who were treated as toddlers for IA. It demonstrated that two-thirds of the children had outgrown their feeding disorder whereas one-third did not. Regardless of their malnutrition at the time of diagnosis or at follow-up, there was no correlation between their weight and intellectual functioning. Indeed, one-third of the children functioned in the superior range of intelligence.

To date, few studies have followed children with feeding disorders over time with the exception of the Italian study described earlier. Other longitudinal studies which focused on the development of infants/toddlers with feeding problems have not attempted to differentiate between subtypes of feeding disorders. As a result, it is not known how specific feeding disorders in early childhood are related to eating disorders in adolescence and adulthood. This will be a challenge for future research.

Treatment. This subsection describes a treatment that is based on a transactional model for the development of IA. According to this model, the infant's difficult temperament characteristics of emotional intensity, stubbornness, lack of hunger cues, irregular feeding, and sleeping patterns evoke conflicts over issues of control, autonomy, and dependency in a vulnerable parent who is anxious and insecure in regard to limit setting. The treatment addresses the infant's temperament and the parents' anxiety in regard to limit setting to facilitate internal regulation of eating of the infant.

1. The infant's temperament is discussed with the parents to help them understand that the infant's curiosity and emotional intensity

Telegram: @medical_k

www.konkur.in

interfere with the infant's awareness of hunger. Because the infant is very strong-willed and has learned that food refusal is a powerful tool with which to control the parents' attention, efforts by the parents to distract or entertain the infant to get them to eat may help temporarily but only perpetuate the problem by getting the infant more excited.

2. The parents' source of anxiety in regard to limit setting is explored. Some parents have been sensitized by previous losses of pregnancies, by infertility problems, or by the harshness and/or emotional unavailability of their parents. Understanding the parents' sensitivity in regard to limit setting is critical to helping them to be more effective in this area with their infant.
3. After this ground work, the parents are trained with respect to changing their behavior so as to facilitate internal regulation of eating by their infant. To boost the infant's biologic rhythms of hunger and satiety, the parents are encouraged to feed the infant only at regular 3- to 4-hour intervals and not to offer anything but water in between these regular feedings. They are helped to understand that it is important to encourage the infant's self-feeding by commenting on the infant's feeding skills ("you get the spoon in your mouth all by yourself"), but they are not to comment on how much or how little the infant eats. It is helpful to give the infant only a few bites at a time and after a while change to another food to keep the infant interested in eating and engaged with the parent without the parent becoming intrusive or distracting the infant. In addition, this helps the infant to continue eating until full and to learn to regulate their food intake by their internal signals of hunger and satiety. Eating should not be a performance for the parents. There should be no distractions during feedings, and no television or games, so that the infant is kept focused on eating. If the infant engages in inappropriate behaviors during feeding (climbing out of the high chair, throwing food, or feeding utensils), the parents need to learn to use the "time-out" procedure. The time-out is used to accomplish two goals: to help the infant to stop behaviors that interfere with eating and to learn self-calming when upset because they cannot have their way.

Telegram: @medical_k

www.konkur.in

This three-step intervention with the parents is best accomplished in double sessions, lasting 2 hours each, with the first two sessions being held within a few weeks of each other. The intensity of this brief intervention facilitates a close therapeutic alliance between the therapist and the parents and enables many parents to make major shifts in their interactions with their infants. Many of these parents need only a few follow-up sessions to deal with some specific questions that may arise. Frequently, after the infant has changed their eating pattern, the parents ask for help concerning the sleeping problems that many of these children have as well. However, there are some families who are more deeply entrenched in maladaptive interactional patterns with their infants, and some infants are so severely malnourished that more intensive interventions or hospitalization may be required. In particular, considering the associations between the severity of IA and risk factors such as high mother-child interactional conflict, difficult child temperament, and emotional and eating dysregulation in both the children and their mothers, the therapeutic approach should have a dual focus on the child and on the parents.

Telegram: @medical_k

www.konkur.in

Rachel was 18 months old when she was referred by her pediatrician because of food refusal and malnutrition. The mother looked exhausted as she described how Rachel had never been a big eater from birth but that she stayed on the 25th percentile for weight and height on the growth chart until she was about 10 months of age. Her refusal to be fed by spoon became so strong that her intake of solid food became less and less. She depended primarily on bottles with milk for her nutrition. In spite of all of the parents' efforts to distract Rachel during feeding, to offer different foods, and to feed her whenever she would accept anything (including at night) and their desperate efforts to force food into her mouth, Rachel's food refusal had gotten worse, and she had fallen below the 5th percentile on the growth chart for weight and height. The mother admitted that trying to feed Rachel had taken over her entire life and that she felt exhausted and envious when she watched her friends' children eating without any effort on the part of the parents.

The observation of mother and infant during feeding and play revealed that Rachel was a thin little girl who seemed "all eyes," observing everything in the room, including the pictures on the wall and her image in the mirror. However, she paid little attention to the food. She ate some finger food but refused to open her mouth and arched her back when her mother tried to feed her with spoon. After a few minutes, she appeared bored sitting in the high chair, threw the food, and indicated by grunting that she wanted to be taken out of the chair. Once she had her freedom, she ran around the room entertaining herself by exploring the furniture while her mother sat in her chair looking anxious and defeated.

The treatment addressed Rachel's special temperament characteristics, her intense curiosity and emotional intensity, her strong will, and her poor awareness of hunger, which seemed to have led to her increasing food refusal. The parents were helped to understand that they had a child with special temperament characteristics that required special parenting with special

Telegram: @medical_k

www.konkur.in

emphasis on limit setting. Specific instructions were discussed on how to handle mealtime, how to deal with Rachel's food refusal, and how to use "time-out" with a young child.

Although the mother struggled initially with how to set limits to Rachel's inappropriate behaviors—for example, stopping her from throwing food and keeping her in the high chair—the parents supported each other in implementing the new feeding instructions and were pleased with the change in Rachel's behavior. Once Rachel realized that her screaming did not change the rules, she stayed in the high chair without protest and became interested in feeding herself with the spoon. Within a few weeks, she seemed more aware of hunger, and her food intake increased accordingly. When seen for follow-up 1 year later, there was no longer conflict over Rachel's eating. Rachel had gained weight and grown in length, which brought her back to the 10th percentile on the growth chart.

In recent years, several studies have explored the effects of cyproheptadine therapy on children with feeding difficulties and poor growth. Although most children seem to tolerate the medication quite well, their appetite and food intake improves and resulting in better weight gain. The initial positive effect often wears off after a few weeks, and the medication is then given 3 weeks on and 1 week off or in shorter intervals of 4 days on and 3 days off in order to maintain the positive effect on appetite stimulation,

Avoidant/Restrictive Food Intake Disorder

Subtype: avoidance based on the sensory characteristics of food (DSM-5-TR)

Sensory Food Aversions (DC: 0–3R)

Diagnosis and Clinical Features. Sensory food aversions are common. However, whereas some children refuse to eat only a few specific foods, others may refuse most foods and take in only a

Telegram: @medical_k

www.konkur.in

limited diet of a few foods. The diagnosis of a feeding disorder should only be made if the food selectivity results in dietary deficiencies, and/or has led to oral motor and speech delay, and/or in older children is associated with social anxiety around eating and has led to marked interference of psychosocial functioning.

Within this disorder, food refusal is related to the taste, texture, temperature, or smell of particular foods. When the infant is fed specific foods, the infant's aversive reactions range from grimacing to spitting the food out and wiping the tongue or mouth to gagging and vomiting. After an initial aversive reaction, the infants usually refuse to continue eating that specific food. In addition, infants tend to generalize and refuse to even try foods of similar color, appearance, or smell. Occasionally, sensory food aversions become apparent in the newborn period when the infant is switched from breast milk to formula or from one formula to another. However, most commonly, infants begin to show aversive reactions when introduced to baby foods with different flavors and different textures or in the second year of life, during the introduction of different table foods. After the initial aversive reactions described earlier, some infants show such intense food refusal that they become limited to eating only a small variety of foods. They may refuse to eat whole food categories, such as vegetables, fruits, or meats. In extreme cases, they even refuse to eat a preferred food if it touched a "feared" food on the plate or if the food is not prepared by a specific restaurant or company. Children who refuse to eat vegetables and fruits usually develop vitamin deficiencies, and children who refuse to drink milk or eat meats may develop protein, zinc, and/or iron deficiencies. In addition, children who refuse to eat foods that require more chewing, such as meats, hard vegetables, or fruits, present with delay in oral motor development, which may be associated with articulation difficulties.

In addition to their sensory food aversions, many of these children experience hypersensitivities in other sensory areas as well. Parents frequently report that these children do not like to get their hands "messy," become distressed when asked to walk on grass or sand, and do not like to wear socks or shoes, certain fabrics, or labels on

Telegram: @medical_k

www.konkur.in

clothing. Many of these children are also hypersensitive to smells, and some may have difficulty with loud sounds.

Differential Diagnosis. This feeding disorder needs to be differentiated from oppositional food refusal which is common during the toddler years. Toddlers who like to exercise control over their parents may state that they do not want to eat a certain food and demand something else to eat. However, the food choices of oppositional toddlers are inconsistent and vary according to the mood of the toddler, whereas toddlers with sensory food aversions are usually consistent in their food choices, and they become distressed when the parents insist that they eat a certain food to which they are averse. Sensory food aversions also need to be differentiated from ARFID subtype: concern about aversive consequences of eating (DSM-5-TR) or described as post-traumatic feeding disorder by Chatoor, which is characterized by the child's refusal to eat all solid food or to drink from the bottle, depending on what mode of eating the child associates with the traumatic event(s). However, some children with sensory food aversions may develop a post-traumatic feeding disorder if they have a strong aversive reaction to a food resulting in gagging or vomiting, and/or the parents continue to insist that the child eat a food to which the child is averse. These children may become fearful of eating altogether.

Etiology and Course. There are no empirical studies that have examined the etiology of sensory food aversions in infants and toddlers. However, research with preschool and older children and with adults has related taste sensitivities to the bitter substance propylthiouracil, to strong food preferences, and to the number of taste buds on the individual's tongue (those with strong taste sensitivities, the "supertasters," have significantly more taste buds than "nontasters"). A study by Cooke and colleagues that examined food neophobia (the fear to try new foods, which is one of the characteristics of sensory food aversions) in a large sample of twins aged 8 to 11 years estimated that 78% was heritable and another 22% of the variance was explained by nonshared environmental

Telegram: @medical_k

www.konkur.in

factors. Some studies have documented that parents and their biologic children can share taste sensitivities and various models of heritability—for example, incomplete penetrance, a two-locus model, and multilocus and multiallele models—have been suggested. In 2003, Kim and colleagues reported that specific polymorphisms on the taste receptor protein gene family Tas2r on chromosome 7 differentiated supertasters from nontasters.

In addition, certain aspects of the eating environment have been linked to the development of food preferences. For example, parents with strong taste sensitivities may offer a restricted range of food to their children, and limited exposure to a variety of foods may enhance toddlers' food selectivity. On the other hand, if parents try to coax children or become forceful to get their children to try new foods, the children become oppositional and increasingly anxious and scared to try new foods. This pattern of forcing children to eat certain foods without adequate support to manage their anxiety may be a risk factor in sensory food aversions outcome. In support of this, longitudinal research by Nicholls and colleagues has shown that selective eating is associated with anxiety and obsessive-compulsive symptoms, social limitations, and school difficulties.

A longitudinal study of children's food preferences by Skinner and colleagues, who followed children from 2 to 3 years to 8 years of age, found that the number of foods liked at 8 years was predicted by the number liked at 4 years of age. Children were more likely to accept newly tasted foods between 2 and 4 years of age than during school-age years. School-age children with sensory food aversions may experience social anxiety and try to avoid social activities (parties, sleepovers, summer camp) that involve eating. Parents of children with sensory food aversions often report that they were unable to eat a variety of foods as young children and that they learned to eat new foods primarily during their adolescent or young adult years when they wanted to fit in with their peers.

Treatment. Research by Birch and colleagues indicated that repeated exposures to new foods enhance young infants' acceptance not only of that food but also of similar foods. However,

Telegram: @medical_k

www.konkur.in

toddlers required more than 10 exposures to the same new foods until acceptance was reached. In addition, it is very difficult to get toddlers to try new foods if they are reluctant to do so. Birch and colleagues demonstrated that coercive techniques, such as threatening children to have them remain seated at the table until they finished eating everything on their plate or depriving them of certain privileges unless they tried the new food, have a significant negative effect. On the other hand, toddlers are very responsive to modeling by their parents. They are more willing to try a new food if they observe their parents eating the food but not offering it to them.

No empirical studies have systematically examined how best to treat infants and young children with sensory food aversions, but clinical experience suggests that if infants or toddlers show strong aversive reactions to a new food, such as by spitting the food out or gagging or vomiting, the parents are best advised to give up on having the child eat this food. On the other hand, if the infant just grimaces, the parents may expose the infant to the new food at another time and pair a small amount of the aversive food with a preferred food. A gradual increase of the aversive food over several meals may allow the infant to get used to the new food.

Modeling eating new foods by the parents and waiting until the toddler asks to try a new food generally is more effective than putting new foods on the toddler's plate and requesting that the toddler try them. If the parents stay neutral as to whether the toddler likes the requested food, the toddler remains neutral as well and does not appear to become afraid of trying new foods. Once children fear trying new foods, their diet becomes more and more limited, and, by 3 years of age, most young children are not swayed by what their parents eat. Occasionally, preschool children may be willing to try new foods in a preschool setting, but more often they become anxious in social situations and try to avoid eating with others. On the other hand, preschool children are rich in phantasies, and feeding the baby dolls with playfood can help to explore their fears and encourage them to first feed the baby doll and then eat themselves new foods.

www.konkur.in

John was brought for an assessment by the multidisciplinary feeding disorders team because he refused to eat vegetables, fruits, and meats. His parents had started to give him a multivitamin daily, but they were worried that he was missing other essential nutrients in his limited diet, and they were concerned that his articulation was so poor that nobody outside of the family could understand what he was saying. At the age of 2½ years, his daily diet consisted of Cheerios or pancakes in the morning and peanut butter sandwiches, some cheese (which had to be “American”), pasta, cake, crackers, ice cream, and milk during the rest of the day. His feeding problems started when he was introduced to baby food. He accepted baby food sweetened with fruit but grimaced when given baby food with vegetables and spat it out. He gagged when introduced to baby food with lumps of meat, and he refused to accept any baby food after that. At 9 months of age, John was offered soft table foods, which he ate only if he could finger-feed himself. He had another episode of gagging when introduced to green beans at 15 months of age, and consequently, he refused to touch any green vegetables and fruits. He never tried any meats, and he became very distressed when his parents put any food on his plate that he did not want. When his parents insisted that he should at least try one bite of a new food before he could leave the table, John cried throughout the whole meal and ate nothing, not even his preferred foods. The parents had strong disagreements about how to handle John’s food refusal. The father had similar food dislikes as a child and wanted to leave him alone. The mother was very concerned about John’s health because of his limited diet, and she tried everything—bribing, coaxing, distracting, and threatening—just to get John to try new foods. Both parents experienced mealtime as very stressful and felt that John was getting increasingly rigid about his food likes and dislikes.

The observation of feeding revealed intense conflict between John and his mother regarding the various foods that he refused to eat. The nutritional assessment showed that although John

Telegram: @medical_k

www.konkur.in

was taking in adequate calories, he was not getting enough zinc and iron from his diet and, without the multivitamin, his diet was deficient in vitamins. The oral motor assessment revealed that John used an immature chewing pattern that was felt to be due to his lack of practice with chewing crunchy and chewy foods. This oral motor delay was felt to account for his articulation problems.

The parents were instructed to obtain vitamins complete with zinc and iron to compensate for the nutrients missing in John's diet. They were also offered speech therapy for John to help with his articulation problems. In addition, the parents were given a few parent training sessions to help them emotionally neutralize mealtime. After the mother's anxiety about John's health was alleviated, she was able to offer John his preferred foods without attempting to get him to eat new foods. The parents were instructed to eat their regular diet in front of John without offering him any of their food and to give him only a small piece of their food if he were to ask for it. They were not to praise him if he liked the food nor become disappointed if he no longer wanted to have it. After she had stopped offering John any new food for about 2 months, John surprised his mother by asking her to have some of her peach. He liked it and asked for more on another day. Gradually, he began to eat soft fruits without the peel, and after several months, he tried chicken nuggets. His diet increased in variety very slowly, and when he entered preschool, he tried a number of foods at school that he had not touched at home. His diet became more complete. However, John was not able to eat the variety of foods the rest of his family enjoyed.

Avoidant/Restrictive Food Intake Disorder

Subtype: concern about aversive consequences of eating (DSM-5-TR)

Feeding Disorder Associated with Insults to the Gastrointestinal Tract (DC: 0–3R)

Telegram: @medical_k

www.konkur.in

Post-Traumatic Feeding Disorder (Chatoor et al., 1988)

Clinical Features. This feeding disorder may present with total food refusal, refusal to swallow solid food, or refusal to drink from the bottle, depending on what mode of feeding the child associates with the traumatic event. The onset of the food refusal is frequently rather sudden and follows traumatic experiences that involve the oropharynx or gastrointestinal tract, such as severe gagging, choking, vomiting, insertion of feeding or endotracheal tubes, or force-feeding. It is estimated that post-traumatic feeding disorder may affect 4% of infants with gastroesophageal reflux who do not have a history of esophageal surgery and up to 40% of children who undergo esophageal surgery. Frequently, the parents are not aware that the event was so frightening to the child that it triggered the food refusal because other children who may undergo the same experience will not necessarily develop a post-traumatic feeding disorder. It appears that children who develop a post-traumatic feeding disorder are more prone to anxiety and/or are more sensitive to pain than the average child. Older children who refused to eat solid food after an incident of gagging or choking reported that they were afraid that the food would get stuck in their throat and choke them to death. Infants and young children express this fear through their behavior by crying in anticipation of being fed or when seeing the high chair, the bottle, or the spoon. Some infants or children are brave enough to put the food in their mouths but cannot bring themselves to swallow it. They keep the food in their cheeks and/or spit it out. In severe cases, the infants refuse to feed altogether. These infants are in acute danger of dehydration because the fear of eating appears to override any awareness of hunger or thirst.

Often the food refusal of these children is so intense that the parents react with severe anxiety to their child's food refusal. They worry about their child's nutrition. Frequently, they try to coax and distract the child, they offer various types of food, and they try to feed the child day and night without success. However, some very young infants who are afraid to drink from the bottle when they are awake may drink when they are asleep and not aware of what they

Telegram: @medical_k

www.konkur.in

are doing. However, if they wake up and see the bottle, they usually push it away and cry. In general, the food refusal of these infants poses an acute threat to their health, and they require acute intervention.

Differential Diagnosis. This feeding disorder needs to be differentiated from IA and from food refusal because of sensory food aversions. IA is characterized by an inconsistent pattern of food refusal, depending on the mood of the child. Anorectic children are not afraid to eat and can eat all types of food if they want to eat. Sensory food aversions usually involve foods with a certain taste, texture, temperature, and/or smell. Usually, the food refusal is more selective and not as global as seen in a post-traumatic feeding disorder. However, sometimes children with sensory food aversions develop a post-traumatic feeding disorder if they experience a strong aversive reaction or if they are force-fed aversive foods that trigger gagging and vomiting.

Etiology and Course. The observation of infants with a post-traumatic feeding disorder reveals that their food refusal seems to be caused by fear. However, no empirical studies have been done to explain why only some infants with distressing experiences with the oropharynx react with a post-traumatic feeding disorder. There are also no systematic longitudinal data on the course of this feeding disorder. However, individual case studies indicate that many infants and children get locked into their fears of eating. Some drink milk from the bottle and eat only pureed food until they reach school age, when the social embarrassment of their eating behavior causes the parents to seek help. In extreme cases, when the infants refuse all food, gastrostomy feedings have to be implemented. To survive, some of these children may depend on gastrostomy feedings for years.

A recent study by Lucarelli and colleagues showed that children with a post-traumatic feeding disorder scored in the clinical range of the aggressive behavior on the Child Behavior Checklist, which is mainly characterized by angry moods, temper tantrums,

Telegram: @medical_k

www.konkur.in

stubbornness, child screams a lot, easily frustrated, and wants a lot of attention. Taking into account the history of traumatic feeding experiences, the emotional dysregulation in these children may further contribute to their ongoing feeding problems. Moreover, this study found that their mothers had significantly higher scores in anxiety symptoms, and some of them received a diagnosis of anxiety disorder. These data suggest reciprocal influences between the dysregulation in emotional functioning of these children and the anxiety symptoms of their mothers. Actually, maternal anxiety may compromise their parenting capacity to moderate the impact of the child's traumatic experience and consequent emotional dysregulation.

Treatment. Because of the complexity of many of these cases, particularly those that result from trauma inflicted by unavoidable medical procedures (e.g., intubation, suctioning), a multidisciplinary team consisting of a pediatrician or gastroenterologist, nutritionist, occupational therapist, and a psychiatrist or psychologist is best equipped to meet the needs of these infants. In cases of total food refusal, the infant is in acute medical danger of dehydration and malnutrition, and intravenous fluids need to be given. It is important to assess whether the infant might be coaxed into accepting any form of food or whether nasogastric tube feedings need to be instituted. Unfortunately, the insertion of feeding tubes can intensify the fear of feeding, and, if this is the case, the infant is better served by a gastrostomy tube. In any case, the infant's nutritional requirements need to be addressed prior to the implementation of the psychiatric treatment.

The psychiatric treatment of patients who exhibit total or partial food refusal centers on the desensitization of the infant to the fear of eating. Outpatient treatment can only be carried out if the infant accepts bottle feedings or receives adequate nutrition through a nasogastric or gastrostomy tube. It is best if the child is given the tube feedings at night and during the day there are scheduled oral feedings at 3- to 4-hour intervals with no feedings in between. If the child feeds from the bottle, the bottle feedings should follow the oral

Telegram: @medical_k

www.konkur.in

feedings in the high chair, and there should be no bottle feedings at other times, to make the child hungry at mealtimes. Behavioral techniques of positive reinforcement, praise and social interactions of food acceptance, and preferred toys or favorite videos for distraction are instituted in the initial management to overcome the child's fear of eating. Encouragement of self-feeding is frequently helpful for these infants to gain mastery over the anticipatory anxiety of eating. When the infant begins to accept food from the spoon, it is important to proceed slowly when advancing the texture of food to avoid any incident of gagging that may set back the infant. The behavioral manipulation of the infant's eating frequently leads to external regulation of eating in response to the reinforcers. Once the infant has overcome the fear of eating, it is important to phase out the external reinforcers and to encourage eating according to internal signals of hunger and satiety. The same principles described with regard to facilitating internal regulation of eating in children with IA should also be applied in this final stage of the treatment.

Inpatient treatment becomes necessary if the child is unable to overcome the fear of eating and remains dependent on bottle or tube feedings. Inpatient treatment involves two major components: appetite manipulation and contingency management. For children who have feeding tubes, manipulating calories and ensuring hydration through water or Pedialyte are used to allow the child to become hungry. Positive and negative reinforcements for food acceptance and food refusal are the behavioral interventions most commonly used. However, these techniques need to be adjusted to the individual child and require a skilled team to help the child to overcome the resistance to feeding and to learn to eat in response to hunger and fullness. Counseling and psychological intervention for parents are necessary to help them cope with the child's traumatic and stressful experiences and support their parenting capacities during the interventions for their child.

www.konkur.in

Robert was 7 months old when he was referred by a gastroenterologist for an urgent psychiatric evaluation because of severe crying when offered the bottle and refusal to drink unless he was almost fully asleep and seemed unaware of his feeding. The mother reported that Robert was an 8-lb, full-term baby who had a vigorous suck and was feeding well from birth. However, after a few weeks he started to spit up during and after feedings, and by 3 months he developed projectile vomiting. In spite of the vomiting, he gained weight until he was about 4 months of age when he was referred to a gastroenterologist and diagnosed with gastroesophageal reflux. Several medications were tried, but the vomiting continued, and by 6 months of age Robert started to arch himself during feedings as if he were in pain. He would cry and refuse to continue with the feeding. Soon afterward, the mother noticed that he would start to cry at the sight of the bottle, and he refused to accept the bottle totally, as long as he was awake. To stave off starvation, the mother relied on feeding him during the night when he was asleep. His food intake greatly diminished, and he started to lose weight. The mother tried to introduce solid food, but Robert seemed to have difficulty moving the food back to his throat and spat most of it out. At the time Robert was referred, his mother was exhausted and frightened because of Robert's continued weight loss. A recent examination by the gastroenterologist had shown that the reflux was markedly improved and that Robert's ongoing feeding difficulties could not be explained by his medical condition.

The observation of mother and infant during feeding revealed that Robert became distressed the moment his mother positioned him for feeding, and he started to cry and arch himself as soon as he saw the bottle. His mother put the bottle away and tried to comfort him, but it took more than 10 minutes until he could settle in her arms. When the mother got the bottle and tried to feed him again, he cried even louder and would not be calmed until the bottle was out of his sight. Because it was obvious that Robert was too frightened to feed from the bottle, the mother

Telegram: @medical_k

www.konkur.in

tried to feed him in his infant seat with the spoon, but he batted the spoon away and did not want to have anything put in his mouth.

As the first step of treatment, the parents were made aware that infants as young as Robert can make associations between pain, vomiting, or other distress and feeding and consequently become frightened of feedings. The parents were instructed to get Robert on a schedule of regular naps and to feed him from the bottle only when he appeared almost asleep to prevent any further activation of his fears while looking at the bottle. After a successful attempt at the hospital to feed Robert in the high chair with a spoon in his hand and lots of encouragement to put it in his mouth, the mother was able to use another spoon and put some food in Robert's mouth. Consequently, she was encouraged not to focus on the amount of food she was able to get into him, but to look at the feedings as practicing sessions to help Robert overcome his fear of feeding and to develop oral motor skills that would allow him to handle solid food.

In the first 2 weeks, Robert would cry and refuse to continue feeding if he woke up and saw the bottle. However, gradually he seemed to realize that it was safe to drink from the bottle. The mother reported that after 4 weeks, she could even start bottle-feeding when Robert was still awake. Robert also progressed quickly from accepting very little food from the tip of the spoon to eating several spoonfuls. After 3 weeks, Robert was finishing a whole baby jar at one meal. When Robert was 9 months old, the mother called to report that Robert was feeding better and starting to gain weight. At 10 months of age, Robert was taking the bottle when awake, and he had learned to use the spoon and feed himself.

Avoidant/Restrictive Food Intake Disorder (DSM-5-TR)

Subtype: Very young infants may present as being too sleepy, distressed, or agitated to feed

Telegram: @medical_k

www.konkur.in

Feeding Disorder of State Regulation (DC: 0–3R)

Clinical Features. This feeding disorder begins in the postnatal period and is characterized by irregular, poor feedings and inadequate food intake by the infant. Infants with this feeding disorder exhibit difficulties in state regulation, which interfere with their ability to feed effectively. They have difficulty reaching and maintaining a state of calm alertness necessary for feeding. Some are too irritable and cry excessively and cannot calm themselves for feeding. Others are too sleepy and cannot wake up or stay awake long enough to feed adequately. The parent may be anxious or depressed or may present with more severe psychopathology. Mother-infant interactions during feeding are characterized by irritability and/or sleepiness of the infant, maternal tension, and poor engagement between mother and infant.

Feeding disorder of state regulation can be seen in infants without any organic problems, but it is frequently associated with prematurity or dysmaturity and gastrointestinal, cardiac, or pulmonary disease.

Differential Diagnosis. This feeding disorder needs to be differentiated from pure organic disorders that can interfere with the regulation of the state of the infant. As described earlier, organic problems can trigger the feeding disorder and should always be addressed first. The diagnosis of feeding disorder of state regulation should be considered if treatment of the organic problem—for example, cardiac or pulmonary disease—cannot resolve the infant's difficulty in state regulation.

Etiology and Course. There are no empirical studies that have explained why some infants have more difficulty in regulation of state than others. However, the foundation for the regulation of feedings, which is so closely linked to the regulation of state, is further developed in the first months of life. Infants with feeding problems during the early months trigger anxiety in their mothers and frequently continue to have difficulty in self-regulation of their food intake during the transition to self-feeding in the second year of life.

Telegram: @medical_k

www.konkur.in

In a longitudinal study from Sweden, 70% of infants with feeding difficulties and food refusal in the first year of life were observed to have eating problems during childhood.

Treatment. Treatment needs to be individualized and can be directed toward the infant, toward the mother, and toward the mother-infant interaction. If the infant is too sleepy to feed and difficult to arouse, gentle infant massage to stimulate the baby may help to improve the infant's alertness and facilitate better feeding. If the infant is too irritable and fidgety to feed, reducing stimulation before and during feedings by taking the child to the quietest room in the house and swaddling the baby during feedings may help to settle the infant and facilitate better feedings. However, if the infant tires easily and is unable to take in adequate calories to grow in spite of all efforts to improve the feedings, nasogastric tube feedings may have to be considered to supplement oral feedings. On the other hand, if the mother is exhausted, overly anxious, or depressed, her difficulties have to be addressed to enable her to be more effective with her infant.

Videotaping the feedings and observing the tape together with the mother is frequently helpful to heighten the mother's awareness of the infant's cues and to explore alternative methods that she can use to facilitate the infant's regulation of state and ability to feed.

www.konkur.in

Thomas was 3 months old when he was referred for a psychiatric evaluation because of his feeding difficulties and poor weight gain since birth. His parents were college educated, and both had pursued their professional careers until Thomas was born. Although Thomas was full-term and weighed 7 lb at birth, he had difficulty drinking from the breast. When he was 4 weeks old, his mother reluctantly switched him to bottle feedings because he was losing weight. Although his intake improved somewhat on bottle feedings, he gained weight very slowly and was still less than 8 lb at 3 months of age. His mother appeared tired and described how Thomas would drink only 1, 2, or 3 oz at a time, wiggle and cry, and refuse to continue with the feeding. After a few hours, however, he might cry again as if he were hungry. However, she could not settle him to feed, and he would continue to cry inconsolably. The mother described that she would attempt to feed him on an average of 10 to 15 times in a 24-hour period, that Thomas would cry a lot during the day and at night, and that everybody in the family was getting very little sleep.

The observation of mother–infant interactions during feeding and play revealed that Thomas was a very alert and wiggly baby who had difficulty settling in his mother's arms. While drinking from the bottle he would kick his feet and move around with his arms, and soon the nipple of the bottle would slip out of his mouth. This upset him, and he started crying. His mother appeared anxious and tried to restart him by changing his position in various ways, but this only agitated him more. After repeated unsuccessful attempts to continue the feeding, mother and baby appeared exhausted, and the mother gave up.

The assessment revealed that Thomas was a very active and excitable baby who had difficulty keeping calm during feedings. After reviewing the videotape with the mother, the therapist explored ways in which the mother could better facilitate calming during feedings. Using a quiet corner in the house, swaddling Thomas in a blanket, and singing to him before starting the feeding were the most useful suggestions. Thomas stayed calm

Telegram: @medical_k

www.konkur.in

during feedings, was able to drink larger amounts of milk, and waited longer between feedings. This, in turn, relieved the mother's anxiety and helped both to have calmer interactions.

Avoidant/Restrictive Food Intake Disorder (DSM-5-TR)

Subtype: Infants and young children may not engage with the primary caregiver during feeding.

Feeding Disorder of Caregiver–Infant Reciprocity (DC: 0–3R)

Clinical Features. This feeding disorder is characterized by a lack of engagement between mother and infant, leading to inadequate food intake and growth failure of the infant. The onset of growth failure is usually between 2 and 8 months of age. The infant shows a lack of age-appropriate social responsivity—for example, lack of smiling response, lack of vocal reciprocity, lack of anticipatory reaching out when about to be picked up, and lack of molding and cuddling when held. The mother frequently presents with acute or chronic depression, drug or alcohol abuse, and/or high psychosocial stress, which appear to interfere with her care of the infant. Mother–infant interactions are characterized by a lack of mutual engagement and a lack of pleasure in their relationship. The mother frequently appears detached and noncontingent in her responses to the infant's cues.

Differential Diagnosis. This feeding disorder needs to be differentiated from organic conditions that lead to a lack of weight gain and weakness in the infant. However, the mother and infant usually show better mutual engagement and the infant responds more readily to the examiner.

Etiology and Course. This feeding disorder has been referred to in the literature as "maternal deprivation" or "deprivation syndrome." It has been postulated that lack of emotional nurture and infrequent feedings lead to growth failure and developmental delays in these

Telegram: @medical_k

www.konkur.in

infants. Characteristically, infants with this feeding disorder become engaged and gain weight when admitted to the hospital and are in the care of a nurturing nurse.

This feeding disorder has also been referred to as “nonorganic failure to thrive,” and in the DSM-III, this disorder was defined as “Reactive Attachment Disorder of Infancy” associated with FTT. However, in the DSM-IV, the same diagnosis was changed to encompass only problems in relatedness without growth failure. However, several studies of infants with the diagnosis of “nonorganic failure to thrive” have demonstrated very high rates of insecure attachment, ranging from 50% to 90% of the infants studied. However, not all infants with insecure attachment are failing to thrive. It appears that only a severe degree of a disturbance in the attachment process of the infant to the caretaker, or what some authors describe as “nonattachment,” results in the severe disturbances in relatedness and growth failure seen in infants with this feeding disorder.

Children with a feeding disorder of caregiver–infant reciprocity are at high risk for delayed cognitive and disturbed emotional development. When such children are followed up to school age, deficits in cognitive performance, behavioral organization, ego control, and ego resiliency and behavioral symptoms have been reported.

Treatment. Depending on the severity of the growth deficiency and the evidence of neglect, various interventions have been suggested. In cases of no evidence of deprivational behavior on the part of the mother, or if the parents have sought medical care in the past and have some support in the extended family or the community, an outpatient approach may be safe. However, if the growth deficiency is more severe, if there is serious hygiene neglect, if the mother is abusing drugs or alcohol, or if the mother lives a chaotic lifestyle, immediate hospitalization is indicated. During hospitalization, it is critical to assign a warm and nurturing nurse to engage the infant during feedings. While the nutritional, emotional, and developmental rehabilitation of the infant takes place, a more in-

Telegram: @medical_k

www.konkur.in

depth evaluation of the mother and the mother–infant relationship needs to be addressed as well.

Many of the mothers have experienced unsatisfactory relationships with their caretakers when they were growing up, and consequently, they are distrustful and avoidant of professionals. It is important to identify any positive behavior the infant shows toward the mother to see whether the mother has any potential to engage in a mutually satisfying relationship with her infant. In addition, the mother's support system and her ability to become engaged with a therapist need to be explored prior to returning the infant to her care. In some situations of severe neglect and associated abuse, Protective Services need to be involved, and the infant has to be placed in foster care.

Discharge from the hospital is a critical time when all services need to be in place to ensure the follow-through of the treatment plan. The treatment plan should be individualized and may range from home visits by a health care professional to daycare for the infant, to mother-infant psychotherapy, and to family therapy for the parents.

Anna was 8 months old when she was admitted to the hospital through the emergency room because of a respiratory tract infection and severe “failure to thrive.” After she had recovered from the infection and a medical workup for her malnutrition was found to be negative, a psychiatric consultation was requested. After repeated unsuccessful attempts, the psychiatrist finally reached the parents and set up an appointment to obtain more history and to observe the mother and infant during feeding. The parents explained that the father had difficulty obtaining time off from his construction job and that the mother did not have any means of transportation to the hospital. The couple was not married because the father had not gotten his divorce from his first wife, but they lived together with Anna in one room in a house that they shared with nine other members of the father’s extended family.

The mother, who became pregnant with Anna during her last year in high school, described Anna as a quiet baby and denied any feeding problems. However, when the mother temporarily left the room, the father turned to the therapist and complained that the mother did not give enough attention to Anna and that she would talk on the phone or read from a magazine while feeding the baby.

The observation of the mother and infant during feeding revealed that the mother looked sad and preoccupied while she held the baby loosely on her lap. The infant lay in a “surrender position” with her arms raised beside her head, and she looked away while drinking from the bottle. However, when she looked at her mother, the mother looked away as if she could not stand to have eye contact with her infant.

Further evaluation of the mother revealed that she felt very lonely and depressed. She was unable to finish high school because of the pregnancy with Anna. Her family had abandoned her for becoming involved with a married man. She described the father’s family as hostile toward her. The baby’s father worked long hours and was hardly around. The telephone calls the

Telegram: @medical_k

www.konkur.in

mother made to her girlfriends from high school were the only relief in her unhappy life.

During the hospitalization, Anna gained weight, became more engaged, and rewarded her favorite nurse with frequent smiles. After the social worker had arranged for transportation for the mother, she came regularly for her appointments with the social worker and spent more time with Anna. While nurturing the mother and trying to help her work on her situation with her family and the father's family, the social worker also spent time with mother and infant during play. She would point out how the baby was making progress, how she was trying to get her mother's attention, and how she had that special smile for her mother.

After 4 weeks in the hospital, Anna seemed stronger, and her mother seemed committed to continuing working with the social worker. The hospital staff felt comfortable about discharging Anna. After Anna had returned home with her mother, a visiting nurse came to the home twice a week to check on the mother and infant, and the mother visited weekly with Anna at the hospital to see the social worker. After 6 months, the visiting nurse came less frequently, but the mother and Anna stayed in treatment with the social worker for another year, when both seemed engaged and comfortable with each other.

Avoidant/Restrictive Food Intake Disorder

ARFID can be diagnosed if the feeding disturbance may persist after being triggered by a medical condition and following resolution of the medical condition.

Feeding Disorder Associated with Concurrent Medical Condition (DC: 0–3R)

Clinical Features. Although respiratory problems or cardiac diseases that may tire out the infant during feeding are easily recognized, some medical conditions are not readily diagnosed, and

Telegram: @medical_k

www.konkur.in

food refusal may be the leading symptom. For example, food allergies can be difficult to diagnose in infants, and “silent” gastroesophageal reflux without vomiting can be overlooked because vomiting is usually the leading symptom that alerts pediatricians to this condition. Typically, infants with reflux can drink 1 to 2 oz until the reflux becomes activated. However, once reflux occurs, the infants experience distress and may arch, cry, and refuse to continue feeding. Some infants can be calmed and resume feeding, but others may become increasingly agitated while their caretakers continue to offer the bottle or food. Infants with respiratory distress may feed for a while and take a few ounces until they tire and stop feeding. In general, the feeding difficulties of these infants lead to inadequate food intake, failure to gain weight, or loss of weight.

Differential Diagnosis. This feeding disorder needs to be differentiated from other feeding disorders characterized by food refusal, such as IA, sensory food aversions, and post-traumatic feeding disorder. What helps in understanding this feeding disorder is the observation of feeding, which reveals that the infant usually initiates feeding without difficulty and that mother and child engage in pleasant reciprocal interactions until the infant experiences distress and stops feeding.

Etiology and Course. FTT of infants and young children was initially believed to be caused by either organic or nonorganic causes (e.g., maternal deprivation). In 1981, Homer and Ludwig described a third category of FTT, which is caused by a combination of various organic and nonorganic problems. Since then, it has been accepted that organic conditions can be complicated by psychological difficulties and lead to severe feeding problems and growth failure. However, although many young infants suffer from gastroesophageal reflux, only less than one-third of them are reported to present with feeding difficulties and growth failure. Clinically, these infants appear particularly alert and sensitive. However, no empirical studies have

Telegram: @medical_k

www.konkur.in

been done to explore why some infants develop severe reactions to their reflux, whereas others hardly seem bothered by it.

Only a few studies have been reported on the follow-up of these infants. Fortunately, with therapy, up to 80% of children with gastroesophageal reflux improve within 12 months. For those with more serious feeding difficulties and the inability to take in adequate amounts of food for growth, modern technology allows for gastric tube feedings over a long time to safeguard their survival. However, the regulation of oral feedings is often very difficult, and even after the medical condition has been successfully treated, it may take time until the child learns to eat independently.

Treatment. Because of the interaction of organic and psychological factors contributing to the severe feeding difficulties of these children, a collaboration between the pediatrician or pediatric specialist and the psychiatrist is critical. Optimal medical treatment of the child's illness is necessary before psychological interventions can be successful. Direct observation of infants with their primary caregiver during feeding is most helpful in monitoring how well the medical condition is responding to the treatment. In addition, the observations during feeding can guide the therapist in helping the parents to develop more appropriate strategies that allow infants to calm down instead of escalating their distress during feeding. However, in situations in which the medical illness cannot be adequately treated, and the infant continues to experience distress during feedings, supplemental nutrition through nasogastric or gastrostomy tubes must be considered. Then the therapist must work with the parents to maintain the infant's oral feeding skills while most of the nutrition is given via tube feedings. The parents need to learn to feed the infant to the point of discomfort but not beyond it. Reviewing the videotape of the infant's feeding and discussing the infant's cues with the parents is usually helpful in sorting out how to best feed the infant. In general, these are very difficult cases that require individualized attention by an experienced multidisciplinary team.

www.konkur.in

Sarah was 6 months old when she was referred by her pediatrician to the Multidisciplinary Feeding Disorders Team because of severe food refusal and poor growth. The mother reported that since birth Sarah occasionally “spat up” a little during and after feedings, but during the last 6 weeks, she had become increasingly difficult to feed. Usually, she took 1 or 2 oz of her formula and then started to arch and push the nipple out from her mouth. If her mother tried to continue feeding Sarah, she cried and became increasingly agitated until her mother picked her up and comforted her by holding her on her mother’s shoulder and walking her. Sometimes after 10 to 20 minutes, her mother could resume feeding Sarah, but often, Sarah started to cry again after suckling from the bottle for a few minutes only. In spite of her mother’s efforts to feed Sarah every 2 hours, Sarah drank only half of the formula that she was supposed to take in for her age, and in recent weeks, she had started to lose weight.

The observation of feeding revealed pleasant mother-infant interactions at the beginning of the feeding, but after a few minutes of suckling, Sarah pushed the nipple of the bottle out of her mouth, arched her back, and started to cry when her mother tried to get her back to feeding. The harder her mother tried, the more agitated Sarah became, and mother and baby looked very distressed and gave up feeding. These feeding interactions raised concerns that Sarah experienced gastroesophageal reflux that caused her pain and interfered with her feeding. Further medical testing confirmed the diagnosis of moderate gastroesophageal reflux, which was somewhat surprising to the pediatrician and the gastroenterologist because Sarah had not shown any vomiting, the most common symptom of reflux.

Sarah was treated with medications for reflux, and her food intake doubled quickly. However, if she drank more than 3 or 4 oz at a time, the symptoms recurred. However, once the mother understood the reason for Sarah’s food refusal, she learned to ease Sarah’s feeding difficulties by thickening the formula and feeding her smaller amounts at more frequent intervals.

Telegram: @medical_k

www.konkur.in

Gradually, Sarah tolerated larger amounts of formula at each feeding, and at 15 months of age, she was found to have outgrown the gastroesophageal reflux.

Rumination Disorder

Clinical Features. Rumination has been defined as repetitive regurgitation of gastric contents that are subsequently rechewed and then reswallowed or spit out. The regurgitation occurs very soon after a meal and tends to persist for 1 to 2 hours. The sequence of events leading to regurgitation has been documented by using combined multichannel intraluminal impedance and manometry. These events include an increase in intra-abdominal pressure identified in the stomach, which initiates the reflux, followed by peristaltic fore contractions, which clear the intraesophageal content. Rumination has been described in infants, individuals with developmental disabilities, and in children, adolescents, and adults with psychiatric or neurologic disorders. The major change for rumination disorder in the *Diagnostic and Statistical Manual for Mental Disorders,* Fifth Edition, was its relocation from the section titled “Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence” to the new section, “Feeding and Eating Disorders.” This change emphasizes that this disorder occurs across the age range, including adulthood. Minor changes have been introduced to the DSM-5 and DSM-5-TR phrasing of diagnostic criteria for rumination disorder to improve clinical utility by ensuring applicability across the age range and removing some ambiguity inherent in the DSM-IV phrasing.

Some infants can be observed to put the thumb or the whole hand in the mouth, suck the tongue rhythmically, or arch the back to initiate regurgitation. However, some infants ruminate when left alone after they have been placed in the crib to sleep. They are frequently found in a puddle of vomitus, which is then falsely attributed to some organic problem. The latter type of rumination is most commonly observed in infants who have received little

Telegram: @medical_k

www.konkur.in

emotional stimulation and who have learned to stimulate and soothe themselves through rumination. Although initially most of the regurgitated food is vomited, some infants gradually learn to hold more of the food in their mouth, to rechew, and to reswallow it. “Experienced” ruminators are able to bring up the food through tongue movements and reswallow it without losing any of it. Their rumination can only be discovered by observing the movements of their cheeks and the foul oral odor. Social functioning may be significantly impaired due to the recognized social undesirability of this behavior.

Differential Diagnosis. The term *regurgitation* implies that the behavior is volitional, distinguishing it from vomiting or gastroesophageal reflux. The regurgitation is not associated with nausea and is not explained by an illness or medical condition. Individuals may cough, engage in the tongue or abdominal muscle contractions or movements, or place fingers in the mouth to facilitate food being brought back up. Because, in young children, reflux and rumination frequently coexist, it is important to observe the infant in different situations to see the initiation and the rhythmic oral movements of the ruminatory activity. As in pica, the diagnosis of rumination disorder should be given in the context of another mental disorder only if the symptoms require additional clinical attention.

Epidemiology. Rumination is believed to be a rare disorder. It appears to occur more often in males than in females and also in individuals with mental retardation. There are a few reports of children, adolescents, and adults who were diagnosed with rumination disorder, and some had associated eating disorders.

Etiology and Course. Various mechanisms of etiology have been proposed. Several authors have attributed rumination to separations or a disturbed mother-infant relationship—for example, lack of responsiveness or neglect by the mother secondary to stressful family relations or life events. Others have considered rumination as a symptom of gastroesophageal reflux. Several authors have

Telegram: @medical_k

www.konkur.in

postulated that rumination is a learned behavior that is maintained with special attention to the regurgitation. In more recent years, opiate receptor insensitivity or reduced endorphinergic transmission has been implicated in rumination.

A biopsychosocial model has been proposed by which rumination is seen along a continuum in which an infant may have gastrointestinal pathology and little psychopathology at one end of the spectrum, or the opposite, in which an infant may have no organic pathology and severe psychopathology in the mother-infant relationship at the other end of the spectrum. Frequently, vomiting secondary to gastroesophageal reflux or vomiting associated with an acute illness precedes the beginning of rumination. It appears that at some point the infant learns to initiate vomiting and to rechew the food to achieve relief of tension, to self-soothe, and/or to self-stimulate. It seems that in situations in which the infant fails to elicit or loses either caring attention or tension-relieving responses from the mother, rumination becomes a means of self-regulation. Once the infant has experienced rumination as a means of self-soothing or self-stimulation, the rumination develops into a habit that is difficult to break.

The onset of rumination is frequently in infancy, most commonly in the first year of life. However, rumination may start at any point in life. It is believed that in some individuals the disorder remits spontaneously. However, some infants suffer serious complications, such as electrolyte imbalance, dehydration, and weight loss, and in earlier reports mortality rates as high as 25% have been described.

Treatment. Depending on the theories of the etiology of rumination, different treatments have been suggested. These range from mechanical restraints as described in the early literature and surgical interventions (Nissen fundoplication) to prevent reflux, to behavioral and psychodynamic treatments.

Based on the assumption that rumination is a learned habit that is reinforced by the increased attention that is given to the regurgitation, unlearning by behavioral techniques has been suggested. These treatments include the use of aversive taste

Telegram: @medical_k

www.konkur.in

stimuli (lemon juice or hot sauce), oral hygiene, differential reinforcement of incompatible behaviors, and electric shock. Proponents of the assumption that rumination is based on an unsatisfactory mother-infant relationship have suggested a psychodynamic approach. A mother substitute who feeds the infant while the mother is helped through psychotherapy has been proposed.

After a thorough evaluation that should include the assessment of the infant and the mother, the therapist needs to individualize the treatment. In severe situations, if the infant is malnourished and continues to lose most of the food through rumination, a jejunal tube may have to be inserted before any psychosocial treatment can begin. Frequently, a combination of psychodynamic and behavioral interventions to enhance the mother–infant relationship in general and to treat the symptom of rumination, in particular, is most effective.

www.konkur.in

Justin was 9 months old when he was referred by a gastroenterologist for a psychiatric evaluation because of concerns that he continued to vomit because of rumination. Justin was born full-term and had developed nicely until he was about 6 weeks old when he began to vomit increasing amounts of milk during and after feedings. He was diagnosed with gastroesophageal reflux, which was treated with thickened feedings and medication. Justin responded well to the treatment; he stopped vomiting almost completely and gained weight adequately. Because Justin was doing so well, his mother decided to go back to work when Justin was 8 months old. She transitioned his care to a young woman who would come to the house during the mother's working hours. Justin started to vomit soon after his mother left the house. The vomiting seemed to increase from day to day in frequency and in intensity, and after 2 weeks of the mother's return to work, Justin vomited several times daily and was losing weight. He was seen by a gastroenterologist, and during the barium swallow, it was noticed that Justin put his hand in his mouth, which seemed to trigger vomiting. Justin was put back on medication for gastroesophageal reflux, but he continued to vomit with increasing frequency, which led to a psychiatric consultation.

Observation of mother and infant during feeding revealed that as soon as Justin finished feeding, he put his hand in his mouth and vomited. When his mother restricted his hand, Justin moved his tongue back and forth in a rhythmic manner until he vomited again. This happened repeatedly, and Justin continued the rhythmic tongue movements even when he could not bring up any more milk.

Because of his poor nutritional state and moderate dehydration, Justin was admitted to the hospital, and a nasojejunal tube was inserted for feedings. When Justin was awake, a special nurse or the parents played with him and tried to distract him whenever he attempted to put his hand in his mouth or thrust his tongue rhythmically. Justin became

Telegram: @medical_k

www.konkur.in

increasingly engaged, and his ruminatory activity decreased accordingly. After 1 week in the hospital, small feedings were started, but Justin tried to ruminate again, and the oral feedings had to be stopped. At this point, the mother decided to stop working and take Justin home to continue the treatment there. The mother started small feedings, played with Justin after feedings, and was able to keep him from ruminating. After 4 weeks of slow increments in his feedings, Justin was able to take all of his feedings by mouth without ruminating, and the nasojejunal tube could be removed.

Pica

Clinical Features. Young children with this disorder typically eat plaster, paper, paint, cloth, hair, insects, animal droppings, sand, pebbles, and dirt. Many of the children engage in other oral activities, such as thumb sucking or nail biting, which they seem to use for relief of tension and for self-soothing. In some younger patients, as well as those with neurodevelopmental or learning disorders, some clinicians regard pica as a form of self-soothing behavior. The pica may lead to anemia, diarrhea/constipation, worm infestation, toxoplasmosis, lead poisoning, and malnutrition. In some cases, it may lead to intestinal obstruction as the result of hairball tumors. In addition to the heterogeneity of substances consumed, pica's associated behavioral features can differ considerably among individuals (e.g., its compulsive nature and relationship to emotional arousal or need for oral stimulation).

The major change for pica disorder in the *Diagnostic and Statistical Manual for Mental Disorders*, Fifth Edition, was its relocation from the section titled "Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence" to the new section "Feeding and Eating Disorders." This change emphasizes that this disorder occurs across the age range, including adulthood. In particular, changes to the phrasing of diagnostic criteria in DSM-5 are intended to guide clinicians in distinguishing eating behaviors that warrant a

Telegram: @medical_k

www.konkur.in

diagnosis of pica from behaviors that are developmentally normal, culturally supported, or socially normative or that support a diagnosis of a different mental disorder.

Differential Diagnosis. Before the age of 18 to 24 months, mouthing and sometimes eating non-nutritive substances can be relatively common and should only be diagnosed as pica if it is persistent and inappropriate for the developmental level of the child. In DSM-5-TR, 2 years is suggested as the minimum age for a diagnosis of pica; at younger ages, mouthing different kinds of objects is considered developmentally normal. Consumption of substances consistent with local cultural practices or social norms would not warrant a pica diagnosis. Pica may be comorbid with a number of mental disorders, which are more likely to come to clinical attention than pica itself, (e.g., intellectual development disorder, autism spectrum disorder, schizophrenia, and obsessive-compulsive disorder). In addition, pica can co-occur with hair-pulling disorder and skin-picking disorder when hair or skin is ingested. When non-nutritive substances are ingested as a means to suppress appetite in anorexia nervosa, a pica diagnosis is not warranted. Some individuals with ARFID, particularly those whose selective or restricted intake is based on sensory aspects of food, may also present with comorbid pica.

Epidemiology. A survey of a large clinic population with a wide range of ethnic backgrounds revealed that 75% of 12-month-old infants and 15% of 2- to 3-year-old toddlers were reported by their parents to put non-nutritive substances in their mouths. However, the true incidence of pica is not known. Available data suggest that in the United States pica is rare in healthy children older than 2 years. However, a study reported that 33.9% of children in Detroit who were in treatment for sickle cell anemia had pica eating. Pica has also been reported as prevalent in children elsewhere, including in some school-age populations in Africa (as high as 77%). Among individuals with mental retardation, the prevalence of the disorder appears to increase with the severity of the retardation. The

Telegram: @medical_k

www.konkur.in

prevalence of pica among institutionalized individuals with mental retardation has been estimated to range from 10% to 33%.

Etiology and Course. Organic, psychodynamic, socioeconomic, and cultural factors have been implicated in the etiology of pica. Inadequate intake of iron and calcium has been shown in rats to induce pica and has been considered to lead to abnormal cravings and pica in humans. Low plasma levels of iron and zinc have been found to be associated with pica, and it has been suggested that hypozincemia with low iron levels may be a possible cause rather than a consequence of pica. Psychosocial factors—for example, poverty, maternal neglect and abuse, and disorganized family situations with inadequate nurturing and supervision of the children—have been implicated in the etiology of pica. The cultural acceptance of pica in certain population groups has also been considered to play a role in its etiology. Some authors have proposed a multifactorial model of etiology by which organic, familial, socioeconomic, and cultural factors interact with each other.

In most instances, the disorder is believed to last for several months and then remit. However, it may occasionally continue into adolescence or, less frequently, into adulthood. Several authors have pointed to the seriousness of the developmental effect of the disorder. The younger children showed delays in their speech and psychosocial development. Half of the adolescents were observed to suffer from depression and/or personality disorders, engaged in other forms of disturbed oral activities, such as thumb sucking and nail-biting, and abused tobacco, alcohol, or drugs. More recently, some authors pointed to a strong relationship between pica during early childhood and bulimia nervosa during the adolescent years.

Treatment. A variety of treatments have been proposed. These include physical restraints, aversive and nonaversive behavior therapy, the teaching of children to exchange inedible items for edibles, environmental enrichment, and individual and group therapy for the children and their mothers. It is important to conduct a comprehensive evaluation of the child, the caretakers, and the

Telegram: @medical_k

www.konkur.in

child's environment to develop an individualized treatment plan. This should include helping the adults to become aware of the short- and long-term dangers of pica, providing a lead-free and childproof environment, facilitating a more satisfying parent–child relationship, and applying behavioral techniques to extinguish the maladaptive behavior of pica.

www.konkur.in

Susan was 3 years old when her mother took her to the pediatrician because of abdominal pain and lack of appetite. The mother complained that Susan put everything in her mouth but did not want to eat regular food. The pediatrician observed that Susan looked pale, thin, and withdrawn. She sucked her thumb and quietly looked down while her mother reported that Susan liked to chew on newspapers and put plaster in her mouth.

The medical examination revealed that Susan was anemic and suffered from lead poisoning. She was admitted to the hospital for treatment, and a psychiatric consultation was obtained.

Further exploration of the history and the observation of mother and child during feeding and play revealed that the mother was overwhelmed with having to care for three young children and had little affection for Susan. The mother was unmarried and lived with her three children and five other family members in a three-bedroom apartment in an old housing project. Her 4-year-old son was hyperactive and demanded almost constant supervision. Her 18-month-old infant was an engaging and active little girl, whereas Susan would sit quietly, rock herself, suck her thumb, or chew on newspaper.

The treatment plan included the involvement of social services and protective services to remove any lead paint from the walls in the apartment and to look for better living arrangements for the family. The mother was helped to enroll Susan and her brother in a preschool program that provided them with more structure and stimulation and gave the mother a few hours of relief every day. In addition, Susan was seen with her mother and her younger sister in play therapy to help the mother understand the different temperaments of the two children and to make her more responsive to Susan's weak attempts to engage her. Once the mother felt more supported and less overwhelmed by her situation, she became more empathic and understanding of Susan. When Susan put something in her mouth, the mother was able to engage her in a play activity rather than scream at her and scold her for whatever she was doing. Over the period of 1

Telegram: @medical_k

www.konkur.in

year, the relationship between Susan and her mother gradually improved, and Susan seemed less in need of putting her thumb or inedible things in her mouth.

To conclude our chapter, it is pivotal to underline that a problem arises when the children exhibit symptoms that appear to fit the diagnoses of more than one feeding disorders subtype (i.e., IA and post-traumatic feeding disorder, IA, and sensory food aversions). We recommend that the symptoms should be differentiated as much as possible to understand what the underlying diagnoses may be, because, as pointed out earlier in the treatment targeted to specific diagnostic subtypes, each feeding disorder requires a specific therapeutic approach, and the treatment needs to combine these individual approaches for each disorder to be successful.

47 Tic Disorders

Rahil R. Jummani, M.D., Elizabeth A. Deckler, M.D., and Barbara J. Coffey, M.D., M.S.

The best known of the tic disorders is Tourette disorder (TD), also known as Tourette syndrome, named after the French neurologist Georges Gilles de la Tourette, who in 1885, was among the first to recognize and describe the disorder and its comorbid conditions. Since the descriptions of Gilles de la Tourette, a spectrum of tic disorders has come to be recognized and codified in psychiatric nomenclature. No longer is TD viewed as a rare, bizarre psychological entity with primarily disturbing manifestations, such as the shouting of obscenities, screeching, or barking. The comorbid psychiatric disorders that frequently occur in individuals with TD have become more widely recognized in recent years; it is these disorders that may often warrant treatment more than the tics themselves. Although the underlying etiologies of these disorders continue to be elusive, substantial progress has been made in the last few decades using innovative neuroimaging techniques, genomics studies, and clinical science. Tic disorders have emerged as complex, heterogeneous neurodevelopmental disorders that are the manifestation of an intricate interplay of genes and environment. Understanding of the etiology, genetics, neuroanatomy, and epidemiology of tic disorders has been significantly enhanced. Novel treatment approaches have also emerged, providing alternatives to

Telegram: @medical_k

www.konkur.in

the established pharmacologic management of tics. Specific behavioral interventions have been established as first-line treatments for tic disorders. Deep brain stimulation (DBS), botulinum toxin injection, targeted surgery, and stem cell transplantation are examples of promising new treatments. The future holds tremendous possibilities as new insights into the etiology, pathophysiology, and treatment of tic disorders are rapidly developing. This chapter provides a review and update of the history, comparative nosology, epidemiology, etiology, diagnosis and clinical features, pathology, differential diagnosis, course and prognosis, and clinical treatment of tic disorders, including TD.

DEFINITIONS

Tics are rapid, recurring motor movements (motor tics) or vocalizations (phonic or vocal tics) that are nonrhythmic, involuntary or semivoluntary, and sudden in onset. Tics typically involve one muscle or a group of muscles and are characterized by their anatomical location, number, frequency, duration, and complexity (Table 47–1). They can be classified as *simple* (involving one muscle, muscle group, or sound) or *complex* (slower, more purposeful movements involving coordinated muscle groups or multiple sounds). Simple motor tics cause a brief, jerking movement (*clonic tic*); a briefly sustained abnormal posture (*dystonic tic*); or an isometric contraction (*tonic tic*). Examples of simple motor clonic tics are eye blinking, shoulder shrugging, and head-turning. Dystonic tics include sustained eye closure (blepharospasm), ocular deviations, teeth grinding (bruxism), mouth opening, twisting and tilting of the neck (torticollis), and shoulder rotation. Tonic tics are typically manifested by tensing of abdominal or limb muscles. Complex motor tics may include touching objects, jumping, rotating, or imitating others' gestures (*echopraxia*). Examples of simple vocal tics are throat clearing, coughing, and sniffing. Repeating syllables, words, or one's own phrases (*palilalia*) or repeating others' words or phrases (*echolalia*) are examples of complex vocal tics. Less commonly occurring tics include the involuntary vocalization of obscenities

Telegram: @medical_k

www.konkur.in

(*coprolalia*) and the involuntary production of obscene gestures (*copropraxia*).

Tics are often emitted in bouts of one or several tics separated by variable periods of no tic activity. Tics change in frequency, anatomical location, number, complexity, and severity over minutes, hours, and days, as well as over longer periods of time. Tics may persist during sleep. Simple motor tics are the most common initial presentation of a tic disorder, and eye blinking is the most common initial tic.

Tics are experienced as irresistible but can be suppressed for varying periods of time. Some patients describe suppressing tics for several hours, for example, while at work or school, and then experiencing a bout of tics. There is usually a reduction in the frequency and severity of tics during concentration on mental or physical tasks such as reading. Stress, excitement, boredom, fatigue, and exposure to heat can exacerbate tics. Tic frequency may also increase during relaxation following a period of stress or sometimes when an individual is actively attempting to suppress tics. Some children, and occasionally adults, are unaware of their tics.

Many individuals with TD characterize their tics as a voluntary response to an uncomfortable feeling that precedes them. These feelings, or premonitory sensations, have been described by many individuals with TD; they can be localized or general, and physical or mental, in nature. These premonitory sensations distinguish tic disorders from other movement disorders. An example is a burning feeling in the eye before an eye blink. However, there are often nonlocalizable and more generalized premonitory phenomena, such as urges, sensations, or anxiety. Many individuals report a “just right phenomenon,” that to relieve the uncomfortable urge they must repeat a particular movement or sound or pattern of movements or sounds, until “it feels good” or “it feels just right.”

Telegram: @medical_k

www.konkur.in

Table 47–1.
Examples of Tics

Motor		Vocal	
Simple	**Complex**	**Simple**	**Complex**
Eye blinking	Touching objects or self	Throat clearing	Syllables or words
Nose twitching	Hitting or kicking	Coughing	Phrases
Shoulder shrugging	Hand gestures	Sniffing	Swearing
Sustained eye closure	Throwing	Blowing	Repeating one's or others' words
Tensing of abdominal or limb muscles	Squatting or jumping	Barking	Changes in the rate, rhythm, and volume of speech

Complex tics may be difficult to distinguish from compulsive behaviors. This is further complicated by the frequent presentation of obsessive-compulsive disorder (OCD) symptoms with tics. The difference between some complex tics and compulsions is subtle. It is important to determine whether the behavior is being pursued as a strategy to prevent or relieve anxiety rather than simply to satisfy an urge. If anxiety relief or prevention is the case, a compulsion rather than a tic is likely. Studies by Miguel and coworkers demonstrated that more cognitions and autonomic anxiety, and fewer sensory phenomena are reported with repetitive behaviors in individuals with OCD without concomitant tics, whereas more sensory phenomena, such as the "just right phenomenon," and fewer cognitions are associated with repetitive behaviors in individuals with TD.

The fifth edition of the Diagnostic and Statistical Manual of Mental Disorders text revision (DSM-5-TR) and the eleventh revision of the International Statistical Classification of Diseases and Related Health

Telegram: @medical_k

www.konkur.in

Problems (ICD-11) provide diagnostic criteria in common use for tic disorders. According to the DSM-5-TR (with the equivalent ICD-11 diagnoses in parentheses), tic disorders include provisional tic disorder (transient motor tics in ICD-11), persistent motor or vocal tic disorder (chronic motor or vocal tic disorder in ICD-11), TD (Tourette syndrome in ICD-11), and other specified tic disorder and unspecified tic disorder (other specified primary tics or tic disorders, primary tics or tic disorders, unspecified, other specified tic disorders, and tic disorders, unspecified in ICD-11).

By DSM-5-TR criteria, a provisional tic disorder is characterized by the presence of single or multiple motor and/or vocal tics for less than 1 year. A persistent motor or vocal tic disorder is diagnosed when either motor or vocal tics, but not both, are present for more than 1 year. For this category of tic disorders, DSM-5-TR provides specifiers to indicate whether motor or vocal tics are present: *With motor tics only* and *With vocal tics only.* TD (Tourette syndrome in ICD-11) is defined by the presence of both multiple motor and one or more vocal tics for more than 1 year.

According to the DSM-5-TR, other specified tic disorder is a tic disorder that does not meet the criteria for any of the other tic disorders, and the clinician specifies the reason criteria are not met. An unspecified tic disorder, on the other hand, is a condition that also does not meet criteria for any of the other tic disorders, but for which the clinician does not elaborate a specific reason. Included are presentations for which information to make a more specific diagnosis is lacking.

In addition to the foregoing criteria that the DSM-5-TR and ICD-11 share for the diagnosis of a specific tic disorder, the DSM-5-TR specifies a few common criteria that must be met to diagnose provisional tic disorder, persistent motor or vocal tic disorder, or TD. The onset of tics must be before the age of 18 years, and a substance or medical condition must not be causally implicated. The DSM-5-TR notes that tics wax and wane in frequency.

HISTORY

Telegram: @medical_k

www.konkur.in

In 1825, the French physician Jean-Marc Gaspard Itard provided the first clinical description of Tourette syndrome in a French noblewoman, the Marquise de Dampierre, who displayed body tics, barking sounds, and uncontrollable utterances of obscenities. In his description, Itard also noted the presence of comorbid obsessive thoughts. In 1885, Georges Edouard Albert Brutus Gilles de la Tourette, a French neurologist, described eight patients, in addition to the patient originally reported by Itard, with childhood-onset tics and coexisting emotional symptoms and behavioral problems, such as inattention, hyperactivity, impulsivity, obsessions, and compulsions. Gilles de la Tourette coined the term *coprolalia* for vocal tics that manifested as uncontrollable utterance of obscenities. Furthermore, he and his mentor, Jean-Martin Charcot, viewed the disease as progressive and believed they had identified a hereditary degenerative disorder.

Psychoanalytic views of TD, introduced in the 1920s and 1930s, thrived in the early twentieth century and interpreted tics as expressions of repressed childhood sexual conflict. In the 1940s, Margaret Mahler attributed tic symptoms to infantilization, parental overindulgence, and overprotection, as well as sexual conflict. Serge Lebovici, the leading French child psychoanalyst during the 1950s and 1960s, asserted that neurotic mothers were the cause of tics in their children.

As more biologically based theories of the etiology and pathophysiology of tic disorders emerged, sedatives, stimulants, carbon dioxide inhalants, and other agents came to be used in the treatment of tics, in conjunction with, or as alternatives to, psychoanalytic psychotherapy. In the 1960s and 1970s, as the scientific era of the understanding of Tourette syndrome began with the work of Arthur and Elaine Shapiro, the first randomized clinical trials using neuroleptic medications were published. The perception of Tourette and tic disorders as rare, bizarre, psychological conditions slowly began to change. Advances in the last 50 years have led to the use of the α-adrenergic agonists and second-generation neuroleptics as the primary psychopharmacologic agents for the treatment of tics. Comorbid psychiatric disorders have come to be

Telegram: @medical_k

www.konkur.in

more widely recognized and treated. Over the last several decades, the Tourette Association of America (TAA) (https://tourette.org) has effectively promoted clinical awareness of the condition and supported research into its causes and treatment. Behavioral interventions have come to the forefront. The quest for a more comprehensive understanding of the underlying etiology and pathophysiology of tic disorders continues.

COMPARATIVE NOSOLOGY

The nosology of the tic disorders has depended, since their recognition, on the presence and classification of their primary symptom—tics. The two predominant current classification systems of tic disorders, the DSM-5-TR and the ICD-11 criteria, are based primarily, as described earlier, on the type of tics present (motor, vocal, or both) and the duration of symptoms (greater or less than 1 year). ICD-11 also distinguishes between primary tics and tic disorders and secondary tics in its categorization. As new information about the etiology and pathogenesis of tic disorders emerges, a new nosology based on an etiologic or pathogenic understanding may replace the current symptom-based taxonomy. Over the years, with newer iterations of the DSM, individual criteria have changed slightly as advances in the understanding of the prevalence and course of tic disorders have emerged. For example, the age of onset of TD has varied from before age 15 years to before age 21 years. The most recent version, DSM-5-TR, has instituted changes to the criteria that reflect the current understanding of the neurodevelopmental and temporal nature of tics, as tic disorders are now contained in the section on Neurodevelopmental Disorders. Tics are now recognized to wax and wane, and restrictions on the time frame of tic-free periods have been removed.

EPIDEMIOLOGY

Provisional tic disorder, which can encompass both motor and vocal symptoms, is the most common of the tic disorders; the prevalence is

Telegram: @medical_k

www.konkur.in

estimated at up to 20% of school-aged children. A methodologically rigorous study of more than 800 schoolchildren ages 4 through 16 years in the Basque region, however, indicated a prevalence of approximately 6.5% for all tic disorders. The vast majority of tics were mild in severity and duration. The prevalence of persistent tic disorders is between 2% and 4%. Prevalence estimates for TD also vary. As in all population-based studies, results may be influenced by a variety of factors, including criteria used for diagnosis, methods of sampling and inquiry, gender and age distributions in the study population, and size of the sample. Once considered an extremely rare disorder, current lifetime rate estimates vary from 1 to 10 per 1,000 children in European and Asian populations, and a common prevalence figure for individuals meeting criteria for TD is 1 per 200 for the full spectrum of chronic tic disorders. A population-based, epidemiologic study of lifetime prevalence of TD in Israel estimated a point prevalence of 3.1 to 5.5 per 10,000 in 16- and 17-year-olds. Prevalence rates have been estimated to be as high as 4% in one community-based study, and 3% in a survey of middle school youth in the United Kingdom. In a school-based community survey, Kurlan and colleagues reported prevalence rates of tic disorders of 23% in special education classes and as high as 8% for TD, as compared to 19% for tic disorders and about 3% for TD in regular classrooms. The 2007 U.S. National Survey of Children's Health (NSCH) surveyed parents of children and adolescents aged 6 to 17 years. The estimated prevalence of a lifetime diagnosis of TD by parent report was 3 per 1,000. In a meta-analysis of 13 studies of children, Knight and colleagues reported a prevalence of TD at 0.77% (95% confidence interval, 0.39% to 1.51%).

The average age of onset for TD is age 6 years with peak tic severity between 10 and 12 years of age. Limited and somewhat contradictory information exists on the longitudinal course of the disorder. Recent studies suggest that whereas tics may often persist into adulthood, tic severity often declines significantly in adolescence. Only 20% or fewer of those with TD continue to experience significant functional impairment by age 20 years. In most cases, tics in adults represent the persistence or recurrence of childhood-onset tics, but in

Telegram: @medical_k

www.konkur.in

extremely rare instances, patients may have their first occurrence of tics during adulthood. Studies in both children and adults suggest that males are at least three to four times more likely than females to manifest TD.

Comorbidity with psychiatric disorders, especially attention-deficit/hyperactivity disorder (ADHD) and OCD, is common in both clinically referred individuals and community samples. In addition, mood disorders and anxiety disorders, such as separation anxiety disorder and generalized anxiety disorder, often co-occur. In the 2007 U.S. National Survey of Children's Health (NSCH), 79% of those with TD had at least one comorbid mental health or neurodevelopmental condition. ADHD was the most frequent co-occurring condition, and the prevalence of comorbid ADHD with TD was reported to be as high as 60% to 70%. In addition, approximately 50% of patients with TD have prominent obsessive-compulsive symptoms. A more recent estimate of psychiatric comorbidity in those with TD at about 86% is the result of the work of Hirschtritt and collaborators.

Jeffrey was a 5-year-old boy whose parents sought evaluation for recent onset of tics. Jeffrey developed onset of eye-blinking tics at age 4 years and subsequently began to repeatedly push out his hands and legs in front of him, kicking and stomping his feet. These symptoms persisted for about 3 months and remitted. The movements returned about 1 year later, somewhat abruptly, according to his parents. At that time, Jeffrey developed eye blinking and nose twitching. Sometimes, he hopped while walking. He also developed vocal tics around that time, including clicking, throat clearing, sniffing, and coughing. Approximately 1 month prior to the evaluation, Jeffrey developed truncal tics that occasionally began to disrupt his gait.

Jeffrey's parents were also concerned about his problems paying attention in school in the last year. Hyperactive since preschool, he had a very short attention span and was often distracted. He could be impulsive, often unaware that he was doing things that could be dangerous. He often interrupted his parents when they were speaking. He was restless and fidgety in school, and his teachers were concerned that he might disrupt his classmates.

Jeffrey was the product of a pregnancy complicated by intrauterine growth retardation. When the amniotic fluid was found to be at low volume at 36 weeks, delivery was induced. The delivery was uncomplicated, and the birth weight was 5 pounds, 10 ounces. Except for a minor delay in the acquisition of speech, developmental milestones were within normal limits.

Currently in kindergarten, Jeffrey has attended a well-regarded public school since he was 2 years of age. He lived with his parents and 2-year-old sister, had many friends, and enjoyed play dates.

Jeffrey had frequent upper respiratory infections. There were no known allergies and no major medical problems. There was no known family history of TD, tics, or OCD.

MENTAL STATUS EXAMINATION

Telegram: @medical_k

www.konkur.in

Jeffrey was a healthy-looking 5-year-old boy, well-groomed and dressed. He was initially very shy, clinging to his mother. He appeared to be quite active and restless. Multiple tics were noted, including nose twitches, finger-snapping, and a cough. Jeffrey was somewhat oppositional when asked to do a drawing.

IMPRESSION

In summary, Jeffrey was a 5-year-old boy with multiple motor and vocal tics for short episodes, including a bout lasting 3 months at age 4 years, and just over 2 months currently, consistent with provisional tic disorder. TD could not be entirely ruled out, but there was no diathesis based on family history. Jeffrey also appeared to meet criteria for ADHD, combined presentation, which may have predisposed him to the development of tics. The ADHD symptoms were causing impairment in his academic functioning.

TREATMENT PLAN

Parent and teacher ratings of ADHD symptoms were recommended at initial evaluation, and at follow-up after treatment was initiated. Treatment of ADHD was recommended, starting with a cautious trial of a methylphenidate-based stimulant. The plan was to add a low dose of an α-adrenergic agonist such as guanfacine or clonidine if tics increased significantly. Consultation and psychoeducation were recommended for Jeffrey's teacher.

ETIOLOGY AND PATHOPHYSIOLOGY

The etiology and pathophysiology of TD and other tic disorders remain unknown. Considerable data accumulated during the last few decades from neuroanatomical and neurochemical studies of TD point to a diffuse process in the brain involving cortico–striato–thalamic–cortical (CSTC) pathways in the frontal lobes and basal ganglia, including the striatum (caudate nucleus and putamen). Several neurotransmitters and neuromodulators have been

Telegram: @medical_k

www.konkur.in

implicated, including dopamine, serotonin, glutamate, GABA, and endogenous opioids. Although a specific animal model has not been identified, some parallels may exist with horses with crib biting, which display spontaneous motor tics accompanied by vocalizations, dogs with acral lick syndrome, and mouse models with repetitive movements and stereotypies.

A host of biochemical, imaging, neurophysiologic, and genetic studies support the concept that TD is an inherited neurodevelopmental disorder. Twin studies have reported 89% to 94% concordance for TD. However, environmental factors have also been implicated. In one study of 16 pairs of monozygotic twins, low–birth-weight was a strong predictor of more severe tics. Several gestational and perinatal insults, including hypoxia–ischemia, exposure to androgens, heat, and infectious agents, have been implicated in the pathophysiology of tic disorders. The effect of prenatal ischemic events may be to alter dopamine signaling, heralding the development of tics. Delivery complications, especially forceps deliveries, and fetal exposure to high levels of coffee, cigarettes, or alcohol were associated with male gender and OCD in a sample of TD probands.

Androgen exposure is speculated to play a role in the development of tics, given the higher prevalence of TD in males. Studies in both children and adults suggest that males are at least three to four times more likely than females to manifest TD. X-linked genomic transmission has also been considered, but this appears less likely in the context of frequent male-to-male transmission within families. The role of stress, given the strong association of tics with anxiety, is also compelling. TD patients have been found to have significantly higher levels of cerebrospinal fluid (CSF) corticotrophin-releasing factor (CRF) than normal controls or patients with OCD who do not have a tic disorder, demonstrating a heightened reactivity of the hypothalamic–pituitary–adrenal axis. Increased reactivity of the noradrenergic sympathetic system has also been shown in patients with TD. A dopamine-mediated pathway in the hypothalamus that modulates sweating in response to changes in temperature has also been linked with tic activity. Increases in ambient and core body

Telegram: @medical_k

www.konkur.in

temperatures have been shown to transiently increase tics in some individuals. A stress diathesis model modulated by the hypothalamic–pituitary–adrenal axis, the associated stress-related neurotransmitters and hormones, and their targets may represent the final common pathway that may explain the variable expression of the tic disorders.

Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infection

A postinfectious mechanism for the development of tics and OCD has been postulated since the late 1800s. A poststreptococcal infection autoimmune etiology has long been well established for Sydenham chorea, the movement disorder that was the model for the development of pediatric autoimmune neuropsychiatric disorders associated with streptococcus (PANDAS) hypothesis. In addition to chorea, some Sydenham's patients display motor and phonic tics, as well as obsessions, compulsions, hyperactivity, impulsivity, and inattention. In 1998, Swedo and colleagues first described a putative subgroup of 50 children with PANDAS with OCD and/or tic disorders with acute symptom onset and/or exacerbation precipitated by infection with group A β-hemolytic Streptococcus (GABHS). Although GABHS is considered the initial autoimmune response-inciting event in children with PANDAS, viruses, other bacteria, and even noninfectious immunologic responses are thought to be capable of precipitating later symptom exacerbations. Case reports have also implicated Lyme disease and Mycoplasma pneumonia in the development of infection-triggered tics. By molecular mimicry—the postulated autoimmune mechanism—antibodies are formed against the inciting agent and subsequently attack neurons because of some structural similarity.

Specific diagnostic criteria for PANDAS have been described, including the presence of OCD and/or tic symptoms, prepubertal onset, episodic course with sudden, explosive onset and/or exacerbations and remissions, and a temporal relationship of GABHS infection and neuropsychiatric symptoms. A case-control study of 144 children with OCD, TD, or another tic disorder conducted by Mell and colleagues provided the strongest evidence for the involvement of

Telegram: @medical_k

www.konkur.in

GABHS in the onset of tic disorders and OCD. Patients with OCD, TD, or another tic disorder were found to be more likely than controls to have had a streptococcal infection in the 3 months prior to the onset of symptoms. Risk was greatest among those with multiple streptococcal infections in the preceding 12 months. Others have found no more than a chance association between GABHS infections and tic symptom exacerbations. A case-control study by Perrin and colleagues found little evidence of increased tics, obsessions, or compulsions after well-documented and treated GABHS infections.

Several groups have reported increased antistreptococcal antibody titers in individuals with OCD and tic disorders, but several other groups have not found this association. A double-blind, placebo-controlled, crossover study of prophylactic oral penicillin to attempt to reduce PANDAS recurrences failed to show differences between drug and placebo. More recently, in two prospective case-control studies of children with PANDAS, Kurlan and colleagues reported that Group A B-hemolytic streptococcus infection was not the only antecedent associated with exacerbations of tics and OCD symptoms in the cases; similarly, Leckman and colleagues found there was no evidence for a temporal association between GABHS infections and tic/OC symptom exacerbations in children who met published PANDAS diagnostic criteria.

Treatments based on a postulated autoimmune mechanism have been nonspecific, and the results have been inconsistent. Immune therapies such as intravenous immunoglobulin (IVIG), plasmapheresis, corticosteroids, and plasma exchange have been explored with inconsistent results. Immunomodulatory treatments remain experimental, and current recommendations are for use only in research protocols.

The link between an infectious etiology and tic disorders/OCD remains a work in progress. Building on previous work, the most recent investigation has shifted its focus on acute, explosive onset OCD symptoms, which Swedo and colleagues have described as pediatric acute onset neuropsychiatric syndrome (PANS). Anxiety, emotional lability, developmental and behavioral regression,

Telegram: @medical_k

www.konkur.in

deterioration in schoolwork and handwriting, and excessive urination are among the secondary characteristics.

Other new areas of research include the investigation of proinflammatory cytokine elevation, as well as decreased numbers of regulatory T-cells in some TD patients. Clinical implications suggest vigilance in the evaluation of tic or OCD patients with pharyngitis or streptococcus exposure, a low threshold for obtaining streptococcus throat culture, antistreptolysin O (ASO) and anti-DNAse B titers, and vigorous treatment with antibiotics when a streptococcal infection is confirmed. Antibiotic treatment has been shown to be remarkably effective in some unambiguous cases of sudden onset or exacerbation of tics with associated laboratory-documented streptococcal infection.

Neuroimaging Studies

Structural MRI studies in TD demonstrate volume changes in brain regions associated with CSTC circuits. Some studies have shown a loss of the normal basal ganglia asymmetry, as well as decreased basal ganglia volume in TD patients. In ten pairs of monozygotic twins, the right caudate was smaller in the more severely afflicted individuals, supporting evidence for the role of epigenetic mechanisms. A large study of basal ganglia volume in 154 patients with TD and 130 controls, conducted by Peterson and colleagues, found a significant decrease in the volume of the caudate nucleus in both children and adults. Larger dorsal prefrontal regions in children, but significantly smaller volumes in adults, were also reported by this group. Dorsal prefrontal volume was inversely related to tic severity, such that patients with greater prefrontal volumes exhibited decreased tic severity. Larger prefrontal volumes in children with TD may be a manifestation of synaptic plasticity associated with the constant need to suppress tics in social contexts. Adults with persistent tics may represent a subsection of the overall TD population who do not generate a neuroplastic, compensatory response in the prefrontal cortex, leading to increased severity of the tic disorder and its continuity into adulthood.

Telegram: @medical_k

www.konkur.in

Larger parieto-occipital region volumes and smaller inferior occipital volumes have also been observed in individuals with TD when compared with controls. Bloch and colleagues found an inverse correlation between caudate volume in childhood and tic severity in late adolescence and early adulthood. Smaller caudate volumes were associated with more significant later tic activity, as well as with OCD symptoms. Another more recent study reported increased volume of the putamen bilaterally in boys with TD.

Decrease in corpus callosum size in children and an increase in corpus callosum size in adults with TD have also been reported. Corpus callosum size correlates inversely with prefrontal volume and is positively related to tic severity. These findings may indicate age-dependent changes in the white matter tracts in the disorder. Alternatively, decreased corpus callosum size, like increased dorsolateral prefrontal volume, may represent a compensatory mechanism children with TD develop to facilitate suppression of tics. Adults with TD tend to show the opposite pattern, exhibiting relatively decreased dorsal prefrontal and increased corpus callosum volumes that may be associated with the persistence of symptoms into adulthood.

Several studies consistently implicate primary cortical dysfunction in TD. Cortical thinning has been documented in frontal and parietal lobes, especially the sensorimotor cortex; the degree of thinning may correlate with tic severity. Increased sensorimotor cortical volume has been correlated with strength of premonitory sensations in a study of adults with TD. Evaluation of subgroups of TD patients has shown a relationship between symptoms and location of cortical thinning. While most have found thinner cortex or decreased volume in several different cortical areas, a few studies have reported overall brain volume decreases in TD subjects.

Larger left thalamic volumes were found in 18 patients with TD compared to 16 control subjects in one study. Increased gray-matter volumes bilaterally in the ventral putamen and decrease in gray matter in the left hippocampal gyrus have also been shown. Peterson and team demonstrated significantly increased overall hippocampus and amygdala volumes in TD patients, with a decline in volume with

Telegram: @medical_k

www.konkur.in

age in the TD group, but not in healthy controls. In children and adults with TD, these volumes were inversely correlated with the severity of tics, OCD symptoms, and ADHD symptoms. An explanation for these findings is that the subregion plays a compensatory and neuromodulatory role in tic, OCD, and ADHD symptoms. In addition, cerebral hyperintensities—bright patches in brain parenchyma on T_2-weighted MRI that are indicative of neuroinflammatory or neurodegenerative processes—have been detected at increased rates in children and adolescents with TD, OCD, or ADHD in subcortical regions (primarily the basal ganglia and thalamus). Taken together, volumetric studies suggest that cortical and subcortical impairment, including striatal anomalies, and disruption of the temporolimbic pathways of the CSTC circuits are implicated in the pathophysiology of TD.

Functional neuroimaging studies using state-dependent cerebral blood flow, oxygenation, and energy (glucose) metabolism parameters as a measure of brain activity (e.g., functional MRI [fMRI], positron emission tomography [PET], and single photon emission tomography [SPECT]) suggest altered activity (increased or decreased) in various areas of the brain (e.g., frontal and orbital cortex, striatum, putamen) in TD patients compared to controls, or across brain regions within TD patients. An fMRI study by Bohlhalter and colleagues that analyzed activity two seconds before and after tic onset indicated that paralimbic and sensory association areas are critical to tic generation. Other fMRI studies in individuals with TD indicate that greater ability of basal ganglia structures to suppress cortical activity may be related to decreased tic severity, supporting findings from PET and SPECT studies of the role of the basal ganglia in TD. Functional neuroimaging studies suggest that voluntary tic suppression involves deactivation of the putamen and globus pallidus, coupled with partial activation of regions of the prefrontal cortex and caudate nucleus.

Event-related PET scanning has connected increased or decreased activity in many brain areas with the presence of tics, including the prefrontal cortex, premotor and primary motor cortex, anterior cingulate cortex, putamen, and caudate. fMRI scanning has

Telegram: @medical_k

www.konkur.in

demonstrated increased neural activity in individuals with TD compared to controls throughout various motor areas, including the sensorimotor cortex, putamen, pallidum, and substantia nigra; this increased activity correlates with symptom severity. On the other hand, weaker activity has been demonstrated in the TD patients' motor control pathways, including the caudate and anterior cingulate cortex. More severe tics have been observed in those with progressively less activity in these regions, suggesting a disruption in these areas results in failure to control tics or premonitory urges. Other fMRI studies have also shown age-related abnormalities in frontostriatal and frontoparietal connections, implicating abnormal maturational changes in TD patients, strengthening the understanding that tics are the result of neurodevelopmental deficits.

Abnormal dopamine neurotransmission that contributes to the pathophysiology of TD is supported by increased levels of dopaminergic innervation of the striatum of TD patients in SPECT studies. A study in monozygotic twins concordant for TD but discordant for severity demonstrated abnormalities in D_2 receptors in the caudate area in the more severely afflicted twin. These neuroimaging findings are consistent with results of well-established tic suppression treatments with neuroleptic drugs that block dopamine receptors. Furthermore, TD patients have been shown to release more dopamine in response to amphetamine at dopaminergic synapses than healthy controls and dopamine-releasing drugs may precipitate or exacerbate tics. Midbrain dopaminergic neurons play a central role in motor control and attentional processes through direct connections to the striatum and cortex, respectively. Glutamatergic, GABAergic, serotonergic, cholinergic, noradrenergic, and opioid systems may also be implicated, given that they are present in CSTC circuits and interact with the dopaminergic system.

Taken together, structural and functional neuroanatomical findings support the understanding that TD results from abnormal activity in diverse cortical and subcortical brain regions. Active suppression of tics may require activation of dorsolateral prefrontal circuits that increase overall activity in the caudate nucleus, thereby inhibiting activity in the putamen.

www.konkur.in

Genetic Findings

Genetic data have been derived historically from family pedigree and twin studies. TD, persistent tic disorders, and OCD cluster in families. Twin studies have shown a high concordance rate for tic disorders among monozygotic (MZ) pairs (ranging from about 50% to 90%), in contrast to a relatively low rate among dizygotic twins (often around 20%). Other studies have shown that first-degree relatives of TD patients have a higher risk of TD, persistent tics, and OCD than normal controls. One large population cohort, multigenerational family study with 4,826 individuals diagnosed with TD or chronic tic disorders in the Swedish National Patient Register, estimated the heritability of tic disorders to be 0.77.

Historically, genetic analyses were thought to be consistent with an autosomal dominant mode (with incomplete penetrance) of inheritance; some investigators argued that a semidominant, semirecessive pattern could also exist. However, older studies were confounded by relatively high rates of bilineal transmission with apparent genetic contributions from both paternal and maternal lines.

More recently, investigators have proposed multiple gene loci in combination with environmental factors. The precise type or severity of tic disorder may be different from one generation to another and may be modified by nongenetic factors. A systematic genome scan of 76 affected sibling pair families with 110 sib pairs conducted by the Tourette Syndrome Association International Consortium for Genetics (TSAICG) demonstrated that 4q, 8p, and four other regions on chromosomes 1, 10, 13, and 19 were regions of interest. Efforts to confirm and extend these findings, however, have led to the identification of new regions and a failure to replicate the original findings.

Specific TD populations have been studied in South Africa, Costa Rica, and French-speaking Canada. Regions near the centromere of chromosome 2, as well as on 6p, 8q, 11q, 14q, 20q, 21q, and X, have been implicated. A linkage analysis study of a large pedigree of multigenerational TD patients in the United Kingdom is suggestive of linkage at loci on chromosomes 5, 10, and 13 in at least one of the

Telegram: @medical_k

www.konkur.in

families. The largest genetic linkage study, undertaken by the TSAICG, consisting of more than 2,000 individuals, using a whole-genome scan with 390 microsatellite markers, demonstrated strong evidence of linkage for a region on chromosome 2p.

Cytogenetic abnormalities in TD families have also been studied. A TSAICG study reported disruption of the contactin-associated protein 2 gene (CNTNAP2) on chromosome 7, coding for a membrane protein important for signal conduction along myelinated neurons at the nodes of Ranvier, in TD patients. Affected individuals were found to have alterations in chromosomes 2 and 7. Other TD patients have been described with *de novo* duplication of the long arm of chromosome 7, a balanced translocation between chromosomes 6 and 8 with a translocation breakpoint on chromosome 8q, and an 18q21.1–q22.2 inversion. Abelson and colleagues identified a candidate gene, SLITRK1, on chromosome 13q31.1 in some individuals with TD, with expression of the gene product in the basal ganglia and deep layers of cortex, brain regions implicated in the pathophysiology of TD. Ercan-Sencicek and colleagues reported a rare functional mutation in the *HDC* gene encoding l-histidine decarboxylase, the rate-limiting enzyme in histamine biosynthesis, in linkage analysis in a two-generation TD pedigree.

Overall, the current understanding of TD and tic disorders implicates multiple vulnerability genes that likely determine the form and severity of tics in the wide variety of afflicted individuals and their families. Candidate genes have been identified in individuals with TD, including the dopamine receptor genes, the dopamine transporter genes, several noradrenergic genes, and some serotonergic genes. The TSAICG genome-wide association study (GWAS) reported that no genes reached threshold significance. A more recent analysis by Huang and colleagues of a European ancestry sample of 2,434 TD cases and 4,093 ancestry-matched controls for rare copy number variants has led to the identification of two genome-wide significant loci, *NRXN1* deletions, and *CNTN6* duplications, each contributing a significant increase in TD risk.

Willsey and peers have used whole-exome sequencing and *de novo* variant detection techniques to identify four likely risk genes with

Telegram: @medical_k

www.konkur.in

multiple *de novo* damaging variants in unrelated individuals: *WWC1*, *CELSR3*, *NIPBL*, and *FN1*. They estimate that *de novo* damaging variants in about 400 genes contribute risk in 12% of clinical cases.

DIAGNOSIS AND CLINICAL FEATURES

A comprehensive, detailed history with observations derived from multiple sources is the cornerstone of clinical evaluation of tics and comorbid neurodevelopmental and psychiatric disorders. Neurologic, laboratory, and imaging examinations in patients with tic disorders are usually normal. Since tic disorders are diagnosed based on history, reliable sources of information are essential. This is particularly important because in many patients tics may be suppressed during the initial examination. It is critical to determine the degree to which tics interfere with emotional, social, family, and academic functioning, as treatment strategies are most effective when the severity and impact of tics are taken into consideration. Diagnostic evaluation is closely connected with the first steps of treatment.

Historical inquiry should include detailed medical and developmental information, medication history (including substances of abuse or recreation), educational and occupational data, social and interpersonal history, and a thorough family pedigree covering at least three generations. A careful, descriptive, longitudinal assessment of the tic disorder is important, including onset, course, current severity, presence of premonitory sensations and the capacity for tic suppression, overall burden, and treatments to date. The physical examination should include height, weight, presence or absence of dysmorphic features, posture, gait, reflexes, and a systematic rating of current abnormal movements. The Abnormal Involuntary Movement Scale (AIMS) is a systematic assessment procedure (and rating form) that can be adapted for use with children. Videotaped standardized interviews and evaluation procedures are used in some research studies; these could also be used in the clinical setting. However, the absence of observed tics on initial examination does not preclude the diagnosis of a tic disorder. Unusual histories, co-

Telegram: @medical_k

www.konkur.in

occurring mental status changes, or the presence of seizures always warrant referrals for thorough neurologic evaluation.

Psychiatric evaluation should include a formal assessment of the behavioral and emotional problems known clinically to co-occur with tic disorders, including ADHD, OCD, anxiety disorders, mood disorders, and manifestations of impaired or dysregulated affect (e.g., aggression). The use of structured or semistructured interviews, such as the Diagnostic Interview Schedule for Children (DISC) or the Children's Schedule for Affective Disorders and Schizophrenia (K-SADS), can improve classification and evaluation of psychiatric comorbidity. Standardized rating scales developed specifically for the tic disorder population have improved diagnostic reliability in research studies and can also be helpful in clinical care. The Yale Global Tic Severity Scale (Y-GTSS) and the Tourette Syndrome Symptom List (TSSL) rate tics, compulsions, and other associated features. Specific rating scales for OCD (the Children's Yale-Brown Obsessive-Compulsive Scale [C-YBOCS]) and ADHD (the IOWA Conners parent and teacher rating scales, or the Swanson, Nolan, and Pelham [SNAP] scale) can also be used. Because rating instruments can provide quantifiable baseline data, such as frequency and intensity of tics, these data can also be used to measure treatment response (Table 47–2).

Clinical Global Impressions Scale (CGI)	Clinician	Excellent	Yes

Auxiliary data from outside sources are essential. Pediatric and medical records may document developmental and medical history, adequacy of medication trials, hospitalizations, and laboratory findings. Review of educational records is advised for children because many TD patients manifest tics or associated problems in school settings. Report cards document academic performance. Direct phone contact with teachers may provide data about attentional functioning, learning challenges, social and emotional competencies, and any behavioral difficulties. Neuropsychological or speech and language testing may be indicated for patients with impairments in school or occupational functioning. Identified areas of strength and weakness are subsequently conveyed to appropriate personnel for inclusion in educational or vocational planning.

PATHOLOGY AND LABORATORY EXAMINATION

In general, laboratory tests are indicated only to rule out other disorders when such conditions are highly implicated in the differential diagnosis of a given patient. For example, specific tests are available for the definitive diagnosis of Huntington disease, Wilson disease, and neuroacanthocytosis.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of tic disorders can be challenging (Table 47–3). Medical and family histories, physical and neurologic examinations, and baseline laboratory testing enable clinicians to rule out potential causes of *de novo* tics such as infection, trauma, substance use, or

Telegram: @medical_k

www.konkur.in

toxin ingestion. Diagnostic hallmarks of tic disorders include the waxing-and-waning natural history, onset in childhood or adolescence, repetitive, rapid, nonrhythmic phenomenology, and involuntary features. In the absence of at least some history of simple tics, the diagnosis of a tic disorder may be questioned. Furthermore, the presence of vocal tics is helpful in ruling out other disorders because phonic manifestations are rare in other neurologic conditions. Tics must be distinguished from other types of abnormal movements: myoclonus, tremors, chorea, athetosis, dystonias, akathisia, and compulsive rituals.

Diagnostic considerations among the movement disorders include Sydenham chorea, poststreptococcal neurologic complications such as choreiform, writhing, and truncal movements; Huntington disease, an autosomal dominant disorder presenting with chorea and dementia and with an onset typically in the fourth or fifth decade; Parkinson disease, typically a late-life disorder, characterized by flattened facies, bradykinesia, rigidity, cogwheeling, and “pill-rolling” resting tremor; Wilson disease, an autosomal recessive disorder of copper metabolism that presents with liver abnormalities and neurologic symptoms: early dementia, mood disorders or psychosis, asterixis (a flapping tremor of the hands); Parkinsonism; structural diseases such as hemiballismus associated with subthalamic nucleus impairment; and neuroacanthocytosis, a rare movement disorder marked by progressive muscle weakness and atrophy, progressive cognitive loss, chorea, acanthocytosis (spiked red blood cells), and, sometimes, facial tics. In psychiatric settings, patients who have been exposed to neuroleptics are at risk for neuroleptic-related dyskinesias, including tardive and withdrawal dyskinesias. It is important to remember that dyskinesias may also be observed in tic disorder patients secondary to neuroleptic therapy but may be easily overlooked.

Telegram: @medical_k

www.konkur.in

Table 47–3.
Differential Diagnosis of Abnormal Movements

Telegram: @medical_k

www.konkur.in

Descriptive Terms	Observable Movement Pattern(s)
Akathisia	Motor restlessness (unpleasant need to move), usually in the lower extremities
Athetosis	Slow, irregular, writhing movements, usually in the hands and fingers but often involving the neck
Ballismus	Intermittent, coarse, large amplitude, jerking, shaking, flinging movements
Chorea	Irregular, spasmodic movements, usually affecting the limbs or face
Compulsion	Repetitive behavior that is more goal-directed and may be undertaken to prevent or reduce anxiety or distress
Dyskinesia	Choreiform or dystonic movement that is involuntary, stereotyped, and not suppressible
Dystonia	Sustained, tonic contraction that progresses to abnormal postures
Myoclonus	Sudden, brief, clonic, shock-like jerks, usually involving the limbs
Periodic movements of sleep	Periodic dorsiflexion of the foot and flexion of the knee, occurring during sleep
Spasm	Stereotypic, prolonged movement involving the same group of muscles
Stereotypy	Repetitive, usually meaningless, gestures, habits, or automatisms
Tic	Stereotyped, rapid, recurring motor movement (motor tic) or vocalization (phonic or vocal tic) that is nonrhythmic, involuntary or semivoluntary, and sudden in onset

Telegram: @medical_k

www.konkur.in

Tremor	Unintentional, somewhat rhythmic muscle movement involving oscillations of one or more parts of the body

COURSE AND PROGNOSIS

The typical course of TD is characterized by onset of simple motor tics of the eyes, face, head, or neck by about age 6 or 7 years, followed by a rostral-caudal progression of motor tics over several years to involve the shoulders, trunk, and extremities. Eye blinking is the most common initial tic. Vocal tics typically start at ages 8 to 9 years; more-complex tics often begin later, as do obsessive-compulsive symptoms, at about ages 11 to 12 years. As many as half of clinically referred TD patients may show signs of ADHD, such as hyperactivity, impulsivity, and distractibility, prior to the onset of tics. Tics range from mild to severe and tend to stabilize over time; most children evaluated even in specialty clinics have mild to moderate tics. Some patients have lengthy periods during which most or all manifestations attenuate or remit. Recent studies indicate that tic severity improves significantly in most patients by early to mid adolescence.

Social functioning may be impaired because of bullying or rejection by peers or anxiety about having tics in social situations. Tics may impair academic functioning by their disruptive impact in class or interference with homework completion. Academic underachievement across educational levels is seen in many seeking treatment for TD or chronic tic disorders. Occupational functioning may be impaired by inability to use a computer or complete work tasks. By early adulthood, tics are greatly diminished in most individuals, and some are tic-free. Persistent tic symptoms may cause considerable distress and can lead to social isolation and personality changes. In severe cases, tics may directly interfere with daily activities. For example, violent head and neck tics may cause physical complications, such as compressive cervical myelopathy.

Fernández de la Cruz and peers report that there is a fourfold increase in the risk of suicide in individuals with tic disorders. The

Telegram: @medical_k

www.konkur.in

strongest predictor of risk is the presence of tics beyond the second decade of life. Psychiatric comorbidity and a history of suicide attempts increase risk as well.

Comorbid Psychiatric Disorders

Hirschtritt and colleagues conducted a large cross-sectional study of TD patients and unaffected family members, estimating a lifetime prevalence of psychiatric comorbidity in those with TD at 85.7%. 57.7% had two or more psychiatric comorbidities. The relationship between TD and frequently observed comorbid psychiatric disorders has not yet been disentangled. Obsessive-compulsive symptoms, developmentally inappropriate motoric hyperactivity and inattention, anxiety, and aggressive dyscontrol have often been described in patients with TD. Motor, vocal, behavioral, cognitive, and emotional dysfunction may represent manifestations of an underlying central core disinhibition.

A majority of clinically referred individuals with TD meet full or subthreshold diagnostic criteria for ADHD, OCD, or both at some time during the course of their illness. Interestingly, these findings are also reported in community samples. ADHD and OCD are more likely to interfere with overall functioning and academic and work performance than the tics. Investigation of functional impairment in youth with TD conducted by Storch and colleagues found that non–tic-related problems caused more dysfunction than the tics per se, most often either ADHD or OCD symptoms.

ADHD is diagnosed by history of an enduring pattern of developmentally inappropriate inattention and/or hyperactivity and impulsive behavior; there is a bidirectional relationship between tics and ADHD. Some investigators have reported that 50% to 75% of TD patients also meet criteria for ADHD, whereas about 10% to 30% of ADHD patients also meet criteria for a tic disorder. Co-occurring TD and ADHD are often associated with academic difficulties, peer rejection, family conflict, and disruptive behaviors such as explosive outbursts, overt aggression, low frustration tolerance, and poor treatment adherence. The nature of the relationship between ADHD and TD is not firmly established, but it has been clearly demonstrated

Telegram: @medical_k

www.konkur.in

that ADHD predicts greater disability than that associated with tic disorders alone, including an earlier diagnosis of TD, and a much higher rate of anger control problems and oppositional defiant disorder, sleep difficulties, learning disability, mood disorders, social skills deficits, sexually inappropriate behavior, and self-injurious behavior.

There also appears to be a bidirectional relationship between TD and OCD in most patient cohorts. OCD is characterized by obsessions—recurrent, intense, intrusive ideas, thoughts, impulses, or images that cause anxiety or distress, or compulsions—repetitive behaviors or mental acts sought to prevent or ward off anxiety or distress caused by an obsession. 20% to 40% of TD patients meet full criteria for OCD, and up to 90% have been reported to have subthreshold symptoms such as repetitive counting, touching, ordering, arranging, or symmetry needs.

Family studies provide the most compelling evidence for the association of tic disorders with OCD. First-degree relatives of TD probands have higher frequencies of TD, as well as OCD, and first-degree relatives of OCD probands have higher frequencies of OCD and tic disorders than relatives of control subjects. Studies of OCD probands indicate that the earlier the onset of obsessions or compulsions in the proband, the higher the genetic loading in family members for both OCD and tics.

In addition to ADHD and OCD, mood and anxiety disorders have been described in clinically referred and community samples of TD patients, including major depression, bipolar disorder, generalized anxiety disorder, separation anxiety disorder, panic disorder, and simple and social phobias. Some estimates suggest that up to 60% of children with TD will experience major depression at some point, and about 40% will have a non-OCD anxiety disorder. Vermilion and team compared anxiety symptoms in anxious youth with and without tic disorders. The anxiety profile in youth with tics appears to be different from those without tics. Those with tics are more likely to experience separation anxiety and physical symptoms of anxiety than anxious youth without tics.

Telegram: @medical_k

www.konkur.in

Coffey and colleagues reported that comorbid mood disorders were the most robust predictors of psychiatric hospitalization and illness severity in a cohort of TD patients. Tic severity was only marginally significant as a predictor of psychiatric hospitalization. In a controlled study of older adolescents with TD, Gorman and colleagues found that, independent of comorbidity with ADHD, TD patients had significantly higher rates of depression and poorer overall outcome than healthy controls.

More recently, the work of Rizzo and peers demonstrated that depression in those with TD is associated with tic severity, the presence of comorbid ADHD, co-occurring anxiety, disruptive behavior, and a family history of depression. Whether mood symptoms are primary (i.e., related to the underlying pathophysiology of TD) or secondary to the demoralization and/or impairment related to having a chronic illness remains to be further clarified.

A substantial minority of youth with TD evaluated in clinical settings may meet criteria for intermittent explosive disorder manifested by rage attacks or oppositional defiant disorder. Budman and colleagues reported that children with TD as well as ADHD and OCD are more likely to experience explosive outbursts, and the number of outbursts is positively correlated with the number of comorbid conditions. Tic type and severity are not linked to the presence of explosive outbursts.

Learning and academic problems are common in children with TD; in a database of 5,450 patients with TD, 1,235 (22.7%) had learning disabilities. Young patients with TD may experience problems with executive functions, such as planning, persistence, organizational skills, and social problem-solving. Patients with TD have been consistently shown to have difficulties with procedural learning, fine motor control, motor inhibition, nonverbal memory, and visual motor integration. In addition, handwriting may be poor. Comorbid ADHD confers a greater risk of learning and academic problems in those with tic disorders.

Many clinically referred children with TD are reported to have difficulty with sensory-perceptual functioning, such as extreme sensitivity to touch or sound. Investigators have hypothesized that

Telegram: @medical_k

www.konkur.in

dysregulation of central sensory integration and/or sensory gating problems may result in these sensitivities, but more research is needed. Some of these children may have comorbid autism spectrum disorder (ASD), which occurs at higher rates in children with TD than in the general population. Estimates range from 6% to 16%. Emerging research examining other conditions that may frequently co-occur with tic disorders includes stuttering, sleep disturbances, migraine headaches, asthma, and metabolic and cardiovascular disorders.

Telegram: @medical_k

www.konkur.in

Mark was a 13-year-old boy referred by his pediatrician for consultation for tics and anxiety. Mark developed the onset of collar chewing at around age 4 or 5 years. Between ages 5 and 6 years, he began to make sniffing and snorting sounds, and at age 6 or 7 years, he developed eye blinking and head and neck movements. Mark was subsequently referred at age 8 years to a pediatric neurologist who diagnosed TD. No treatment was initiated at that time because Mark's tics were not causing any distress or impairment. His parents reported that since age 10 years, the severity of Mark's tics had diminished. He was currently repeating words and making guttural sounds and bird noises at times.

His parents reported that Mark had a long history of anxiety. As a very young child, he was anxious about separation for preschool. He was described as a child who was slow to warm, with a cautious temperament, waiting until he was familiar with a situation to enter a group. Over the years, teachers commented that they would like to see more class participation from him. His parents reported that Mark often preferred to stay at home rather than go out to see friends on play dates.

Mark reported that he did not like to speak in public because he was afraid that what he would say would "not be perfect." Mark described ruminating on "things he should have said or done differently." Mark always worried about performance, about his mother dying, and about bad things happening. Mark had slept with his parents until the age of 10 years because of a history of nightmares.

Mark had concerns about contamination, and he used Purell and washed his hands frequently. Mark hoarded objects and preferred to do things a certain number of times; in his backpack, he kept 20 books, 20 blue pencils, and 20 black pencils. In the past, he used to sharpen pencils excessively to get them to a "just right" point.

Mark was the product of a full-term, uncomplicated pregnancy; developmental milestones were described as entirely within

Telegram: @medical_k

www.konkur.in

normal limits. Currently in eighth grade, he had attended private school since kindergarten and was an A student. Mark enjoyed sports and spending time with friends.

There was no family history of TD or OCD. Mark's father had been treated for anxiety. A paternal uncle had a long-standing history of eye blinking. Mark had no history of hospitalization, head injury, seizures, allergies, or other major medical problems.

MENTAL STATUS EXAMINATION

Mark was a slender, peripubertal boy in age-appropriate casual clothing. He was very restless. There were multiple motor and vocal tics, including eye blinking, shoulder shrugging, facial grimacing, mouth opening, coughing, and grunting. Mark showed a range of affect and was pleasant and cooperative. Mark reported that his tics did not really cause him any problems, but he worried a lot.

IMPRESSION

In summary, Mark was a 13-year-old peripubertal boy with a long history of multiple motor and vocal tics consistent with TD. Given the contamination concerns, obsessional worries and ruminations, and the tendency to count and arrange, Mark also met the criteria for OCD. In addition, there were symptoms suggestive of social anxiety disorder, given his reluctance to speak up in class, his slow-to-warm-up behavior, and his history of shyness. The excessive worry about performance was suggestive of a generalized anxiety disorder.

TREATMENT PLAN

Treatment of Mark's anxiety was indicated because it appeared to be pervasive and was causing distress. The recommendation was to start cognitive-behavioral therapy to address both his social anxiety and obsessive-compulsive behaviors. Given that Mark was neither in distress nor impaired by his tics, and was probably past his lifetime peak severity, simple monitoring of the tics was recommended. It was likely the tics would decrease once the anxiety was treated.

Telegram: @medical_k

www.konkur.in

TREATMENT

Individuals with mild and even some moderate tics may not need treatment if the tics are not causing significant distress or impairment. Simple, active monitoring may be all that is necessary for some individuals with mild tics. Indications for treatment of tics include physical pain or discomfort, interference with social interactions, and impairment in any aspect of educational or occupational functioning. The first step in treatment is proper education of the patient, family members, teachers, and others who interact with the patient. Parents, educators, and physicians must work as partners to advocate for the optimal school environment for children with tic disorders. National and local support groups, such as the Tourette Association of America (https://www.tourette.org), can provide additional information and can serve as a valuable resource for patients and their families.

Nonpharmacologic treatments have been developed that are as successful as pharmacotherapy. In fact, the first-line treatment for mild to moderate tics is cognitive-behavioral intervention. Medications are usually considered only when symptoms are unable to be addressed by psychotherapeutic interventions and/or interfere with academic or occupational performance, peer relationships, social interactions, or activities of daily living. Pharmacotherapy for tic disorders is individualized and tailored specifically to the needs of the patient; the most distressing and/or impairing symptoms are targeted first. The goal of treatment is not to eliminate tics but to relieve tic-related discomfort or distress and to achieve a degree of control of tics that allows the patient to function as normally as possible.

General Guidelines

Behavioral intervention is the cornerstone of effective treatment for tic disorders. Treatment goals should be to reduce symptoms, support adaptive functioning and strengths, and enhance developmental progress. Self-esteem should always be supported, given that most patients with tic disorders will have at least some sense of personal and emotional vulnerability. Early in the diagnostic process, education in phenomenology and the natural history of tic disorders is essential.

Telegram: @medical_k

www.konkur.in

Clarification that the patient's symptoms are not voluntary in most situations eases psychological burdens for both patients and families. This is especially important because families observe that tics, at times, can be suppressed. Struggles over whether the symptoms are tics or "negative behavior" are pointless and should be curtailed; a more practical goal involves personal management of, and responsibility for, symptoms and behavior, regardless of their origin.

Containment is another cornerstone of treatment. Even with the use of effective medications, it is rare for tics to remit completely. The use of a "tic room" or a "time out" area provides an opportunity to contain problematic tics or compulsions and to "de-stimulate." Because emotional conflicts and stress frequently increase symptom intensity and frequency, time-limited withdrawal from stressful situations can be beneficial. A balanced, healthy diet and exercise regimen may contribute to stress reduction and overall well-being. Caffeine and excess amounts of sugar should be minimized because they might exacerbate tics in some patients.

Psychoeducational Approaches

Educating patients and their families is essential. Patients and their parents frequently experience relief at the time of diagnosis. There should be ongoing opportunities for discussion of patients' and families' questions and concerns. Referral to the Tourette Association of America and to its local chapters is recommended for all newly diagnosed patients and their families to maintain continuing education and support.

Behavioral Therapies

Behavioral treatment is a primary intervention for many tic disorder patients. Simple behavioral approaches can be used with the majority of TD patients to "de-stimulate" and contain the symptoms. Specific paradigms are indicated for obsessions, compulsions, and tics. Relaxation techniques, such as deep breathing, guided imagery, mindfulness, and the use of relaxation tapes, can be useful for the anxious TD patient.

Telegram: @medical_k

www.konkur.in

Habit-reversal therapy or training (HRT) forms the essence of therapeutic intervention in a cognitive behavioral treatment known as comprehensive behavioral intervention for tics (CBIT) in youth and adults. The superiority of CBIT over psychoeducation and supportive therapy alone is well established; CBIT is considered the first-line treatment for mild to moderate tics when intervention is warranted. The primary components of CBIT include awareness training, competing response training, relaxation training, contingency management, social support, and relapse prevention. Awareness training teaches patients to identify the premonitory urges or sensations that typically precede tics, as well as to recognize the situations in which tics are likely to occur. The second component of CBIT, teaching the patient a competing response to the targeted tic, has been developed to prevent the emergence of the tic. Parents are taught to provide appropriate support and encouragement to the child in practicing the technique at home. Tic substitution (substituting a more socially tolerable tic for a less socially tolerable one) can be useful.

Due to barriers to accessibility of behavioral interventions for tics, Singer and co-workers examined home-based parent-administered HRT. Their study found the home-based intervention to produce tic reduction comparable to in-person behavior intervention with a therapist. However, there were more dropouts from the parent-administered therapy group. Various interactive online treatment programs based on CBIT are now available for youth with tic disorders.

Behavioral interventions are also critical for the management of oppositional, defiant, or explosive outbursts, which are not uncommon in clinically referred youth with tic disorders. Scahill and colleagues demonstrated that parent management training is helpful in improving disruptive and explosive behavior problems in children with tic disorders, and Sukhodolsky and team have developed anger control training (ACT) for adolescents with TD and disruptive behavior. In children and adolescents, cognitive-behavioral paradigms are also the cornerstone of the treatment of mood and

Telegram: @medical_k

www.konkur.in

anxiety disorders, which often co-occur in clinically referred individuals with TD.

Psychotherapy

Individual, group, and family therapies are supportive adjuncts to behavioral interventions and pharmacotherapy. Individual supportive therapy is indicated for patients having difficulty adjusting to the disorder, to their peers or family, or with school or occupational functioning. It is particularly useful when there is evidence of moderate stress or anxiety or another comorbid psychiatric disorder responsive to this form of psychotherapy (e.g., mild depression). It can help to restore or maintain self-esteem and promote mastery and coping. Furthermore, supportive psychotherapeutic interventions may facilitate the normal developmental tasks of friendship development, school adjustment, and day-to-day stress management.

Family therapy is extremely useful in dealing with the many complex interpersonal and family issues that arise for children with TD. At a minimum, both parents should be involved in the initial evaluation. Ideally, family members can be sources of support and nurturance. Ongoing family therapy is indicated when family development (i.e., growth and maturation) has slowed or halted because of the focus on the patient with the tic disorder. It may also help with maladaptive reactions from or to siblings or with specific symptoms that are affecting the entire family.

Group therapy is another important adjunct treatment. Support and education for parents and family members of patients with TD can be found through the Tourette Association of America, which has created a well-organized network of state and community support groups. Informal, unstructured activities can be arranged through local chapters of the Tourette Association of America. Formal, structured support is also possible through social skills groups.

School and Occupational Interventions

Learning problems and classroom difficulties occur commonly in tic disorder patients. Specific developmental disorders and ADHD- or

Telegram: @medical_k

www.konkur.in

OCD-related symptoms may interfere with academic performance.

Clinicians should be available to provide consultation, guidance, and education to teachers or employers of patients with tic disorders. Useful special educational interventions include creating a moderate, task-oriented structure in the classroom, preferential seating, one-to-one support, and individualized educational or work plans. Flexibility is a key element in educational and occupational intervention. To promote tic control, there may be a need for optional “time outs” from class or work settings. Time limits may have to be extended or eliminated for exams. Some patients may also benefit from writing aids, such as laptops. Laptop and tablet computers may allow patients with handwriting difficulties to take notes in class without disturbing others. Adaptive, as contrasted to regular physical education, can be particularly helpful for children with TD. This form of physical education can be arranged through special education departments in local schools. Programs can be tailored to each child’s needs, strengths, and challenges.

Specific workplace interventions include structured tasks, organization of tasks into smaller units, flexible time limits, and ample physical space.

Pharmacotherapy

The decision to treat tics and/or comorbid symptoms with medication should be based on a comprehensive evaluation. Patients with symptoms that significantly interfere with adaptation to family, school or work life, peer relationships, or developmental progress should be treated, especially if psychotherapeutic options are either unavailable or not optimally beneficial. Patients who suffer significant emotional distress or inadvertently cause distress to significant others in their lives may also be candidates for treatment, even when symptoms are relatively mild. Most patients with very mild symptoms need only monitoring, education, guidance, and support. Moderate to severe symptoms should usually be treated aggressively.

The clinical workup before initiating pharmacologic treatment should include a complete physical examination and neurologic screening, psychiatric evaluation, vital signs including height, weight,

Telegram: @medical_k

www.konkur.in

and body mass index (BMI), an Abnormal Involuntary Movement Scale (AIMS) screening, basic laboratory screening (including a complete blood count with differential, urinalysis, and a comprehensive metabolic panel including liver and thyroid function tests, fasting blood glucose, and metabolic screen including cholesterol and triglycerides), and an electrocardiogram (ECG).

Medication should be initiated at the lowest possible dose, and dose titration should be gradual in general. Most maximum doses will be low (compared to doses needed for other indications for these same medications) in TD patients. When possible, a single medication (monotherapy) should be used initially. At times more than one agent will need to be prescribed simultaneously (targeted combined pharmacotherapy) when monotherapy has not been effective or has resulted in limiting adverse effects or when target symptoms include more than one disorder.

Determining an adequate duration for a medication trial for patients with tics can be quite challenging because the natural history of TD is characterized by the waxing and waning of symptoms over time. A 1-month baseline observation period before treatment is initiated is recommended, if feasible. In general, it is best to wait at least several weeks after changing a dose before making any conclusions about a therapeutic response. External stressors must always be considered as potential determinants of increased symptomatology during medication trials. Comorbid conditions, such as ADHD and OCD, which significantly affect the individual, should be targeted aggressively because it is well established that these conditions are often more impairing than tics, and they respond to treatment.

α-Adrenergic Agonists. The α-adrenergic agents are recommended as a first-line pharmacologic treatment for most patients with mild to moderate TD, especially in those with comorbid ADHD, in whom they are more effective. Clonidine (Catapres), an α_2-adrenergic (presynaptic) agonist, has been used for over three decades for the treatment of TD. When given in low doses, it is postulated that presynaptic noradrenergic effects mediate the observed clinical improvement in motor and vocal tics. Clonidine

Telegram: @medical_k

www.konkur.in

activates presynaptic autoreceptors in the locus coeruleus to reduce norepinephrine release and turnover in the cerebral cortex. In addition, clonidine also reduces the disinhibition, impulsivity, inattention, and hyperactivity often present in young TD patients. Data supporting its use have been mixed, but there have been well-designed studies that demonstrate clinical effectiveness.

Clonidine should generally be started at 0.025 mg daily to twice daily for prepubertal children and increased by 0.025 mg every 5 to 14 days. Prepubertal patients will generally need dosing three or four times daily. Adolescents or adults can be started on 0.05 mg daily and increased by 0.05-mg increments to twice-daily dosing. The total daily dose typically is 0.05 mg to 0.45 mg (i.e., up to 8.0 μg/kg). Common side effects include sedation, bradycardia, orthostatic hypotension, headache, dry mouth, stomachache, midsleep awakening, and irritability. Sedation, the most common and sometimes limiting side effect, usually abates over several weeks; when it does not, dose reduction may be helpful. Hypotensive effects are minimal in this dose range, but blood pressure, pulse, and ECG should be monitored at baseline and follow-up visits. More concerning is the risk of rebound increases in blood pressure, anxiety, and tics if abrupt discontinuation of clonidine occurs. A transdermal form (Catapres TTS-1, TTS-2) is available and may be an alternative when patients require very frequent dosing and/or cannot tolerate the sedative effects. A long-acting oral formulation is also available (Kapvay) and designed to be administered twice daily.

Guanfacine (Tenex), an alternative α_2-adrenergic agonist, may also be efficacious for hyperactivity, impulsivity, and tics. Guanfacine activates postsynaptic prefrontal α-adrenergic cortical receptors. Prepubertal patients are typically started on 0.25 mg daily and increased by 0.25-mg increments every 5 to 14 days given twice daily; older patients and adults are typically started on 0.5 mg daily and increased by 0.5-mg increments to about 3.0 mg daily. Adverse effects, generally less significant and more tolerable than with clonidine, include sedation, fatigue, midsleep awakening/insomnia, irritability, stomach upset, constipation, and hypotension/lightheadedness. A long-acting, once-daily extended-

Telegram: @medical_k

www.konkur.in

release form (Intuniv) is also available. While previous uncontrolled studies and randomized control trials have supported the clinical use of guanfacine, a recent small, randomized, double-blind, placebo-controlled pilot study conducted by Murphy and colleagues found that there was no difference in efficacy between extended-release guanfacine and placebo.

Neuroleptic Agents. Since the late 1960s, when haloperidol was first introduced as a treatment for TD patients, haloperidol (Haldol) and pimozide (Orap) have been the only Food and Drug Administration (FDA)–labeled, formally approved agents for the treatment of TD. These typical neuroleptic medications block postsynaptic D_2 (dopamine) receptors in the basal ganglia, decreasing dopaminergic input from the substantia nigra and ventral tegmentum and thus reducing tics. These medications are generally effective in tic reduction; however, considerable variation exists in clinicians' and patients' thresholds for neuroleptic use. The decision to use a neuroleptic may be guided by both symptom severity and quality-of-life concerns. Significant adverse effects, including acute dystonic reactions, oculogyric crises, torticollis, Parkinsonism, akathisia, tardive dyskinesia, weight gain, sedation, dry mouth, blurred vision, galactorrhea, gynecomastia, constipation, urinary retention, social phobia, loss of drive/energy/personality, and electrocardiographic changes including tachycardia and QTc prolongation, limit their use to second- or third-line treatments. In general, neuroleptic agents are not recommended for mild tics. Of the typical neuroleptics, haloperidol and pimozide have been the most investigated, with double-blind, placebo-controlled studies supporting their use.

The newer, atypical neuroleptics, or second-generation antipsychotic agents, are recommended as a first-line treatment when a neuroleptic is indicated for moderate to severe tics. These agents, which block both D_2 dopamine and 5-HT_2 serotonin receptors, have the potential advantage of fewer extrapyramidal adverse effects (EPSs) (acute dystonic reactions, oculogyric crises, torticollis, Parkinsonism, akathisia, tardive dyskinesia). Their dual

Telegram: @medical_k

www.konkur.in

pharmacologic activity appears to protect against the neurologic adverse effects associated with typical neuroleptic agents. Among them, risperidone (Risperdal) has been found to be efficacious for tics. Risperidone is a 5-HT2 receptor antagonist at low doses and a D2 antagonist at high doses. It acts at the α-2, D3, D4, and H1 receptors with moderate to high affinity as well. Multiple trials, including randomized, controlled trials, support risperidone's efficacy. It has been shown to be superior to placebo and equally effective as pimozide and clonidine for tic reduction. Doses are typically in the 1 to 4 mg range. Common adverse effects include appetite increase, weight gain, lipid and glucose metabolism abnormalities, and sedation. Sleep disturbance, social phobia, galactorrhea, gynecomastia, menstrual irregularities, and erectile dysfunction have also been reported.

Aripiprazole (Abilify) is a novel atypical neuroleptic with partial agonist-antagonist effects on the dopamine and serotonin system. It is a partial D2, D3, and D4 receptor agonist as well as a partial 5-HT1A and 5-HT2C receptor agonist. Several published placebo-controlled studies and open-label trials have reported effectiveness and tolerability in TD. A meta-analysis of ten studies with a total of 302 patients conducted by Liu and peers confirms that aripiprazole is safe and effective for the treatment of tics in children and adolescents. The most common adverse effects include weight gain, akathisia, and sedation. Aripiprazole became the most recent and only the third agent to be FDA-approved for the treatment of tics in 2014.

Additional atypical options with some evidence base for efficacy in TD include ziprasidone (Geodon), olanzapine (Zyprexa), and quetiapine (Seroquel). Results of one placebo-controlled trial of ziprasidone indicated that it was as efficacious as risperidone for tic reduction. Weight gain is typically less likely than that with other neuroleptic agents. Ziprasidone carries the added risk of altered cardiac conduction, especially QTc prolongation. An ECG is recommended before initiating treatment, during dose adjustments, on reaching the maintenance dose, and annually thereafter. Other adverse effects include somnolence, sedation, and akathisia.

Telegram: @medical_k

www.konkur.in

Evidence for the effectiveness of olanzapine is supported by open-label and case-report studies, but its significant association with weight gain, the highest among the atypical neuroleptics, limits its use. Only two open-label studies demonstrate quetiapine's effectiveness for treating tics. Sedation and weight gain are the most common adverse effects.

Fasting glucose and a lipid panel are recommended before initiating treatment with a second-generation antipsychotic, as well as at the maintenance dose and at regular intervals thereafter. Weight, waist circumference, and BMI should also be monitored. An ECG may be helpful, especially when there is a known individual or family cardiac history.

Neuroleptics should be initiated at the lowest possible dose and increased very gradually. The starting dose for aripiprazole is between 1 to 2 mg per day with maximum doses of 10 to 20 mg daily. Risperidone is typically started at 0.125 to 0.25 mg daily to twice daily and titrated upward over weeks to about 1 to 2 mg daily in prepubertal children; adolescents are typically started on 0.25 mg daily to twice daily. For haloperidol, children are typically started at 0.125 to 0.25 mg daily to twice daily and increased by 0.125- to 0.25-mg increments weekly or biweekly. Adults are usually started on 0.5 mg with weekly or biweekly increases of 0.5 mg. Pimozide is an alternative D_2-blocking agent, which may cause fewer side effects than haloperidol. However, because pimozide also has calcium-channel–blocking properties, normal cardiac function (ascertained from cardiac assessment and an ECG) is a prerequisite to its use. Pimozide has been shown to prolong QTc intervals, and the risk for cardiac conduction abnormalities may increase when pimozide is combined with drugs that inhibit the cytochrome P450 3A4 isozyme. An ECG is also recommended during dose adjustments, on reaching the maintenance dose, and annually thereafter. Approximately half as potent as haloperidol, pimozide should be started at 0.5 mg to 1.0 mg for children and at about 1.0 mg for adolescents or adults. Most patients require less than 10 mg daily.

Common adverse effects of neuroleptics include weight gain, sedation, muscle cramps, and stiffness. Dose reduction or switching

Telegram: @medical_k

www.konkur.in

to an alternative drug is the best way to address these adverse effects. Fortunately, EPSs do not appear to be common sequelae from neuroleptic use at usual doses in tic disorder patients; nevertheless, clinicians should be alert to the possibility of these reactions and consider appropriate interventions (e.g., dose reduction, anti-Parkinson agents) on a case-by-case basis. EPSs may be less common with the atypical agents than with the typicals. Tardive dyskinesia, although probably not common, has been described in patients with TD and may be difficult to differentiate from tics.

Weight gain is likely with both typical and atypical neuroleptics, but the risk appears to be greater with the use of atypical agents such as olanzapine and risperidone. The possibility of weight gain should be addressed proactively in all youth who are candidates for neuroleptics. Education at the outset of treatment regarding the need for a healthy diet and regular exercise is helpful; at times nutritional consultation may be indicated.

Tiapride, sulpiride, and amisulpride are D_2-receptor–blocking neuroleptics used in tic treatment in Europe but not available in the United States. Tetrabenazine and deutetrabenazine, nonneuroleptic dopamine antagonists that act by inhibiting central vesicular monoamine transporter type 2 (VMAT2), may be useful for the treatment of tics but are currently FDA-approved only for the treatment of chorea in Huntington disease and tardive dyskinesia. There are two open-label studies of tetrabenazine for tics with limited demonstrated effectiveness, and more study is needed. A recent randomized, double-blind, placebo-controlled study of deutetrabenazine in children and adolescents with TD did not demonstrate efficacy for the management of tics. Although results indicated active drug did not separate from placebo, it was well tolerated and was not associated with depressive symptoms (unlike tetrabenazine).

Selective Serotonin Reuptake Inhibitors. Serotonergic agents such as fluoxetine (Prozac), paroxetine (Paxil), fluvoxamine (Luvox), citalopram (Celexa), escitalopram (Lexapro), and sertraline (Zoloft)

Telegram: @medical_k

www.konkur.in

are first-line agents for pharmacologic treatment of significant OCD, anxiety disorders, and mood symptoms. All the selective serotonin reuptake inhibitors (SSRIs) except citalopram and escitalopram have been studied in placebo-controlled investigations in children with OCD. Although there is no evidence to support the use of SSRIs for tics, their use may be warranted. Since many TD patients have obsessions, compulsions, anxiety, and depression, and neuroleptics and α_2-agonists do not effectively alter these specific symptoms, the SSRIs may be beneficial in some patients. In addition, complex motor tics such as repetitive squatting and touching may be very similar to compulsive rituals. Furthermore, stress and anxiety are known to exacerbate tics, and the use of SSRIs to reduce anxiety may indirectly serve to reduce tics.

Fluoxetine has received the most study in TD, but efficacy is likely relatively comparable among serotonergic agents. The choice typically rests with consideration of the adverse-effect profiles of the agents. Often, higher doses of SSRIs are required for the treatment of OCD symptoms than for anxiety disorders or depression, and many patients with co-occurring OCD and a tic disorder respond less well to SSRIs. The addition of small doses of a neuroleptic or an atypical neuroleptic, which increases the response to the SSRIs, may be required.

Mild OCD symptoms often respond to cognitive behavioral therapy alone, which is equally effective for OCD symptoms with or without comorbid tics. When obsessions or compulsions are of moderate to severe intensity or impair adaptive functioning, SSRIs are potentially indicated in addition to therapy. Fluoxetine is typically started at 2.5 to 5.0 mg daily for children and at 5.0 to 10 mg for adolescents or adults. Dose ranges are not well established for children and adolescents with TD. It appears that most children will respond to 10 to 20 mg daily; adults may require 20 to 80 mg daily. Fluoxetine, in combination with a neuroleptic, can be useful for both tics and obsessive-compulsive symptoms; neuroleptic doses may require reduction or adjustment because of the cytochrome P450 enzyme–inhibiting properties of fluoxetine. Common adverse effects include activation, insomnia, headaches, anorexia, and weight loss.

Telegram: @medical_k

www.konkur.in

Sertraline, fluvoxamine, citalopram, and escitalopram are also options. There is also considerable data available on the use of clomipramine (Anafranil), a tricyclic antidepressant, in OCD, but adverse effects may be more problematic. These medications may represent alternatives for patients who experience limiting side effects on fluoxetine. Current recommendations for the treatment of comorbid tics and OCD are to use the appropriate agent indicated for each symptom. For example, an α-agonist or atypical neuroleptic can be combined with an SSRI to target significant tics and OCD symptoms.

Table 47–4.
Pharmacotherapies for Tourette and Tic Disorders

Class/Medication	Typical Range (mg)	Starting Dose (mg)	Maximum Dose[a] (mg)	Common Side Effects
Neuroleptics				
Haloperidol	0.25–5.0	0.25–0.5	10–20	Sedation, weight gain, dysphoria, extrapyramidal effects, dry mouth, blurred vision, constipation, urinary retention, tardive dyskinesia
Pimozide	1.0–10	0.5–1.0	15–20	Sedation, weight gain, dysphoria, extrapyramidal effects, dry mouth, blurred vision, constipation, urinary retention, ECG changes (QTc prolongation and cardiac arrhythmias)
Risperidone	1.0–3.0	0.25–0.5	4–6	Weight gain, sedation, lipid and glucose metabolism abnormalities, extrapyramidal effects, gynecomastia, galactorrhea, menstrual abnormalities, sexual dysfunction
Aripiprazole	2–15	1–2	20	Akathisia, sedation, agitation, weight gain, lipid, and glucose metabolism abnormalities, extrapyramidal effects
Ziprasidone	20–80	5–10	120–160	Weight gain, sedation, lipid and glucose metabolism abnormalities, extrapyramidal effects, ECG changes (QTc prolongation)
Partial α_2-Adrenergic Agonists				
Clonidine	0.05–0.45	0.025–0.05	0.45	Sedation, headaches, insomnia, stomachaches, hypotension, dry mouth, midsleep awakening, irritability
Guanfacine	1.0–3.0	0.25–0.5	3–4	Sedation, headaches, hypotension, midsleep awakening, constipation
Tricyclic Antidepressants				
Desipramine	25–300	10–25	250–300	Sedation, dry mouth, weight gain, tachycardia, constipation, blurred vision, ECG changes

ECG, electrocardiogram.
[a]These are usual maximum doses for adults.

Tricyclic Antidepressants. Some studies of desipramine (Norpramin) have suggested potential efficacy for the treatment of tics as well as ADHD symptoms in patients with comorbid ADHD. Doses are not established but may parallel doses used in ADHD without tics. Careful cardiovascular monitoring must take place, including blood pressure, pulse, and baseline and follow-up ECGs (Table 47–4).

Clomipramine is used for the treatment of OCD when the patient has failed to respond or cannot tolerate two trials of an SSRI. It can be started at 10 to 25 mg daily in children and 25 to 50 mg in adolescents or adults. Total dose ranges are typically 100 to 200 mg

Telegram: @medical_k

www.konkur.in

daily; blood levels may be obtained, but no therapeutic range has been established. Common adverse effects are those seen typically with other tricyclic antidepressants, including sedation, dry mouth, constipation, blurring of vision, weight gain, tachycardia, and ECG changes.

Benzodiazepines. Benzodiazepines have not been well investigated in tic treatment but may hold some promise (e.g., clonazepam [Klonopin]). Some studies suggest a reduction in tics independent of anxiolytic effects. This effect may also result from a reduction in anxiety that, in turn, could reduce tic frequency. In addition, benzodiazepines can be used to treat comorbid anxiety symptomatology or panic attacks that can also occur in TD patients. Doses are not established but are often quite low (e.g., 0.125 mg daily to twice daily for clonazepam). Adverse effects of particular concern in the juvenile population are sedation, disinhibition, cognitive impairment, and dependence.

Stimulants. Stimulants are first-line agents for the treatment of ADHD. There has been controversy over the role of stimulants in TD and whether their use causes or exacerbates tics; however, recent studies have demonstrated that TD patients with clinically significant ADHD symptoms may be candidates for stimulants. In the first systematic investigation of methylphenidate use by Gadow and colleagues, behavior improved, and tics did not worsen at moderate doses of 0.1 to 0.5 mg/kg methylphenidate. When group data are analyzed, there is no significant increase in tics when stimulants are used in patients with tic disorders; however, individual patients may experience at least a transient increase in tics. Interestingly, in some studies, stimulant use is associated with a decrease in tics.

Stimulants are equally effective in improving ADHD symptoms with or without comorbid tics. A randomized, controlled study of clonidine and methylphenidate in ADHD and chronic tics conducted by the Tourette Syndrome Study Group reported that the combination and each drug alone was more effective than placebo in reducing both tics and ADHD symptoms. An increase in tics did not occur in the

Telegram: @medical_k

www.konkur.in

methylphenidate group to any extent more significantly than in the placebo group. Additionally, a meta-analysis examining pharmacotherapy for youth with comorbid ADHD and tics demonstrated methylphenidate, α_2 agonists, desipramine, and atomoxetine (Strattera) were effective for ADHD symptoms. Supra-therapeutic doses of dextroamphetamine appeared to worsen tics. There was no short-term evidence that methylphenidate exacerbated tics.

A more recent meta-analysis of 22 randomized, double-blind, placebo-controlled trials involving 2,385 children with diagnosed ADHD conducted by Cohen and colleagues demonstrated that the risk of new-onset or worsening of tics associated with stimulant use (5.7%) was similar to that observed with placebo (6.5%). Age, type or dose of stimulant used, and duration of treatment did not affect risk.

A judicious approach to the treatment of ADHD in the context of a tic disorder is to evaluate whether tics or ADHD symptoms are causing the most distress or impairment. If ADHD is more problematic, it is reasonable to start with a methylphenidate-based stimulant. Stimulants should be initiated in low doses and gradually increased, monitoring for any exacerbation of tics. If tics are more problematic, an alpha agonist is recommended first. Both medications can be safely combined if necessary. Common adverse effects of stimulants include insomnia, appetite suppression, and weight loss.

Nonstimulant ADHD Treatment: Atomoxetine. Atomoxetine, a selective norepinephrine reuptake inhibitor, is approved for treatment of ADHD in children, adolescents, and adults. It has also been studied in youth with ADHD and chronic tics. One study reported that atomoxetine improved both ADHD symptoms and tics in children and adolescents with comorbid ADHD and TD. It is dosed based on body weight and titrated from a daily starting dose of 0.5 mg/kg to 1 to 1.5 mg/kg. Therapeutic response, unlike stimulants, takes a few weeks. Common adverse effects include headache, nausea, fatigue, and stomachaches.

Telegram: @medical_k

www.konkur.in

Other Alternatives. Many other medical treatments have been used in TD patients. Immune therapies such as IVIG, plasmapheresis, and corticosteroids have been explored in patients with PANDAS/PANS. These remain experimental treatments under investigation. Opioid antagonists (e.g., naltrexone) may be an alternative for patients with self-injurious behaviors. The dose range for naltrexone may be approximately 25 to 75 mg per day. Nicotine, both in gum and in the transdermal form, has also been studied in TD. Results have been equivocal. In a double-blind, placebo-controlled trial of 61 patients with TD at doses up to 7.5 mg daily, mecamylamine (Inversine), a nicotine antagonist, was found to be no more effective than a placebo. In addition, a randomized, controlled trial of pramipexole, a mixed dopamine agonist with presynaptic autoreceptor effects, failed to show efficacy.

Baclofen, a GABAergic muscle relaxant used to treat spasticity, has been studied in one large open-label and one controlled trial. In the controlled trial, there was no difference between drug and placebo in Yale Global Tic Severity Scale Total Tic score, but baclofen was superior to placebo with regard to tic-related impairment. A placebo-controlled study of omega-3 fatty acids derived from fish oil revealed no improvement in tic measures, but clinically meaningful improvement in tic-related impairment compared to placebo was reported.

The use of botulinum toxin to suppress tics by injection into discrete muscles involved in tic generation has been examined in several studies. Botulinum toxin blocks acetylcholine release at the neuromuscular junction and produces a temporary, reversible diminution of muscle activity, which may last weeks to months for dystonic tics. Placebo-controlled and open-label trials have demonstrated efficacy for isolated tics. Botulinum toxin may be the most useful agent for the treatment of solitary, focal dystonias. There are reports of suppression of ear-wiggling tics and laryngeal tics. Adverse effects include soreness at the injection site and muscle weakness.

Targeted combined pharmacotherapy—the specific combination of two or more medications at one time—has evolved as a treatment

Telegram: @medical_k

www.konkur.in

option. Ideally, this approach should be used only after adequate trials of monotherapy have failed. However, many patients with TD also have comorbid ADHD or OCD, and often both, and frequently monotherapy addresses one problem but not the other. Judicious use of SSRIs and neuroleptics for TD and comorbid OCD is one example of this approach; in some patients with OCD and tics, this approach may be more effective than monotherapy. Another example is the combination of methylphenidate and clonidine to target tics and ADHD symptoms. In general, for comorbid tic disorders and OCD or ADHD, each condition should be treated with its respective first-line option.

Surgical Treatment. Initial reports on surgical interventions for TD appeared in the 1960s. Stereotaxic neurosurgical techniques have since been used in a few cases of severely impaired adults. Bilateral capsulotomy was associated with at least 50% improvement in both motor and vocal tics in 12 patients who had TD, with no severe adverse effects. In 1999, deep brain stimulation (DBS) was introduced for the treatment of intractable tics. Several patients have since undergone bilateral thalamic stimulation with promising results. However, given the significant medical risks of these procedures, there has been limited experience with use of these techniques in youth, and they have generally been reserved for severe and refractory tics that significantly interfere with function and persist into adulthood.

Transcranial magnetic stimulation involves generating a brief, powerful magnetic field by a small coil positioned over the skull, inducing an electrical current in the brain. This noninvasive approach has been demonstrated to effect long-term changes in cortical excitability, which may be abnormal in tic disorders. It is an exciting potential future treatment for tics. Neural stem cell transplantation is another proposed treatment for tics, and studies are underway.

Telegram: @medical_k

www.konkur.in

Jack was a 14-year-old boy referred by his mother for management of his TD. Jack developed the onset of skipping and clapping episodes when he was approximately age 7 years. This was followed by stretching movements of his mouth and nose accompanied by facial grimaces. His mother reported that Jack's tics remitted entirely until just before his 12th birthday when he began to "give the finger" for no apparent reason and began to curse using the "F" word. Children often teased him, and he was in significant distress about this.

Jack was the product of a full-term, uncomplicated pregnancy; developmental milestones were described as within normal limits. Jack's parents divorced when he was 2 years of age. Jack attended private school from prekindergarten through, at the time of referral, the ninth grade. He had difficulty with mathematics. He had a group of friends, including a best friend, and enjoyed music and video games.

Jack's maternal grandmother had OCD, and maternal great-uncles had eye-blinking tics. Jack had no history of head injury or seizures. Electroencephalographic and computed tomography scans were within normal limits. Past medication included adequate trials of clonidine, guanfacine, risperidone, and ziprasidone. Medications at the time of referral included haloperidol 4 mg, which led to excessive sedation, including somnolence in school.

MENTAL STATUS EXAMINATION

Jack was a moderately overweight adolescent boy. Of note were multiple motor tics, including pelvic thrusting, hand movements, outward leg twisting, head and neck thrusting, eye blinking, abnormal inhalation, chin hitting, shoulder licking, and genital scratching. In addition, there was copropraxia in the form of "giving the finger." There was also a change in his vocal inflection intermittently and a tendency to yawn on occasion.

IMPRESSION

Telegram: @medical_k

www.konkur.in

In summary, Jack was a 14-year-old adolescent referred for management of his TD. His clinical picture was consistent with moderately severe TD. He had been treated with a variety of tic medications that were ineffective or intolerable.

TREATMENT PLAN

The recommendation was for a trial of aripiprazole. In addition, a trial of Comprehensive Behavioral Intervention for Tics (CBIT) was recommended. Jack and his parents were also counseled that at age 14, it was possible he was currently seeking treatment at his lifetime peak tic severity, and tic symptoms might begin to attenuate over the next few years.

SUMMARY AND FUTURE DIRECTIONS

The French neurologist Georges Gilles de la Tourette in 1885 was among the first to recognize and describe the neurodevelopmental disorder that now bears his name, as well as its psychiatric comorbid conditions. Since the first case descriptions of Gilles de la Tourette, a spectrum of tic disorders has come to be recognized and codified in psychiatric nomenclature. Tic disorders are complex neurodevelopmental disorders with heterogeneous phenotypes characterized by core disinhibition mediated by the CSTC tracts. Tic disorders are genetically determined in most cases. There is a growing appreciation and understanding of the role of psychiatric comorbidity in the diverse clinical presentation, and it is often the neurobehavioral, occupational, and psychosocial problems that co-occur in clinically referred individuals that warrant treatment rather than the tics per se. Treatment strategies should be multimodal in nature and include cognitive-behavioral, individual and family intervention, social and educational monitoring and support, and, where indicated, pharmacotherapy. Future investigation is needed to better understand the phenomenology, developmental psychopathology, and novel approaches to the treatment of tics. Tremendous progress has been made in the last few decades using innovative neuroimaging techniques, genetic studies, and clinical

Telegram: @medical_k

www.konkur.in

interventions. Understanding of the etiology, genetics, neuroanatomy, and epidemiology of tic disorders has been significantly enhanced. Novel treatment approaches have also emerged, providing alternatives to the pharmacologic management of tics. Targeted behavioral intervention has been proven to be as effective as medication and is now first-line treatment. DBS, botulinum toxin, targeted surgery, and stem cell transplantation are examples of promising new treatments. Complementary and integrative treatments such as music, exercise, and herbal remedies are also being investigated. The future holds tremendous promise as new insights into the etiology, pathophysiology, and treatment of tic disorders are rapidly developing.

48 Elimination Disorders

EDWIN JENS MIKKELSEN, M.D.

ENURESIS

The disorder of enuresis has been recognized for centuries. However, substantial progress in the understanding of the disorder did not begin to occur until there were effective treatments. The first effective treatment was the application of the bell-and-pad method of conditioning, which was subsequently followed by pharmacologic treatment in the form of imipramine (Tofranil) and, more recently, desmopressin acetate (DDAVP). Each of these advances has led to etiologic research that might explain the efficacy of the particular intervention. This chapter reviews the accumulated clinical knowledge concerning enuresis, as well as the emerging research that may lead to a greater understanding of the disorder.

Definition

Enuresis is defined as the involuntary or intentional voiding of urine. The severity is determined by the frequency of urination; quantity is not a diagnostic consideration per se. Quantity can become a factor in treatment decisions if a child emits only small quantities of urine; in actual practice, quantity usually does not figure heavily into the treatment plan. Frequency, however, can be important in planning a hierarchy of treatment approaches. The major diagnostic qualifier

Telegram: @medical_k

www.konkur.in

relates to the age of onset. Finally, the definition precludes a physical cause for the disorder.

The length of time before continence is considered established varies in the literature between 6 months and 1 year. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and its text revision (DSM-5-TR) require a chronologic age of 5 years or, alternately, a developmental level equivalent to that age. In practical clinical terms, children who have never maintained continence for more than 1 year are referred to as having *primary enuresis*, whereas children who have achieved continence for 1 year or longer and then resume wetting are referred to as having *secondary enuresis.* The DSM-5-TR requires a frequency of at least two episodes a week for 3 consecutive months. However, it allows an exception for distress or impairment in functions. This means that an individual can receive the diagnosis if they are deemed to experience significant distress and do not meet the frequency criteria.

The disorder is also further defined according to the timing of the episodes throughout the day. Episodes occurring only at night are referred to as *nocturnal*; daytime wetting is labeled *diurnal.* The term "nocturnal and diurnal" refers to a combination of these two subtypes. Most children display only nocturnal enuresis, but some manifest diurnal or nocturnal and diurnal patterns.

History

A scholarly review of the history of enuresis found references dating back about 3,550 years to the Papyrus Ebers. The term derives from the Greek word *enourein*, which means "to void urine." In retrospect, many of the treatment approaches that were used in the past now appear almost sadistic in nature. Although some of these interventions may have been misguided but well-intentioned therapies (as in the use of leeching for other disorders), they may also reflect the commonly held view that the disorder is somehow under the (direct or indirect) control of the child and that punishment would lead to its cessation.

Telegram: @medical_k

www.konkur.in

A confluence of somewhat disparate observations contributed to the evolution of the current understanding of enuresis. Although each of these is discussed in more detail in the following sections, a brief reference to them here will provide an overview of the various lines of research and their relative contributions to the present understanding of the disorder. The long-standing observation that enuresis tends to run in families evolved into the observation that a positive family history was a positive prognostic indicator for response to pharmacologic interventions and, ultimately, to sophisticated research with large pedigrees pointing toward specific genetic loci and modes of transmission. The observation that imipramine was an effective treatment for enuresis ushered in the modern era of research because the efficacy of imipramine suggested biologic contributions to the etiology of the disorder. Imipramine has now been largely supplanted by DDAVP as a pharmacologic treatment modality, and related research into its mechanism of action has contributed interesting insights into the pathophysiology of the disorder. Juxtaposed with the research into pharmacologic treatment and organic contributions to the disorder has been the impressive literature, which now dates back several decades, indicating that behavioral treatment in the form of the bell-and-pad method of conditioning is equally effective as the two leading pharmacologic interventions for the disorder. The observation that the wetting episodes usually occur at night also led to decades of research investigating the relation between sleep architecture and the occurrence of enuretic events. Although none of these lines of research has provided a parsimonious explanation, each has provided important contributions to the evolving understanding of the disorder. The accumulating literature with regard to enuresis increasingly suggests that a single unified theory of enuresis that applies to all children will not be identified.

Comparative Nosology

The variety of differing nosologic and diagnostic schemas seen with many disorders does not exist for enuresis. The behavior is concrete

Telegram: @medical_k

www.konkur.in

and definite: The child wets or does not. That criterion makes it possible to integrate research data from different countries, cultures, and treatment centers with greater reliability than is possible for many other disorders. The efficacy of a given treatment is reported in terms of its effect on the frequency of enuretic events. The primary differences with regard to diagnosis concern the frequency required to make a diagnosis of enuresis as a pathologic state and the period of continence necessary to separate primary from secondary enuresis, with a duration of 6 months occasionally being used instead of 1 year. Only slight differences exist between the eleventh revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-11) and the DSM-5-TR (Tables 48–1 and 48–2).

Telegram: @medical_k

www.konkur.in

Table 48–1.
DSM-5-TR Diagnostic Criteria for Enuresis

A. Repeated voiding of urine into bed or clothes, whether involuntary or intentional.
B. The behavior is clinically significant as manifested by either a frequency of at least twice a week for at least 3 consecutive months or the presence of clinically significant distress or impairment in social, academic (occupational), or other important areas of functioning.
C. Chronological age is at least 5 years (or equivalent developmental level).
D. The behavior is not attributable to the physiological effects of a substance (e.g., a diuretic, an antipsychotic medication) or another medical condition (e.g., diabetes, spina bifida, a seizure disorder).

Specify whether:

Nocturnal only: Passage of urine only during nighttime sleep.

Diurnal only: Passage of urine during waking hours.

Nocturnal and diurnal: A combination of the two subtypes above.

Epidemiology

The first comprehensive data concerning the incidence of enuresis came from the Isle of Wight Study. They found that 15.2% of boys (7 years of age) were enuretic less than once a week, whereas 6.7% were wetting at least once a week or more. In 7-year-old girls, the frequency was 12.2% for those wetting less than once a week and 3.3% with a frequency of once a week or more. By 9 and 10 years of age, 6.1% of the boys were wetting less often than once a week, and 2.9% were wetting once a week or more. The corresponding figures for 9- and 10-year-old girls were 3.5 % wetting less than once a week and 2.9% wetting once a week or more. The frequency for

Telegram: @medical_k

www.konkur.in

boys decreased considerably by 14 years of age, at which time 1.9% were wetting less than once a week, and 1.1% were wetting at a frequency of once a week or more. The rates also decreased for girls by 14 years of age, with 1.2% wetting less than once a week and only 0.5% wetting once a week or more.

Table 48–2.
ICD-11 Diagnostic Criteria for Enuresis

- Repeated and persistent voiding of urine into bed or clothes (e.g., several times per week over several months), which may occur during the day or at night.
- The individual has reached a developmental age when urinary continence is ordinarily expected (approximately equivalent to a chronologic age of 5 years).
- The symptoms are not better accounted for by the physiologic effects of a substance or medication or by another medical condition (e.g., a Disease of the Nervous System, a Disease of the Musculoskeletal System or Connective Tissue, or congenital or acquired abnormalities of the urinary tract).

Specifiers:

Nocturnal Enuresis:

Inappropriate voiding of urine occurs only during the night. This is the most common form of enuresis and typically occurs during the first part of the night soon after the individual has gone to sleep.

Diurnal Enuresis:

Inappropriate voiding of urine occurs only during waking hours. This form of enuresis is also referred to as urinary incontinence.

Nocturnal and Diurnal Enuresis:

Inappropriate voiding of urine occurs both during the night and during waking hours.

Telegram: @medical_k

www.konkur.in

A New Zealand study involving 8-year-old children found the prevalence of nocturnal enuresis to be 7.4%, with 3.3% primary, and 4.1% labeled secondary. A similar large Scandinavian study involving 7-year-old children reported a prevalence of 9.8%, with the highest prevalence (6.4%) involving children with nocturnal enuresis, 1.8% with diurnal enuresis, and 1.6% with mixed nocturnal and diurnal enuresis. A report from Australia described an incidence of 5.1% for children in the range from 5 to 12 years of age. A review of the published epidemiologic literature concerning enuresis indicates remarkably consistent findings from different countries and cultures, even though the research methods are somewhat variable. A standard consensus format that defines uniform reporting parameters would greatly enhance the epidemiologic literature base.

The epidemiologic literature is consistent in confirming that enuresis is a self-limiting disorder that will eventually spontaneously resolve. Common point prevalence figures are in the range of 7% of boys and 3% of girls at 5 years of age, dropping to 3% of boys and 2% of girls by 10 years of age. Only 1% of boys still wet at age 18 years of age, and still fewer girls wet at this age. A spontaneous remission rate of between 5% and 10% per year after 5 years of age is usually cited. Secondary enuresis may occur at any time, but most commonly, it begins between 5 and 8 years of age.

Etiology

Inclusion in the DSM-5-TR (as well as previous editions) definition of enuresis of children who wet intentionally with those whose enuresis is involuntary can be problematic. The vast majority of enuretic children do not wet intentionally or even on a subconsciously motivated basis. Increasingly, the research is pointing toward causal factors that may involve irregularities in physiologic processes. Clearly, children who wet intentionally are in a different phenomenologic grouping than those who do so on an involuntary basis, even if they do meet the other diagnostic requirements. The most likely explanations for voluntary intentional wetting are an oppositional defiant disorder (ODD) or a psychotic disorder. There

Telegram: @medical_k

www.konkur.in

are also a small number of children who originally have enuretic events involuntarily and subsequently manifest the behavior on a voluntary learned basis as well.

There is a correlation between enuresis and psychological disturbance that increases with age. This association is even more significant for enuresis, which persists into adolescence. Children living in socially disadvantaged situations and experiencing psychosocial stress have a greater frequency of enuresis than those who are not. The type and range of behavioral disturbance seen in children with enuresis are broad, and no marker can reliably differentiate between behaviorally disturbed and nondisturbed enuretic children. Thus, the associated behavioral disturbances are nonspecific and may represent a coincidental or secondary relationship rather than a causal correlation. Further supporting a secondary correlation are the repeated findings that children with enuresis have significantly more developmental delays and minor neurologic dysfunction than nonenuretic children compared to controls and other children attending a psychiatric clinic. Reports of delayed bone development in children with enuresis have also been linked to a possible general delay of maturation as a common underlying factor. However, new studies refute this finding, and no clear conclusion can be drawn at this time. The most recent research into a general developmental delay contributing to enuresis has used evoked potentials and electromyographic recording of startle eye-blink performance. Separate investigations using these methods have pointed to delayed maturation of brainstem functions.

Another approach to this etiologic question is represented by a large, longitudinal, population-based study in the United Kingdom, which compared the intelligence (as assessed by the Wechsler Intelligence Scale for Children–Third Edition [WISC-III]) of controls with children who still exhibited bedwetting in the age range of 7 years and 6 months to 9 years and 3 months. The authors reported that the bedwetting was associated with lower intelligence quotient (IQ) even after children with an IQ of less than 70 were excluded. However, this finding was primarily related to lower scores on the Performance section of the WISC-III. This observation led the

Telegram: @medical_k

www.konkur.in

authors to conclude that enuresis may be related to deficits in the maturation of the central nervous system.

One comprehensive effort reviewed the psychodynamic literature concerning enuresis and encopresis to define the concepts conveyed in that literature and then to determine empirically how often those concepts were verified and supported by the analysis of clinical material. The literature review yielded 24 generalizations that were consistently applied to enuretic and encopretic children. In subsequent statistical analysis of the clinical material, only 2 of the 24 generalizations reached statistical significance. Another recent study in this regard used a standardized behavioral rating scale, the Eyberg Child Behavior Inventory (ECBI), which was applied to children with primary nocturnal enuresis (PNE) (N = 92), a nonclinical control sample (N = 92), and a clinical sample (N = 92). The results indicated that the children with PNE had higher scores than the nonclinical control sample but significantly lower scores than the clinical sample. However, the mean score for the children with PNE was actually lower than the clinical cutoff score that had been determined for the ECBI.

Related to the association between behavioral disturbance and PNE are studies that address the frequency of diagnostic comorbidity. The most commonly reported comorbid diagnosis is attention-deficit/hyperactivity disorder (ADHD). In general, studies have reported that the co-occurrence of ADHD and PNE is approximately 30% greater than the frequency that would be expected from chance alone. A large contemporary study found that 32% of children diagnosed with ADHD also met diagnostic criteria for enuresis, whereas only 14% of a control group met the criteria. This finding was statistically significant at the $P < .001$ level. The rates of primary and secondary enuresis were not significantly different in the two groups. This study then investigated the degree of psychopathology and impairment in ADHD children (with and without comorbid enuresis) and found no significant differences. Similar findings were reported for the rates of psychopathology when the control children with enuresis were compared to those without the condition. Thus, the diagnosis of enuresis did not appear to increase

Telegram: @medical_k

www.konkur.in

the risk of psychopathology for the controls or the degree of impairment in the children who also had a diagnosis of ADHD. However, there was a higher incidence of learning disabilities and impaired academic performance in the control children with enuresis when compared to the control children without enuresis. This difference in the incidence of learning disabilities was not found when the ADHD children with enuresis were compared to those without the comorbid disorder. Thus, the co-occurrence of enuresis did not appear to increase the risk of learning disabilities in children with ADHD.

Another investigation used a family pedigree methodology to study the transmission of enuresis in the relatives of index family members who were diagnosed with PNE and in control probands who were diagnosed with ADHD as compared to those without this diagnosis. The results indicated that the two disorders were transmitted independently of one another.

Enuresis has been noted to occur statistically more frequently in the premorbid histories of children who develop early adolescent bipolar I disorder as compared to controls. An increased incidence of enuresis and other childhood psychiatric disorders has also been found in the history of adults with bipolar disorder and is associated with earlier onset of the disorder.

The association between behavioral disturbance and enuresis is stronger with secondary enuresis. This has been demonstrated by controlled studies and anecdotal reports of an association between the onset of enuresis and the loss of a parent through divorce or death. However, it should be noted that a large study from the Netherlands reported similar rates of psychopathology in children with primary enuresis as compared to those with secondary enuresis. The prevalence of psychodynamic factors in children with secondary enuresis would intuitively make sense because they have, by definition, demonstrated the physiologic competence to maintain continence for a prolonged period of time before losing that ability. The most specific study of this association indicated that exposure to four or more stressful life events in a year and delayed acquisition of nocturnal continence were risk factors for the

Telegram: @medical_k

www.konkur.in

development of secondary enuresis. An association between the occurrence of traumatic events and the development of secondary enuresis has also been demonstrated.

There has been one innovative attempt to explore the possible relationship between physiologic and psychological factors. Specifically, it was postulated that children with enuresis who did not present with a concomitant behavioral disturbance would be those with dysfunctional or abnormal bladders, whereas those with a behavioral disturbance would be more apt to have normal bladders. The study found the converse to be true: The group with behavioral disturbance had more dysfunctional bladders with lower volumes. The behaviorally disturbed group also had a greater number of developmental delays. A subsequent investigation reported no difference in bladder size among controls, children with PNE, and those who had been diagnosed with PNE but who were now continent. It also was demonstrated by two independent investigations that fluid loading can precipitate enuresis in children who have no prior history of enuretic events. The most recent investigations into this issue have used ultrasound techniques, which investigate both the volume capacity of the bladder and the thickness of the bladder wall in both controls and children with enuresis. This research suggested three subtypes: large-capacity bladder with a thick wall, normal-capacity bladder with normal wall thickness, and low-capacity bladder with a thick wall. The children with enuresis were then assessed with regard to their response to treatment with DDAVP. The results indicated that the children with the two abnormal bladder subtypes were less responsive to treatment than those with normal bladder physiologic characteristics.

The observation that enuresis tends to occur in family members has been known for decades. A large Scandinavian study involving more than 3,000 children found that a child's risk for developing enuresis was 5.2 times greater if the mother also had the disorder and 7.1 times greater if the father had the disorder, lending further support to a genetic influence. Within the last few years, there have been tremendous advances in the study of the genetic transmission of enuresis, which suggests that genetic contributions are likely to be

Telegram: @medical_k

www.konkur.in

significant in families with multigenerational histories of enuresis. A Scandinavian group identified 11 families that manifested PNE over three generations in a pattern that was suggestive of an autosomal-dominant inheritance, with a penetrance greater than 90%. Genetic linkage studies with these families indicated markers on chromosome 13q. Similarly designed studies have also implicated chromosomes 4p, 8, 12q, and 22, suggesting genetic heterogeneity. A large multigenerational study that specifically investigated chromosome 22 found that only 39.3% of families had linkage to genetic markers on this chromosome. The genetic modes of transmission that have been discussed include sporadic, autosomal recessive, and autosomal dominant. Linkage studies have also suggested the possibility of mutation in the aquaporin-2 (AQP2) water channel locus in families with a dominant mode of transmission of primary enuresis, in that AQP2 appears to be essential for concentrating urine. Although genetic linkage studies continue to provide important information with regard to the etiology of enuresis, it increasingly appears that the genetic contributions are heterogeneous in nature and vary substantially among pedigrees that contain multiple generations of individuals with enuresis. Thus, it is likely that there is more than one mode of genetic transmission that contributes to the disorder; and different mechanisms may be operating in different family pedigrees.

One particularly important etiologic hypothesis was that urinary tract obstruction frequently caused enuresis. The significance of that belief revolves around the related implications for surgery to correct the obstruction. An extensive review of the relevant literature found no basis for concluding that bladder neck repair or urethral dilation was a reasonable or effective treatment for enuresis. That generalization does not apply to patients with specific anatomical or pathophysiologic findings.

Research into the association between sleep physiology and enuretic events has evolved steadily since the 1970s. The research can be seen as evolving through the following four stages. During the first phase of the research, it was postulated that enuretic events were dream equivalents that occurred in a deep sleep. The second

Telegram: @medical_k

www.konkur.in

major theory grew out of the observation that enuretic events originated in delta sleep and followed arousal signals. Thus, enuresis was seen as a disorder of arousal, which led to the hypothesis that enuretic children who were not psychologically disturbed did not produce arousal signals, whereas behaviorally disordered children did but failed to respond to them. The third phase of sleep research is represented by the two largest controlled studies, both of which found that when the time of night is also considered, enuretic events occur in all sleep stages in proportion to the amount of time spent sleeping in each stage. A fourth phase of investigation has attempted to couple cystometry with sleep studies in an attempt to identify subtypes. These investigations have yet to produce any definitive results that can be replicated.

A long-debated issue has been whether children with nocturnal enuresis are more difficult to awaken from sleep than other children. Earlier literature had suggested that anecdotal reports from the parents of children with enuresis that they were difficult to arouse stemmed from their lack of experience in attempting to arouse their other children, who did not have enuresis, from a deep sleep. However, studies have suggested that children with enuresis may, in fact, be more difficult to arouse than control children. Recent reports have also found that obstructive sleep apnea may play a role in the development of PNE in some children.

The efficacy of DDAVP as a treatment for enuresis has led to the theory that some children lack the ability to concentrate urine produced during the night and thus cannot reduce urine volume, and manifest enuretic episodes as a result. That hypothesis has led to studies investigating the circadian variation of plasma atrial natriuretic peptide (ANP). Children with enuresis have not consistently been found to differ from controls with regard to ANP. In one study, 14 of 55 children with enuresis had lower ANP concentrations than controls, and 9 of the 14 children had an excellent response to treatment with DDAVP. An investigation into the concentration of vasopressin in plasma and urine in 18 children with PNE and 20 matched controls found the concentration of

Telegram: @medical_k

www.konkur.in

vasopressin in plasma at 8:00 AM was significantly lower in the enuretic group. Total 24-hour urinary vasopressin excretion was also lower in the enuretic group but not significantly so.

Another hypothesis that has been investigated is that endogenous arginine vasopressin (AVP) levels would be different in children with enuresis who respond to DDAVP as opposed to those who do not. This would suggest the existence of a specific subgroup of children with enuresis based on their endogenous AVP levels and their positive response to DDAVP. A study involving a small number of subjects supported this hypothesis by indicating that AVP levels in the morning differentiated between controls and children with enuresis, as well as between DDAVP responders and nonresponders. However, a large study that also controlled for water intake over 72 hours and that sampled AVP more frequently found that only 14 of the 55 children with enuresis had a significant decrease in AVP when compared to controls. Of these, 9 had a significant positive response to DDAVP. Further complicating this line of research is the finding that AVP is not secreted in a continuous manner over 24 hours but rather is secreted in a pulsatile pattern, suggesting that definitive studies of this variable require frequent sampling. Investigations that have adopted this methodology have yielded conflicting results, in that one reported no differences between DDAVP responders and nonresponders, whereas another study with a small number of subjects that used hourly measurements found that in the 11:00 PM to 4:00 AM time period, children with enuresis (N = 9) had significantly lower AVP levels than did controls (N = 8).

There have also been related studies into the role of urine osmolality. One hypothesis is that a decreased ability to concentrate urine could contribute to an increase in the volume of urine. In general, these studies indicated that children with enuresis do have lower urinary specific gravities (as compared to controls) but not to a level that reaches statistical significance. It has also been reported that the levels of AVP can be increased in controls and children with enuresis by fluid restriction and, furthermore, that plasma osmolality

Telegram: @medical_k

www.konkur.in

can affect AVP secretion. In this regard, a comparison of controls, DDAVP nonresponders, and DDAVP responders indicated that fluid deprivation produced an increase in AVP levels in all groups, but the response was less robust in the DDAVP responders than in the other groups.

Another variation on this line of research is that refractory enuresis persisting into adolescence and adulthood may be secondary to a relative insensitivity to AVP, which can be positively affected by DDAVP. These observations contribute to the hypothesis that the primary pathophysiology of enuresis may occur at the receptor level, and this may also explain why some children do not respond to DDAVP.

Further complicating the research into the mechanism of action of DDAVP are two independent investigations that suggested that there is a central nervous system mechanism that may account for its efficacy in some children with enuresis.

Thus, as the foregoing review suggests, what initially appeared to be an intuitive explanation for the mechanism of action of DDAVP has not been supported by a number of studies and a precise mechanism that applies to all children who respond to DDAVP has not been identified.

There have also been investigations that have implicated tubular mechanisms with regard to the urinary excretion of potassium and sodium by children with enuresis. Although this research has primarily focused on the possible mechanism of action of DDAVP, it has also led to a reanalysis of imipramine's mechanism of action. Imipramine can produce a decrease in the excretion of sodium and potassium, which then produces a reduction in osmolal clearance and a decrease in urinary output. It has also been reported that imipramine can affect the secretion of nocturnal urinary antidiuretic hormone (ADH) and that this may account for its efficacy.

Diagnosis and Clinical Features

The concreteness and simplicity of enuresis make the diagnosis relatively easy. The DSM-5-TR continues the same age criteria that

Telegram: @medical_k

www.konkur.in

were used in the DSM-IV and DSM-IV-TR by specifying that the diagnosis is not made in a child whose chronologic or mental age is younger than 5 years of age. The stated rationale is that, by this age, continence can be expected to have occurred. As noted by the reference to a mental age of 5 years, children with developmental disabilities may have a greater chronologic age. The wetting must occur at least twice per week for at least 3 consecutive months, or, if less frequent, it must produce significant distress or functional impairment. Physical causes, such as a bladder infection, must be excluded. Qualifiers to the diagnosis indicate whether it is primary or secondary enuresis. As previously noted, *primary enuresis* refers to those children who have never maintained continence for any length of time, whereas *secondary enuresis* refers to those who had achieved continence for at least 6 to 12 months and then resumed wetting. The other qualifiers refer to the timing of the enuretic event during the day. Although most children exhibit only nocturnal enuresis, some have daytime (diurnal) patterns or a combined nocturnal and diurnal pattern.

The inclusion of children who wet intentionally with those who wet involuntarily under the same diagnostic heading can be problematic because that distinction has significant clinical implications. Children who are wetting intentionally almost certainly are doing so as a manifestation of a psychological disturbance. Although there is an association between behavioral disturbance and involuntary enuresis, the nature of the correlation is relatively nonspecific. Thus, although the coexistence of other behavioral problems is not a diagnostic issue per se, it is of clinical importance.

Telegram: @medical_k

www.konkur.in

John was a 10-year-old boy who had consistently wet the bed throughout his life. He averaged three to four nocturnal episodes per week, and his longest period of continence was a few weeks. Thus, John warranted a diagnosis of primary enuresis. John's father had been enuretic until 12 years of age, as were his father and a paternal uncle. Accordingly, the family had always assumed that this was a hereditary genetic disorder that John could not control. In keeping with this perception, John's parents had never adopted a punitive approach to the bedwetting. The wetting was handled in a matter-of-fact manner, with John washing his sheets every morning and showering before going to school.

The family sought consultation at this time because John was increasingly being asked to sleep overnight at the homes of friends and also wanted to attend an overnight Boy Scout camp. These concerns led the family to meet with their pediatrician, who suggested a trial of the bell-and-pad method of conditioning. This approach was not effective, in part because the family lived in cramped quarters and the alarm that was meant to awaken John also woke his two brothers who shared the bedroom with him.

At this point, the family's pediatrician suggested that they meet with a child psychiatrist with whom she worked. The child psychiatrist described the clinical literature on DDAVP. However, when John's father indicated that his health insurance did not cover prescriptions and that the family was having difficulty covering their household expenses on his income, which was only moderately above minimum wage, the psychiatrist felt compelled to discuss the relative costs of DDAVP and imipramine, which was less expensive than DDAVP. However, the psychiatrist also indicated that John would require a baseline electrocardiogram (ECG) (which his insurance could cover).

Ultimately, the family decided that John would need medication only for brief, discrete periods (overnights at friends and 1 to 2 weeks of summer camp) because they had worked out an

Telegram: @medical_k

www.konkur.in

acceptable plan for responding to the wetting on a day-to-day basis. Furthermore, they reasoned that, within approximately 2 years, John would experience a spontaneous remission of his enuresis, given that this was the family pattern. Thus, they decided that, because DDAVP has a rapid onset of action, they would pay out of pocket for the relatively small amounts of DDAVP that would be needed for these discrete periods over the next 2 years. The pediatrician advised the family of the Federal Drug Administration (FDA) alert regarding the risk of hyponatremia and seizures. They decided to use the oral form of DDAVP because the FDA identified the nasal spray as being more likely to produce hyponatremia and indicated that this form of DDAVP was no longer indicated for childhood enuresis. They were also advised to (1) limit John's fluid intake on the nights when DDAVP was administered, (2) discontinue its use if John developed the flu or another illness that could affect his fluid balance, and (3) discontinue the medication and notify their physician if symptoms of nausea, vomiting, or headache developed.

Pathology and Laboratory Examination

Because urinary tract infections can produce enuresis, a urinalysis should be part of every evaluation. Using radiographic procedures with contrast media to detect an anatomical or physiologic cause for the enuresis is more problematic because the procedures are invasive and painful and the diagnostic yield is low. A large study carried out in a pediatric primary care setting found a 3.7% incidence of obstructive lesions in children with enuresis. Others have reported similar findings. The literature cited earlier in the section on etiology concerning the use of noninvasive ultrasound techniques to establish bladder capacity and wall thickness have not been replicated to a degree that would warrant their use on a routine basis. However, they may be of use for children who are refractory to standard treatment.

Telegram: @medical_k

www.konkur.in

Differential Diagnosis

As suggested previously, the primary differential diagnosis is a urinary tract infection. This is especially true for girls, who are more prone than boys to develop urinary tract infections. A urinary tract infection should be the first consideration for a girl who has been continent for a considerable period of time and has recently begun wetting. Although the diagnostic yield is smaller with boys, a urinalysis should still be carried out.

Enuresis can result from anatomical malformations or obstructive lesions, but the percentages are relatively low. If the history and interviews with the child suggest that the enuresis is intentional, then it is almost certainly related to an underlying psychological disturbance. The relation between psychological disturbance and involuntary enuresis is less clear. The coexistence of another behavioral disturbance should be noted and attended to clinically. The most common comorbid psychiatric disorder is ADHD.

It has also been documented that enuresis has a negative effect on self-image and that enuretic children have more negative feelings about their disorder as compared to children who have other chronic illnesses.

There have also been case reports linking the onset of enuresis in children to the administration of both the selective serotonin reuptake inhibitor (SSRI) antidepressants and the atypical antipsychotic agent risperidone (Risperdal). Thus, the possibility of enuresis as a side effect of these medications should be considered if a chronologic correlation exists.

Secondary enuresis has also been identified as an important symptom of the abrupt onset of Type 1 Diabetes in children and is related to the polydipsia and polyuria that accompany that disorder.

Course and Prognosis

The natural history of enuresis is significant because it is a self-limited disorder that can spontaneously remit. The fact that the diagnosis is not made until 5 years of age takes into account children who have delays in toilet training that are not outside the accepted

Telegram: @medical_k

www.konkur.in

range (between 2 and 5 years of age). The prevalence of enuresis is relatively high, between 5 and 7 years of age, and then drops off substantially. The vast majority of enuretic children experience a spontaneous resolution of the problem at some time, and only a few remain enuretic into adulthood. By 14 years of age, only 1.1% of boys wet once a week or more. The peak age for secondary enuresis is between 5 and 8 years of age.

Treatment

The methods for the treatment of enuresis that have been empirically proven to be effective are primarily behavioral and pharmacologic. Psychotherapy may be useful for ameliorating some of the associated behavioral problems that can be seen with enuresis, especially secondary enuresis. A particularly common clinical scenario for secondary enuresis is the development of wetting after the loss of a parent through death or divorce. In these patients, psychotherapy is the primary treatment modality. A review of the efficacy of psychotherapy for primary enuresis found a 20% success rate, which is probably not significantly greater than would be expected by the rate of spontaneous remissions and random chance.

Behavior Therapy. A comprehensive review of several studies determined the success rate for behavioral interventions as 75%. Recent studies have yielded comparable response rates. The primary behavioral intervention is the bell-and-pad method of conditioning. A pad is placed on the bed, with a wire running to a bell. When the child wets, the moisture completes a circuit in the pad, ringing the bell and waking the child. With repeated use, the child learns to awaken before wetting occurs. Several studies have indicated that concomitant behavioral disturbance reduces the likelihood of success of behavioral interventions.

Recent behavioral studies have focused on embellishment of the standard method and comparisons with different methods. For example, no difference was found between an audio alarm and a

Telegram: @medical_k

www.konkur.in

vibratory alarm. A study that compared the basic bell-and-pad method with methods in which the bell and pad were coupled with more response contingencies for wetting versus not wetting found no statistical difference other than a slightly lower relapse rate with the adjunctive use of reward contingencies. One innovative strategy involved replacing the bell and pad with an alarm clock timed to go off after 2 to 3 hours of sleep when maximum bladder capacity would be expected. The authors reported responses that were equal to results with the standard bell-and-pad method.

The relationship between bladder capacity and response to behavioral treatment has also been investigated. One study found that bladder capacity did not affect outcome with the bell-and-pad method of conditioning, whereas another found that children with smaller bladder capacities tended to do slightly better when retention-control training was linked to the bell-and-pad method. A meticulous investigation into which treatment variables might relate to the efficacy of the bell-and-pad method found that the inability to be awoken by the alarm correlated significantly with failure, as did low functional bladder capacity.

There is some evidence to support the use of biofeedback for children who have small bladder capacities and unstable detrusors and who have been refractory to prior treatment. The newest advance in this behavioral methodology has been the use of an external ultrasonic monitor that is attached to a waistband. The monitor then signals the alarm when the bladder reaches maximal capacity. Clinical research with this device has yielded success rates similar to those with the basic bell and pad and has also reported increases in bladder capacity. The bell-and-pad approach has also been coupled with the use of DDAVP for children who have been refractory to prior treatment owing to family dysfunction or a concomitant behavioral disorder, or both. Although the bell and pad is the most intensively studied method of behavioral intervention, it is not the only type of behavioral treatment. A recent comprehensive review of this subject also noted other behavioral methods, such as evening fluid restriction, night-time toileting, rewards, overlearning, and retention-control training.

www.konkur.in

Pharmacotherapy. The initial description of imipramine's efficacy for enuresis was followed by more than 40 double-blind studies that confirmed its therapeutic value. This marked the advent of the pharmacologic era of the treatment of enuresis, with imipramine being the dominant pharmacologic entity used for more than two decades. Although imipramine has now been largely replaced by DDAVP, there are still reasons to include a discussion of its use in a comprehensive review of enuresis. Imipramine is still a consideration for children who are refractory to other forms of treatment. There is also a significant cost differential between imipramine and DDAVP, so that imipramine may well be the first pharmacologic choice for those families who do not have any form of insurance and who have limited financial resources.

Later studies with imipramine focused on the relation between response and concentration of imipramine in the blood. Although one study found no connection between positive response and imipramine concentration alone or in combination with its metabolite desipramine (Norpramin), three studies found a significant correlation between positive response and total concentration of imipramine and desipramine. More specifically, optimal response was found at combined concentrations (imipramine plus desipramine) of greater than 60 ng/mL in one study and of greater than 80 ng/mL in another. The most recent study also found that efficacy was related to increasing doses but noted tremendous variation in serum concentrations among individual children receiving the same dose. The adverse effect of dry mouth also correlated with concentration in blood, providing clinicians with a crude index of blood concentration in children who are extremely reluctant to have their blood drawn.

Clinically, when one encounters a history of a lack of response to imipramine, one must ascertain the specific dose used because nonresponse is frequently related to dose: primary care physicians often prescribe only 25 to 50 mg per day. However, low-dose responders do exist, and it is reasonable to start treatment at a daily dose of 25 mg, titrating up by 25 mg every 4 to 7 days. This enables identification of the low-dose responders because the response to

Telegram: @medical_k

www.konkur.in

imipramine usually occurs within 1 to 2 days. The majority of children exhibit a positive response in the range from 75 to 125 mg. The standard maximal limit for dose is 5 mg/kg body weight, and ECG monitoring is recommended at doses greater than 3.5 mg/kg. A pretreatment baseline ECG is also recommended. Blood concentration values may also be clinically useful if higher doses fail to elicit a response.

There is also a possible risk of overdose by the child with enuresis. Children can engage in magical thinking, and there have been reports of children who believed that, if taking a few pills would stop the wetting for a night, then consuming the whole bottle would make it disappear forever. Thus, parents should be advised to control the medication carefully and to store it in a secure place. Severe overdoses may require treatment with physostigmine (Antilirium), whereas more moderate overdoses may be treated by the symptomatic management of arrhythmias and seizures.

Because almost all children at some point experience spontaneous remission of the enuresis, it does not make sense to prescribe medication for years without checking for a spontaneous remission. One solution to that problem is to taper the imipramine dose at 3-month intervals. Should enuresis reappear as imipramine dose is tapered, it can simply be returned to the optimal level for another 3-month period. Clinically, one often finds that more children remain dry after 3 to 6 months of treatment than can be expected from spontaneous remission alone. In general, treatment with imipramine should be viewed as necessary until spontaneous remission occurs.

Three clinical subtypes of enuretic response to imipramine exist: true nonresponders, true responders who maintain a response over time, and transient responders who respond for a few weeks and then resume wetting. Increasing the dose for transient responders usually recaptures the response but only for another few weeks, and ultimately one reaches a point at which the dose cannot be increased further. However, the initial transient response can be replicated after a medication-free interval; thus, one can use the

Telegram: @medical_k

www.konkur.in

medication for especially important, time-limited social events, such as summer camp.

As indicated previously, DDAVP has now surpassed imipramine as the first-line pharmacologic approach for enuresis. A thorough review done as early as 1993 revealed 18 randomized, controlled trials, including a total of 689 subjects. Many subjects had been refractory to previous treatment for enuresis. DDAVP reduced enuretic frequency by 10% to 91% in these studies. Positive prognostic factors were age (older than 9 years of age) and lower pretreatment frequency of enuretic events. In most studies, wetting resumed after the medication was discontinued. Follow-up studies indicated that 5.7% of children remained dry after cessation of medication, but many of those cases could have been due to spontaneous remission. The most commonly reported adverse effects were mild abdominal pain, epistaxis, headache, and nasal stuffiness. Several subsequent studies attempted to find factors that might predict or relate to an increased likelihood of a positive response to DDAVP. No one factor appears to predict a positive response, but larger functional bladder capacity and a positive family history of enuresis appear to be positively correlated with treatment success. Factors that are not reliably related to treatment outcome are urine osmolality, plasma osmolality, ADH secretion, urine production, and nocturnal AVP concentration. However, individual studies can be found that link these factors with a positive outcome.

A large multicenter follow-up treatment study of DDAVP from Sweden (N = 399) used a 4-week baseline observation phase, a 6-week dose titration period (range from 20 to 40 μg), and a 1-year follow-up period. The study design also included an assessment for the rate of spontaneous remission by means of a 1-week medication-free period every 3 months. Sixty-one percent (N = 245) of the children met the requirement of at least a 50% reduction in frequency during the dose titration period that was required to enter the 1-year follow-up phase of the study. The average frequency of enuretic events in the baseline observation period was 5.3 events per week, and this declined to 0.8 nights by the end of the year-long follow-up period. As with other studies, older age was a positive

Telegram: @medical_k

www.konkur.in

prognostic sign. Of interest was the observation that 77 children experienced a complete remission of their enuresis within the first 6 months of the active treatment phase. There has been one report of an attempt to increase the rate of spontaneous remission by aggressively titrating the dose until cessation of wetting is obtained and then maintaining this dose for 4 to 6 weeks before beginning to decrease the dose by 10 μg per month until it is discontinued. The authors reported that, by using this strategy, complete remission was achieved for 71% of the children. The median length of follow-up was 18 months, and the mean dose of DDAVP was 20 μg.

Studies have also specifically investigated the efficacy of DDAVP for children who were refractory to a conditioning treatment and imipramine. One of these involving 52 children (dose range from 20 to 40 μg intranasally) found complete cessation of wetting in 53%, a partial response in 19%, and minimal or no response in 28%. A long-term follow-up study (mean length of follow-up of 13 months) of children treated with DDAVP found no hematologic or hormonal adverse effects.

Treatment with DDAVP has been compared to the bell-and-pad method of conditioning. The difference in response rate was not statistically significant; 86% improved with the bell and pad, and 70% improved with DDAVP. Another investigation comparing the combined use of the bell-and-pad method and DDAVP with placebo indicated that the combination achieved significantly more dry nights. Similar results were found in a study comparing alarm monotherapy to alarm treatment coupled with DDAVP. The combination proved superior, especially for children with severe, almost nightly, wetting.

The development of oral tablets greatly simplified the administration of DDAVP. The nasal spray was difficult for some children to use, and this could (in some cases) contribute to variable administration. A controlled multicenter study found no difference in response between oral DDAVP and the traditional nasal spray. A dose of 400 μg produced more dry nights than did a 200-μg dose.

A significant dose-effect correlation was found in a placebo-controlled study that used 200-, 400-, and 600-μg oral doses. In a separate follow-up study (7 years), the rate of spontaneous

Telegram: @medical_k

www.konkur.in

remission at 2 and 7 years was reported as greater than would be expected solely on the natural history of the disorder. As with other treatment modalities, consistent findings in the clinical literature concerning positive responses to DDAVP are older age, larger bladder capacity, and lower pretreatment frequency of enuresis. The newest innovation in the use of DDAVP has been the development of a sublingual desmopressin oral lyophilisate (MELT). A randomized, controlled study that compared this formulation to oral tablets found it to be equally effective. The children also expressed a greater preference for the MELT. This increase in preference was especially pronounced in the younger age group (5 to 11 years of age).

As the use of the DDAVP nasal preparation became more common, there were an increasing number of case reports of hyponatremic seizures with prolonged use. A review of 14 articles that reported data on serum sodium concentration in DDAVP-treated patients and 11 articles that reported individuals who developed altered consciousness or a seizure while taking DDAVP for enuresis concluded that hyponatremia is a potential adverse effect of DDAVP treatment. The authors also noted that excess fluid intake was a contributing factor in 6 of the 11 case reports. They concluded that patients receiving DDAVP for nocturnal enuresis should be advised not to consume more than 8 oz of fluid on nights when DDAVP is administered. The data on hyponatremia also suggest that periodic monitoring of serum sodium concentration would be prudent. The number of reported cases of hyponatremia and seizures, including two deaths, prompted the FDA to issue an alert concerning DDAVP in December 2007. The alert identified 61 postmarketing incidents of hyponatremia-related seizures that were related to the use of DDAVP. Sodium levels obtained at the time of the seizure ranged from 104 to 130 mEq/L. A particular concern was that two of the individuals who experienced seizures with hyponatremia died. The intranasal formulation of DDAVP was implicated in 36 of the cases, and 25 of these were individuals younger than the age of 17 years, most of whom were receiving DDAVP for treatment of nocturnal enuresis. The FDA alert concluded that the intranasal formulation of

Telegram: @medical_k

www.konkur.in

DDAVP was no longer indicated for the treatment of PNE. The alert also suggested that treatment with the tablet form should be halted during illnesses that could produce disturbances in fluid dynamics and/or produce electrolyte imbalance. The alert also recommended that fluids should be restricted from 1 hour before to 8 hours after the administration of the tablets. The latter recommendation is consistent with earlier published reports that linked the amount of fluid intake to the risk of acute hyponatremia.

Although imipramine and DDAVP have been the dominant pharmacologic treatment modalities over the last several years, there continue to be reports of success with anticholinergic agents. The majority of these reports relate to oxybutynin, both as a first-line intervention and for individuals who are refractory to other interventions.

General Treatment Considerations. The results of the studies reviewed, in conjunction with the natural history of enuresis, can help the clinician to develop a decision tree tailored to a given child. The first decision, naturally, is whether to treat at all. That decision is affected by the frequency of the wetting, the age of the child, and the amount of psychological distress that the wetting causes the child. Enuresis has a negative effect on the self-esteem of these children, and self-esteem improves after successful treatment. One may choose not to treat a child who is infrequently wetting and who is at an age at which spontaneous remission may be expected.

If one does elect to treat, it makes sense first to try the bell-and-pad method of conditioning because its efficacy has been repeatedly demonstrated, and behavioral intervention is considered less invasive than pharmacologic approaches. A large follow-up study that compared observation only with imipramine, DDAVP, and the bell and pad indicated that, although all of the active treatments were significantly superior to observation alone, the positive response was much more likely to be sustained after treatment cessation with the bell and pad than with either pharmacologic treatment. Despite these apparent advantages, one large population-based investigation revealed that only a relatively small number of enuretic children

Telegram: @medical_k

www.konkur.in

(38%) saw a physician, and, of that number, only 3% were treated with the bell-and-pad method of conditioning, whereas more than one-third received pharmacologic treatment. A more geographically restricted survey of primary care physicians yielded significantly different responses, in that 80% of physicians indicated that they recommended the bell-and-pad method of conditioning. The most recent comparative study of the long-term efficacy of DDAVP versus the enuretic alarm involved 142 children who were randomized to either form of treatment for 6 months, with the determination of success rates at 6 and 12 months. Interestingly, only 5.2% of the DDAVP group withdrew after randomization, as compared to 30.7% of those assigned to the enuretic alarm group. The results for those who completed 6 months of treatment (defined as at least 90% in wet nights) indicated that 76.8% of the DDAVP group was deemed to be successful, as compared to 61.8% of the alarm group. The success rates at 12 months were comparable, with 77.8% of the DDAVP group meeting success criteria, as compared to 75% of the alarm group. However, when the large drop-out rate after the assignment to the alarm group was taken into account, the success rates were adjusted to 68.8% for the DDAVP group and 46.2% for the alarm group. Thus, this study essentially confirmed the results of numerous prior studies in that the two treatment modalities were found to be equally effective, but the ability to implement the bell-and-pad alarm system was too difficult for many families to implement successfully.

When the bell-and-pad method of treatment is unsuccessful or not feasible, it makes sense to proceed to pharmacologic treatment, assuming that the enuresis is severe enough to warrant pharmacologic intervention. For decades, imipramine was the first choice for pharmacologic treatment. Although precise figures are not available for its relative use in the treatment of PNE, DDAVP has surpassed imipramine as the most popular pharmacologic treatment.

ENCOPRESIS

Telegram: @medical_k

www.konkur.in

Definition

The DSM-5-TR criteria are virtually unchanged from those of the DSM-IV and DSM-IV-TR and define *encopresis* with four related criteria: (1) the repeated inappropriate passage of feces, usually involuntary, (2) occurrence at least once a month for at least 3 months, (3) a chronologic or mental age of 4 years of age, and (4) exclusion of a substance or medical condition as a cause.

For several years, the clinical and research literature concerning encopresis has distinguished between retentive and nonretentive encopresis. The DSM-5-TR recognizes this distinction and lists two subtypes: With constipation and overflow incontinence and without constipation and overflow incontinence. The subtype with constipation and overflow incontinence corresponds to retentive encopresis. The subtype without constipation and overflow incontinence corresponds to nonretentive encopresis.

Some clinicians refer to a *primary type* in which the person has never established fecal continence and a *secondary type* in which the disturbance develops after a period of established fecal continence.

History

The history of encopresis is not as richly detailed as that of enuresis, possibly because encopresis affects fewer children, and the events are less frequent. Unless the feces are particularly fluid, it may also be easier for children to hide the symptoms. A high frequency of encopresis and enuresis was found in children who were separated from their parents in World War II, thus documenting the effect of environmental factors.

The more contemporary history of encopresis is noteworthy for the establishment of a treatment methodology that involves cathartics to re-establish bowel dynamics (coupled with education), which has proven to be quite successful. The innovative use of biofeedback technology showed much initial promise after its introduction in the 1980s, but it now appears that it is not more effective than the older method. Constipation is a common precursor to encopresis, and

Telegram: @medical_k

www.konkur.in

recent research has also focused on effective treatment for this disorder.

Table 48–3.
DSM-5-TR Diagnostic Criteria for Encopresis

A. Repeated passage of feces into inappropriate places (e.g., clothing, floor), whether involuntary or intentional.
B. At least one such event occurs each month for at least 3 months.
C. Chronological age is at least 4 years (or equivalent developmental level).
D. The behavior is not attributable to the physiological effects of a substance (e.g., laxatives) or another medical condition except through a mechanism involving constipation.

Specify whether:

With constipation and overflow incontinence: There is evidence of constipation on physical examination or by history.

Without constipation and overflow incontinence: There is no evidence of constipation on physical examination or by history.

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Text Revision, DSM-V-TR, p. 402 (Copyright © 2022). American Psychiatric Association. All Rights Reserved.

Comparative Nosology

As noted above, the DSM-5-TR has adopted the widely held clinical distinction between retentive and nonretentive encopresis, although the terminology differs slightly. The current DSM-5-TR definition includes voluntary and intentional encopresis, which is obviously a distinction of major clinical importance. This statement appears to minimize the importance of a rather substantial subgroup of children with nonretentive encopresis who are encopretic because they cannot adequately control the anal sphincter or do not recognize the need to defecate in time (Table 48–3).

Telegram: @medical_k

www.konkur.in

The ICD-11 diagnostic classification for encopresis essentially follows the DSM-5-TR approach (Table 48–4).

The most comprehensive categorization of encopresis distinguishes three types of patients: (1) intentional—children who do have bowel control but intentionally deposit feces in inappropriate places for psychological reasons; (2) involuntary—those who cannot adequately control the sphincter or lack an awareness of the process, or both; and (3) involuntary—those whose soiling is related to excessive fluid from retentive overflow (75% of this category), diarrhea, or anxiety. Thus, this classification schema incorporates the retentive and nonretentive dichotomy and the distinction between voluntary and involuntary incontinence.

Telegram: @medical_k

www.konkur.in

Table 48–4.
ICD-11 Diagnostic Criteria for Encopresis

- Repeated and persistent passage of feces in inappropriate places (e.g., at least once per month over a period of several months).
- The individual who has reached the developmental age when fecal continence is ordinarily expected (approximately equivalent to a chronological age of 4 years).
- Fecal soiling is not better accounted for by the physiological effects of a substance (e.g., excessive use of laxatives) or another medical condition (e.g., aganglionic megacolon, spina bifida, anal stenosis, chronic diarrhea, congenital or acquired abnormalities of the bowel, or gastrointestinal infection).

Specifiers

Encopresis with constipation and overflow incontinence:

- Encopresis with constipation and overflow incontinence is the most common form of fecal soiling, and is characterized by retention and impaction of feces. Stools are typically—but not always—poorly formed (loose or liquid) and leakage may range from occasional to continuous.
- There is often a history of toilet avoidance leading to constipation.

Encopresis without constipation and overflow incontinence:

- Encopresis without constipation and overflow incontinence is not associated with retention and impaction of feces, but rather is characterized by reluctance, resistance, or failure to conform to social norms in defecating in acceptable places in the context of normal physiologic control over defecation.
- Stools are typically of normal consistency and inappropriate defecation is likely to be intermittent.

Reprinted from World Health Organization. ICD-11 for Mortality and Morbidity Statistics, 2023. https://icd.who.int/browse11/l-m/en#/http://id.who.int/icd/entity/313374467.

Epidemiology

Telegram: @medical_k

www.konkur.in

Two large epidemiologic studies have yielded consistent results. The Isle of Wight Study reported a prevalence of 1.3% for boys and 0.3% for girls (10 to 12 years of age) soiling at least once a month. A large study involving 8,863 children found a 1.5% prevalence rate for boys (7 and 8 years of age). In that study, the ratio of boys to girls was more than 3:1. A significant correlation between encopresis and enuresis has also been found.

Etiology

The dramatic nature of fecal soiling has contributed to psychodynamic speculation. The term *chronic neurotic encopresis* has been used to describe the small number of children whose encopresis is predominantly psychological. The clinical characteristics described in these children are (1) a distant father and neurotic mother, (2) early and often harsh bowel training, and (3) a history of neurologic delay. The one systematic study that attempted to verify the clinical features usually attributed to enuretic and encopretic children in the literature by analyzing actual case material could not substantiate the existence of 20 of the 22 factors developed through the literature review. As with enuresis, the distinction between primary and secondary encopresis relates to the issue of associated psychopathology. A study involving 63 boys with encopresis found that boys with primary encopresis were more likely to have developmental delays and associated enuresis, whereas those with secondary encopresis were more likely to have experienced higher levels of psychosocial stressors and to be diagnosed with conduct disorder. Another large study examined several psychological and physiologic variables in children with chronic constipation as compared to children with encopresis unrelated to constipation. The group with constipation had significantly longer colonic transit times (CTTs), whereas both groups had relatively high frequencies of abnormal defecation dynamics. A subsequent independent investigation of CTT in children with chronic constipation found that a CTT greater than 100 hours was related to a poor outcome at 1-year follow-up.

Telegram: @medical_k

www.konkur.in

A large population-based study in the United Kingdom involving 8,242 children (7 to 8 years of age) investigated the association of soiling with a variety of psychological disturbances. The children with encopresis were divided into those who frequently soiled (at least once a week) or occasionally (defined as less than once a week). There was also a large control group. Both of the symptomatic groups had significantly higher rates of behavioral and psychological disturbance than the controls. The rates of disturbance were also higher in the group that frequently soiled than in the occasional-soiling group. However, there was no particular behavioral profile that correlated with encopresis. The authors noted higher rates of attentional, obsessive-compulsive, and oppositional presentations in the symptomatic children than in the controls.

A premorbid history of encopresis has been found to occur more frequently in individuals with prepubertal and early adolescent bipolar disorder phenotype (PEA-BP) than in controls. A recent large, retrospective study (in a military health-system database) involved 32,773 children who were identified as having ADHD. The results indicated that 4.1% of those children had constipation, as opposed to 1.5% of control children without ADHD. The corresponding rates for fecal incontinence were 0.9% in the children with ADHD, as compared to 0.15% of the controls. Both of these results were statistically significant with high levels of confidence, leading the authors to conclude that ADHD was a risk factor for fecal incontinence.

A recent large birth cohort study involving 358 children also found higher rates of both enuresis and encopresis among children with ADHD.

No correlation between encopresis and social class was reported in two independent studies. The issue of neurologic competence as a contribution to encopresis has been investigated. One study found no abnormalities of anal–rectal motor or sensory function but did find that a significant number of encopretic boys had abnormal anal–rectal expulsion dynamics. A sophisticated physiologic study using a triple-lumen catheter attached to a hydraulic manometry infusion system found that age of onset, frequency, and duration of

Telegram: @medical_k

www.konkur.in

encopresis were all highly correlated with the amount of anal sphincter spasm that occurred when defecation was attempted. The amount of pain reported with bowel movements correlated positively with the frequency of encopresis and inversely with maximum squeeze pressure. An investigation involving the concentrations of gastrointestinal (GI) hormones in controls and children with retentive encopresis indicated that the latter had higher concentrations of pancreatic polypeptide after a meal and less of a motilin response. However, the authors noted that these abnormalities could be the result of, or the cause of, chronic constipation.

An extensive series of studies concerning physiologic factors and the interplay of physiologic and psychological factors has been carried out. The principal physiologic findings were (1) 56% of children with retentive encopresis could not defecate rectal balloons (research technique used to assess sphincter competency), and most had abnormal anal sphincter contractions; (2) only 14% of those who could not defecate the balloons were found to have responded to treatment at 1-year follow-up, compared to a 64% success rate for those who could; (3) at 1-year follow-up, 70% of children who could relax the anal sphincter at the time of initial evaluation were improved, as opposed to 13% of those who could not; and (4) none of the children who initially presented with an abdominal fecal mass was improved at 1-year follow-up, regardless of other factors.

One subset of these studies physiologically compared constipated children to controls during the act of bearing down. All of the control children displayed decreased anal sphincter activity when bearing down, compared to 58% of the constipated children who could defecate a balloon and 7% of constipated children who could not defecate the balloon. The constipated children who could not defecate the balloon were also significantly less likely to respond to laxative treatment. Nonrelaxation of the anal sphincter was found in 75% of encopretic children, as opposed to 13% of a control group in a study that used anal electromyography. This study also reported lower pressures for the encopretic children at rest and on squeezing; this observation has also been described by other investigators.

Telegram: @medical_k

www.konkur.in

An attempt was also made to assess the relative effect of physiologic and psychological factors. Specifically, anal–rectal manometric and electromyographic assessments were correlated with behavioral and social competence profiles as related to treatment outcome. Psychological variables were not found to be predictive of outcome, but physiologic variables were.

Diagnosis and Clinical Features

The objective and concrete nature of the encopretic event makes diagnosis relatively easy and uncomplicated from a phenomenologic perspective if the child meets the frequency, duration, and age requirements set forth in the DSM-5-TR. The involuntary versus intentional dichotomy is not a requirement or reason for subclassification according to the DSM-5-TR, but it has important clinical implications. Similarly, the retentive versus nonretentive schema has clinical usefulness. Differentiating between primary and secondary encopresis is important, given that one might expect medical or psychological factors to play a greater role in secondary encopresis.

Telegram: @medical_k

www.konkur.in

Henry was an 11-year-old boy with almost-daily encopresis and a number of associated behaviors, including hiding the feces around the house. He resided in a specialized foster care setting, having been removed from his biologic parents at 7 years of age because of physical and sexual abuse. Both parents were involved with substance abuse, and his early history was not well documented. However, the parents did indicate that he had never exhibited sustained bowel continence for several months. Henry had also been enuretic until 6 years of age, but this had resolved to an occasional nocturnal episode every 4 to 6 months.

Henry also qualified for a diagnosis of ODD. Although he had experienced physical and sexual abuse, he did not have flashbacks or other symptoms that would meet the criteria for post-traumatic stress disorder (PTSD). Henry also had ADHD and was being effectively treated with 10 mg of methylphenidate (Ritalin) twice a day.

The foster family resided in an urban area that had access to a nationally recognized children's hospital. The ambulatory care department had a specialized behavioral encopresis program that coupled the bowel training method with a psychoeducational component and psychotherapy. The psychiatric consultant to the specialized foster care program doubted that this program would be successful for Henry because he had so much associated psychopathology, and the feces were often deposited around the house in a symbolic manner. In addition, the encopresis was not of the retentive-overflow type, and the feces were always well-formed. However, because no apparent harm could come from the referral, the consulting child psychiatrist agreed to it. Much to the surprise of the consultant, the several-week outpatient bowel training course, coupled with the psychoeducational component and psychotherapy, resulted in a complete cessation of the encopresis. On one of her visits to the home, Henry proudly showed his case manager a diagram of the functioning of the digestive system that was part of the psychoeducational program. In retrospect, it appeared that, although there were

Telegram: @medical_k

www.konkur.in

symbolic aspects to Henry's encopretic behavior, the soiling was ego-dystonic, and he was highly motivated to change the behavior, although this motivation could not be prospectively detected by the treatment team because of his oppositional defiant manner of responding to adults.

Pathology and Laboratory Examination

The extensive, detailed physiologic studies cited previously suggest that physiologic factors are important in many children with encopresis, given that they correlate with treatment outcomes at 6-month and 1-year follow-up. However, that does not imply that a physiologic workup that is this thorough is required for every child who presents clinically. The clinician needs to rule out definite physiologic illnesses, such as Hirschsprung disease. Beyond that, clinicians might consider more detailed physiologic investigations, such as those used in the experiments described previously, for children who prove refractory to conventional treatment. That type of specialized testing could also be difficult to obtain outside of an academic research center. A simple plain abdominal roentgenogram may aid in the diagnosis and confirmation of retentive encopresis. In one study, 78% of children who met the diagnostic criteria for encopresis also met roentgenographic criteria, whereas 22% did not.

Children with a condition referred to as *slow transit constipation* may present with intractable encopresis. Although the etiology of this disorder is not fully understood, some of these children appear to have abnormal innervation of the colon. Clinical signs of this disorder include severe constipation within the first year of life and refractory encopresis at an early age. Colonic transit studies are necessary to confirm the diagnosis.

Psychological testing can be useful for those children who exhibit concomitant behavioral problems or for those who are intentionally encopretic. Finally, clinicians should not overlook the importance of a detailed history obtained from the parents and the child that documents the time course, frequency, and circumstances surrounding the encopresis.

Telegram: @medical_k

www.konkur.in

Differential Diagnosis

Encopresis can be a symptom of other processes or can be a syndrome in itself, as described previously. The medical illnesses that need to be ruled out include stenosis of the rectum or anus, endocrine abnormalities, smooth muscle disease, and Hirschsprung disease.

The child's psychological profile should be considered because children with intellectual deficits or pervasive developmental delay may have episodes of soiling related to those processes. Children with impulse-control disorders or attention-deficit disorder may, at times, have episodes of soiling related to lack of attention. Encopresis has been reported as one of a number of symptoms that can be seen following sexual abuse. A large retrospective study investigated the hypothesis that the association between encopresis and sexual abuse was of sufficient significance and that encopresis could be classified as an indicator of sexual abuse. The three study groups (4 to 12 years of age) included 466 children with documented sexual abuse, 429 children with externalizing psychiatric disorders, and 641 controls. A history of sexual abuse had been ruled out in the latter two groups. The rates of fecal soiling were similar in both the abuse (10.3%) and psychiatric groups (10.5%). The soiling rate in the control group was much lower (2%). Thus, the authors concluded that the symptom of fecal soiling could not, in and of itself, be used as a predictive indicator of sexual abuse. A thorough history and psychiatric assessment should make it possible to identify those children, as well as those children who soil on an intentional-oppositional basis. Extreme stress may also provoke encopretic episodes in children who are otherwise functioning well.

Course and Prognosis

As with enuresis, continued maturation provides increasing numbers of spontaneous remissions over time. However, the rate of spontaneous remission is not as clearly defined as that for enuresis. That trend should be factored into the assessment of the efficacy of any long-term intervention. The results from relatively simple

Telegram: @medical_k

www.konkur.in

behavioral interventions involving educational, behavioral, and physiologic components are striking (78%), suggesting that the disorder responds to treatment in most cases.

Treatment

The first clinical approach to encopresis is primarily behavioral, with educational and physiologic components. That method entails initial educational interventions with the child and family around bowel function. The process is meant to correct misconceptions that the family may have and to dissipate anxiety that may develop around the soiling. The physiologic component is instituted next with an initial bowel catharsis, followed by daily doses of laxatives or mineral oil. The behavioral element of the program entails daily timed intervals on the toilet, with success being rewarded. Follow-up studies have reported a 78% success rate for this method. The physiologic research findings concerning abnormal defecation dynamics in children with encopresis led to an interest in biofeedback training as an adjunctive treatment. Although this treatment received positive reports from uncontrolled studies, a review of controlled studies indicated that biofeedback training did not provide additional benefit over conventional treatment. A large, long-term, controlled outcome study that compared conventional treatment with biofeedback training plus conventional treatment indicated that the positive results for both groups were high and quite similar. Specifically, the conventional method yielded an 86% improvement rate, as compared to 87% for the combined group. This suggests that the combination treatment was no better than the conventional treatment alone. However, it was also found that length of time at follow-up was a powerful factor because it significantly correlated with improvement for the group as a whole at the $P < .01$ level. This indicates that the passage of time is an important variable to consider in any investigation of treatment approaches.

A recent systematic meta-analysis of the literature with regard to behavioral and/or cognitive treatments for fecal incontinence

Telegram: @medical_k

www.konkur.in

concluded that treatment with biofeedback did not improve the results obtained from the traditional treatment.

One element of the aforementioned physiologic studies, namely, the ability to defecate a rectal balloon, has been shown to correlate with treatment outcome. A study involving 139 children with constipation and encopresis and 20 controls found that all of the controls were able to defecate the balloon, as compared to 47% of the encopretic group.

One year after beginning treatment, 51% of the children who could defecate the balloon at baseline were considered to be recovered, but only 34% of those who could not defecate the balloon were improved. Although the group comparisons were considered significant, the balloon test alone could not predict response to treatment on an individual basis.

Psychotherapy may be of use for children who have concomitant behavioral problems and those with psychodynamic factors that appear to be especially strong and are contributing to the disorder. This would also be true for those who began soiling after a stressful or traumatic event. Naturally, psychotherapeutic approaches are of primary importance for children who are intentionally soiling or depositing feces in inappropriate places.

Pharmacologic treatment for encopresis has not been extensively studied or reported. There are six case reports (encompassing 15 individual patients) that have described imipramine as effective for encopresis. Twelve of the 15 patients were boys. The therapeutic effect had relatively rapid onset (as it does with enuresis), occurring within a few days to 2 weeks, usually at doses of 25 to 75 mg. Although the subtype of encopresis is not clearly delineated in all of the case reports, one would anticipate that, if imipramine were to be helpful, it would be in those with nonretentive encopresis. There is one well-controlled study that substantiated the efficacy of the prokinetic-propulsive agent cisapride (Propulsid). This agent is no longer commercially available in the United States, having been removed from the market owing to concerns about side effects.

The relatively high success rate of the combined educational, physiologic, and psychological approach described makes it a

Telegram: @medical_k

www.konkur.in

reasonable first approach once other diagnoses have been ruled out. Psychotherapeutic and pharmacologic approaches could be considered for children who prove refractory to that form of treatment.

Other Disorders of Infancy, Childhood, and Adolescence

49.1 Reactive Attachment Disorder and Disinhibited Social Engagement Disorder

Karin M. Best, Ph.D., Mary Margaret Gleason, M.D., and Charles H. Zeanah, M.D.

As early as the 13th century, astute observers and lay researchers documented a range of atypical reactions among some children who experience social neglect or physical and social neglect. Observational data and research findings coalesced in the 1970s with the inclusion of reactive attachment disorder (RAD) in infancy and early childhood in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III, 1980). The description of RAD was framed in the observational and theoretical work of John Bowlby.

The DSM-III's revision (DSM-IIIR, 1987) and the next *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV, 1994; DSM-IV-TR, 2000) delineated two subtypes of RAD—an emotionally

Telegram: @medical_k

www.konkur.in

withdrawn/inhibited pattern and an indiscriminately social/disinhibited pattern. The differentiation was grounded in emerging research that provided evidence suggesting that the subtypes differed in presentation, neurobiology, and developmental course. Research continued to demonstrate that both subtypes emerged only after an infant or very young child experienced significantly inadequate caregiving.

Informed by the seminal research of the English-Romanian Adoption (ERA) study and the Bucharest Early Intervention Project (BEIP), the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) and its text revision (DSM-5-TR) defined the subtypes as two distinct disorders: RAD, which describes children who display the emotionally withdrawn/inhibited pattern of behavior; and disinhibited social engagement disorder (DSED), which describes children who demonstrate the indiscriminately social/disinhibited pattern. These disorders often continue to be categorized as “disorders of attachment,” and the criteria for each reference are early-rearing conditions that limit the development of attachments. However, whether DSED should be considered an attachment disorder remains controversial. DSM-5 classified both Trauma and Stress-Related Disorders, and DSM-5-TR took the same approach. RAD and DSED in DSM-5-TR are also defined in the *International Classification of Disease, eleventh edition* (ICD-11), with similar criteria.

The ERA study and BEIP have contributed to the behavioral delineation of RAD and DSED and the development of “gold standard” methodology and measures for the diagnosis of young and early school-age children. In the past 10 years, research has broadened to include efforts to characterize them in adolescence and in the adult years, with the goal of better understanding their respective sequelae. This research includes a detailed follow-up of the ERA and BEIP samples as well as a retrospective application of childhood diagnostic criteria to high-risk adolescent samples, some of which have extensive childhood health registry data available. The diagnostic precision of studies that apply diagnostic criteria retrospectively is limited, and findings must be interpreted with due

Telegram: @medical_k

www.konkur.in

caution as exploratory. The efforts include attention to delineating the adolescent behavioral equivalents of RAD and DSED, which both the DSM-5-TR and ICD-11 define with criteria specific to younger children. Additional research also focuses on identifying familial and life experience risk factors for the development of RAD and DSED, exploring child characteristics and skills that may mediate and moderate the long-term sequelae, and identifying alterations in brain structure and activity associated with each diagnosis. This work is central to the development and refinement of evidence-based intervention techniques and programs.

Clinically, the diagnoses of RAD and DSED have been embraced, and there is evidence that both are *overdiagnosed in community settings*. In 2016, the American Academy of Child and Adolescent Psychiatry published practice parameters to guide accurate diagnosis and to discredit dangerous and unproven interventions, such as various holding/restraints, that have resulted in the death of children.

In what follows, we highlight contexts and details relevant to the diagnosis of RAD and DSED. Our goals are to support accurate assessment and diagnosis, provide an update on emerging information about the long-term sequelae of RAD and DSED symptomatology, and provide information regarding care and evidence-informed treatment.

ATTACHMENT THEORY

The normal development of the infant and young child's attachment system, first described by John Bowlby, is the trajectory to which behavior indicating disordered attachment is compared (Table 49.1–1).

Attachment, as described by Bowlby's influential theory, refers to a biobehavioral system that coordinates the balance between the very young child's need, on the one hand, to seek safety by proximity to a caregiver or set of caregivers and, on the other, to explore surroundings, to seek novelty, and to develop mastery. Bowlby argued that human infants are motivated by an attachment behavior control system to seek proximity to a small number of identified

Telegram: @medical_k

www.konkur.in

caregivers. He inferred that the reason for seeking proximity was to attain an internal feeling of security. This internal sense of security is reinforced by repeated experiences of the caregiver's emotional and physical availability in times of need.

Table 49.1–1. Developmental Features of Attachment in Early Childhood

	Birth–2 Months	2–7 Months	7–12 Months	12–18 Months	Older than 18 Months
Phase of attachment	Limited discrimination	Discrimination with limited preference	Preferred attachment	Secure base	Goal-oriented partnership
Characteristics	Physical attributes of babyishness attract caregivers, but infant expressions of preference are limited to olfactory and auditory realms and require experimental conditions to be demonstrated.	Infant differentiates among different interactive partners; infant may seem more comfortable with primary caregiver but is willing to interact readily with other social partners.	Clearly expressed preference for a small number of caregiving adults; separation protest and stranger wariness are normative.	Use of the attachment figures as a secure base from which to venture out confidently and to explore the world and a safe haven to return to in times of danger; proximity to caregiver promotes feeling of security in infant.	Co-operation with caregiver despite frequent conflicts; goal is to balance autonomous functioning with reliance on caregiver for help when needed; verbal relatedness is important, including attention to emotional integration and fluency of discourse.

Beginning between 7 and 9 months of age, infants are thought to develop internal representations of their relationships with important caregivers. These representations, or internal working models, form the basis for the intense emotional bond between infants and their primary caregivers and their behavior in later relationships. The normal developmental progression of attachment, captured in attachment-related behaviors, is summarized in Table 49.1–1. The commonly accepted method for classifying patterns of attachment is the strange situation procedure, which includes interaction with an attachment figure and an unfamiliar adult in various combinations. Differences in the balance between attachment and exploratory behavior and how those are expressed are used to classify the infant's attachment to this caregiver into one of four types of attachment: *secure*, in which children express distress directly, seek comfort actively, and obtain soothing readily from attachment figures; *avoidant*, in which children minimize signs of distress and show no comfort seeking efforts despite physiologic arousal; *resistant*, in

Telegram: @medical_k

www.konkur.in

which children show significant distress to separation but fail to obtain comfort from their attachment figure and cannot be soothed; or *disorganized*, in which children show some mixture of the secure, avoidant or resistant, or anomalous behaviors that preclude classification as another pattern. These patterns of attachment represent risk or protective factors rather than diagnoses.

IMPACT OF EARLY ENVIRONMENT

The importance of an infant's early experience was recognized as far back as the 13th century when the Holy Roman Emperor Frederick II reportedly initiated an experiment to see what language children would develop independently. He ordered that a group of infants be provided simple physical care but not spoken to by their caregivers. According to the Franciscan monk whose chronicle recounted the events, the experiment ended with the premature death of the children, who "could not live without clapping of the hands, and gestures, and gladness of countenance, and blandishments."

The relatively common practice of institutionalizing infants in the United States in the first half of the 18th century unwittingly provided more evidence of the detrimental effects of what has been called "maternal deprivation." Although pediatricians had long argued against the practice of institutionalization, particularly because of the high mortality rates related to failure to thrive, other healthcare providers did not take notice of the effects of institutionalization on social and emotional development until René Spitz (in the 1940s) and James and Joyce Robertson (in the 1950s) conducted more rigorous studies (including control groups). Spitz subsequently proposed a diagnostic entity that he called *anaclitic depression*, which foreshadowed the DSM-III criteria for RAD. Anaclitic depression, which included mood and social symptoms as well as immunologic and growth problems, seemed to follow the prolonged separation of infants from their caregivers. It was most severe when the infants were old enough to have developed a preference for the caregiver from whom they were separated.

Telegram: @medical_k

www.konkur.in

In the 1970s, research by Barbara Tizard identified the two sets of behaviors that inform the current DSM-5-TR and ICD-11 classifications of attachment disorders. The children she studied resided in institutions with relatively low caregiver-to-child ratios, mixed age groups, and toys and books to enrich the environment. Their caregivers, however, were explicitly instructed not to form attachments to the children. Eight of the 26 children managed to form secure attachments, 8 were emotionally withdrawn and socially unresponsive (similar to children with RAD), and 10 were indiscriminately social with unfamiliar adults (as seen in children with DSED and DAD).

Recognition of the detrimental clinical consequences of institutional rearing eventually led to a marked decrease in state-run orphanages in the United States and the United Kingdom. Nevertheless, institutional care remains widely used for orphaned, abandoned, and maltreated young children in Asia, Central and South America, and Europe, particularly Eastern Europe.

Since the early 1960s, spurred by C. Henry Kempe's classic 1962 article on the *battered child syndrome*, recognition of and research on the developmental effects of maltreatment on children have grown. The research documents substantial consequences of abuse and serious neglect, including associations between abuse and serious disturbances of attachment.

Thus, descriptions of the phenotypes associated with attachment disorders emerged in early case reports and descriptive studies, but systematic research appeared only in the past four decades. Studies of institutionalized and maltreated infants and young children provided broad support for the phenotypic patterns of disordered attachment, now referred to as RAD and DSED.

EVOLVING NOSOLOGY

The criteria for RAD have evolved markedly since the diagnosis was introduced. The DSM-III description included as central features growth failure and lack of social responsivity. The diagnosis had to start by 8 months of age (the age at which preferred attachment to a

Telegram: @medical_k

www.konkur.in

restricted set of caregivers is usually just beginning to be evident) and could not result from a diagnosable medical condition. Gross neglect of the infant's physical and emotional needs had to be evident, and the presence of autism or mental retardation precluded the diagnosis. Pertinent behaviors cited in the criteria included poor tone, weak cry, excessive sleep, lack of interest in the environment, and weak rooting and grasping when feeding.

Although failure to thrive is an important problem in infant mental health, it is not equivalent to an attachment disorder. The DSM-III's restrictive age range criterion and the requirement for growth failure significantly restricted the application of the diagnosis. Furthermore, it is rarely possible to rule out an autistic disorder or mental retardation in severely malnourished infants younger than 1 year of age. DSM-III-R dropped the failure to thrive criterion and broadened the age of onset to within the first 5 years of life. DSM-III-R also introduced two subtypes of RAD—inhibited and disinhibited—and these were retained through the DSM-IV versions. DSM-IV criteria continued to highlight the etiologic link between RAD and "pathogenic care" at the hands of the young child's primary caregivers and excluded children whose symptoms might be due to cognitive delay or one of the pervasive developmental disorders.

With the publication of the DSM-5, the subtypes of RAD were defined as separate disorders: RAD and DSED. This separation more closely aligned DSM and ICD nosology. The ICD-10 included Reactive Attachment Disorder of Childhood (RAD), which is similar to RAD in the DSM-5, and Disinhibited Attachment Disorder of Childhood (DAD), which is similar to DSED in the DSM-5. ICD-11 instead mirrored the DSM-5 approach with the diagnoses of RAD and DSED, using similar criteria to the DSM.

A significant body of research examining RAD and DSED criteria has affirmed that they can be reliably identified in high-risk children, and the diagnoses are rare in clinical samples, absent histories of severe neglect. Research also indicates that children with RAD respond to improvements in the caregiving environment. For example, in a prospective randomized controlled trial of foster care as an alternative to institutional care in Romania (BEIP), children with

Telegram: @medical_k

www.konkur.in

RAD randomized to foster families demonstrated a reduction in symptomatology within months of placement, with symptom levels decreasing to levels in a community sample of never-institutionalized children. In contrast, children with DSED randomized to foster care continued to exhibit behaviors consistent with the diagnosis after family placement, typically exhibiting a reduction but not an elimination of their signs of DSED. Consistent with this, postplacement studies of Romanian children adopted from institutions by English families (ERA) show that these children do not continue to manifest RAD but do demonstrate persistent signs of DSED. That signs of RAD, which reflects a lack of attachment, diminished when children had the opportunity to form an attachment to foster or adoptive parents, and that signs of DSED may persist in a minority of children even after they form attachments to foster or adoptive parents suggests that the core deficit in DSED may not be the lack of an attachment relationship.

ETIOLOGY

Although research has established that the risk of RAD and DSED increases in the context of grossly neglectful care, the degree of neglect that is necessary for the disorders to emerge is not clear. In fact, even in environments characterized by severe deprivation, most children do not develop signs of RAD or DSED. Of note, however, relatively few children who experience extended institutional care emerge without symptoms of psychopathology. (Only 15% of children who were adopted after at least 6 months of institutional care in Romania did not meet the diagnostic threshold for any disorder at any point through their mid-20s.) More research on vulnerability factors and the critical elements of neglectful care responsible for RAD, DSED, and other disorders is needed.

The longer children live in conditions of deprivation, the more likely they are to develop an attachment disorder. Additionally, for children removed from institutional care, the number of caregiving disruptions or changes is associated with the persistence of RAD up to age 12. A critical age of vulnerability to the disorder may exist, as research has

Telegram: @medical_k

www.konkur.in

found attachment disorders to be very rare in children adopted before 6 months of age, and signs of DSED have not been reported in children whose deprivation began only after age 2. Children with lower IQs and stunted growth may also have attachment disorders because deprivation compromises both IQ and growth; hence, it is difficult to know whether these problems precede, co-occur, or are merely additional consequences of deprivation. Studies are beginning to identify possible genetic polymorphisms as risk factors for attachment disorders.

Preliminary research suggests that children who have experienced serious deprivation may show differences in brain structure and functioning compared to nondeprived children, and many of these children may show signs of attachment disorders. For example, researchers have found reductions in gray and white matter volumes and reduced electrical activity in higher frequencies, and increased electrical activities in lower frequencies in children who have experienced institutional deprivation. Importantly, reduced white matter volume mediated the effect of institutional rearing on electroencephalogram (EEG) alpha power, meaning that reductions in myelinated circuitry likely account for the reduced EEG power. If children were placed with families before 24 months of age, the differences in electrical activity between deprived and nondeprived children were no longer seen at 8 years of age. These findings have been demonstrated in children with histories of institutional deprivation and are not specific to those with attachment disorders, however. At age 16, the institutionalized children not randomized to foster care had higher relative theta and lower relative alpha power on EEG, a pattern characterized as immature, compared to those who experienced foster care. The brain activity of the fostered children did not differ from that of a community comparison group. Of note, however, the number of placement disruptions (but not the age of placement) among the fostered group was associated with adverse changes in brain activity.

Difficulties with inhibitory control also have been shown in children with indiscriminate social behaviors, implicating ventral frontostriatal circuitry, though findings are not consistent across studies. Children

Telegram: @medical_k

www.konkur.in

adopted from institutions also showed reduced amygdala discrimination between mothers and strangers on functional magnetic resonance imaging (fMRI), and these reductions were moderately associated with the children showing indiscriminate behaviors. Thus, preliminary research is demonstrating that early deprivation has an impact on brain development, although this relationship has been shown primarily in children with behaviors consistent with a diagnosis of DSED and requires replication.

Studies employing a variety of magnetic resonance imaging (MRI) techniques have variously associated RAD with decreased volume in the left visual cortex and differences in the corpus callosum and projections in thalamic pathways. These studies, however, have been conducted with children diagnosed in the community as early adolescents and may be compromised by diagnostic imprecision.

Recent research suggests that institutional rearing increases the risk of lower executive functioning, externalizing, and “p” (a latent measure of risk for general pathology) at age 12; each measure is further associated with the risk of general pathology at age 16, suggesting that lower executive functioning contributes to challenges over time.

Although research on what causes caregivers to be neglectful is limited, caregiver characteristics, from severe personality disturbance to psychopathology, appear to be important. Research using registry data exploring risk factors for the development of RAD among children who did not experience early institutional placement suggests that prenatal maternal smoking, advanced paternal age, maternal or paternal psychiatric disorder, and single motherhood all increase the risk of the RAD diagnosis. Parental intellectual disability and difficulty meeting a baby’s basic needs, particularly in the context of limited social support, may also increase the risk of neglect, though neglect sufficiently severe to contribute to RAD and DSED is rare, even in families with these challenges. Infants who are cared for by multiple caregivers in succession, as sometimes happens in the foster care system in the United States, are also at increased risk of attachment disorders. The traumatic experience of prolonged separation from a caregiver in early childhood, as documented by

Telegram: @medical_k

www.konkur.in

Spitz, the Robertsons, and Bowlby, is enough to cause attachment disturbance (as distinct from RAD and DSED). Repeated, prolonged separations typically cause more severe symptoms, and when these separations are accompanied by neglect, DSED and RAD appear to be more likely.

EPIDEMIOLOGY

Very little data exist on the prevalence of either RAD or DSED in the general population. RAD is rarely diagnosed in children with adequate caregiving environments and requires but does not necessarily follow a history of severe deprivation. DSED appears to be more prevalent, though it also is diagnosed only in a small minority of children who experienced inadequate caregiving.

Among high-risk groups diagnosed retrospectively, such as adolescents in tertiary therapeutic treatment settings, prevalence estimates for RAD and DSED each approach 10%.

DIAGNOSIS AND CLINICAL FEATURES

The diagnosis of RAD or DSED requires that a child have a developmental age of at least 9 months (the cognitive level at which attachment formation is possible) and have experienced a high level of insufficient care, which is presumed causative of each disorder.

RAD is characterized by both inhibition of positive emotional and social engagement *and* the lack of selective or discriminating attachment behaviors directed at an adult caregiver. At times when young children should be motivated to seek closeness or comfort for distress or protection from danger, children with RAD do not seek or readily respond to adults' efforts to comfort, reassure or protect them. Instead, the children may appear withdrawn and unresponsive or may show distress with no anticipation of comfort. Emotion regulation abnormalities include reduced or absent expression of positive emotions and unexplained displays of irritability, sadness, or anxiety. Among children with the requisite history of severe neglect, operationalized as social neglect/deprivation, repeated changes of

Telegram: @medical_k

www.konkur.in

primary caregivers that limit opportunities to form stable attachments (e.g., frequent changes in foster care), and/or rearing in group settings that severely limit opportunities to form selective attachments (e.g., institutions with high child-to-caregiver ratios), signs of RAD typically recede within weeks of placement in an adequate caregiving environment. Occasionally, symptoms of RAD persist following placement. Symptom persistence often marks continuing de facto neglect. The de facto neglect occurs because the child's withdrawn and negative behavior is off-putting to adult caregivers. The caregivers fail to override their natural responses to the child's behavior, which obscures the child's needs and avoids interactions.

For diagnosis of RAD, a child must first exhibit symptoms before age 5 and not meet the criteria for autism spectrum disorder (ASD).

DSED is characterized by a lack of stranger wariness, which ordinarily becomes apparent between 7 and 9 months of age. The disinhibition in DSED is social, leading to behaviors in which a child actively approaches and interacts with unfamiliar adults. Although sometimes referred to as indiscriminate friendliness, the behavior is often experienced as intrusive and may include overly familiar verbal or physical behavior that goes beyond culturally sanctioned and age-appropriate social boundaries. Children with DSED often fail to track their caregiver's whereabouts, even in unfamiliar settings, and may even be willing to go off with an unfamiliar adult without hesitation. DSED criteria stipulate that the disordered behaviors include socially disinhibited behaviors beyond the behavioral impulsivity that occurs in attention-deficit/hyperactivity disorder (ADHD; ADHD may co-occur).

Diagnosis of RAD or DSED requires a multisession evaluation, particularly when the child's history does not include multiple placements and the caregiver's behavior has not previously been identified as abusive or neglectful. Ascertaining whether the child's behavior is less atypical in the presence of the clinician or another trusted adult is important to differential diagnosis and may take time. This comparison may be especially helpful in distinguishing highly social children, for example, from those with DSED or somewhat behaviorally inhibited children from those with RAD. The child's relationship with the primary caregiver can be adequately assessed

Telegram: @medical_k

www.konkur.in

with a combination of a careful history and observations of interactions during free play, structured tasks (that stress the dyad), and a brief separation and reunion. Videotaping the assessment is a useful way to document social responses, and the introduction of a clinically trained person whom neither partner has met is often informative. Children who meet the criteria for this disorder may look quite different, depending on their developmental stage.

An 11-month-old girl was recently placed in foster care. Foster care placement occurred after police, who were called to the home during an episode of violence, found squalid conditions, including narcotic pain pills strewn on the floor. Her parents both had chronic and serious histories of substance use disorders, violence in their relationship, and grossly inadequate care of the child and her older siblings. The girl, with her biologic and foster families, was referred for clinical services by state child protective services to assist with long-term case management.

The foster mother reported that the child looked frightened much of the time, cried sporadically and was not soothed by her, and did not respond to social overture when she first arrived in the foster home. For the initial 2 weeks of placement, the child exhibited little interest in exploring and mostly rocked quietly by herself. The girl's appetite increased over the first few days, and she began to stuff herself to the point that the foster mother, at the direction of the child's pediatrician, limited the food offered at meals and snacks. The foster mother reported it was weeks before the girl smiled. This behavioral pattern was suggestive of RAD.

The clinicians encouraged the foster mother to interact with the child despite the girl's lack of interest and to respond to the girl's distress as if the girl had requested it in order to teach her that she could be comforted when distressed. Gradually, the girl seemed to relax more and began to smile—at first fleetingly but then more frequently, to accept comfort for distress and then to seek comfort for her distress. By one month following placement, the foster mother reported the child seemed to be showing attachment behaviors toward her. The foster mother also described feeling closer to the girl, whom the foster mother had found hard to connect with initially. After this point, the ravenous behavior slowly dissipated. The girl became somewhat clingy with her foster mother and was quick to show distress to even minor changes in routine. Her affect brightened, and she came to demonstrate better emotion regulation.

www.konkur.in

A 45-month-old boy was referred for services by his adoptive parents because of hyperactivity and disruptive behavior at school. He had joined his parents at 30 months, after living most of his life in a Romanian orphanage, where a rotating staff of caregivers provided his care. When he arrived at his new home, he was below the fifth percentile for height and weight; his growth accelerated, and he quickly approached the 10th percentile. Both his adoptive parents were frustrated by their inability to “reach him.” They had initially worried he might have a hearing impairment, but testing and his capacity to engage many adults and children verbally suggested otherwise. He approached and engaged socially with complete strangers and, more than once, had followed strangers willingly. Teachers liked him; they also found him attention-seeking and sometimes disruptive. At times, teachers experienced him as appealing, even charming, but at other times, they characterized his feelings as shallow. He was injured frequently due to seemingly reckless behavior and had an extremely high pain tolerance. He was diagnosed with DSED. The intensive intervention focused on decreasing his self-endangering behavior, enhancing his ability to read emotional expressions and describe social situations, and rewarding him for culturally appropriate social hesitance. With several months of treatment, his reckless behaviors decreased, and his ability to read and describe social situations improved. His tendency to engage with unfamiliar adults persisted at a reduced and more manageable level.

DIFFERENTIAL DIAGNOSIS

Since RAD and DSED differ in clinical presentation, various diagnoses must be evaluated in the differential diagnosis of each. For RAD: ASD, and depressive disorders require evaluation; for DSED: ADHD. Additionally, a child’s intellectual ability must be considered; classifying some behaviors as atypical occurs in relation to a child’s developmental level.

Telegram: @medical_k

www.konkur.in

Depressive Disorders

Children with RAD, and those with depression, both show reduced or absent positive affect and social withdrawal. In a longitudinal study of current or previously institutionalized young children, there was a moderate-to-high association between RAD and signs of depression, but the majority of children who were diagnosed with a depressive disorder did not meet the criteria for RAD. In general, children with depression turn to caregivers for comfort and show behaviors that are indicative of an attachment. The neurovegetative signs of depression and the excessive guilt associated with depression are not characteristic of RAD. Only if a child with depression has a history of significant social neglect and does not seek comfort should the diagnosis of RAD be considered.

Autism Spectrum Disorder

The differential diagnosis of RAD and ASD may be challenging in some cases because quasi-autistic behaviors have been noted in formerly institutionalized, adopted children. Of note, however, the course of quasi-autism varies from that of ASD in that at least partial remission may occur after several years of familial placement.

Children with both ASD and RAD show impaired social behaviors, especially social withdrawal, and minimal reciprocity. However, children with ASD typically also show atypical language development; the language skills of children with RAD may be delayed but are not stereotyped or otherwise deviant. Additionally, children with ASD exhibit restricted and repetitive behaviors; these are not found in children with RAD. Finally, children with ASD demonstrate attachment behaviors with caregivers some of the time and very rarely have the history of social neglect or maltreatment required for the diagnosis of RAD.

Attention-Deficit/Hyperactivity Disorder

Deprivation is known to increase the risk both of inattentive and hyperactive behaviors and of DSED. Children with DSED can also meet the criteria for ADHD, requiring careful assessment of ADHD as

Telegram: @medical_k

www.konkur.in

an alternative diagnosis as well as a potential comorbid condition. Young children who are hyperactive and impulsive may appear socially disinhibited. The social disinhibition of DSED, however, is not necessarily accompanied by inattention or hyperactivity.

Intellectual Disability (Intellectual Developmental Disorder)

The adverse caregiving environment necessary for the manifestation of RAD or DSED may include environmental deprivation associated with developmental delays. However, in longitudinal studies of children from institutions, RAD and DSED were only moderately associated with cognitive delays. In terms of differential diagnosis, children with intellectual disability typically demonstrate social and emotional development that is relatively consistent with their cognitive functioning. Further, it is well established that children with intellectual disability are capable of forming stable attachments as long as their developmental ages are greater than 9 months.

COURSE AND PROGNOSIS

Research addressing the natural course of RAD and DSED diagnoses and symptomatology is limited but increasing.

Among children in institutions, RAD appears relatively stable; young children who met the criteria for RAD at one point in time continued to show the behaviors at other times. Children who are placed into families typically do not show significant signs of RAD over time, which suggests that a stable caregiving environment ameliorates symptoms of the disorder. In the Bucharest study, symptoms of RAD at age 12 were associated with poorer social functioning. Data from the same study, utilizing variable and person center models, identified four patterns of RAD symptomatology through age 12: children who never evidence symptoms, children who evidence an early and swift decrease in symptoms, children who demonstrate persistent and low-level symptoms, and children who, although demonstrating an initial drop in symptoms, maintain a relatively higher level across time. As one might expect, the persistently high group was primarily populated with children who

Telegram: @medical_k

www.konkur.in

were not placed with foster families; they also spent significantly more time in institutions and experienced a greater number of placement disruptions. Diagnosis of RAD was associated with internalizing and externalizing symptoms and symptoms of ADHD.

Studies of young children diagnosed with DSED suggest that the diagnosis is moderately stable from year to year. Studies that have followed children into later childhood find that those with over-friendly and attention-seeking behaviors at the age of 4 tend to continue to show these behaviors at the age of eight. At age 12, symptoms of DSED were associated with lower social competence and with the caregiver's viewing the child as a victim (e.g., of bullying, relational victimization, rejection). At the age of 16, these children demonstrated superficial and conflicted relationships with peers. In adulthood, DSED symptoms may persist, with an indication that the level of these symptoms does not interfere with overall adaptation.

As only a fraction of institutionalized children are diagnosed with RAD or DESD, and most symptoms decrease, studies of long-term outcomes frequently characterize outcomes by comparing groups based on length of institutionalization before adoption and/or type of placement following initial institutionalization. Children with shorter-term institutionalized care or foster care placement resemble comparison groups (in-county adoptees or never placed children) on most measures at most ages. In the ERA study, young adults (ages 22 to 25) with longer institutional care prior to adoption had lower educational achievement, higher unemployment, and greater mental health service use in early adulthood. Group differences include increasing levels of self-reported emotional symptoms from the cusp of adolescence through adulthood; the difference in self-reported psychopathology emerged 20 years postplacement. Additionally, longer institutional care is associated with high rates of ADHD (as well as ASD and callous-unemotional traits).

Studies of adolescents in residential placement, diagnosed retrospectively with RAD or DSED, suggest those diagnosed with DSED may differ from the general population, from other adolescents in placement, and from those with RAD in aspects of self-esteem;

Telegram: @medical_k

www.konkur.in

however, the findings require follow-up and may be compromised by diagnostic imprecision.

In sum, the expanding research corpus highlights the many persistent risks associated with all but very short-term institutionalized care to the children who experience it. Only a fifth of the Romanian adoptees who spent 6 months or more in institutions scored in the typical range across assessments of psychopathy over a 20 period. Simultaneously, research also clearly documents the potent effect of devoted care and raises hope that appropriate intervention can ameliorate symptoms, mitigate long-term risk and improve adult functioning.

TREATMENT

The first step in the diagnostic evaluation of and treatment planning for children exposed to grossly inadequate care is assessing and securing the child's safety. Child maltreatment is associated with significant morbidity, and mortality is not uncommon, particularly in children younger than 48 months of age. Children may not have had appropriate medical care, and medical referral is usually indicated. Child protective services involvement may be warranted, and assessment of parental fitness may be a necessary part of the child's evaluation. In some cases, the placement of the child may be necessary. Unfortunately, the foster care system and the family court system sometimes lead to multiple placements in the first years of life, thus further increasing the risk of RAD, DSED. The clinician may play a crucial role in staying involved with the child who is placed in foster care, providing expert testimony in court and individual or family treatment.

Once the child's safety is established, full attention can be paid to the diagnosis and psychosocial intervention, which must be tailored to the child and living situation. For children who exhibit RAD and DSED, providing and supporting a primary attachment figure is the goal. Caregivers who foster secure attachments in infants and young children are those who are sensitively responsive, value the child as an individual, and place the needs of the child ahead of their own.

Telegram: @medical_k

www.konkur.in

Caregivers with such characteristics are well-suited to assist children who have experienced severe early social deprivation.

In general, research following children with RAD suggests that the symptoms of the disorder resolve with placement in a family that can provide a positive caregiving environment. This research additionally finds that these children may continue to show insecure or disorganized attachments in the Strange Situation Paradigm, suggesting that treatment to improve attachments with foster or adoptive caregivers is important.

For children who exhibit the high levels of indiscriminate behavior seen in DSED, the clinical consensus is to advise adoptive or foster parents who are establishing attachment with the child to limit the child's unnecessary contact with adults outside the family for several months, if possible. The rationale is that children need time to consolidate attachment relationships within their family before they experience other relationships. Although this approach has face validity, it has not been evaluated formally. Research finds that some children diagnosed with DSED continue to show indiscriminate behavior, even after being placed in enhanced caregiving environments and forming secure attachments, an indication that more than enhanced caregiving may be necessary to reduce the signs of DSED significantly. It is important to note that the quality of caregiving for children with DSED is associated with the rate of decline of symptoms, even when they do not fully resolve. It has been suggested that intervention to target social cognitive abnormalities that may underlie the indiscriminate social behaviors shown in DSED would be a possible way to improve these behaviors, but research is needed in this area.

Additional interventions should be formulated to reduce child or adult (caregiver) barriers to attachment. Child barriers include behaviors that provide miscues about their needs, including aggressive and oppositional behavior, emotional dysregulation, and withdrawn behavior. Adult barriers include distractions from the newly developing relationship, such as here-and-now crises, their own problematic relationship histories—including unresolved losses and trauma—and lack of psychological commitment to the child.

Telegram: @medical_k

www.konkur.in

Attachment-specific treatments often focus on the adult–child dyad and include the Circle of Security, which weaves together psychoeducation with psychotherapy, and Attachment and Biobehavioral Catch-Up, which is manualized and more prescriptive about which behaviors are coached. Both treatments rely heavily on a review of videotaped parent–child interactions. Other interventions that involve caregiver–child dyadic therapy include child–parent psychotherapy. These approaches typically combine developmental training and guidance with an active attempt to address pressing instrumental issues (e.g., poor housing and inadequate medical care). The complexity of these treatment approaches reflects the complexity of the clinical problem. Long-term interventions are often necessary; family and individual treatment are bolstered by other early intervention programs and ongoing medical care.

CONCLUDING THOUGHTS

In the 40 years since the addition of attachment disorders (as they were originally labeled) to the diagnostic canon, a great deal has been learned about the sequelae of profound deprivation in some children. The diagnoses RAD and DSED have been delineated, instruments and methods of assessment developed and validated, and evidence-informed treatments created. Longitudinal research, including a randomized controlled trial, indicates that placement with caring adults after deprivation effectively lessens or dissipates children's symptoms of RAD and, to a lesser degree, of DSED. Emerging longitudinal data suggest that patterns and sequelae of these disorders may persist into young adulthood. Additionally, emerging work suggests RAD and DSED may be associated with structural and functional differences in the brain. Much remains to be learned.

Forty years of research continue to indicate that RAD and DSED are rare disorders and that they may be overdiagnosed in community settings when established diagnostic assessment instruments and procedures are not embraced and employed. The challenge in future research is to bridge, differentiate, generalize, and/or extend, as

Telegram: @medical_k

www.konkur.in

appropriate, findings from rigorous research on RAD and DSED to work on the broader topic of child abuse and neglect, as clinicians are eager for guidance.

49.2 Stereotypic Movement Disorders in Children

ROBERT LLOYD DOYLE, M.A., D.D.S., M.D.

Stereotypic movements are defined as repetitive, sometimes rhythmic, seemingly volitional, but purposeless movements. They encompass a wide range of behaviors, including the tapping of hands or feet and nail biting, and may occur in typically developing children or those with developmental disorders such as spinning behaviors often seen in children with autism spectrum disorders. A stereotype can be as benign as eye blinking or can be quite dangerous, as in the case of intense head banging resulting in traumatic brain injury. However, the term “stereotypy” may be applied to many types of behaviors, including normal repetitive behaviors of infancy, abnormal repetitive behaviors in autistic individuals, dyskinesias caused by psychotropic medications, and symbolic gestures associated with schizophrenia, to name a few, this section focuses on stereotypic movement disorders of childhood as described in the text revision of the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5-TR) and the eleventh edition of the *International Classification of Diseases and Related Health Problems* (ICD-11).

HISTORY

Telegram: @medical_k

www.konkur.in

The first mention of purposeless, repetitive behaviors in the clinical literature dates back 300 years to Nehemiah Grew, who wrote, “We see also Mad people … run upon some one action … without variation.” Possibly the first description of a dopamine-driven stereotypy should be attributed to Samuel Gee, who conducted an experiment in which he injected a large dose of apomorphine into a dog. A few minutes after the animal vomited, it began to pace around the room in a “curiously persistent methodical manner.” In the early 1900s, Emil Kraepelin linked stereotypic behaviors to dementia praecox. Of note, Kraepelin’s careful observations of stereotypic behaviors were made before the development of antipsychotic medications, and so the behaviors were likely related to a pathologic brain state rather than to medication-induced dyskinesia. Several seminal papers published in the 1940s set the stage for the following 50 years of research on the subject.

Landmark research on stereotypic behaviors began with Lauretta Bender and Paul Schilder in the early 1940s. Their contribution differentiated impulsions from obsessions and compulsions based on the premise that impulsions were associated with positive affect, whereas obsessions were notably negative. They also speculated that impulsions could have connections to the primitive motor stereotypic behaviors of infancy and that impulsions might become obsessions and compulsions in adolescence. In 1949, Reginald S. Lourie theorized that the feedback from infantile rhythmic behaviors fostered normal motor development. For instance, infants will assume the four-point crawling position on hands and knees, then rock front to back as if rehearsing the more complex coordinated movement in which only the arm and leg on one side of the body moves forward to provide locomotion. This simple repetitive rocking in place could serve as the basis for a repertoire of more-coordinated movements needed to crawl. Thus, according to this theory, repetitive behaviors occur in a normally developing child, but these recede as the child masters more complex, functional behaviors. These behaviors become stereotyped if they persist beyond the developmental purpose they serve, as seen in persons who are blind or have autism or intellectual disabilities,

Telegram: @medical_k

www.konkur.in

ETIOLOGY

Several theories have been proposed to explain the emergence and maintenance of stereotypic behaviors. As just described, stereotypic movements may be the precursor to mastery of more sophisticated motor tasks. This path toward more complex motor behaviors may veer in a pathologic direction based on the interplay among abnormal development, behavioral reinforcement, and psychological conflict. In Down syndrome, for instance, stereotypic behaviors are similar to those seen in children without a diagnosis of mental retardation but differ in that in Down syndrome, they appear at a later-than-expected chronologic age and do not disappear. Therefore, developmental factors could contribute to the manifestation of stereotypic behaviors.

Behavioral factors might maintain the stereotypic behavior through positive or negative reinforcement. Careful behavioral analysis can identify social reinforcers and then aim to eliminate them. From a psychodynamic standpoint, stereotypies are considered instinctual, autoerotic, and self-soothing or gratifying behaviors. The psychodynamic factor implies that a stereotypic behavior, such as nail biting, might be a reaction to intense feelings about one or more conflicts. Biologically based theories have replaced most psychodynamic formulations explaining stereotypic behaviors.

Early observations in animals and humans indicated that environmental factors might modify the expression of stereotypic behaviors. For example, R. J. Gallagher and Gershon Berkson showed that even short periods of normal social interaction reduced the expression of stereotypic behaviors in institutionalized infants with profound intellectual disabilities. Most studies show that substituting alternative activities for stereotypic behaviors effectively reduces their expression.

Even though enriched environments usually diminish stereotypic behaviors they do not eliminate them. The predictable persistence of stereotyped behaviors in childhood autism and other conditions, despite environmental enhancement, indicates that organic factors might play a role. One organic theory proposes that endogenous opioid compounds are released in persons with autism as they

Telegram: @medical_k

www.konkur.in

engage in stereotypic behaviors. The pleasurable *effect* of the endorphin *release* could reinforce the repetitive maladaptive behaviors. Although studies using the opioid antagonists naloxone (Narcan) and naltrexone (Trexan) resulted in modest improvements in stereotypic behaviors, these have not been a definitive cure for stereotypic behaviors in individuals with autism. Therefore, an organic-based explanation is not entirely satisfactory either. Perhaps an interplay between experiential effects on the brain and physiologic processes within the brain might best account for stereotypic behaviors. Bender and Schilder theorized that a common connection must tie all sorts of stereotypy together; however, studies fail to support the existence of an encompassing stereotypic factor.

Nevertheless, research has pointed to several factors that might act independently or in concert to bring about the expression of a stereotypic movement. These include genetic factors, as seen in nail biting and Lesch–Nyhan syndrome, and neurobiologic factors, as evidenced by the many compounds that can precipitate stereotypic or self-injurious behaviors (SIBs). For example, dopamine supersensitivity due to chronically low levels of dopamine has been described in animal models of SIBs. Of interest, postmortem tissue from patients with Lesch–Nyhan syndrome appears to be dopamine deficient as well. Furthermore, dopamine antagonists have successfully treated nonsyndromal SIBs and at least one case of Lesch–Nyhan syndrome. Dopamine has also been implicated in the emergence or exacerbation of certain repetitive behaviors related to stimulant use. Psychostimulants work by blocking the reuptake of dopamine, thereby causing a relative increase in the availability of dopamine in the synaptic cleft. Stimulant-induced repetitive behaviors include bruxism, skin picking, lip biting, compulsions, nail biting, perseveration, tics, and various other stereotypes. Other neurotransmitters, such as serotonin, opioids, and γ-aminobutyric acid, may be involved as well.

EPIDEMIOLOGY

Telegram: @medical_k

www.konkur.in

Many stereotypic behaviors emerge in early childhood and are considered part of normal development. These rhythmic, repetitive behaviors appear and progress in a cephalocaudal direction and can be correlated with chronologic age. An estimated 80% of normal children display rhythmic activities that disappear by the age of 4 years. Although determining the prevalence rate in the general population is difficult, studies estimate that some 3% to 15% of children without disabilities engage in head banging. About 20% of children exhibit repetitive body rocking. If these behaviors continue beyond the normal developmental age range for such behaviors, they might evolve into a stereotypic movement disorder. Consider thumb sucking. Endearing in infants, thumb sucking easily becomes a reason for teasing in the school-age child. In an extreme case, an adolescent boy with profound developmental and intellectual disabilities sucked his thumb until a large portion of soft tissue eroded away and exposed the underlying bone. Although rarely to such a degree, finger, and thumb sucking occurs more often in girls than boys and more in whites than in African Americans.

Bruxism—the habitual grinding of teeth—occurs in approximately 56% of normally developing infants. Even if chrome bruxism wears down enamel, this rarely results in long-term problems in young children because deciduous teeth will be replaced by the permanent dentition. Bruxism in adolescents and adults can cause major dental pathology ranging from periodontal disease to temporomandibular joint dysfunction.

Telegram: @medical_k

www.konkur.in

Sean was a burly but affable dental student with severe bruxism. He had no personal or family history of psychiatric illness. He was the eldest child of a large, upper–socioeconomic status family. Sean had always maintained a respectable grade point average, and he continued to do so in dental school. By age 23 years, Sean had worn the cusps of his posterior teeth completely away due to his chronic bruxism, which began in childhood. Although bruxism is often caused by malocclusion between maxillary and mandibular dentitions, this could not explain his persistent problem. Sean's posterior teeth had been worn down to flat occlusal surfaces without any cusps to cause interferences in his bite. His case was so impressive that his professors requested permission to take photographs and make models of his teeth to teach future generations of dental students. Ironically, his bruxism worsened as the stress of dental school caused him to chronically clench his teeth together. His dental health was compromised by broad areas of exposed dentin in places once covered by enamel. Sean was at risk of losing his molar teeth, as well as developing painful temporomandibular joint dysfunction.

The treatment took a multimodal approach. Sean was advised to monitor himself for clenching and grinding during the day. Whenever he became aware of these behaviors, he was instructed to simply separate his upper and lower teeth. To prevent neuromuscular programming, his dentist recommended that he stop chewing gum. These interventions helped during the day; however, nocturnal bruxing continued. Sean was not aware of grinding his teeth in his sleep, but he did notice tenderness around his jaw in the morning. On exam, his dentist noted crepitus—the sound of bone rubbing against bone—with mandibular movement. Because crepitus is a sentinel sign of temporomandibular joint dysfunction, the dentist fitted Sean with a custom night guard that served two purposes: it prevented further eroding of enamel, and it curtailed the chronic temporomandibular joint inflammation. Sean also took ibuprofen to relieve inflammation and pain. His dentist offered a prescription for

Telegram: @medical_k

www.konkur.in

clonazepam (Klonopin) to help hint deal with the pressures of his professional education. Sean, however, did not want to become addicted to a benzodiazepine, so he chose to try other measures first. Buspirone (BuSpar) was also offered as an option because of its reduced abuse potential. Fortunately, his dental condition stabilized fairly quickly, and he set his sights on having his left tooth structure restored with ceramic crowns.

Nail biting occurs quite commonly in childhood and frequently continues into adulthood. Occasionally, nail biting progresses to the point of causing dermatologic or even dental problems. It does not seem to be associated with the child's age, level of intelligence, or socioeconomic status, but nail biting seems to have a familial basis. Toenail biting, however, does appear to be much more prevalent in girls. An estimated 50% of children exhibit nail biting. It can be seen as early as 4 years of age, with peak prevalence between ages 10 and 18 years. According to one study, 4.5% of adults continue to bite their nails. Adults with onychophagia may not have comorbid psychiatric illness, and children with nail biting do not appear to be more anxious than peers who do not bite their nails. In most adult cases, nail biting seems to cause distress rather than result from stress.

As mentioned earlier, genetics seems to play a factor in the expression of some stereotypic behaviors. In twin studies, children born to parents who were nail biters were nearly three times as likely to be nail biters as control subjects. The concordance rate for monozygotic twins was 66% versus 34% in dizygotic twins. Onychophagia is the most severe type of nail biting. Monozygotic twins with onychophagia had a 75% concordance rate, whereas dizygotic twins only had an 18% concordance.

Of interest, stereotyped behaviors often occur in blind children. Elise Fazzi and others studied a group of congenitally blind children. In their group of 11 boys and 15 girls with and without developmental disabilities, 73% showed stereotypic behaviors. The most frequently encountered stereotypic behaviors were body rocking (30.7%),

Telegram: @medical_k

www.konkur.in

repetitive handling of objects (30.7%), and eye pressing along with eye poking (30.7%). These researchers also found that the stereotypic behaviors could be decreased by encouraging appropriate adaptive behaviors and increased by restricting the environment, reducing sensory stimulation, and limiting mobility.

Stereotypic behaviors are more common among children with a history of parental neglect, but they may be present in children who do not have emotional problems. An estimated 20% of individuals with severe intellectual disabilities exhibit stereotypic behaviors. Alfred A. Baumeister and Rex L. Forehand found that two-thirds of a population institutionalized with intellectual disabilities exhibited stereotyped behaviors, and J. R. Dura and colleagues later reported that 34% of nonambulatory individuals with profound retardation who were institutionalized exhibited at least one stereotypic behavior. Despite the need for longitudinal studies, evidence from cross-sectional studies suggests that developmental age and experiential history, rather than chronologic age, are the relevant mediating variables for stereotypic movements. Stereotypic movements frequently peak in adolescence and then diminish thereafter.

The prevalence of SIBs varies from between 2% and 3% for children and adolescents in the community to about 10% to 15% for adults with severe or profound intellectual delays living in residential facilities. In individuals with severe intellectual disabilities living in institutions, stereotyped movements increase with chronologic age; however, the opposite is true of children without disabilities. In individuals with intellectual disabilities, the most common stereotypic movements are body rocking, head rolling, repetitive hand movements, self-hitting, head banging, and self-biting. The prevalence of head banging ranges between 3% and 15% in normally developing children. Approximately three times as many boys as girls exhibit the behavior. Head banging usually emerges between 5 and 11 months of age, but only 5% of these cases persist beyond 3 years of age.

Per the DSM-5, stereotypic movements may occur with or without SIBs. A study by Gal and colleagues monitored SIB and stereotypy in typically developing children as well as those who were intellectually

Telegram: @medical_k

www.konkur.in

impaired, visually impaired, hearing-impaired, or autistic. In this sample of 90 subjects with at least one SIB, only 3 did not exhibit a co-occurring stereotypy. Interestingly, the rank order of prevalence of SIB and stereotypy was same across all five groups.

Given that the strongest predictor for the presence antiseverity of SIB was other repetitive behavior, an earlier model proposed by Guess and Carr in which SIB was thought to evolve from stereotyped movements makes some sense. SIBS, such as head banging, and stereotypy occur in typically developing children, but the SIB emerges later in development than stereotypy. In individuals with intellectual disabilities, SIB and repetitive behaviors appear temporally related; however, stereotypic behaviors still precede SIB.

Of note, Cornelia de Lange syndrome (mutations including the NIPBL gene in region 5p13, SMC1L1 in the Xp11.2 region, SMC3 gene in region 10q125), Fragile X syndrome (mutation at Xq127.3), Smith–Magenis (3.7 Mb interstitial deletion in chromosome 17p11.2), Cri-du-Chat syndrome (deletion in chromosome 5p15), and Rett syndrome (mutation in the methyl CpG—binding protein 2) are genetic disorders that present with various forms of stereotypic movements and SIB. Since these genetic defects are quite diverse, yet each gives rise to stereotypies with and without self-injury in the same individual, finding treatments for stereotypic behaviors remains a challenge.

Nevertheless, theories for stereotypic movements abound, and research continues to reveal new information regarding the etiology of these behaviors. An array of new research techniques will allow genetic information to be linked with neuroimaging results and facilitate understanding of the phenotypic expression of stereotypic behaviors.

NOSOLOGY

In many cases, the origin of stereotypic movements seems contextual to certain psychiatric illnesses or medical conditions in which they occur. The evolution of the DSM has tried to reflect such insights in its various iterations. Recent versions of the DSM had reserved the

Telegram: @medical_k

www.konkur.in

diagnosis of stereotypic movement disorder for cases in which the stereotypic behavior is not a core symptom of another psychiatric disorder or the expected manifestation of a medical condition. Therefore, the repetitive facial movements due to either prolonged neuroleptic use or rapid discontinuation of this class of medication would be described as stereotypic movements, but these would not have met DSM-IV-TR criteria for stereotypic movement disorder. Although this continues to be the case in DSM-5, the current criteria require the clinician to specify whether stereotypic movement is associated with a known medical or genetic condition, neurodevelopmental disorder, or environmental factor. For instance, a person with Down syndrome and stereotypic movements would be coded as (307.3) stereotypic movement disorder associated with Down syndrome. In the case of autism spectrum disorder, a comorbid diagnosis of stereotypic movement disorder should be made whenever the stereotypic behaviors cause injury or appear sufficiently severe to become a focus of treatment.

Also, the DSM-5 has placed more emphasis on culture-related issues. Although stereotypic movements, with or without self-injury, manifest in all races and cultures, the attitudes of a particular culture may delay diagnosis. Clinicians need to be aware of cultural context and remain sensitive as they explain the diagnosis to patients and their families who come from a different country or culture. This will help patients accept and maintain appropriate treatment for the condition.

At first, the DSM criteria were somewhat broad. The DSM-III provided criteria for a diagnosis of atypical stereotypic movement disorder for conditions such as rocking, head banging, and repetitive hand movements characterized by quick, rhythmic hand rotations or tentative voluntary movements that usually involved the arms or fingers. The DSM-11 stipulated that such movements differed from tics in that they were voluntary but not spasmodic or distressing. In the DSM-III, atypical stereotypic behaviors were considered often to occur in patients with extreme psychosocial deprivation, intellectual disabilities, and pervasive developmental disorders; however, another mental disorder did not have to be present.

Telegram: @medical_k

www.konkur.in

In the revised version of the DSM-III (DSM-III-R), atypical stereotypic movement disorder was renamed stereotypy/habit disorder. The criteria for stereotypy/habit disorder became broader so that intentional, repetitive, nonfunctional behaviors such as nail biting, nose picking, skin picking, and object mouthing were included. The DSM-III-R also specified a severity criterion, which required the behavior to cause injury or markedly interfere with normal activities to be considered a clinically significant “disorder.” The severity criterion allowed clinicians to determine whether the stereotypic movement was part of normal development, as is often seen with transient nose picking or a more pathologic picture, in which chronic nose picking causes significant tissue trauma or social stigmatization. A stereotypy or habit described by DSM-III-R criteria could include more intense forms of normal motor patterns seen in childhood, or they might be associated with some type of psychiatric or organic pathology. An additional criterion, however, excluded the diagnosis if the patient met the criteria for pervasive developmental disorder or tic disorder. This exclusion criterion recognized and eliminated the redundancy of making the diagnosis of stereotypy/habit disorder in these disorders, which have repetitive behaviors as core symptoms.

Another name change occurred with the publication of the DSM-IV. In an effort to be compatible with the ICD-10, the DSM-IV renamed the disorder stereotypic movement disorder. Because the intentional nature of a stereotypic movement might be impossible to determine in certain cases—for example, individuals with severe intellectual disabilities with limited ability to communicate, the clinician is no longer obligated to prove that the movement was intentional. The DSM-IV also drew boundaries between stereotypic movement disorders and several other disorders, including pervasive developmental disorder, tic disorder, obsessive-compulsive disorder (OCD), trichotillomania, and intellectual disabilities. As in the DSM-III-R, the diagnosis is not made if the stereotypic behavior is attributable to pervasive developmental disorder or tic disorder. Given the similarity between tics and compulsions, the DSM-IV excluded stereotypic behaviors that were compulsions related to OCD. The DSM-IV also stipulated that the stereotypic behavior could not be due

Telegram: @medical_k

www.konkur.in

to the physiologic effects of a substance or a general medical condition. A diagnosis of stereotypic movement disorder would not be made for repetitive hair pulling if DSM-IV criteria for trichotillomania were met. In addition, a diagnosis of stereotypic movement disorder with SIB could be made in persons with intellectual disabilities if the SIB was significant enough to become a focus of therapy. Subsequent versions of the DSM—the DSM-IV-R and the DSM-IV-TR—used those criteria established by the DSM-IV.

In general, the DSM-IV-TR and DSM-5 as well as ICD-10 criteria for stereotypic movement disorder describe the diverse and unrelated stereotyped movements that are not part of any other recognized neurologic or psychiatric condition. According to the DSM-5, a stereotypic movement disorder is a repetitive, seemingly driven, and nonfunctional motor behavior. It lists hand shaking or waving, body rocking, head banging, mouthing of objects, self-biting, picking at skin or body orifices, and hitting one's body as examples. The DSM-5 definitions exclude behaviors with a clear purpose or adaptive function, but, as acknowledged in the DSM-IV-TR, the driving force behind a stereotyped movement may be difficult to determine in cases in which the person has limited ability to communicate internal states. What is more, a stereotypic behavior may provide a signal that an undiagnosed neurodevelopmental disorder exists, especially in children younger than 3 years of age.

The DSM-5 specifies that for a repetitive motor behavior to be considered a stereotypic movement disorder, it must interfere with social, academic, or other activities and may result in self-injury. In severe cases, the behavior can cause death, but even less severe cases might result in disabling or disfiguring impairments.

Telegram: @medical_k

www.konkur.in

Consider the case of Ruth, a middle-aged woman, who was admitted to the inpatient unit at a university-based teaching hospital due to unrelenting head scratching. Her outpatient psychiatrist had tried the full array of pharmacologic interventions, including combinations of anxiolytic, antidepressant, and antipsychotic medications, but the stereotypic scratching progressed to the point that she required surgical intervention. Ruth had scratched through her scalp and penetrated the skull, exposing the dura mater.

In Ruth's case, a complete DSM-5 diagnosis would be stereotypic movement disorder with self-injurious behavior, severe. Per the DSM-5, the diagnosis is specified as with or without SIB. Note, however, that the disorder should be specified as "with self-injurious behaviors," if injury would occur in cases where protective measures were not present to prevent injury. Ruth obviously displayed severe symptoms, given that continuous monitoring and protective measures were required to prevent serious injury. Moderate symptoms require protective measures and behavioral modification; whereas, mild symptoms can be easily suppressed with sensory stimulus or distraction. Clinicians should also specify whether the stereotypic movement is associated with a known medical or genetic condition, neurodevelopmental disorder, or environmental factor. An additional code identifying the associated medical/genetic condition or neurodevelopmental disorder aids in billing and communicating with third-party payers.

The ICD-10 diagnostic criteria for stereotypic movement disorders appear more succinct. Per the ICD-10, the stereotyped movements must either cause physical injury or markedly interfere with normal activities. The duration of symptoms lasts at least 1 month. In contrast to DSM-5, no other mental or behavioral disorder can be present, except for intellectual disabilities.

DIFFERENTIAL DIAGNOSIS

Telegram: @medical_k

www.konkur.in

The outward appearance of a complex tic or a compulsion may closely resemble stereotypic movements, and this may lead to diagnostic difficulties. James W. Bodfish, T. W. Crawford, and colleagues found high rates of stereotyped behavior in adults with comorbid mental retardation and compulsion disorder. Compared with a noncompulsive matched control group, their sample showed an increased prevalence of stereotypy (32%), an increased prevalence of self-injury (40%), and an increased prevalence of stereotypy plus self-injury (37%) in those with compulsive disorder. A review by J. L. Rappoport reported that 20% of patients with OCD also exhibit motor tics, which complicates the diagnosis further. Nevertheless, some simple caveats can help to sort out stereotypic movements from other repetitive movements:

Generally speaking, a stereotypic movement is a rhythmic, repetitive motor behavior. It usually is simpler than other forms of repetitive behaviors. Although a stereotypic behavior appears purposeless, it can also serve to alleviate anxiety or another aversive state. Tics ordinarily have an involuntary quality even though tics may be suppressed for limited periods of time and they are not rhythmic. Compulsions appear more complex and ritualized. A stereotypic movement differs from a complex tic and a repeating compulsion in that it is not performed as a preventative measure, nor is it motivated by a sense of incompletion. In addition, complex tics and compulsive behaviors typically are not rhythmic.

With regard to autism, a study by Fiona Zandt and colleagues suggested that compulsions coexist with stereotypic behaviors in children with autism spectrum disorder. They found that children with OCD had more obsessions and compulsions than children with autism spectrum disorder; however, both the OCD group and the group with autistic stereotyped behaviors exhibited more obsessions and compulsions than a comparison group with a typical developmental trajectory. Similarly, J. M. Ringman and J. Jankovic reported on a series of 12 patients with autism spectrum disorders and stereotypic movements. These patients were referred to a specialized movement disorder clinic for the evaluation of tics. Tics were clearly present in seven of the patients, and six of these patients

Telegram: @medical_k

www.konkur.in

met the criteria for both Asperger syndrome and Tourette syndrome. Even though the diagnosis of stereotypic movement disorder excludes repetitive movements that may be core symptoms of other DSM-5 disorders, the literature suggests, and this author observes, that stereo behaviors in autistic spectrum disorders may be comorbid with OCD or tic disorder.

The DSM-IV-TR specifies that the stereotypic behavior is not due to the direct physiologic effects of a substance or a general medical condition. This criterion would exclude tardive dyskinesias, as in chronic neuroleptic exposure or skin picking secondary to stimulant use. Although tremors associated with Parkinson syndrome and Parkinson disease are abnormal and stereotypic, neither would fit the current criteria for stereotypic movement disorder because they are due to the physiologic effects of neuroleptic medication in Parkinson syndrome and a medical condition in the case of Parkinson disease.

Intellectual disability is a common feature of numerous genetic disorders. If the stereotypic or SIB occurs in the context of intellectual disability, the behavior no longer must be severe enough to become a focus of the treatment to meet the diagnostic criteria for DSM-5. Repetitive motor behaviors noted in a person with intellectual disabilities would be correctly recorded per the DSM-5 as stereotypic movement disorder associated with intellectual developmental disability. In Lesch–Nyhan syndrome, the degree of intellectual disability does not seem to predict the magnitude of self-mutilation. Some patients with mild mental intellectual disability may display extreme forms of self-injury. Notably, stereotypic movements occur in approximately two-thirds of individuals with intellectual disabilities living in residential facilities.

In addition, the DSM-5 criteria no longer require that the repetitive movement must be present for 4 weeks or more. Typically, stereotypic movements peak in adolescence, but they have no typical age of onset. Stereotypic movements in persons with severe or profound intellectual disabilities may last for years; however, an abrupt onset of stereotypic behaviors may signal the presence of an underlying acute medical condition in nonverbal individuals with severe mental retardation. Clinicians should be mindful of clues that

Telegram: @medical_k

www.konkur.in

such individuals may be experiencing pain, distress, anxiety, or mood shifts and then promptly treat any identified problems. Stressful events also may precipitate stereotypic behaviors. However, stereotypic movements may emerge and become a focus of treatment in individuals with mental retardation who are institutionalized in nonstimulating environments.

ICD-10 AND 11

The ICD-10 and ICD-11 define stereotypic movements in childhood in a fashion similar to the DSM-5 since one of the goals of DSM-5 aimed to provide compatibility between the two diagnostic systems. As in the DSM, physical injury or marked impairment in normal activities must be present for the diagnosis. This criterion attempts to sort out stereotypic movement disorder from stereotypic movements that are benign or typical of normal development. The duration criterion provides another dimension to the impairment and ensures that the stereotypic movement is more than a passing novelty. In addition, a history of another psychiatric or behavioral disorder should not be present and account for the stereotypic movement.

DIAGNOSIS

No clinical tests are available to make the diagnosis of stereotypic movement disorder. Nevertheless, the history and physical exam may be revealing. Dental and physical exams may provide evidence of tissue trauma that would raise suspicions for stereotypic behaviors, especially the self-injurious type. Anemia may be a sign of self-induced rectal bleeding. The delicate architecture of the eye is particularly vulnerable to repetitive trauma from behaviors such as head banging and eye poking. Sometimes a subtle physical sign clues the clinician to stereotypic behaviors and movements that go unobserved by others.

Rating scales assist in diagnosing and tracking responses to treatment in many psychiatric conditions; however, rating scales for stereotypic behaviors have not been so helpful. Several rating scales

Telegram: @medical_k

www.konkur.in

have been developed, but none provides optimal psychometric properties across the spectrum of stereotypic behaviors. Even commonly used instruments for tracking drug-induced stereotypic behaviors, such as the Angus Involuntary Movement Scale (AIMS) and the Barnes Scale, focus on involuntary movements rather than the wide range seen with stereotypic movements. Berkson and Davenport developed a stereotypy checklist to track stereotyped behaviors mainly due to social deprivation. Unfortunately, experiments intended to test the reliability and validity of the Berkson and Davenport Stereotypy Checklist have shown variable results.

Recently, video- and computer-assisted technologies have been used to study tardive dyskinesia. These technologies may elucidate the characteristics of other stereotypic behaviors, such as that developed for use in monitoring attention-deficit/hyperactivity disorder (ADHD). These motion-detecting devices connected to sophisticated computer programs can give detailed descriptions of the randomness, as well as the range of movements on a second-by-second basis. This type of technology might prove valuable in research or for clinical applications related to stereotypic behaviors.

Eventually, research may lead to feasible diagnostic tests using genetic and/or neuroimaging techniques to assist in the diagnosis and treatment of stereotypic behaviors. In the meantime, a comprehensive clinical exam remains the standard for making an accurate diagnosis.

INJURIOUS BEHAVIORS

Stereotypic movements can manifest in a variety of injurious behaviors that put patients and caregivers at risk. The ramifications of head banging range from hematomas and head injuries to retinal detachment and blindness. However, even seemingly benign stereotypic behaviors could cause cumulative damage over time. For example, hair loss could be a consequence of chronic head rolling. In addition, parents and caregivers are at risk of accidental bites and bruises as they attempt to protect children and many adults who engage in stereotyped self-injury. Even children who typically do not

Telegram: @medical_k

www.konkur.in

exhibit self-injury can be hazardous to others. A child being held may surprise a parent or caregiver with spontaneous swift lead bobbing that results in a broken nose or blackened eye. Stereotypic movements, with or without the potential for self-injury, may cause major management problems, which hamper habilitation and stifle social adaptation.

Onychotillomania refers to compulsive picking or tearing at the nails. It can produce ridges and a central depression on the nail from chronic rubbing by the nail or another finger. Most commonly, the thumbnail of the dominant hand produces trauma to the nail plate of the second or third finger. Onycholysis refers to the separation of the nail from the nail bed. Onychotillomania and onycholysis may be manifestations of rare conditions involving self-mutilation like Lesch–Nyhan syndrome and congenital insensitivity to pain.

Appropriate attention to the patient's history will help to sort out other stereotypic or SIBs. For example, a stereotypic behavior may have been present in a patient with schizophrenia prior to any neuroleptic medication exposure. A careful history of symptom onset can prevent a misdiagnosis of medication-induced stereotypy. Secondary gain in fictitious disorders might be the driving force in some instances. In other cases, the inability to control anger or anxiety may lead to repetitive cutting, as seen with patients with borderline personality disorder.

TREATMENT

A variety of treatment options, from psychotherapy to pharmacotherapy, have been used to treat stereotypic and SIBs. Even surgery and electroconvulsive treatments have been used in refractory cases. Behavioral treatments have been used with some success, and these include positive reward techniques such as differential reinforcement of behaviors other than the targeted maladaptive behavior (Differential Reinforcement of Other Behavior [DRO]) and differential reinforcement of behavior incompatible with the targeted maladaptive behavior (Differential Reinforcement of Incompatible Behavior [DRI]). Rewards may be immediate or

Telegram: @medical_k

www.konkur.in

delayed, as in token economies, but they must be individualized so that they produce the maximum motivation. Rewards also may lose their novelty over time; therefore, changing rewards may provide a fresh incentive for motivation. Punishment can range from misting water into the face to applying mild electric shocks to the patient. Although these techniques might seem mean-spirited, they should be employed if self-injurious or stereotypic behaviors have a high potential for severe harm. Of course, the clinician should document a thoughtful risk versus benefits analysis and discuss this with the guardian or family before using such methods. Other forms of punishment include positive practice, removal of reinforcement, and restitution. A study by Jonathan M. Miller and others used behavioral modification techniques of habit reversal and differential reinforcement of other behaviors in an attempt to suppress stereotypic behaviors in 12 nonautistic children between the ages of 6 and 14 years. After a mean follow-up time of 12.1 months, motor stereotypies were significantly reduced on the Stereotypy Linear Analog Scale and the Stereotypy Severity Scale. These results correlated with the subject's motivation and the number of sessions attended. The Child Global Assessment Scale also improved, but no correlations were seen with the level of motivation or number of sessions.

Pharmacologic approaches have been a mainstay treatment of stereotypic behaviors. An estimated 50% of persons with intellectual disabilities living in residential or institutional settings are prescribed high doses of antipsychotic medication, but this statistic does not give an accurate account of the percentage of these patients who have a known psychotic illness. About 75% of patients receiving psychotropic medications develop some form of motor dysfunction. In the early days of treatment, movement disorders occurred at even higher rates due to the misconception that motor dysfunction was the definitive sign that a patient had achieved an adequate dose of medication to treat psychosis. Even though antipsychotic agents are used to treat stereotypic movements, they also can cause repetitive, purposeless movements. For instance, akathisia secondary to neuroleptic medication may appear clinically as shifting from foot to

Telegram: @medical_k

www.konkur.in

foot, crossing, and uncrossing of legs, pacing, hand wringing, or rocking, among other manifestations.

The newer generation of atypical antipsychotic medications does not pose the typical risk for motor dysfunction seen in older drugs. To date, risperidone (Risperdal) and aripiprazole (Abilify) have been approved by the U.S. Food and Drug Administration (FDA) for self-injurious and disruptive behaviors in children with autism. For the double-blinded, placebo-controlled clinical trial of risperidone, the dose ranged from 0.5 to 3.5 mg per day in the 101 children studied. In a placebo-controlled study of chlorpromazine (Thorazine) used in doses ranging from 2 to 3 mg/kg per day, four adolescents and young adults with profound intellectual disabilities exhibited a 35% reduction in stereotypic behaviors. Unfortunately, the improvement in stereotypic behaviors was offset by a cognitive decline. Several double-blinded placebo-controlled studies used haloperidol (Haldol) in daily doses of between 0.5 and 4 mg to treat stereotypic behaviors in youth with autism. In these studies, haloperidol significantly reduced stereotypic behaviors without causing notable cognitive impairment.

With FDA approval of risperidone and aripiprazole for the treatment of disruptive behaviors, including stereotypic SIBs, these medications have been used more frequently in individuals with autism. This increase in these and other neuroleptic medications in the autism population may lead to other types of repetitive movement disorders, such as Parkinson syndrome with a “pill-rolling” tremor or tardive dyskinesia. Anticholinergic agents such as benztropine (Cogentin), diphenhydramine (Benadryl), and others effectively counteract extrapyramidal movements associated with neuroleptic use. Until recently, the only way to address tardive dyskinesia was to immediately stop or taper off the neuroleptic and hope that it would resolve over the course of weeks to months. In many cases, tardive dyskinesia would decrease to a degree but not fully resolve. Although not life-threatening, the prospect of social stigma from permanent tardive dyskinesia had been one of the main limiting factors in the use of this class of medications. In 2017 however, the FDA approved valbenazine and deutetrabenazine for the treatment of tardive

Telegram: @medical_k

www.konkur.in

dyskinesia. These vesicular monoamine transporter type 2 (VMAT 2) inhibitors are not approved in Canada, but tetrabenazine is. Tetrabenazine was approved by the U. S. FDA in 2008 for chorea movements in Huntington disease. In the randomized 6-week trials of valbenazine, Abnormal Involuntary Movement Scale (AIMS) mean scores were reduced (−3.2) on 80 mg/day, (−1.9) on 40 mg/day, and (−0.1) on placebo at week six compared to baseline. For the 12-week trials of deutetrabenazine, AIMS score reductions with a mean daily dose of 39 mg/day was (−3.0) compared to (−1.6) with placebo in the smaller study of 117 subjects. In a larger trial of this drug, AIMS scores were reduced (−3.3) on 36 mg/day and (−3.2) on 24 mg/day compared to (−1.4) on placebo. The 12 mg/day dose did not show improvement compared to the placebo. Although FDA-approved, these medications can reduce yet not necessarily eliminate symptoms of tardive dyskinesia. Thus, judicious use of antipsychotic medications continues to be the best approach for individuals with autism and stereotypic self-injurious, disruptive behaviors. Otherwise, attempts to eliminate stereotypic movements could lead to the emergence of other types of movement disorders.

A variety of other agents have been tried, but these have fallen short due to limitations of study size or design. Although lithium carbonate (Eskalith) has been studied for SIBs in patients with intellectual disabilities, the results of the few studies are inconsistent. Fenfluramine (Ponderax, Pondimin) reduced stereotypic behaviors and other problem behaviors in individuals with autism; however, the results also varied across studies. In addition, fenfluramine has been associated with cardiovascular and pulmonary problems. Several other serotonergic agents have been tried, including fluoxetine (Prozac), sertraline (Zoloft), citalopram (Celexa), trazodone (Desyrel), and buspirone (Buspar), but methodologic issues related to the size or design of each study limited their usefulness.

Clomipramine (Anafranil) and desipramine (Norpramin) have been studied for their effect on stereotypic behaviors in autism and onychophagia. Gordon and coworkers showed that clomipramine was superior to desipramine, but both were better than placebo in reducing stereotypic behaviors associated with autism. Clomipramine

Telegram: @medical_k

www.konkur.in

was better than desipramine in treating severe onychophagia, but the dropout rate was greater than that seen in other studies of its use in OCD and trichotillomania. Henrietta L. Leonard and colleagues concluded that clomipramine was not the optimal treatment for severe onychophagia.

An endogenous opioid theory for SIBs has prompted the use of opioid antagonists. The original study of naloxone (Narcan) successfully reduced SIBs in two young adults with profound intellectual disabilities. SIBs with low frequency of occurrence responded best to the intervention at low doses. Subsequently, several other studies showed that individuals responded variably to naloxone or naltrexone. However, these two agents may decrease stereotypic, self-injurious, and hyperactive behaviors in some patients.

Clearly, more controlled studies are needed to evaluate these and other therapies based on behavioral and pharmacologic interventions. Recent technologic advances in genetic analysis, neuroimaging, and movement monitoring will promote this goal.

Although stereotypic behaviors manifest in many ways, diagnostic criteria for a stereotypic movement disorder in the DSM-5-TR and the ICD-11 describe repetitive, rhythmic movements that are not due to another psychiatric disorder, medical condition, or medication effect. Criteria for impairment help to clarify whether a stereotypic movement is an inconsequential habit or part of normal development. The careful clinician should use a thorough history and exam to identify the presence and possible causes of stereotypic behaviors. Once the clinician accurately characterizes the stereotypic movement, behavioral therapy with or without medication intervention may be applied. Although the literature on the treatment of stereotypic behaviors is limited, it does provide a starting point for developing treatment plans that will likely be subject to change as warranted.

50 Mood Disorders in Children and Adolescents

50.1 Depressive Disorders and Suicide

Karen Dineen Wagner, M.D., Ph.D., Tami Benton, M.D., and Catharyn A. Turner, II, M.D., M.Ed.

Depressive disorders in children and adolescents have a significant adverse effect on a youth's emotional, social, and cognitive development. Early onset of major depression is associated with more lifetime depressive episodes and suicide attempts, greater psychiatric and medical comorbidity, and poorer quality of life than later age onset of depression. Disruptive mood dysregulation disorder leads to impairments in school functioning and relationships with family and peers. Recognition of these disorders is essential so that children and adolescents may receive effective evidence-based treatments.

DEFINITION

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5-TR) includes in the category of depressive disorders the following: disruptive mood dysregulation disorder, major depressive disorder, persistent depressive disorder, premenstrual dysphoric disorder,

Telegram: @medical_k

www.konkur.in

substance/medication-induced depressive disorder, depressive disorder due to another medical condition, other specified depressive disorder, and unspecified depressive disorder. To be in the category of depressive disorders, there cannot be a history of ever having had a manic or hypomanic episode. There are coded specifiers for the depressive episode for severity (mild, moderate, severe, with psychotic features) and course (in partial remission, in full remission). The uncoded specifiers for the current episode include with anxious distress, with mixed features, with melancholic features, with atypical features, with mood-incongruent psychotic features, with catatonia, with peripartum onset, and with seasonal pattern.

Disruptive mood dysregulation disorder in children is characterized by recurrent verbal or behavioral temper outbursts (>3 or more times per week) that are excessive and age inappropriate. In between these episodes, mood is irritable or angry most of the day, nearly every day. These symptoms occur in at least two settings (school, home, or with peers). The duration of symptoms must be more than 12 months, without a 3-month symptom-free period in this time frame. The age of onset of the symptoms must be before 10 years old, and the diagnosis should not be made before age 6 years or after age 18 years.

Criteria for major depressive disorder in children and adolescents are at least one major depressive episode in which there has been at least a 2-week period of either depressed or irritable mood or a loss of interest or pleasure. In addition, at least four of the following symptoms are required: weight loss, weight gain, failure to make expected weight gain, or an increase or decrease in appetite; insomnia or hypersomnia; psychomotor agitation or retardation; fatigue or loss of energy; feelings of worthlessness or excessive or inappropriate guilt; diminished ability to think or concentrate or indecisiveness; and recurrent thoughts of death, recurrent suicidal ideation, suicide attempt, or suicide plan. The symptoms must cause impairment in functioning or cause clinically significant distress.

Persistent depressive disorder in children and adolescents is a chronically depressed or irritable mood for at least 1 year. In addition, there must be at least two of the following symptoms: poor appetite or overeating; insomnia or hypersomnia; low energy or fatigue; low self-esteem; poor concentration or difficulty making decisions; and feelings of

Telegram: @medical_k

www.konkur.in

hopelessness. During the 1-year period, the youth also has not been without depressive symptoms for more than 2 months at a time.

Premenstrual dysphoric disorder requires at least five symptoms in the final week before the onset of menses which start to improve a few days after the onset of menses and are either minimal or absent in the week following menses. One or more of the following symptoms must be present: affective lability, irritability/anger/interpersonal conflict, depressed mood/hopelessness/self-deprecating thoughts, or anxiety/tension/keyed up or on edge. In addition, at least one of the following symptoms must be present: decreased interest, concentration difficulties, fatigue/low energy, appetite changes, hypersomnia/insomnia, feeling overwhelmed/out of control, and physical symptoms. The symptoms must be severe enough to interfere with functioning or cause clinically significant distress.

A diagnosis of other specified depressive disorder is used when full criteria for a depressive disorder are not met, but the symptoms cause significant distress or impairment. The specific reason for not meeting the full criteria is identified. The diagnosis of unspecified depressive disorder is used when the reasons for not meeting the full criteria are not identified.

HISTORY

Although depression in children and adolescents is now recognized as a common and serious illness, it was not until the 1980s that studies demonstrated that children do develop depressive disorders that can be diagnosed in a standardized manner. It was originally thought that children and adolescents developed a “masked” form of depression with predominantly behavioral symptoms, but subsequent studies have shown that children and adolescents have symptoms similar to those of adults with depression.

Disruptive mood dysregulation disorder is a new diagnosis in DSM-5 depressive disorders to address issues related to the potential overdiagnosis of bipolar disorder in children and adolescents. Children with severe nonepisodic irritability were increasingly diagnosed with bipolar disorder but did not have distinct episodes of mania or hypomania. Disruptive mood dysregulation disorder had its origins in the construct of severe mood dysregulation developed by researchers (Leibenluft and colleagues) at the National Institute of Mental Health.

Telegram: @medical_k

www.konkur.in

EPIDEMIOLOGY

The prevalence of major depressive disorder in children is approximately 2%. In adolescence, there is a substantial increase in the prevalence of major depression, with lifetime prevalence rates of 12%. In children, the sex ratio is 1:1, whereas, with puberty, adolescent females are two to three times more likely to have an episode of major depression than adolescent males. Children with a family history of affective disorders are about three times more likely to develop a major depressive disorder than children with a first-degree relative without a lifetime affective disorder. The prevalence rate for persistent depressive disorder in children ranges from 0.6% to 4.6%, and in adolescents, it ranges from 1.6% to 8.0%.

Estimates of the prevalence rate of disruptive mood dysregulation disorder are about 3%. The prevalence is higher in young children (3% to 8%) than in adolescents (0.8%). This disorder is more commonly diagnosed in males compared to females.

ETIOLOGY

Genetic

The most predictive factor for a child or adolescent to develop major depressive disorder is a high family loading for major depressive disorder. There is an increased risk of depression in relatives of depressed children (odds ratio = 3.98 compared to healthy controls) and among offspring of depressed adults (odds ratio = 2.12 compared with healthy controls). Younger age of onset of depression in parents increases the risk of depression in children. Parental major depression is associated with greater severity of illness, longer episode duration, more impairment, and more recurrences in depressed offspring. Twin studies have demonstrated that depression is moderately heritable, with rates of about 31% to 42%.

Heritability of disruptive mood dysregulation disorder has not been specifically determined, although there may be a heritable component to the phasic irritability.

Neurobiology

Neuroendocrine studies have evaluated the hypothalamic–pituitary–adrenal (HPA), hypothalamic growth hormone (HGH), hypothalamic–pituitary–thyroid (HPT), and hypothalamic–pituitary–gonadal (HPG) axes

Telegram: @medical_k

www.konkur.in

in youth to determine whether there are abnormalities related to depression. HPA-axis abnormalities have been detected in depressed children and adolescents with some evidence of nonsuppression in stimulation studies and higher baseline cortisol values. Growth hormone–axis abnormalities have been found in prepubertal depressed children who have a blunted growth hormone response to stimulation with growth hormone–releasing hormone. There have been inconsistent findings regarding abnormalities in the HPT axis in children and adolescents with depression. The majority of studies of corticotropin-releasing hormone have found no abnormalities in depressed youth.

Abnormalities in the serotonergic system have been examined in depressed youth. Serotonin challenge agents that cause the release of prolactin have shown greater prolactin release in depressed children compared to controls.

Neuroimaging studies of depressed youth have found smaller left subgenual prefrontal cortex in adolescent girls, smaller frontal white matter volumes, larger frontal gray matter volumes, and larger lateral ventricular volumes. Amygdala functioning has been shown to be disrupted in depressed children. Disconnectivity in frontolimbic circuitry has been associated with depression in adolescents. Larger pituitary- and amygdala-to-hippocampal volume ratios have been found in depressed youth compared to healthy controls. Depressed children and adolescents have been found to have smaller left and right amygdala volume than healthy controls. Increased pituitary gland volume has been found in treatment-naive youth with major depressive disorder, particularly in males with nonfamilial major depressive disorder. Magnetic resonance spectroscopic imaging has found an increase in choline in the left dorsolateral prefrontal cortex and orbitofrontal cortex and increased choline/creatinine and choline/*N*-acetylaspartate ratios in the left anterior medial frontal lobe in depressed youth. A functional magnetic resonance imaging (fMRI) monetary task showed disruption in reward system neural circuitry in adolescent depression. Highly irritable youth with disruptive mood dysregulation disorder showed increased frontal striatal activation on fMRI following a frustrating task.

A meta-analysis of depression and inflammation among children and adolescents showed significant associations between depression and c-reactive protein (CPR) and interleukin-6 (IL-6). Sleep abnormalities have been examined in depressed youth, and the findings from

Telegram: @medical_k

www.konkur.in

polysomnography have been mixed. Some studies found no differences between children with major depressive disorder and controls, whereas other studies have found shorter rapid eye movement (REM) latencies, longer sleep latency, a higher number of REM periods, and increased REM time for depressed children. In studies of depressed adolescents, shorter REM latency, more REM sleep, more REM density, and longer sleep latency have been reported. Subjective reports by youths of sleep disturbance (sleep quality, waking in the middle of the night, morning tiredness) were not confirmed by an electroencephalogram (EEG). Of interest, the depressed children who rated their sleep most poorly had a better sleep by EEG measures than those who rated their sleep more positively. In a study using polysomnography as a measure of the recurrence of depression in youth, those youth who had a later recurrence had decreased sleep efficiency and delayed sleep onset at baseline sleep polysomnography. No clinically significant associations have been shown between disruptive mood dysregulation disorder and findings on polysomnography.

Environmental

Adoption studies have supported the role of environment more than genetic factors in the development of pediatric depression. Family factors, including parental substance abuse, poor marital adjustment, parent–child conflict, and lack of family cohesion, are risk factors for depression in children and adolescents. Life stressors, such as abuse, neglect, death of a parent, bullying, and psychosocial adversities, may contribute to depression in youth. Cigarette smoking, physical illness, and functional impairment have been associated with youth depression. Recurrence of major depression may also be affected by environmental stressors.

There may be gene–environment interactions with regard to pediatric depression. Twin studies of life events have shown that the effect of life events on depression is greater in youth with higher genetic liability. Family conflict and family adversity have also been demonstrated to interact with genetic liability and contribute to depression in youth.

Preliminary findings suggest that environmental factors such as parenting, peer victimization, and adverse life events may have a role in development of irritability and disruptive mood dysregulation disorder.

DIAGNOSIS AND CLINICAL FEATURES

Telegram: @medical_k

www.konkur.in

It is important for the clinician to conduct a comprehensive evaluation of a child to ensure the accuracy of the primary diagnosis, as well as of comorbid diagnoses. The clinician should interview the child and parent separately so that each can express their concerns. Teenagers are often reluctant to disclose their feelings or issues related to peers in the presence of their parents. Similarly, parents may be reticent to discuss sensitive topics with their children present. Other sources of information may be obtained from discussion with school personnel, from school records, or from medical records.

Children with a diagnosis of disruptive mood dysregulation disorder are persistently irritable or angry most of the day nearly every day and have severe recurrent (>3 times per week) temper outbursts, either verbal or behavioral. These temper outbursts are developmentally inappropriate and are out of proportion to the situation. To make this diagnosis, the symptoms must be present for at least 12 months (no period >3 months without symptoms in this time frame) and be present in at least two settings (school, home, or with peers). The diagnosis cannot be given to children under the age of 6 years, and the onset of symptoms must be before age 10 years.

The irritability/angry mood state for children with disruptive mood dysregulation is chronic (tonic irritability). Particularly when faced with frustration, these children have marked difficulty regulating their emotions and respond with verbal or behavioral outbursts (phasic irritability). For example, a child may throw a chair in school during one of these outbursts. This persistent irritability and severe temper outbursts lead to significant impairment in school, at home, and in social settings. Children and adolescents with major depression have depressed or irritable mood and/or loss of interest or pleasure, along with at least four of the following symptoms: Weight or appetite change, sleep disturbance, psychomotor retardation or agitation, fatigue or loss of energy, feelings of worthlessness or guilt, diminished concentration, and suicidal ideation, intent, or plan. The symptoms must cause impairment in the child's functioning with regard to, for example, social or school performance or peer relationships, which is critical to the diagnosis in youth. Impairment helps to distinguish these symptoms from a passing phase of childhood or adolescence.

Youth with major depressive disorder often display irritable mood rather than dysphoria. Typically, they are not aware of the extent of their

Telegram: @medical_k

www.konkur.in

irritability or its effects on their interaction with other people. Teenagers who have some insight into their irritability might say that everything makes them angry whether it is important or not. Loss of pleasure or interest may be noted by the youth's withdrawal from school or sports activities and from friends. Sleep disturbance is common in depressed youth, particularly difficulty falling asleep. Weight loss or failure to gain weight is more common than significant weight gain. Youth with depression are often fatigued and may nap after school. Diminished concentration may be manifested by declining school grades. A child often describes a feeling of worthlessness as no one liking them, including peers, teachers, and family members. Suicide attempts and psychotic features are more common in depressed adolescents than in depressed children.

Depressed youth may not view themselves as having depression if their mood is irritable rather than depressed. Parents often do not recognize individual symptoms of an adolescent's depression, but they recognize the burden on the family in dealing with an extremely irritable adolescent. Children and adolescents with depression are more likely to be brought for evaluation because of declining school grades, substance abuse, suicide attempt, or a change in behavior.

For a diagnosis of persistent depressive disorder, a child or adolescent must have depressed or irritable mood for at least 1 year. In addition, the youth must have two of the following symptoms: poor appetite or overeating, insomnia or hypersomnia, low energy or fatigue, low self-esteem, poor concentration or difficulty making decisions, and feeling of hopelessness. Youth with persistent depressive disorder have fewer melancholic and neurovegetative symptoms than youth with major depressive disorder. Although the depressive symptoms are milder in persistent depressive disorder than in major depressive disorder, the chronicity of persistent depressive disorder results in significant psychosocial impairment (e.g., relationships with friends and family).

Depressive disorders in youth are often comorbid with other psychiatric conditions. Rates of comorbidity range from 40% to 90% of children and adolescents with a depressive disorder, with up to 50% of depressed youths having two or more comorbid disorders. Anxiety disorders often precede the onset of depression and are a very common comorbid disorder. Major depression and persistent depressive disorder also frequently co-occur in youth. Other common comorbidities especially with

Telegram: @medical_k

www.konkur.in

disruptive mood dysregulation disorder are attention deficit hyperactivity disorder (ADHD), oppositional defiant disorder (ODD), conduct disorder, and substance use disorder. It is important for clinicians to identify comorbid disorders that are associated with depressive disorders in youth, since these comorbidities may adversely affect the course and treatment outcomes of depressive disorders.

LABORATORY EXAMINATIONS/ASSESSMENT INSTRUMENT

No laboratory findings are diagnostic of depressive disorders in youth. If a child presents with symptoms of depression and hypothyroidism (e.g., dry skin, feeling cold, and memory difficulties), then thyroid function tests should be obtained. If hypothyroidism was found, the diagnosis would be depressive disorder due to another medical condition.

The Patient Health Questionnaire-9 modified for adolescents (PHQ-A) is a widely used self-report screening instrument for depression in youth aged 11 to 17 years. The scale has nine depression symptom items rated on a 4-point scale from 0 (not at all) to 3 (nearly every day). Scores range from 0 to 27. PHQ-A score ≥10 is typically the cut-off threshold for further evaluation to determine a diagnosis of major depression. This scale may also be useful for monitoring treatment outcomes.

The Children's Depression Rating Scale-Revised (CDRS-R) is a 17-item, clinician-administered instrument that assesses symptoms of depression in children and adolescents. The scale assesses cognitive, somatic, affective, and psychomotor symptoms. The items are rated for severity on a scale of 1 to 7 for some items and 1 to 5 for other items for a total score of 113. Typically, a score of 45 or greater is considered a marker of clinically significant depression. The CDRS-R is useful for obtaining baseline symptomatology prior to treatment and for monitoring treatment outcome.

Given that youth with bipolar disorder may present with a depressive episode, it is important to ask about symptoms of mania or hypomania. Some diagnostic checklists for mania have been shown to discriminate bipolar from nonbipolar disorder in youth of ages 5 to 18 years, including the Mood Disorder Questionnaire-Adolescent (MDQ-A), the Parent General Behavior Inventory 10-item short form (PGBI-SF10), and the Parent Young Mania Rating Scale (P-YMRS). These checklists are

Telegram: @medical_k

www.konkur.in

completed by the parents about their child's behavior. Adolescent self-report measures about symptoms of mania have demonstrated low validity in identifying bipolar disorder.

DIFFERENTIAL DIAGNOSIS

Depressive symptoms may be related to stressors and fulfill criteria for an adjustment disorder with depressed mood. A child may have experienced the death of a significant person in their life, and the depressive symptoms may be related to bereavement. Depression or irritability may be attributable to substance use or withdrawal, which would be considered a substance-induced depressive disorder.

When a child presents with depressive symptoms, it is important for the clinician to consider bipolar disorder within the differential diagnosis. The clinician should ask about a past or present history of manic or hypomanic symptoms.

There is substantial symptom overlap among various psychiatric disorders, which might complicate the differential diagnosis. Irritability may be found in disruptive mood dysregulation disorder, major depression, persistent depressive disorder, bipolar disorder, post-traumatic stress disorder, and generalized anxiety disorder. Children with ADHD who are failing in school and having difficulty with peer relationships may exhibit symptoms such as depressed mood, low self-esteem, irritability, and behavioral outbursts. Anxiety disorders and ODD may have some symptom features of depression and disruptive mood dysregulation disorder. Children with pervasive developmental disorder may present with depressive symptoms but not fulfill diagnostic criteria for a depressive disorder.

Medical conditions may manifest with symptoms of a depressive episode and should be diagnosed as depressive disorder due to a general medical condition if the mood disorder is attributable to the consequences of the medical condition. Neurologic disorders (e.g., seizure disorder and multiple sclerosis), endocrinologic abnormalities (hypothyroidism, hypopituitarism, Cushing disease), infections (e.g., pneumonia, AIDS, and mononucleosis), autoimmune diseases, and cancer are some medical conditions to consider within the differential diagnosis. Medications such as anti-inflammatory agents, antibiotics, steroids, stimulants, and oral contraceptives may lead to depressive symptoms.

Telegram: @medical_k

www.konkur.in

COURSE AND PROGNOSIS

Disruptive mood dysregulation disorder has its onset after the age of 6 years. It has been found that disruptive mood dysregulation disorder at age 6 predicted disruptive mood dysregulation disorder, depressive disorders, and ADHD at age 9 years. Academic difficulties, use of education support services, school suspensions, peer relationship problems, and impaired relationships with parents and siblings are frequent outcomes of this disorder. The symptoms are predominantly limited to childhood. Of children who were diagnosed with disruptive mood dysregulation disorder, only 19% continued to meet criteria for the disorder at 12- and 24-month follow-up. Children with disruptive mood dysregulation disorder are at risk to develop depression and anxiety disorders in adulthood.

The mean length of an episode of major depression in children and adolescents is 8 months. Recovery rates from an index episode of depression are high in youth, even independent of treatment. More than 90% of depressed children and adolescents typically recover from an episode of major depression within 1 to 2 years.

Depression relapse rates, with relapse being defined as a return of symptoms in the index episode, are between 34% and 50%, with the greatest likelihood of relapse in the first 6 months to 1 year after treatment discontinuation. Recurrence rates (onset of a new episode of depression) are high, with rates ranging from 20% to 60% after 2 years of remission and up to 70% at 5-year follow-up.

Risk factors for relapse or recurrence include severity of illness, suicidality, comorbid disorders, residual symptoms, psychosocial stressors, family conflict, family history of recurrent depression, negative cognitive style, low socioeconomic status, early onset of parental mood disorder, baseline social difficulties, and history of sexual abuse.

Youth who present with an episode of major depression are at risk of developing bipolar disorder. Overall estimates are that 20% to 40% of youth with a major depressive episode are at risk of subsequent development of bipolar disorder. In a longitudinal study of prepubertal children diagnosed with major depression, the rate of bipolar I disorder was 33% and that of bipolar spectrum disorders (I, II, not otherwise specified [NOS]) was 48% by young adulthood. Risk factors for switch to bipolar disorder are prepubertal onset of major depression, loaded or

Telegram: @medical_k

www.konkur.in

multigenerational family history for mood disorders, psychotic features, and hypomania when treated with antidepressant medications.

There is increased recognition of the continuity between depression in youth and depression in adulthood. In a follow-up study of depressed school-aged children in community and clinic samples, 18% continued to have major depression into adulthood. In a clinical sample, adolescent-onset major depressive disorder increased the risk twofold of major depressive disorder in adulthood. In a community sample, 53% of adolescents with a history of major depressive disorder developed a new major depressive disorder in young adulthood.

Early age of onset of depression increases the risk of anxiety disorders, substance abuse, psychiatric comorbidity, suicide attempts, psychiatric and medical hospitalization, impairment in relationships with parents, siblings, and friends, more lifetime depressive episodes, nicotine dependence, increased adulthood body mass index, educational underachievement, unemployment, early parenthood, and worse overall quality of life.

The duration of persistent depressive disorder ranges from 2 to 3 years in clinically referred and community-based youth. After recovery after an episode of persistent depressive disorder, the estimated relapse rate is 45%. Youth with persistent depressive disorder are at increased risk of psychosocial difficulties, substance use disorder, episodes of major depression, and suicidality. The risk of suicide attempts in youths with persistent depressive disorder increases with comorbid conduct disorder or substance use disorder.

Children and adolescents with both major depressive disorder and persistent depressive disorder have a worse course of illness than those with either disorder alone. These youth have more-severe depression, longer depressive episodes, more comorbid disorders, more suicidality, and greater psychosocial impairment.

PHARMACOLOGIC TREATMENT

There are no U.S. Food and Drug Administration (FDA)-approved medications to treat disruptive mood dysregulation disorder. There are limited data on pharmacologic treatment specifically for disruptive mood dysregulation disorder in youth. Medications aimed to treat emotional dysregulation, irritability, and aggression include stimulants, selective

Telegram: @medical_k

www.konkur.in

serotonin reuptake inhibitors (SSRIs), mood stabilizers, and second-generation antipsychotics.

Citalopram adjunctive to stimulant medication has recently been studied in a double-blind placebo-controlled trial of youth aged 7 to 17 years with severe mood dysregulation disorder (98% met criteria for disruptive mood dysregulation disorder). After 5 weeks of open treatment with methylphenidate to optimize control of ADHD symptoms, youth who continued to meet criteria for severe mood dysregulation disorder were randomized to citalopram plus methylphenidate (n = 25) or placebo plus methylphenidate (n = 28) for 8 weeks. A significantly higher proportion of response (improvement of irritability) was found for the citalopram plus methylphenidate group (35%) versus the placebo plus methylphenidate group (6%). There was no difference between the groups in measure of functional impairment.

Lithium for treatment of severe mood dysregulation disorder has been evaluated in a 6-week double-blind placebo-controlled trial for youth aged 7 to 17 years. After a 2-week single-blinded placebo run-in, those youth who continued to meet criteria for severe mood dysregulation disorder were randomized to lithium (n = 14) or placebo (n = 11). There were no significant differences in clinical improvement between the youth randomized to lithium or placebo.

Risperidone was evaluated for treatment of 21 youths aged 7 to 17 years with severe mood dysregulation in an open-label trial. A significant reduction in irritability scores was reported from baseline to endpoint.

There are two SSRIs that have FDA approval for acute and maintenance treatment of major depression in children and adolescents: fluoxetine (≥8 years old) and escitalopram (≥12 years old).

Other SSRIs that have also demonstrated efficacy in controlled studies of depressed children and adolescents are citalopram and sertraline. Some studies of SSRIs did not demonstrate superiority of medication to placebo on the primary outcome measure, including citalopram, paroxetine, and escitalopram. A meta-analysis of SSRI trials in youth showed superiority of SSRIs to placebo, with an average response rate of 60% for antidepressants and 49% for placebo.

Other classes of antidepressants have not shown statistically significant improvement with antidepressant medication compared to placebo, including venlafaxine, nefazodone, desvenlafaxine, vilazodone, mirtazapine, and selegiline transdermal system. In failed studies,

Telegram: @medical_k

www.konkur.in

duloxetine and fluoxetine were not superior to placebo and desvenlafaxine and fluoxetine were not superior to placebo on primary outcome measures. Tricyclic antidepressants have not been shown to be effective in the treatment of depressed children and adolescents. There is some speculation that the early maturation of the serotonergic system compared to the noradrenergic system may account for the lack of efficacy in noradrenergic antidepressants compared to serotonergic agents in youth. There are no controlled trials of bupropion in the treatment of major depression in children and adolescents.

There has been much discussion about why controlled studies of antidepressants in children and adolescents with major depression have not shown efficacy, that is, statistically significant separation from placebo. One explanation is the high rate of placebo response in these studies—up to 59%. Other explanations are methodologic issues in the antidepressant trials, including number of sites, experience of site personnel, patient recruitment source, inclusion and exclusion criteria, duration of treatment trial, dosing, and outcome measures.

Adverse Events

Common side effects of SSRIs are nausea, abdominal pain, headaches, dry mouth, insomnia, somnolence, and sexual dysfunction. Impulsivity, agitation, irritability, and behavioral activation may occur, particularly with young children. Potential serious side effects include serotonin syndrome, increased bleeding, and amotivational syndrome. Common side effects of venlafaxine are anorexia, abdominal pain, insomnia, somnolence, dizziness, and elevated blood pressure. Common side effects of mirtazapine are increased appetite, weight gain, and somnolence. Common side effects of duloxetine are nausea, headache, abdominal pain, and somnolence. Common side effects of desvenlafaxine are headache, abdominal pain, nausea, and dizziness. Common side effects of vilazodone are nausea, abdominal pain, vomiting, diarrhea, nasopharyngitis, headache, and dizziness.

FDA Warning and Suicidality

In a combined analysis conducted by the FDA of 24 short-term, placebo-controlled trials of antidepressant medications in children and adolescents with major depressive disorder, obsessive-compulsive disorder, or other psychiatric disorders, the risk of suicidality (suicidal thinking and behavior)

Telegram: @medical_k

www.konkur.in

was 4%—twice the placebo rate of 2%. There were no suicides in any of the clinical trials. The FDA directed manufacturers to add a black box warning to the health professional label of antidepressant medications to describe the increased risk of suicidal thoughts and behavior in children and adolescents being treated with antidepressants, as well as to recommend the need for close monitoring of patients on antidepressant medications.

In a later meta-analysis of 27 trials of pediatric major depression, the risk of suicidality (suicidal ideation and attempts) was 3% in the antidepressant group and 2% in youth who received placebo. The pooled absolute rate of antidepressant response was 61%, and the placebo response was 50%. The number needed to treat (NNT) (number needed to treat to get one positive response to medication) was 10, and the number needed to harm (NNH) (number needed to get one event of suicidality) was 112. Based on this finding, the investigators concluded that the benefits of antidepressants in youths outweigh the potential risk of suicidal ideation or attempts.

There have been recent reports of an increase in suicide rate in youth following the black box warning on antidepressants and a significant decrease in the rates of diagnosis and treatment of pediatric depression.

A medication guide that addresses antidepressant medications, depression, and suicidality has been approved by the FDA. The guide states that depression and other serious mental illnesses are the most important causes of suicidal thoughts and actions and that antidepressant medication may increase suicidal thoughts or actions in some children and teenagers when medication is first started. The patient or family member is encouraged to contact the healthcare provider if there is a change in mood or thoughts.

Informed Consent

Prior to prescribing antidepressant medication to a child or adolescent, an informed consent process should occur with the youth and the parent. Elements of informed consent are the purpose of treatment, description of the treatment process, benefits and risks of the proposed treatment, and alternative treatments. Because there is minimal information about the long-term effects of antidepressant medication in children, parents should be informed that there may be unknown risks of these medications.

Telegram: @medical_k

www.konkur.in

Medication Treatment Algorithm

An evidence-based consensus algorithm for the treatment of major depression in children and adolescents was reported in which four stages of medication treatment were identified. It was recommended that if a child failed to respond to treatment in one stage, then the clinician should move to treatment in the next stage. The first stage of treatment is with an SSRI. The second stage of treatment is with an alternative SSRI. The third stage of treatment is selection of a different class of antidepressant medication. If a child fails to respond to these agents, then it was recommended that there be reassessment of the diagnosis and treatment consultation.

In the Treatment of SSRI-Resistant Depression in Adolescents (TORDIA) study, it was found that there was no difference in response rates for those adolescents switched to venlafaxine or another SSRI (48% vs. 47%) after treatment failure with an SSRI. Therefore, if an adolescent does not respond to the initial antidepressant, there is approximately a 50% chance of responding to the second antidepressant.

Lower initial starting doses of antidepressants are typically used in children and adolescents than in adults. However, the dose range tends to be similar to that used with adults. Doses are usually increased by 3 weeks if there is no symptom improvement. If there is no improvement with additional dose adjustment after 8 to 10 weeks, then switching to another treatment is recommended. Antidepressants should be continued for 6 to 12 months after symptom remission. At the time of discontinuation of an antidepressant, the dose should be tapered slowly, usually over a 2- to 3-month period.

PSYCHOTHERAPY

There are limited evidence-based psychosocial treatments for disruptive mood dysregulation in youth.

The feasibility and preliminary efficacy of dialectical behavior therapy for preadolescent children (DBT-C) was assessed in a randomized clinical trial for 43 children aged 7 to 12 years with disruptive mood dysregulation disorder. DBT-C consisted of 32 weekly 90-minute sessions and included a parent-training component. The primary outcome measure was the positive response on the Clinical Global Impression Improvement Scale (improvements in behavior outbursts and angry/irritable mood). The rate

Telegram: @medical_k

www.konkur.in

of positive response was higher in the DBT-C group compared to the treatment as usual (90.4% vs. 45.5% respectively).

Other psychosocial treatments for symptoms of disruptive mood dysregulation disorder include behavioral therapy, cognitive behavioral therapy (CBT), exposure-based CBT, integrative group therapy (parent–child sessions), and parent management training.

The two most studied psychotherapy modalities for depression in adolescents are CBT and interpersonal psychotherapy (IPT).

Cognitive Behavioral Therapy

CBT focuses on cognitive distortions and behavioral deficits associated with depression in youth. Components of CBT for children and adolescents include psychoeducation and mood monitoring, pleasant activity scheduling and behavioral activation, and cognitive restructuring. Relaxation training and improvement in social and problem-solving skills may be included.

The efficacy of CBT was assessed in adolescents with major depression or dysthymia. The youth were randomly assigned to adolescent group CBT, adolescent group CBT with a separate parent group, or wait-list control. The CBT groups showed higher depression recovery rates (67%) than the wait-list group (48%) and greater reduction in self-reported depression. The addition of a parent group did not affect outcome.

CBT (12 to 16 sessions) was compared to nondirective supportive psychotherapy and systemic behavior therapy in a randomized trial. CBT was significantly superior to the other treatments, with greater reduction in depression, more rapid symptom relief, and a higher remission rate—65%, compared to 39% for nondirective supportive therapy and 38% for systemic behavior family therapy. However, in a 2-year follow-up study, there were no significant differences in outcome among the psychotherapies. Eighty percent of the adolescents had recovered from depression, but 30% had a recurrence of depression.

Computerized CBT in the form of an interactive fantasy game (SPARX) has been developed for adolescent depression. A study comparing SPARX to treatment as usual for adolescents with depressive symptoms showed similar treatment response rates.

Interpersonal Psychotherapy

Telegram: @medical_k

www.konkur.in

IPT focuses on the relationship between depressed symptoms and interpersonal relationships. Four areas of focus are loss, interpersonal disputes, role transition, and interpersonal deficits. IPT has been modified for depressed adolescents (IPT-A) and has added a focus on developmental issues such as separation from parents, authority figures, peer pressures, and dyadic relationships. The adolescent and parents are educated about the association between depressive symptoms and events in interpersonal relationships. The adolescent learns skills to improve interpersonal relationships that may help to relieve depression.

The efficacy of IPT-A was assessed in a 12-week study of 48 adolescents with major depression who were randomly assigned to IPT-A or clinical monitoring. IPT-A led to greater decrease in depressive symptoms, improvement in social functioning, and improved problem solving compared to clinical monitoring.

The effectiveness of IPT-A in school-based health clinics was evaluated in depressed adolescents who were randomly assigned to IPT-A or treatment as usual for 16 weeks. The IPT-A training was done with existing staff at the health care clinics in high school. The adolescents who received IPT-A had greater symptom reduction and improvement in overall functioning. The greatest treatment effects occurred in older and more severely depressed adolescents.

There is also a group format (IPT-AG) that allows for peer support for depressed adolescents who have similar interpersonal problems. Adolescents can receive feedback from their peers about their interpersonal interactions and strategies to improve them. The efficacy of IPT-AG was compared to individual IPT-A, and there was similar improvement in depression for both formats of IPT.

In a recent systematic review and meta-analysis of psychotherapy for depression, across age groups, effect sizes in children were 0.35 and in adolescents 0.55.

A meta-analysis of 50 controlled psychotherapy trials for treatment of depression in youth found an overall modest effect size of 0.36 at posttreatment and 0.21 at follow-up (mean 42 weeks after treatment).

Combination Treatment

The Treatment for Adolescents with Depression Study (TADS) was the largest randomized, controlled trial to compare the efficacy of CBT, fluoxetine, CBT plus fluoxetine, and placebo in adolescent outpatients

Telegram: @medical_k

www.konkur.in

with a diagnosis of major depression. Response rates (much or very much improved) for CBT (43%) were not statistically significant compared to those for placebo (35%). Response rates to fluoxetine plus CBT (71%) and fluoxetine alone (61%) were significantly superior to those to CBT alone and to placebo. Fluoxetine with CBT showed the greatest reduction in suicidal thinking. Although remission rates at the end of 12 weeks of treatment were highest in the combination group (37%) compared to the other treatment groups (fluoxetine, 23%; CBT, 16%; placebo, 17%), these overall remission rates were low. The long-term effectiveness of these treatments was assessed over 36 weeks. It was found that for adolescents with moderate to severe depression, treatment with fluoxetine alone or the combination of fluoxetine with CBT accelerated the improvement of depression compared to CBT alone. The addition of CBT to fluoxetine decreased persistent suicidal ideation and treatment-emergent suicidal events.

A recent systematic review and network meta-analysis was conducted to compare the efficacy of antidepressants, psychotherapies, and their combination for treatment of children and adolescents with major depression. Fluoxetine alone or in combination with CBT was superior to CBT alone and psychotherapy for moderate to severe depression in children and adolescents.

TREATMENT-RESISTANT DEPRESSION

Forty percent of youth with major depression do not respond to treatment with antidepressant medication or psychotherapy.

Ketamine has recently been investigated for treatment-resistant depression in adolescents. In an open-label study, 13 adolescents received intravenous ketamine infusion and 38% met criteria for clinical response. In a double-blind crossover trial that included 17 adolescents with treatment-resistant depression, single-dose intravenous ketamine was shown to be significantly superior to midazolam on depression rating scores. Response rates were 76% for ketamine versus 35% for midazolam. Ketamine was associated with transient dissociative symptoms.

Transcranial magnetic stimulation (TMS) has been investigated in uncontrolled studies which have reported some effectiveness for treatment-resistant depression in adolescents. However, a recent double-

Telegram: @medical_k

www.konkur.in

blind randomized sham-controlled trial did not demonstrate superiority of 10-Hz TMS compared to sham TMS for adolescents with treatment-resistant depression. Response rates were 41.7% for active TMS and 36.4% for sham treatment.

OTHER TREATMENT COMPONENTS

Treatment of depressive disorders in children and adolescents should also include psychosocial factors, psychoeducation, supportive management, family involvement, and school involvement.

Psychosocial factors such as abuse, family conflict, parental psychopathology, peer difficulties, bullying, and family discord might be exacerbating the symptoms of depression and mood dysregulation and should be addressed as part of the treatment plan.

Psychoeducation involves educating the patient and parents about depression, including causes, symptoms, course, and treatment options, including benefits and risks of treatment. Depression should be explained as an illness, not a character flaw of the child or parent. The parent and child should be informed about the importance of adhering to treatment to ensure an optimal outcome.

Supportive management includes assisting the child with problem solving, improving coping skills, and fostering involvement in treatment.

It is important to involve parents in the treatment process. Parents can provide needed information about the child's symptoms over the course of treatment. Parents may also benefit from guidance in managing their depressed child at home.

Regarding school involvement, children with depression may have academic difficulties that require school remediation or accommodation in the child's school schedule or program.

SUICIDAL BEHAVIOR IN CHILDREN AND ADOLESCENTS

Although suicide is not a psychiatric diagnosis, suicidal behaviors are a significant public health problem and a focus of attention. Suicidal behavior is often present in individuals with depression, and the presence of a psychiatric diagnosis of depression is one of the most potent risk factors for suicide. However, not all individuals with depression exhibit

Telegram: @medical_k

www.konkur.in

suicidal behaviors or die by suicide. Furthermore, treatments targeting depression alone have been insufficient for reducing suicide risk.

Definitions

Suicidal behavior is complex and there is no single etiology, it exists on a continuum from wishing to be dead, to thoughts or plans to die by suicide, to death by suicide. Suicidal thoughts or suicidal ideation can vary from passive thoughts of death (e.g., maybe I would be better off dead, I wish I wouldn't wake up in the morning), to active suicidal ideation (e.g., I would like to kill myself, I wonder if I would die if I jumped off the roof.), to suicidal ideation with a plan and intent (e.g., I plan to kill myself with my hunting rifle when my parents go out tonight. I am going to take a bottle of pills after my parents go to sleep). Suicidal threats are the verbalization or a written account of suicidal ideation. A suicide attempt can be defined as "self-destructive behavior with inferred or explicit intent to die." This definition differentiates suicidal behavior from "nonsuicidal self-injurious behavior (NSSI)," which can be defined as a "direct and deliberate destruction of one's own bodily tissue (e.g. cutting, burning, scratching, self-hitting) in the absence of lethal intent and for reasons not socially sanctioned, and without the intent to die. NSSI is most commonly a maladaptive behavior to address affect. Though NSSI is not suicidal behavior, recent literature suggests that for some adolescents, particularly girls in early to midadolescence, NSSI is an independent risk factor for death by suicide. Suicide is an intentional self-destructive act that results in death. Suicide contagion is the exposure to suicide or suicidal behaviors within a person's family, social group, or through media reporting on high-profile deaths by suicide, which can result in an increase in suicidal behaviors and death by suicide among children and adolescents at risk for death by suicide.

Intentional asphyxiation can resemble suicide by hanging. In intentional asphyxiation, there can be a sexual component—often termed autoerotic asphyxiation, or there can be no sexual component. This has been seen more recently in the rise of children and adolescents playing "the choking game." In both forms of intentional asphyxiation, an individual intentionally restricts carotid circulation to the brain using a neck ligature in order to experience euphoria. In autoerotic asphyxiation, there is also simultaneous masturbation or other sexual play to heighten the intensity of sexual climax. The presence of a ligature, sexual paraphernalia, and

Telegram: @medical_k

www.konkur.in

evidence of sexual activity support the autoerotic asphyxiation as an accidental death versus suicide. In intentional asphyxiation not related to sexual behavior (e.g., child or adolescent playing the choking game after being introduced to it at school or through online videos), there may be no suicide note and no sexual paraphernalia present. Although intentional asphyxiation may not be intentional suicide, this does not exclude suicidal intent as a child or adolescent who is engaging in intentional asphyxia may know the risk that they might die by engaging in this behavior, and thus this may still be suicide.

Epidemiology

Suicide in children and adolescents is a significant public health concern. Suicide is the second leading cause of death among children and adolescents aged 10 to 19 years. The Youth Risk Behavior Survey (YRBSS) includes national, state, territorial, and freely associated state, tribal government, and local school-based surveys of representative samples of 9th- to 12th-grade students. The YRBSS for 2019, which gathered data on risk behaviors using self-report, found that, in 2019, about 37% of high school students had experienced periods of persistent feelings of sadness or hopelessness, 16% of youth had a suicidal plan, 9% made a suicide attempt, and 3% made an attempt requiring medical attention.

Telegram: @medical_k

www.konkur.in

FIGURE 50.1–1. U.S. rates of suicide (per 100,000) in youth aged 10 to 19 years: overall by sex. (Centers for Disease Control and Prevention. Accessed Injury Prevention Control: Data & Statistics [WISQARS]. Updated July 16, 2021. http://www.cdc.gov/injury/wisqars/index.html)

Lifetime rates of suicidal behavior using interview data as opposed to self-report yield lower estimates of lifetime suicidal ideation with plan and attempts, both around 4%. However, these rates may also be skewed as certain populations may not be included in such interviews, and secondary to stigma, not all children or adolescents would volunteer information regarding suicidal behavior.

Although deaths by suicide are much rarer than suicidal behavior, occurring in 10.5/100,000 of adolescents aged 15 to 19 years in 2019, and 2.57/100,000 of adolescents aged 10 to 14 years. Suicide remains the second leading cause of death for children and youth aged 10 to 24 years (see Fig. 50.1–1). There is an unstable death by suicide variable of 0.04/100,000 in children aged 5 to 9 years. This may be in part because suicide deaths in this age range are often not listed by coroners or medical examiners as suicide. Governmental agencies tend to believe that children younger than 10 years old may not appreciate the seriousness of suicide, despite the evidence that children as young as 5 years old do die by suicide. Further, even in older children and adolescents, the cause of death by suicide is often misclassified as unintentional accident. The reasons for this misclassification are myriad: they may include reasons related to social stigma, the age of the child, social or cultural norms, or a coroner's unwillingness and/or inability to

Telegram: @medical_k

www.konkur.in

accept suicide death in a young person. It is likely that the true rate of death by suicide among children and adolescents is higher than what is reported.

The rates of suicidal ideation, attempts, and deaths by suicide increase with age across childhood and adolescence, peaking in late adolescence. This increase in ideation may be explained by an increased incidence of depression that occurs during adolescence. The increased rate of attempts and suicide deaths in adolescence relative to childhood may also be explained by higher rates of depression, ongoing emotional dysregulation, any substance use, more sophisticated ability to plan and execute a potentially lethal suicide attempt, and easier access to lethal methods. There is limited evidence suggesting that overuse of social media and internet access may lead to increased exposure to suicidal themes, and to an increased risk of suicide secondary to suicide contagion.

Suicidal ideation has previously been thought to occur more frequently in female than male adolescents, though recent literature indicates there is not a true gender disparity in suicidal ideation or thinking about suicide. Suicide attempts do have a gender disparity with adolescent girls attempting suicide with greater frequency than adolescent boys, particularly after puberty. This is a pattern that is also observed with incidence of depression in adolescents post puberty. However, suicide deaths are 1 to 1.5 times as common in males than females aged 10 to 14 years, (with the exception of indigenous people where the rate is 2:1 males to females) and as much as 3 times as common in males than females aged 15 to 19 years. The higher rate of suicide in late adolescent males relative to females may be due to higher rates of substance abuse and conduct disorder and a tendency to use more lethal means of suicide.

The rate of suicide is particularly high in the United States among the indigenous people (Native Americans/Pacific Islanders) with indigenous males dying by suicide at a rate that is three times higher than the overall death-by-suicide rate for children and adolescents (Fig. 50.1–2). There is an elevated risk of suicide among indigenous peoples worldwide and may be related to erosion of traditional cultural values secondary to colonization and attempted genocide, and resulting social ills most notably poverty, unemployment, substance use, and disruption of traditional family structure.

Telegram: @medical_k

www.konkur.in

White youth have a higher rate of death by suicide than African American youth, although the rate of suicide among African American boys has climbed over the years to around 75% of the rate in white males. There has been an alarming increase in rates of suicide deaths in younger African American boys (aged 5 to 11 years), while rates in White boys in the same age range have decreased. Suicide rates have been increasing for Black boys aged 10 to 19 years for some time, increasing by 114% between 1980 to 1995. There continues to be an upward trend for Black youth, simultaneously with downward trends for Caucasian youth through 2019. This alarming increase in Black youth suicide prompted Congress to convene an emergency task force to address suicidality and mental health for Black youth in 2019.

FIGURE 50.1–2. U.S. suicide rate in 10 to 19 year olds (per 100,000) by sex and race (2019). (Centers for Disease Control and Prevention. Accessed Injury Prevention & Control: Data & Statistics [WISQARS]. Updated July 16, 2021. http://www.cdc.gov/injury/wisqars/index)

After initially peaking in the 1990s, the reported suicide rate in adolescents began to decline until 2004, when it increased for the first time in a decade. Since 2007, there has been a gradual increase in the suicide rate both in males and females, with 2018 showing the highest rate of death by suicide in the past 30 years. The decline in the rate during

Telegram: @medical_k

www.konkur.in

the 1990s had been attributed to several factors, including more restrictive gun control laws and increased prescription of SSRIs though it is difficult to identify causal factors. The use of SSRIs among adolescents has declined since 2004, which is when the FDA initiated a black box warning on antidepressants. Some pharmacoepidemiologic studies have shown a relationship between the decline in use of antidepressants and an increase in the rate of suicide and suicide attempts, but none of these studies are definitive. There are likely other confounders that arose during this period including increased reliance on technology, the use of social media (and media in general), and fewer in-person social interactions as children and adolescents connect with friends through various gaming and online platforms.

The most common method for adolescent suicide attempts is overdose, with the second-most common method being wrist cutting. Although suicide attempts in adolescents are frequently of relatively low intent, ingestion of acetaminophen is associated with a significant risk of liver toxicity and fatality without prompt medical attempt. Much more rarely, adolescents engage in highly lethal suicide attempts, using methods more commonly found in suicide deaths. The most common method in the United States for suicide fatality (in the past 5 years) is by firearm, followed in frequency by hanging (suffocation), drug poisoning, nondrug poisoning, falling or jumping, cutting, and drowning.

Risk Factors, Assessment, and Etiology

Suicide risk is moderated by the interactions between a variety of factors. Most conceptual models of suicide posit that suicide risks result from interactions between predisposing factors (distal, familial/genetic), precipitating factors (proximal, triggering), and developmental factors. The biopsychosocial model for suicide and suicide risks conceptualizes the interplay between genetic, psychological, sociologic, clinical, experiential, and environmental states as causative factors for suicide. While this framework is helpful in understanding the relationships between risk factors, their immediate relevance to suicide risk is imprecise. Any one or all of these factors might be involved at any point in time, and their impacts are moderated by individual traits.

Other relevant risk factors that can help to identify suicide risk are clinical factors that influence the transition from suicidal ideation to attempt, such as prior self-harm events, exposure to suicide by others,

Telegram: @medical_k

www.konkur.in

depressive disorders, substance use, impulse control disorders, anxiety disorders, eating disorders, and traumatic stress-related disorders. Essentially, any disorder that may decrease restraint, such as impulse control disorders, or increase distress, such as panic, may increase the likelihood of moving from suicidal ideation to suicide attempt, especially if a mood disorder is also present.

Other important risk factors and antecedents to suicide include psychiatric disorders, psychological and biologic factors, familial and environmental factors, chronic physical illnesses, risky health behaviors, and personal, community, or public exposure to suicidal behavior that occurs in media reports.

Psychiatric Disorders. Estimates of the proportion of individuals with a mental illness at the time of their death by suicide or suicide death approximates 90%. These disorders, gathered through retrospective chart reviews, family interviews, and psychological autopsy, may have been undiagnosed prior to their deaths. Mood disorders are strongly associated with suicidal ideation, attempts, and completed suicides. Of adolescents who die by suicide, approximately 60% had a mood disorder at the time of their deaths. Most youths with psychiatric disorders never engage in suicidal behavior or die by suicide, suggesting that the treatment of psychiatric disorders may be a modifiable risk factor for suicidal individuals though not sufficient in itself. The presence of a psychiatric disorder does not in itself predict suicide. However, there are specific features of certain disorders that increase suicide risk, such as bipolar disorder, when an individual is experiencing mixed or rapid cycling states or irritable dysphoric states, or when a depressive disorder is accompanied by suicidal ideation, insomnia, agitation, and irritability. Disorders characterized by greater chronicity, severity, or complicated by comorbidity are more likely to be present in psychiatrically ill adolescents with suicidal ideation, attempts, or completion. Recent data suggests high rates of suicidality among clinically referred mood-disordered youths, with approximately one-third of those with bipolar disorder endorsing one suicide attempt. One study found a 10-year rate of suicide of 7.7% when compared with no suicides among a control group.

Anxiety disorders have also been reported to be associated with suicidal ideation and attempts. Social anxiety, panic disorder, and post-traumatic stress disorder have been most commonly associated and

Telegram: @medical_k

www.konkur.in

contribute most strongly to suicide risk in the context of an anxiety disorder.

Studies have shown that alcohol misuse increases the risks of suicide attempts and suicide deaths in clinical and nonclinical samples by decreasing restraint from suicidal behaviors for individuals who are contemplating suicide. The presence of a mood disorder further increases the risk for suicidal behaviors. Alcohol misuse may trigger suicidal ideation even in the absence of high levels of depressive symptoms. Although alcohol has been the most studied substance of abuse in suicide, cannabis, and sedative–hypnotic use are more closely associated with suicidal behaviors than other substances. Schizophrenia and eating disorders are also associated with suicide attempts in adolescence, but increased mortality is more likely to occur in adulthood. There is growing evidence describing increasing rates of suicide among youth with autism spectrum disorders.

Medical Conditions. Studies of adolescents with chronic illnesses have found that the overall risk for suicidal ideation and behaviors is greater when compared to adolescents without chronic illnesses. However, the risk for suicidality is dependent upon the specific medical illness, the required treatments, and pre-existing psychiatric conditions. Some disorders, such as those involving the central nervous system, including migraine and epilepsy, inflammatory disorders, such as inflammatory bowel disorders, respiratory disorders such as asthma, endocrine disorders such as diabetes, and chronic pain may have an increased risk of suicidal behavior. Some disorders, such as cancer, may have increased suicide risks at differing times during treatment as a result of remission or relapse status and/or the treatment itself. Factors that appear to contribute to increased risk for depression and suicidal behavior in chronic illness are related to the general experience of illness, including pain and discomfort, disability, disruption of enjoyable activities and achievement, the pathophysiology of the disease itself, for example, inflammation, and effects of treatments used to treat the disorder, for example, steroids.

Biologic Factors. Understanding the neurobiology of suicidal behavior is complicated by the myriad biologic changes in the brain affecting many different neural pathways. However, parsing out the effects of these changes to determine which are specific to suicide and suicidal behaviors

Telegram: @medical_k

www.konkur.in

or shared with mood disorders and other conditions is not easily achievable. The best-described pathway in suicidal ideation, suicidal behavior, and suicide are the stress response pathway mediated by the hypothalamic-pituitary-adrenal axis (HPA) axis. Disruption of the HPA axis with altered glucocorticoid activity may increase the risk for suicidal behavior. Postmortem brain studies of individuals who died by suicide have shown significant alterations in the prefrontal cortex and hippocampus, areas associated with emotion regulation and executive functioning. These studies also revealed alterations in 5-HT2A binding, decreased activity of brain-derived neurotrophic factor (BDNF) both neuroprotective factors, and dysregulated glutaminergic signaling and gamma-aminobutyric acid (GABA) dysfunction. Several studies have shown an association between inflammation, depression, and suicide generating increasing focus on the microbiome. Neuroimaging studies of depressed people who attempted suicide found alterations of attention and salience networks in that cohort compared with depressed people who did not attempt suicide. In addition, cognitive bias toward suicidal preoccupation, risky decision making, and findings consistent with the characteristics of impulsive aggression, risk taking, and emotion dysregulation have been observed with adolescents who attempted suicide. Neurocognitive testing has demonstrated that adolescents who attempt suicide make impulsive decisions and show a failure to learn from consequences.

Psychological Factors. Personality traits that have been strongly associated with suicidality in adolescents are aggressive–impulsive traits, which are worsened in the presence of depression. Anxiety is weakly linked to suicidality, likely contributing by interacting with individual factors in vulnerable individuals. The aggressive–impulsive behavioral profile has also been found to distinguish those who attempt suicide from psychiatric controls and is more likely to be associated with familial transmission. Also, in studies examining the transmission of suicidal behavior, the transmission of aggressive–impulsive behaviors partially explained the familial aggregation of suicidal behavior. Most adolescent suicide attempts are impulsive, so it is not surprising that impulsivity correlates strongly with suicidality. Other psychological factors include impairments in problem solving, memory bias, and ruminations.

Telegram: @medical_k

www.konkur.in

Disordered emotion regulation, characterized as having a lower threshold for dysregulation (prolonged, severe responses to provocation), has been shown to be associated with suicidal behaviors.

Hopelessness is an important factor that has been associated with suicidal behavior, and among depressed youth signals an increased risk for suicide. A negative cognitive style has been associated with suicide attempts independent of depression. There is also evidence that those who attempt suicide are more likely to show a self-identification with death and suicidal behavior and that this self-identification is a robust predictor of future suicidal behaviors.

Familial and Environmental Factors. Although suicide and suicidal behaviors have been known to cluster in families for some time, recent data have begun to clarify these relationships. Parents of suicidal adolescents have higher rates of psychiatric disorders, including depression, substance use, and impulsive aggression. Suicide and attempted suicide have been found to be increased in families in which a parent has attempted or died by suicide even after controlling for parental psychopathology, suggesting that suicidal behaviors may be transmitted independently. Adoption, twin, and national registry studies suggest a heritability of 30% to 50%, while other studies suggest lower rates after controlling for psychopathology. The children of people who attempt suicide show a fivefold greater risk of suicide attempts than population averages, with suicide risk being doubled for individuals who lost a parent to suicide compared with those who lost a parent abruptly to other causes. It is important to note, however, that fewer than 5% of those who die by suicide have a parental history.

While genetic etiologies for suicide and suicidal behaviors have been sought for many years, no single gene or group of genes has been identified as responsible for suicide. Because suicide deaths are rare, genome-wide association studies (GWAS) have been used to investigate suicide attempts, with few studies including suicide as a primary phenotype. While some studies have found associations between genes identified in GWAS and suicidality, these studies have not met reproducibility and significance testing and have produced inconsistent results. Other proposed mechanisms for genetic transmission suggest familial transmission of impulsive aggression and mental disorders that do not include suicidal behaviors. Higher levels of 5-HT receptors have been

Telegram: @medical_k

www.konkur.in

found in postmortem studies of adults and youth who have died by suicide, suggesting that this may be a marker for suicide death.

The familial transmission of suicide and suicidal behavior is likely explained by familial environmental factors as well as genetic transmission. Environmental factors known to be associated with suicidal behavior are exposure to suicidal behavior within the family. Parent–child conflict increases risk for suicide, especially among younger youth and historically marginalized youth populations. Parental loss, in youth who lose their parent prior to the age of 12, is associated with an increased risk of suicide in offspring.

The most clinically significant familial–environmental risk factor for suicide and suicidal behavior is maltreatment. Physical and sexual abuse and emotional and physical neglect have been strongly associated with suicidal behaviors, even after controlling for parental psychiatric disorders. The strongest associations with suicidality have been reported for sexual abuse. The population-attributable risk of sexual abuse for suicidal behavior has been estimated as slightly less than 20%, suggesting that one in five suicide attempts could be eliminated with the elimination of sexual abuse. In reality, the relationship between abuse and suicidal behavior is more complicated because abuse occurs within the social context of socioeconomic strain, family disruption, parental history of abuse, parental psychopathology—including depression, substance abuse, and suicidal behavior—and low parental monitoring and supervision. The likelihood of suicidal behavior is greater with greater severity of abuse. Studies also show that lesbian, gay, bisexual, transgender, queer (or questioning sexual orientation), and othesr (LGBTQ+) youth are more likely to have experienced sexual abuse than youth who identify as heterosexual.

Youth who are engaged in bullying as victims or perpetrators are at increased risk for suicidal ideation and behaviors. Longitudinal studies suggest that students who were most likely to experience negative outcomes such as suicidal ideation or behaviors showed signs of depression at the time of victimization, suggesting that the impact of bullying may be mediated by the presence of depression. Students at risk of dropping out of school, as characterized by poor academic performance and attendance, are also at high suicidal risk. Youth who live in impoverished communities characterized by violence, trauma, underresourced schools, and lack of community support are at greater

Telegram: @medical_k

www.konkur.in

risk for depression and suicidal behavior. Youth who have a strong connection to school, even in the face of other risk factors, experience some protection from suicidal risk. A deviant peer group is associated with an increased risk of suicidal behaviors, and the presence of a prosocial peer group is protective for youth, including those who are at high risk.

Youth who experience legal problems are at increased risk for death by suicide. While legal problems commonly overlap with other problem behaviors, there is clear evidence that youth who have contact with the juvenile justice system are at high risk for suicidal behavior and death by suicide. Several studies have demonstrated high rates of suicidal ideation and suicide death in juvenile detention facilities. Studies also show high rates of mental illnesses with some studies finding that 75% of youth who died by suicide while in detention had a history of mental illness, 71% had had a history of prior suicidal ideation, and 45% had prior suicide attempts.

Emerging data for Black and Latina/o/x youth found that perceived racial discrimination is associated with increased suicidal ideation and that positive racial identity is protective against suicidal behaviors in Black and Latina/o/x youth.

Youth who identify as gender nonbinary, as well as LGBTQ+ have consistently been at a higher risk for suicide compared to their non-LGBTQ+ peers. LGBTQ+ identity has been identified as a risk factor for suicidal behavior in youth. This association is especially true for those sexual minority youth who are also racial and ethnic minorities. Suicide risks for these youth are in part mediated by family and peer rejection. LGBTQ+ youth who experience significant family rejection has been found to be nine times more likely to make a suicide attempt compared to those with no rejection. This same population of youth appears to be significantly more likely than other youth to experience harassment and bully victimization, and being bullied due to perceived sexual orientation has been found to have a greater impact on the quality of life for youth than bullying victimization for other reasons. Youth who identify as LGBTQ+ at early ages or with cross-gender appearance or behaviors are more likely to experience bullying. Nonetheless, depression and hopelessness remain stronger predictors of suicidal behavior for sexual minority youth than bullying.

Telegram: @medical_k

www.konkur.in

Exposure to Suicidal Behavior. Adolescents are vulnerable to the impacts of suicide contagion that occurs when there has been media coverage of suicide. Studies of media publicity of suicide consistently find that rates of suicide and suicidal behaviors increase, especially among younger adolescents. Research further finds that the increased rates of suicide are proportional to the amount of publicity, the notoriety of the individual who died, details regarding the manner of death, and the extent to which the death was romanticized when compared to presenting the information regarding the death highlighting the relationship between psychiatric illness and the outcome of death by suicide.

Contagion effects can also occur with suicides that occur within the family, community, or among friends. Several studies show increased suicidal thoughts or behaviors following the suicide of a friend or acquaintance. They also found that youth with mental health problems have a greater risk for suicidal behaviors following exposure.

Suicide Risk Assessment

The assessment of suicide risk must consider the spectrum of risky behaviors that impair an adolescent's health. Suicidal behavior most commonly occurs within the context of risky behaviors such as NSSI, binge drinking, substance use, disordered eating, carrying a weapon, and unprotected intercourse. A plethora of studies have shown that common risk factors for these behaviors include impulsivity and poor problem-solving skills, a weak connection between parent and child and/or a conflictual parent–child relationship, low degree of parental supervision and monitoring, poor connection between child and school, and association with deviant peers.

The assessment must also consider protective factors that are present in the adolescent and the family including family connectedness and support, school connectedness and school safety, intelligence and good social–behavioral and communication skills, and reduced access to lethal means.

Suicide is a rare event, and studies of suicide generally investigate nonfatal suicidal behavior including suicidal ideation and attempts. Research has identified factors that are precipitating and strongly associated with future suicidal behavior. The strongest predictor of future suicidal behavior and suicide death is current and recent past suicidal behaviors. The greater the severity of the previous suicidal ideation (e.g.,

Telegram: @medical_k

www.konkur.in

with plan) and suicidal behavior (e.g., lethality of attempt), the greater the likelihood of another suicide attempt. In one study examining individuals who died by suicide, 40% had previously attempted suicide.

The risk for suicide, suicidal behavior, and suicidal ideation are assessed across five domains: intensity, lethality, precipitants, motivation, and availability of lethal agents.

Intensity and intent: Suicidal ideation is assessed both with respect to intensity (how frequent and how compelling) and severity from passive ideation to active planning. Suicidal intensity refers to the degree to which the individual with suicidal ideation intends to carry out a suicidal act; when the individual has made an attempt, intent refers to the degree to which the individual wished to die. The worst-ever level of suicidal ideation is also predictive of future suicidal attempts and suicide deaths. Suicidal ideation is a strong predictor of future suicidal behavior.

Suicidal intent is assessed using the patient's self-report and assessment of the actions occurring during the suicidal behaviors including the degree of preparatory behavior, the timing of the event to minimize discovery, and other factors that convey intent. A recent study found NSSI to be a predictor of suicidal behavior associating more strongly with suicide risk than prior suicide attempts. For adolescents who express regret for having survived a suicide attempt, they remain at risk of recurrent and fatal suicidal behavior.

Motivation: Motivation refers to the reason why the individual engaged in suicidal behavior. An understanding of motivation is essential to developing an effective treatment plan. Approximately a third of adolescents who attempt suicide report that they want to escape their intolerable psychological pain and distress, express hostility, or to get the attention and support that was needed.

Precipitant: Parent–child conflict, difficulties in peer and romantic relationships, and disciplinary problems are the most common precipitants for suicidal behavior. In younger children and adolescents, precipitants are most often parent–child conflict, in comparison to older youth who are more likely to report romantic or peer difficulties.

Availability of Lethal Agents. In the United States, approximately 45% of youth suicides involve firearms, although suicide deaths involving firearms are declining, those involving hanging or strangulation are increasing. Studies show an association between the availability of guns,

Telegram: @medical_k

www.konkur.in

especially handguns, and risk for suicide. Handguns are 2 to 10 times more likely to be found in the homes of suicide victims than in those of psychiatrically matched controls. The only risk factor that differentiated youth who died by suicide and living control youth, all of whom had no clear evidence of psychiatric disorder, is the availability of a loaded gun in the homes of those who died by suicide. Restriction of access to guns has been associated with regional and national declines in firearm-related and overall suicide rates. Restricting the availability of prescription medications and dispensing a limited number of pills/tablets/capsules wrapped in blister packs to prevent easy ingestion of large quantities have been shown to favorably affect rates of fatality by ingestion of prescription drugs. Other prevention methods include placing barriers on bridges to prevent jumping. In countries where poisoning is common with pesticides, using a lock box to contain the poisons has been effective in reducing pesticide ingestions.

Assessment of Imminent Suicidal Risk. Clinicians are frequently asked to assess patients to determine their level of suicide risk in the emergency setting.

Often, the clinician is called upon to assess a patient for imminent risk for suicide, in the emergency or urgent setting—does this person really want to kill themself in the next 24 to 48 hours? When assessing acute risk for suicide, factors that must be assessed urgently are those that increase distress and decrease restraint to determine levels of risk, and availability of lethal means. High levels of distress are found with anxiety and panic, hopelessness, mixed and irritable bipolar states, agitation, psychosis, emotion dysregulation, and insomnia. Insomnia is especially potent as it increases distress and decreases restraint. Factors that decrease restraint include impulsivity, substance use or misuse, a belief that no one cares about the person, or that they are a burden. The most effective interventions target increased restraint and decreased distress, and a plan for safety that will provide resources for recognizing when distress is building and a plan for intervening when risks are increasing, for example, The Safety Planning Intervention.

Treatment

When a child or adolescent is suicidal secondary to an underlying depression, treatment of the depressive episode is important; however,

Telegram: @medical_k

www.konkur.in

this treatment takes time and a more immediate brief intervention can be used in the interim. In the emergency room setting, targeted safety planning such as the Safety Planning Intervention, which can help patients address suicidal thoughts and feelings and reduce the risk of death by suicide. Safety planning intervention is not the same as a no-suicide contract or a safety contract, rather it is a therapeutic-based approach to helping the suicidal adolescent or child engage in crisis management skills prior to engaging in any sort of self-harm. The Safety Planning Intervention involves identifying antecedents to a suicide attempt, stressors or warning signs that a patient is feeling more dysregulated, coping skills or activities for distraction or avoidance of the negative suicidal thoughts, and creating a list of family friends and trusted adults including providers to whom a child or adolescent can turn before acting on any thoughts of suicide. This type of planning is done in conjunction with the patient, the parent, and a clinician. This particular type of planning works well because it's not just a relying on a safety contract, which has not proven to be a deterrent to suicide or suicide attempts, rather it is an attempt to help the child or adolescent build skills on which they may rely when they are feeling suicidal, or more importantly when they are feeling negative affect that may lead to suicidal thinking. This is also a plan that is adjustable based on the needs, mindset, and skills that a child or adolescent has developed. Thus, the safety plan can be modified as needed over time. Other brief interventions have included attachment-based family therapy (AFBT) multisystemic therapy (MST), cognitive behavioral therapy for suicide prevention (CBT-SP) especially when paired with parent interaction, and dialectical behavioral therapy (DBT). Both CBT-SP and DBT show evidence for the prevention of future suicide attempts and self-harm in children and adolescents. Several studies suggest that parent involvement or treatment that also addresses substance use can be efficacious in reducing the risk of death by suicide. Although hospitalization often occurs when patients have had a suicide attempt or are at risk for suicide and unable to engage in safety planning, hospitalization in and of itself is not necessarily treatment. It can be the beginning of treatment especially if specific evidence-based therapies to treat depression, underlying anxiety, ADHD, substance use disorders, or other disruptive behavior disorders are incorporated in hospital treatment plans.

Telegram: @medical_k

www.konkur.in

While there are no medications specifically targeted to treat suicidality, SSRIs used in the treatment of depression may help prevent suicidal behavior. In children and adolescents with schizophrenia disorders, clozapine has been shown to be protective against death by suicide; however, clozapine is rarely used first line in treating psychotic disorders. In children and adolescents with bipolar disorder, there is evidence that lithium may also have a protective effect; however, with its limited therapeutic range and risk of serious adverse outcomes, including death in overdose, this medication must be administered and monitored closely. In the adult literature, there is evidence for ketamine, or its enantiomer esketamine for treatment-resistant depression, although there are no randomized controlled trials (RCTs) involving children, the literature does suggest in small case-controlled studies and case reports involving children and adolescents that IV ketamine has been used to alleviate depression and suicidal thoughts in selected individuals.

In addition to the brief interventions used in emergency or crisis situations, there are several school-based interventions involving social and emotional learning which show some evidence for suicide prevention. Social and emotional learning with an emphasis on cooperation with others, self-regulation, and maintaining self-control while working toward goals valued by school-aged children, have shown some efficacy in decreasing risk of suicide in youth. Social–emotional learning that focuses on the expression, understanding, and regulation of emotional expression has also shown efficacy in school-aged children and beyond. Examples of these programs include “The Good Behavior Game” and “Promoting Alternative Thinking Strategies program (PATHS).”

For adolescents, there is new research using electronic application (app-based) programs to target suicidal thoughts and behaviors. While these programs or apps are still in the early stages, it may be that targeting adolescents, who spend a significant portion of their day interacting with media through the use of apps, can help reduce suicidal behavior as well as nonsuicidal self-injury. In addition, there is a new computer-assisted technology in the form of the computerized adaptive screen for suicidal youth (CASSY), which although is not a treatment model; it may represent an improved screening for children and adolescents at risk for death by suicide or suicide attempt and therefore allow early intervention to prevent suicide deaths. Given the high rate of suicide among indigenous people, one of the CASSY studies particularly

Telegram: @medical_k

www.konkur.in

recruited indigenous children and adolescents. There is a pressing need for development of treatment modalities as well as screening modalities to address specific needs of historically marginalized populations, who may not receive the same benefits of current established treatment protocols which often do not include these populations in initial research protocols.

While there is concern about the use of social media and increased suicide rates, there appears to be some literature that suggests moderate social media use can build social bonds which can be protective against suicide. The role of social media in child and adolescent suicide is one that still needs to be more clearly researched and delineated.

Current guidelines regarding the care of the suicidal adolescent include an assessment and psychiatric evaluation to determine the appropriate level of care to safely deliver treatment, the development of a safety plan that can be modified as needed, encouraging family and caregivers to remove or secure lethal means from the home, treatment of any underlying psychiatric disorders, and addressing specific psychosocial issues that may be affecting the child or adolescent. These issues can be associated with adverse childhood experiences, emotional regulation skills, parental mental illness, parental substance use, and parent–child conflict. Ultimately treatment of the suicidal child or adolescent will primarily be that of prevention.

Course and Prognosis

Although suicidal thoughts are strong predictors of suicide attempts, only a third of adolescents who have suicidal thoughts are estimated to act on those thoughts in a suicide attempt. According to a recent review, one factor that most consistently predicts suicide attempts among adolescents with suicidal ideation is related to suicide capability or rather, the degree to which one feels capable of making a suicide attempt. Unfortunately, suicidal behavior is highly recurrent. Approximately 15% to 30% of adolescents will reattempt suicide within 1 year of their original attempt and, in a more recent study, 5% of adolescents made another suicide attempt within 3 months of an initial attempt. Risk for death by suicide is approximately 0.5% to 1% per year. Although factors for adolescents who attempt suicide are multidimensional and heterogeneous, there are factors that discriminate between those who die by suicide compared with those who are treated for suicide ideation or attempts. Factors contributing to death by suicide are male gender, access to a gun, sleep

Telegram: @medical_k

www.konkur.in

disturbance, mood disorder with comorbid substance abuse or conduct disorder, diagnosis of bipolar disorder, and high suicidal intent. It is important to recognize that suicide is a rare event and that suicide is preventable. Given that suicide is currently the second leading cause of death in adolescents, it is essential that we convey a message of hope when intervening with suicidal adolescents and their families.

50.2 Early-Onset Bipolar Disorder

Gabrielle A. Carlson, M.D., Manpreet Kaur Singh, M.D., M.S., Danella Hafeman, M.D., Ph.D., and Caroly Sue Pataki, M.D.

Recognition of bipolar disorder in young people has had ups and downs over the past 30 years. Some of the controversy stems from inconsistent use of terms like “childhood,” which might or might not include adolescents. We use early-onset bipolar disorder to refer to onsets before age 18; very early onset to refer to onsets through age 12.

Bipolar disorder itself has a number of meanings, but we refer to the spectrum of bipolar I (at least one lifetime episode of mania with or without depression), bipolar II (at least one lifetime major depression and an episode of hypomania), cyclothymia (hypomanic and subthreshold depressive episodes), and other specified bipolar disorder (usually symptoms of mania or hypomania that don’t meet criteria for full-fledged diagnosis. Finally, onset is a tricky concept. Unless a person’s first episode of bipolar disorder is a clear, uncontroversial episode of mania or hypomania, “onset” is something defined in retrospect. If a person has a manic episode at age 24 and remembers being depressed in sixth grade, the assumption is that their onset was in sixth grade. However, in sixth grade, no one at the time knew a manic episode would occur at age 24, and thus bipolar disorder was starting. Similarly, if a child is grumpy, or volatile, or has sleep problems, and subsequently develops a manic

Telegram: @medical_k

www.konkur.in

episode, in retrospect, those symptoms are possibly prodromal. They are, however, common symptoms and usually do not lead to bipolar disorder. Even in the context of having a positive history of bipolar I disorder (BP) in a first-degree relative, psychopathology, in general, is much more common than BP or even bipolar spectrum disorder.

The frequency with which very early-onset BP occurs is controversial compared to onsets after puberty when the condition more closely resembles classic adult BP. It is especially challenging to identify a manic episode in a young child, partly due to the distinguishing mania from severe attention deficit hyperactivity disorder (ADHD) with comorbid oppositional defiant disorder. This confusion evolved from a series of diagnostic criteria changes in earlier versions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), in which *emotion dysregulation* was removed as a core feature of ADHD, and the delineation of an *episode* of mania was not well defined. The subsequent diagnosis of chronically irritable children with severe outbursts led to increased use of neuroleptic medication, prompting the DSM-5 committee to formulate two solutions. First, mania was redefined as: “an abnormal and persistently elevated, expansive or irritable mood” *and* “persistently increased goal-directed activity or energy,” which are present that must vary to a *significant degree* and represent an *observable change* from usual behavior. Furthermore, in an effort to provide a diagnosis for youth who were chronically (vs. episodically) irritable, explosive, and equally disabled, but without other symptoms of mania, a new diagnosis, “disruptive mood dysregulation disorder” was added to DSM-5 to identify children whose mood is “ … persistently irritable or angry most of the day, nearly every day, and is observable to others” (DSM-5) with frequent, impairing behavioral outbursts.

HISTORY

Recognition of manic depression in child and adolescent psychiatry began with the dissemination of Kraepelin’s monograph *Manic Depressive Insanity and Paranoia* after 1921. Child psychiatrists searched for the same condition in their patients but found mostly adolescent depression, which was highly familial. Mania was very rare, even in teens. Brief attempts to broaden the concept of manic depression for younger children were discouraged by a literature review conducted by Anthony and Scott

Telegram: @medical_k

www.konkur.in

in 1960 that used very stringent criteria to identify manic depression in youth. They found only 3 of 60 cases reported prior to puberty. However, the tension between restricting the diagnosis to classical presentations versus altering the criteria to fit children continues to the present.

In the 1960s, evidence of lithium's efficacy for treating adults with manic depression led to an interest in identifying lithium-responsive clinical profiles in children. Early studies suggested that lithium response was most promising in early-onset cases resembling classic manic depression, whereas there was no support for the use of lithium in treating children with broader behavioral dysregulation. When standard symptom criteria became available in the 1970s for describing mania more precisely in adults, Weinberg and Brumback, two pediatric neurologists, adapted these criteria for use with children. The concept of a "manic-depressive variant syndrome of childhood" was subsequently introduced in 1979 and characterized children between 6 and 16 years of age who were hyperreactive to seemingly minor events and were also hyperactive, had disruptions in interpersonal relationships, and often had a family history of manic depression.

By the 1980s, there was increasing acceptance of the diagnosis of manic depression or bipolar disorder, as it became known to the field, in youth. Research efforts initially focused on describing the phenomenology of pediatric bipolar disorder and established standard assessment techniques. In more recent years, there has been a surge of genetic, high-risk, and treatment studies, as well as investigations of neurobiologic, behavioral, and physiologic markers.

As noted earlier, the diagnosis (vs. the actual condition) of bipolar disorder among youth in the community has fluctuated over the last 25 years. A study of outpatient physician visits in the United States found that juvenile-onset cases of bipolar disorder comprised 42% of outpatient mental health–related visits in 2003, an increase from 6.67% of cases in the early 1990s. Another study, using data from the National Hospital Discharge Survey, revealed increases in the rate of bipolar disorder diagnoses among psychiatrically hospitalized children from 10% in 1996 to 34.11% in 2004, and from 10.24% to 25.86% among psychiatrically hospitalized adolescents during that same period. The increased rate of bipolar disorder appeared to reflect a shift in diagnostic practices such that childhood mood lability and aggression, which previously might have been attributed to conduct problems, ADHD, or impaired family

Telegram: @medical_k

www.konkur.in

relationships was reinterpreted as bipolar disorder. The consensus currently is that severe irritability is transdiagnostic, and while some of the children may, in fact, have a bipolar spectrum disorder, that is no longer the only diagnostic home for such children.

EPIDEMIOLOGY

Prevalence rates of bipolar disorder vary depending on whether bipolar I, II, or spectrum conditions are included, the age studied, the definitions and methods used to make the diagnosis, and the type of sample interviewed. Taking wide variability into consideration, an updated meta-analysis calculated a pooled rate of 0.6% (95% confidence interval [CI] 0.3% to 1.2%) of bipolar I in adolescents (children younger than age 9 have not been studied in community samples) (Van Meter et al., 2019). The current prevalence of bipolar spectrum disorder is much higher (3.9% (95% CI 2.6% to 5.8%) because of the use of broad bipolar criteria. Lifetime rates are also higher. While tightly defined bipolar spectrum disorder may have an up to 40% rate of conversion to BPI or BPII, manic symptoms alone are less often associated with such a conversion, as seen in both the Longitudinal Assessment of Manic Symptom Study (LAMS), where mania rarely developed and the Oregon Adolescent Depression Study, where it never developed.

ETIOLOGY, MECHANISMS, AND RISK FACTORS

Bipolar disorder is a serious, recurrent, and complex psychiatric condition. Associated conditions include a uniquely high risk of suicide attempts, co-occurring anxiety and attention deficit with hyperactivity, family dysfunction, cognitive inflexibility, and substance use, among others. While mania is the defining feature of BP, episodes of depression often precede the onset of mania and may predominate a bipolar course of illness. Despite advances in accurately diagnosing bipolar disorder in young people, as well as improvements in the pharmacologic management of this disorder, problems related to symptom relapse, medication nonadherence, and co-occurring conditions continue to affect its long-term morbidity and mortality. The adverse impact of bipolar disorder on families and society is clear, but research toward elucidating

Telegram: @medical_k

www.konkur.in

the pathophysiologic basis of early onset of this disorder has been incremental.

Nevertheless, bipolar disorder is now well established to be brain based, with unique structural, functional, and neurochemical properties in the brain that likely underlie its pathogenesis. Early-onset bipolar disorder is also characterized by dysfunction in the regulation of emotion and cognition. Disturbances in core emotional and cognitive functions aberrant in the disorder provide a basis for understanding the origins of symptom manifestations and the pathophysiology underlying bipolar disorder. In addition, investigating the neural sources of these core features using neuroimaging may be more informative than basing paradigms on nonspecific or transdiagnostic symptoms, particularly when controversies regarding the heterogeneity of symptom presentations in youth inevitably emerge.

Altered interactions among brain networks subserving emotion and cognition must also be developmentally contextualized, with appreciation that key neural features present in adults with bipolar disorder differ from those in youth with bipolar disorder. Traditionally, subcortical gray matter development appeared to precede significant prefrontal development and pruning with a shift in functional dependence from subcortical to prefrontal structures around puberty. Contemporary research suggests there are significant increases in the expression of key presynaptic cell adhesion molecules in the prefrontal cortex prenatally and during the first 3 years of life in individuals at risk for bipolar and other neurodevelopmental disorders. This opens the possibility of a new critical sensitive period for the development of bipolar disorder before puberty when prefrontal–subcortical functional shifts have traditionally been thought to herald the onset of bipolar disorder in adolescence. Early scaffolding of such inborn errors may explain prodromal symptoms that precede mania onset, that can be severe, functionally impairing, and protracted before full threshold symptoms are declared. A family history of bipolar disorder is an independent risk factor for early bipolar development.

Genetic, inflammatory, and environmental stress diatheses have been proposed as etiologic factors for bipolar onset or recurrence. These factors might express themselves phenotypically either through dysregulation of emotion acutely or gradually over time or during a bipolar prodrome. They may also manifest as hyperarousal, hypersensitivity, difficulty with affect decoding or labeling, or as a problem with “repair” of

Telegram: @medical_k

www.konkur.in

maladaptive emotional responses. With time, chronic illness-related physiologic modifications from emotion dysregulation may incite more stress and inflammatory states, which then may have a direct neurotoxic effect, thereby contributing to the onset and recurrence of mood episodes. Although akin to theories of kindling, it may alternatively be the case that forces that compound episodes are dynamically being counteracted by microlevel forces like remodeling or adaptive neuroplasticity and macrolevel forces like cycles of treatment exposure and adherence. These homeostatic forces may lead to episodic (a feature of illness) rather than continuous expression of emotion dysregulation or extended periods of euthymia (a feature of treatment). Indeed, the cumulative effects of familial vulnerability, inhibited temperament phenotypes, environmental stress, inflammation, and disturbances in emotion regulation may converge in the expression of precursor subthreshold forms of bipolar disorder, persistent hypomania, depression, or mixed mood states, episodic irritability, rapid mood fluctuation, and low social functioning. These pathologic processes may elevate the liability for progression to bipolar disorder and to further neurobiologic sequelae.

BRAIN STRUCTURE AND FUNCTION

Untreated or repeated mood episodes may progress into neurobiologic sequelae that could manifest as structural brain changes that are preceded by neurofunctional impairment. Data demonstrating macroscopic structural and functional changes in selective brain regions in bipolar disorder imply underlying cellular and molecular dysfunction. Aberrant prefrontal–subcortical connectivity may result in failure of normal prefrontal regulation of overreactive subcortical processes associated with emotion dysregulation. This failure may, in turn, result in the appearance of disease-specific anatomic abnormalities that may be unique to youth with bipolar disorder, such as reductions in amygdala volumes, thereby predisposing youth to downstream vulnerabilities in the development of coordinated brain networks important for adaptive emotion processing, including the ventrolateral prefrontal cortex (VLPFC), the anterior cingulate cortex (ACC), thalamus, striatum, hippocampus, and the cerebellar vermis. Abnormal emotion regulation and cognition in bipolar disorder may thus arise from aberrant reciprocal connections between the amygdala and dorsal and ventral prefrontal areas as described by others

Telegram: @medical_k

www.konkur.in

in mood disorders in general. Comparisons of pediatric and adult bipolar studies of brain function responses to stress add a developmental component to this model. These data suggest that limbic hyperactivity (e.g., in the amygdala) may occur early in childhood and even prior to illness onset, eventually becoming associated with decreased prefrontal activation and control over amygdala activity expected during typical brain development (e.g., in the VLPFC and dorsolateral prefrontal cortex [DLPFC]). As bipolar disorder progresses, prefrontal abnormalities become more important, and neurodegenerative sequelae of the illness develop that appear akin to molecular, cognitive, and clinical manifestations of accelerated aging and dementia. In this context, the unique regulatory role of the prefrontal cortex may make bipolar disorder exclusive to humans and what challenges modeling of the disorder in other animal species.

Pathologic reactions to stress can be detected acutely by clinical symptoms, and over time, by examining brain structural and functional changes, which interrupt healthy development of networks of brain structures that are important for mood regulation. Disrupted relationships among dorsal regulatory areas, including the DLPFC and dorsal anterior cingulate cortex (dACC), and ventral areas, including the amygdala and subgenual anterior cingulate cortex (sgACC), may lead to mood dysregulation or cognitive impairments. Without adequate intervention, children may eventually develop a full manic episode displaying further functional connectivity abnormalities between nodes in mood regulation networks; for example, inverse functional connectivity between amygdala and DLPFC is lost, or task-dependent excessive medial prefrontal cortex (MPFC) activation is observed. With repeated mood episodes into adulthood, further neurodegeneration of prefrontal areas might occur, leading to rapid cycling, treatment resistance, and more severe episodes, causing increased morbidity and mortality. Progression over the lifespan is variable due to individual differences in intrinsic compensatory adaptations and the buffering effects of individual- and system-level interventions. Longitudinal studies that evaluate risk and resilience factors may clarify the episodic nature of bipolar disorder and enhance prediction about onset and recurrence.

Studies in youth at risk for bipolar disorder indicate that most structural and neurochemical differences do not occur prior to the onset of syndromal mania, suggesting the possibility of preventing disease onset

Telegram: @medical_k

www.konkur.in

and progression if an underlying mechanism can be identified. Further, a relative lack of morphometric abnormalities in symptomatic youth at high risk for bipolar disorder points to the probability that structural effects are a consequence of illness. Studies in healthy offspring of parents with bipolar disorder suggest clues for compensatory or resilience factors that may be important in preventing the onset of illness, including enlargement and increased activation and connectivity in prefrontal regions. Therefore, magnetic resonance imaging (MRI) studies in youth with and at risk for bipolar disorder are identifying brain findings that are now showing demonstrable improvement with early intervention to prevent or ameliorate the natural course of bipolar disorder.

Thus, convergence in network-based abnormalities preceding bipolar onset supports the hypothesis that early neural dysfunction likely underlies the pathophysiology of bipolar disorder. Further, available studies in adults with a prolonged illness have been limited by confounding variables and discontinuous follow-up to make it challenging to elucidate the neurodevelopmental progression of bipolar disorder and its pathogenesis starting from childhood. Many first-generation neuroimaging studies in pediatric bipolar disorder cautiously interpreted early findings with concerns about limitations in small sizes. Although type II error must not be ruled out, and independent replication can strengthen a given finding, indiscriminately large sample sizes as the cost of quality assessments and deep phenotyping are unlikely to facilitate progress in our understanding of early-onset bipolar disorder. To make progress in our field, it is crucial that we find systematic ways of integrating neuroimaging data across multiple modalities, carefully phenotyping youth in a variety of clinical settings, and leveraging multivariate statistical approaches to be able to conduct meaningful next-generation longitudinal neuroimaging studies in at-risk and fully bipolar populations.

ASSESSMENT

The American Academy of Child and Adolescent Psychiatry (AACAP) Practice Parameter advocates (1) screening patients for mania and bipolar depression, both current and past; (2) applying DSM criteria (currently DSM-5); (3) using the designation “bipolar NOS” for children with manic symptoms with a duration of fewer than 4 days (called “other

Telegram: @medical_k

www.konkur.in

specified bipolar disorder in DSM-5); (4) examining for comorbidities; and (5) using extreme caution when diagnosing young children.

Making an accurate diagnosis of bipolar disorder in children requires systematic and thoughtful evaluation procedures that go well beyond the simple application of DSM-5 criteria for mania and depression. For instance, defining a mood episode in children, especially younger children, is complicated by the fact that a baseline or "usual self," developmentally, is a moving target. Thus, a previously docile infant who enters the "terrible two's" may be developmentally normative and yet approximate criteria for mania if this is defined as a persistent mood state different from the child's "usual self." Using the above framework, it is also unclear how long to construe a remission if most of an individual's childhood has been considered an episode. Children stressed by school may have what appears to be mood "episodes" which subside over the summer. In adult studies, in which a typical manic episode lasts for 4 to 8 months, a euthymic period of 8 weeks constitutes remission. Does that mean that a child stressed with "manic symptoms" at school and is better over the summer has had an episode?

Efforts have been made to adapt adult definitions of the cardinal symptoms of mania for young children, taking into account developmental differences. However, children may have difficulties with the concept of elation, or increased self-esteem, which requires an ability to self-assess, a skill absent in young children. Silliness and bravado, which some clinicians construe as childhood manifestations of euphoria and grandiosity, may also be seen in children with ADHD, autism spectrum disorders (ASDs), or children with other social skills deficits. In other words, simply applying criteria using structured interviews without understanding development and context is likely to lead to either the kinds of false positives that artificially inflate rates of bipolar disorder or to cross-site discrepancies in rates of bipolar disorder.

A careful ascertainment of bipolar disorder in youth should start with screening measures completed by multiple informants (i.e., parent, teacher, older child, or adolescent). These are useful in alerting the clinician to current symptoms of mania, depression, and other possible comorbidities. Interviews with caregiver(s) and child and review of other diagnostic information are then required.

Parent rating forms about the child, including the Child Mania Rating Scale, the General Behavior Inventory, and Parent Young Mania Rating

Telegram: @medical_k

www.konkur.in

Scale, are good for both screening and to ascertain severity once the diagnosis has been made.

It is most useful to interview caregivers first because they are likely to provide the most reliable historical and contextual information, and this material can be presented within the child interview to address any discrepant responses. Caregiver interviews should include an overview of current symptoms, developmental history, past history, and longitudinal course of depressive and manic (and comorbid) symptoms.

The child interview is critical for eliciting important information regarding manic (or depressive) symptoms the child is experiencing like euphoria, or depression, or trouble concentrating. It is necessary to interview the child to detect the presence of symptoms and features of other conditions that may be confused or co-occur with mania, including ASD, language or thought disorder, psychosis, anxiety, suicidal behavior, physical/sexual abuse, and substance use. Parents may or may not be able to provide information on these symptoms and situations.

Collateral information, such as teacher input, is helpful in determining whether manic-like symptoms are occurring across settings. Although there are the usual discrepancies between parent and teacher reports, home and school observation can be useful. For instance, a child who is quiet and well behaved for 6 hours a day in school and then dysregulated at home is unlikely to be experiencing a manic episode. Outside assessments, including neuropsychological, occupational therapy, psychoeducational, speech and language assessments, and medical records, can also be extremely helpful in identifying developmental, cognitive, and medical factors that may contribute to emotional dysregulation in other conditions as well as those that complicate episodes of mania and depression.

Structured and semistructured diagnostic interviews are used in research settings to elicit symptoms of bipolar disorder and other childhood conditions. However, they may also be useful in clinical settings to confirm a diagnosis. The Schedule for Affective Disorders and Schizophrenia in Children (K-SADS) is the most commonly used interview and has a number of versions, including the K-SADS-PL (present and lifetime version), a version developed at Washington University, the WASH-U-K-SADS, and now a computerized version. In our opinion, the structured interview is best used as a review of symptoms rather than as a history-gathering tool. Clinical judgment is required to determine whether

Telegram: @medical_k

www.konkur.in

a respondent is under- or overreporting symptoms, misinterpreting developmentally appropriate behaviors, or misunderstanding questions about clinical behaviors. To this end, it is critical that clinicians probe beyond affirmative responses to elicit examples of specific behaviors, as well as the context in which behaviors are occurring.

Several rating scales have been developed to measure the severity of mania once that condition has been diagnosed. One is an interview measure, the Young Mania Rating Scale (Y-MRS), which is used in both adult and youth medication trials.

Family history of mood disorder, bipolar and unipolar, and comorbid psychiatric disorders including oppositional defiant disorder, ADHD, learning disorders, and ASDs should be assessed as part of the parent interview. If there is a positive family history of bipolar disorder, it is important to probe for details regarding clinical presentation, comorbid conditions, and response to treatment in the person who has had bipolar disorder.

Family History

Family history studies estimate that genetic influences explain approximately 60% to 93% of the variance in bipolar disorder. Shared and individual environmental factors account for about one-third and one-fifth of the variance, respectively. Rates of mania in high-risk offspring who have been followed into adulthood occur in 2% to 7%, whereas rates of bipolar spectrum disorder are as high as 20% depending on how broadly the spectrum is defined and how complicated the parent proband is. Mania in high-risk offspring generally starts to emerge in adolescence. There are, however, cross-national differences. Mania onset prior to puberty is not reported in European and Canadian high-risk samples, where it does occur in U.S. samples. The parent probands, however, also differ cross-nationally, with U.S. samples having higher rates of comorbidity, substance abuse, and other psychosocial disadvantages.

The rate of major depression and a wide spectrum of depressive disorders in high-risk children of bipolar parents is higher than the rate of bipolar disorder. That is, major depression, particularly if highly recurrent and remitting, is found more often in families of patients with bipolar disorder and is part of the bipolar diathesis in these families. In fact, depression is the more common mode of onset of bipolar disorder in high-risk samples. Although the estimated heritability of bipolar disorder is very

Telegram: @medical_k

www.konkur.in

high, bipolar variants can be attributed to gene by environment variables and correlations. For example, environmental risk factors such as adverse childhood experiences (ACEs), including physical and sexual abuse, severe parental neglect, and unstable home environments with poor attachments to primary caregivers, may play a role in the risk of developing the disorders. Exposure to parental mental illness, particularly a parent with bipolar spectrum disorder, or harsh and negative parenting styles, exposure, and poor social support may interact with a genetic vulnerability. Evidence suggests that temperament, specifically high emotionality, may be a risk factor for and of mood disorders in high-risk individuals. Irritability in mothers may also be a risk factor.

Bipolar disorder with other comorbidities in parents is an important complication that further contributes to psychopathology in offspring. In utero exposure to alcohol and illicit drugs has been associated with a higher risk for an earlier onset of bipolar disorder in vulnerable individuals. Family history differs in bipolar individuals who are lithium responsive and lithium nonresponsive. Relatives of lithium-responsive patients have a higher rate of episodic, remitting bipolar and unipolar disorders and not of chronic psychiatric illnesses such as schizophrenia, schizoaffective disorder, or substance use disorders, which are found in relatives of patients with the broader subtype.

Comorbidities

Children and adolescents meeting the criteria for BP nearly always present with co-occurring conditions. Symptoms of mania may overlap with those of concurrent ADHD and oppositional defiant/conduct disorder, depression, and anxiety, precisely the conditions with which co-occurrence is highest. ADHD is the most common comorbid diagnosis among children with bipolar disorder, with published rates of 70% to 95% among preadolescent youth and 50% among adolescents. The frequency of comorbid diagnoses is influenced by how different interviews manage symptom overlap between mania and the comorbid disorder. If the interview or investigator deems that a given symptom counts toward all disorders, rates of comorbid ADHD and ODD will be higher than if symptoms counted toward mania are only those presenting an intensity significantly beyond a usual baseline. By counting any overlapping symptoms toward all diagnoses, the Treatment of Early Mania Study

Telegram: @medical_k

www.konkur.in

found that 92.8% of the youth with BP had comorbid ADHD in their index episode.

The LAMS study identified ADHD, bipolar spectrum disorders, and comorbidity in a multisite sample of 707 children who were rated by their parents as having elevated symptoms of mania. The LAMS study found that 76.2% of their sample met criteria for ADHD, 22.9% met criteria for bipolar spectrum disorders, 16.5% had both disorders, and 17.5% of the sample had neither disorder. The majority of children who met the criteria for BP (69%) also had ADHD. The high rate of comorbid ADHD in the entire sample was best explained by independent rates of these disorders in youth rather than a hypothesis that ADHD is a risk factor for bipolar disorder in youth.

Rates of conduct disorder and oppositional defiant disorder are reported to be as high as 79% in youth with BP. The combination of externalizing disorders and bipolar disorder appears to run in families and is associated with significant functional morbidity. Comorbid anxiety disorders have been reported in up to 77% of children with narrow phenotype bipolar disorder, with particularly high rates of generalized anxiety disorder, separation anxiety, and specific phobia. There is some evidence that, in a number of cases, anxiety symptoms may intensify during episodes of depression and mania, resolving when mood symptoms are effectively treated. Finally, features of ASDs appear to be quite common among youth with narrow phenotype bipolar disorder, with one study reporting that approximately 20% of their sample met full criteria for a comorbid autism spectrum condition.

As with adults, substance and alcohol abuse are common comorbidities in adolescents with BP. ADHD and conduct disorder are both risk factors for the development of substance use problems. In an epidemiologic sample, young bipolar patients with substance use problems had conduct disorder rates three times higher (52%) than those without substance abuse (14.8%; $p < .01$). By comparison, young subjects without either mania or substance problems had conduct disorder rates of only 7.75%. Substance abuse in bipolar adults may be more related to childhood conduct disorder than uncomplicated bipolar disorder. Nevertheless, substance abuse and bipolar disorder clearly exacerbate each other, and youth with bipolar disorder are at high risk of substance abuse.

For externalizing disorders comorbid with BP, there appears to be a developmental shift over time. Rates are highest in children (greater than

Telegram: @medical_k

www.konkur.in

75%), lower in adolescence (approximately 50%, especially if both depression and mania have onset after puberty), and lowest, but still present, in adults, in whom the rate of lifetime ADHD has been reported to be approximately 20%. Similarly, conduct disorder/antisocial personality co-occur in adults at double the rates in those with bipolar onset before age 30 years (33%) versus after age 30 years (16%).

DIFFERENTIAL DIAGNOSIS

The five most common clinical conditions to be distinguished from bipolar disorder are ones with which it is most often comorbid. Severe ADHD and oppositional defiant disorder in young children are the ones most often confused with mania. The reason for the emphasis on episodes, euphoria, and grandiosity in making the diagnosis of mania emerges because ADHD is, by contrast, a chronic (rather than episodic) disorder for which elation and grandiosity are not considered symptoms. The clearer these symptoms and behaviors are, the easier the differential diagnosis. If severe irritability and explosiveness are used as the hallmark of early-onset mania, the distinction from severe ADHD with oppositional defiant disorder is extremely difficult. Disruptive mood dysregulation disorder, which identifies youth with temper outbursts and chronic, severe irritability, cannot be diagnosed in the presence of manic symptoms lasting more than a day. This exclusion was added in order to help separate children with nonepisodic irritability from those with mania. Another difficult diagnostic issue is the development of conduct disorder in older children with ADHD. Children with conduct disorder often are very irritable and oppositional, stay out late in defiance of their parents, and thus, may appear to need less sleep, engage in early sexual behavior and drug use (pleasure seeking without regard for consequences), and are hedonistic in their self-interest, caring little for the rights of others.

A third difficult diagnostic distinction is between an agitated, anxious depression and a mixed episode of mania. This complicated differential diagnosis is not unique to children and adolescents. In adult psychiatry, the trend has been to err on the side of making a diagnosis of bipolar disorder and avoiding medications to treat depression and anxiety in order to diminish the potential risk of exacerbating mania. It is necessary to keep an open mind about this issue, and if treatments for mania are not

Telegram: @medical_k

www.konkur.in

helpful, a diagnosis of depression and anxiety alone should be reconsidered.

Substance abuse not only may render a teen depressed, irritable, emotionally labile, and euphoric, it may also precipitate a psychosis that may be indistinguishable from mania. In the short term, it is often impossible to determine whether the psychopathology is primary or substance induced.

Finally, especially in adolescence, first-episode schizophrenia poses an important differential diagnosis. For many years, schizophrenia was considered to be the only psychosis that occurred in adolescents. It is now understood that depression with psychosis (often a harbinger of bipolar disorder) and mania with psychosis are equally likely to occur. In the clearest cases, teens developing schizophrenia will have an insidious onset of psychosis, long-standing cognitive difficulties, and prominent and bizarre delusions. However, that may not be the case, and only careful follow-up over several years will allow the true diagnosis to emerge.

COURSE

There have been five areas of investigation into the course and outcome of bipolar disorder: (1) the duration and recurrence rate of manic and depressive episodes, (2) percent time symptomatic over longitudinal follow-up, (3) functional outcome, (4) diagnostic stability (i.e., how likely is a youth to retain the diagnosis of bipolar disorder), and (5) suicidal thoughts and behaviors.

Episode Duration and Recurrence

The median duration of an episode of mania in adults is 3 to 6 months. Episodes that include both polarities (rapid cycling/mixed), which last longer, have durations of about a year. As with adults, at least 80% of children and adolescents with BD do have a period of recovery, defined as 8 weeks with no or minimal symptoms. The duration of the episode (or time to recovery) in youth is variable, though somewhat longer than typically observed in adult studies. In Geller's sample of children with a mean age at intake of 11 years, the index episode lasted 60.2 (±47.5) weeks; later episodes lasted for shorter periods of time (55.2 and 40 weeks, respectively). The Course and Outcome of Bipolar Illness in Youth study in which bipolar youth aged 7 to 17 years were combined from three

Telegram: @medical_k

www.konkur.in

different sites reported a median episode duration of 52 weeks for BP. Purely adolescent-onset samples fare somewhat better, particularly when focusing only on mania. The median duration of an index episode from one hospitalized sample with mania (mean age 16 years) was 11 weeks, while outpatient teens with mania (average age 14 years) from India had a median episode duration of only 8.7 weeks. The mean episode duration in two other samples was 29 ± 31 weeks and 20 ± 13 weeks (mania/mixed). In older adolescents (mean age 17 years), the median episode duration was 30 weeks. The reasons for these differences in duration are not clear. However, it may relate to the polarity of the episode; as with adults, manic episodes in youth are generally shorter than depressive or rapid cycling episodes. Among those children and adolescents who achieve remission, rates of recurrence ranged from 27% among community-based adolescents at 2-year follow-up to 70% among child and adolescent outpatients at 4-year follow-up.

General risk factors for longer episode duration include nonadherence with pharmacologic treatment, rapid cycling, psychotic symptoms, earlier age of onset, low socioeconomic status, comorbid anxiety, ADHD, and/or disruptive behavior disorders. Alcohol use disorders and exposure to antidepressants have been associated with increased risk of recurrence; involvement in psychotherapy appears to have a protective effect. Notably, males diagnosed with pediatric bipolar disorder appear to have a less severe course with a greater chance of recovery from the initial episode than females. Moreover, compared to children with bipolar I or II disorder, those with *other specified* bipolar disorder endured a more chronic course of illness with persistent subthreshold symptoms and delayed treatment response. Predictors of a more rapid recovery include lithium treatment and living in an intact biologic family. Recently investigators developed a risk calculator to predict mood recurrence in the Course and Outcome of Bipolar Youth (COBY) study using variables known from the literature to increase risk. This risk calculator was able to predict, with good accuracy (area under the receiver operating curve [ROC] curve; AUC >.8), whether an individual would go on to have a recurrence in the next 2 to 5 years. Furthermore, this risk calculator was externally validated in an adult sample (Collaborative Depression Study), showing similar accuracy rates, indicating that a predictive model developed in an adolescent and young adult sample also yields across the lifespan.

Telegram: @medical_k

www.konkur.in

Percent Time Symptomatic

Longitudinal studies indicate that youth with BD spend, on average, 60% of the time symptomatic with threshold or subthreshold mood episodes. While the COBY study found that youth spent a larger percentage of that time in subthreshold and depressive episodes, Geller's study found that youth spent 40% of the time manic.

Regardless, percentages at the group level do not describe what is going on for the individual patient. In the COBY study, latent class growth analysis was conducted on available follow-up data (367 youth followed up every 6 months over an average period of 8 years) to find subgroups of mood trajectories. Four distinct classes were identified: (I) "predominantly euthymic" (24% of the sample), (II) "moderately euthymic" (34.6% of the sample), (III) "ill with improving course" (19.1% of the sample), and (IV) "predominantly ill" (22.3% of the sample). Group I was found to be euthymic, on average for 84% of the 8 years; group II was euthymic for 47.3% of the 8-year study period; group III was euthymic for 42.8% of the 8-year period, and group IV was euthymic for 11.5% of the 8-year follow-up period. Factors related to a better course, with longer periods of euthymia, included (1) older age at onset of symptoms and first episode, (2) less severe depression, (3) less severe manic or hypomanic symptoms, (4) less frequent subsyndromal episodes, (5) fewer suicide attempts, (6) lower rates of sexual abuse, and (7) less family history of bipolar disorder or substance use disorders. The youth in the groups with greater periods of euthymia had a less complicated course overall, with lower rates of comorbid ADHD and anxiety disorders and lower rates of all psychiatric disorders in family members. In fact, almost half of the group with the most time euthymic did not experience another episode during the 8-year follow-up. However, although the other half of group I was also euthymic for about 84% of the 8-year study period, they did continue to have new mood episodes during the follow-up period. In a second cohort of 144 adolescents with BD-I/II, Weintraub, Miklowitz, and colleagues conducted a latent class analysis of mood symptoms over 2 years of follow-up, similar to the COBY study. They identified four latent classes, including a "predominantly euthymic" class (29.9% of the sample).

Psychosocial Functioning

Psychosocial impairment often persists beyond mood episodes in BD. In the COBY study, 92.8% experienced impairment in school activities, and

Telegram: @medical_k

www.konkur.in

40.5% had difficulties with interpersonal functioning. Psychosocial impairment was more common in those with more severe illness, but 44% of the “predominantly euthymic” class continued to experience significant difficulties. Importantly, impairment in psychosocial function preceded depressive episodes, indicating a possible target for intervention. The Child Global Assessment Scale score in Geller and colleagues’ 8-year follow-up of early-onset mania was 33.5 (SD 10.6) for those with the disorder at age 18 or older. Another 1-year follow-up study reported functional recovery in only 39% of the sample. Across studies, predictors of psychosocial impairment include early BD onset, severe illness course, low socioeconomic status, poor medication adherence, and current comorbidity.

Diagnostic Stability

A comprehensive investigation of the stability of diagnosis of bipolar disorder in adults is critical for both prognosis and treatment. The questions regarding BP in youth are for whom will the cycles be mainly depressive or manic, how often will they reoccur, and for whom will BP completely and forever remit? This is important to keep in mind to determine how long a medication (mood stabilizer or antipsychotic) should be administered during and after the resolution of an episode and whether there are observable predictors of longitudinal course. There are a variety of ways to assess diagnostic stability, including via medical records, national registries, and longitudinal follow-up. Based on a Spanish study of medical records, over 95% of 72 youths (median age 12.96, 37.5% with BD-I) maintained a bipolar disorder diagnosis after a median of 3.86 years of follow-up. In an analysis of the Danish population database, 86% maintained a BD diagnosis at 3 years and 73% at 10 years; those who no longer had a BD diagnosis had changed to schizophrenia. Predictors of diagnostic change to schizophrenia included male sex, history of substance abuse, diagnosis given during hospitalization, and parent with a schizophrenia spectrum disorder. A longitudinal study by Wozniak and colleagues found that 73.1% of youth diagnosed with BD-I continued to meet the criteria for this diagnosis 4 years later (at a mean age of 13.4 years old).

The question of diagnostic stability was recently addressed in the COBY study. Investigators found that 57% of youth with child-onset BP continued to have hypomania/mania in adolescence. They found that

Telegram: @medical_k

www.konkur.in

approximately ~40% of participants who had a manic or hypomanic episode in adolescence (13 to 17 years old) also had one during young adulthood; when this outcome was limited to manic episodes, the number was ~25%. The most important predictors of diagnostic continuity were age at most recent manic or hypomanic episode during adolescence and family history (of mania and suicide attempts). After accounting for adolescent course, the age of onset and pediatric comorbid disorders were not significant predictors of diagnostic stability. Even in those without syndromal mania or hypomania, most had subthreshold manic episodes.

Interestingly, the issue of diagnostic stability is not unique to pediatric bipolar disorder but also a challenge in adults diagnosed with BD. In a 10-year follow-up of early-episode 15 to 50 years old patients ever diagnosed with first-episode mania with psychosis by Carlson and colleagues, diagnostic consistency occurred in only half the sample. Much of the diagnostic instability was predicated on a change in the course of illness. BPI became clearer over time in 17% (as people with psychotic depression developed mania, for example), but in the rest, even though BPI seemed obvious early, other conditions emerged. The most powerful predictors of diagnostic instability (i.e., not maintaining a BPI diagnosis) were having any childhood psychopathology (OR 2.8, CI 1.4 to 5.6) and specifically having a childhood externalizing disorder (OR 4.7, CI 2.5 to 8.9). The more acute and uncomplicated the diagnosis at onset, the more stable the diagnosis; however, a poor premorbid adjustment in terms of childhood psychopathology and nonacute onset predicted diagnosis change. Prognostic implications were substantial as the consistently diagnosed bipolar group had significantly better functioning on Global Assessment Functioning (GAF) ($p < .001$), spent less time symptomatic over their first 48 months of illness (26% vs. 47%) ($p < .001$) and much less time psychotic (7% vs. 31%) ($p < .001$).

Suicidal Thoughts and Behaviors

Two separate longitudinal studies, including the COBY study, found a 5-year rate of suicide attempts to be around 20% in children and adolescents with bipolar disorder. In a public mental health system, the lifetime rate of suicide attempts in adolescents with a diagnosis of BD-I was 57%. High quality of interpersonal relationships and treatment with lithium were both identified in the COBY study as protective factors against suicide attempts.

Telegram: @medical_k

www.konkur.in

Functional outcome outside of symptom status has not yet been addressed in longer-term longitudinal studies. The Child Global Assessment Scale score in Geller and colleagues' 8-year follow-up of early-onset mania was 33.5 (SD 10.6) for those with the disorder at age 18 or older. Another 1-year follow-up study reported functional recovery in only 39% of the sample. ADHD comorbidity and poor medication adherence were associated with poor function. However, it appeared that functional outcome was also associated with syndromal status.

TREATMENT

Our current evidence base for the treatment of mania addresses both medication and psychosocial intervention with considerably more data for the former. Industry-sponsored and investigator-initiated clinical trials have addressed the relative efficacy of atypical antipsychotics with less robust data for anticonvulsants and some recent data supporting lithium. Trials of medication for bipolar depression are much smaller, and to date, only two medications have been shown to be more effective than placebo. Psychosocial interventions are beneficial in addition to medication, not replacements for it. Medication management requires obtaining baseline laboratory tests relevant to the medication used and monitoring side effects as well as monitoring symptoms of mania and depression.

Practice parameters and clinical guidelines, such as the AACAP Practice Parameters, are consistent in advocating the importance of medication.

Pharmacotherapy

As part of the *Best Pharmaceutical Act for Children,* newly developed medications to be used in children or adolescents must be tested for safety and effectiveness in that sample. U.S. Food and Drug Administration (FDA) labeling requirements allow fewer studies to be done if the condition—in this case, mania—is the same condition that exists in adults, such that similar measures to test safety and efficacy are valid in that age group. A consensus conference convened in 2002 established that youth between ages 10 and 17 years can experience the same condition. The same BP disorder in younger children was less well established, hence the cutoff at age 10 years. This is important because it means that the medications and doses used for adults are being studied

Telegram: @medical_k

www.konkur.in

in older children and adolescents. As a result of this mandate, we have the most information on antipsychotic medications, which will be discussed first.

As of 2021, the following medications which are approved for the treatment of acute mania in adults are also approved for youth: chlorpromazine for children down to age 1 (no studies were ever done, however), olanzapine (ages 13 to 17), for children ages 10 to 17, quetiapine, risperidone, aripiprazole, and asenapine, and lithium is now approved for mania and mixed mania down to the age of 7. There has been a positive randomized clinical trial in youth for ziprasidone, and there is a second trial underway but no FDA approval yet as of this writing.

Olanzapine was the first second-generation antipsychotic to be studied and approved. With doses ranging between 10 and 20 mg, 44.8% of youth on olanzapine showed at least a 50% reduction in symptoms compared to a placebo response rate of 18.5%. This was significant ($p < .001$). The mean decrease from the baseline Y-MRS entry score of 33 was 17.7 points, and the effect size was 0.84.

Other atypical antipsychotic trials for risperidone, aripiprazole, and quetiapine were required to use low- and high-dose alternatives. Both high and low doses of risperidone and aripiprazole were significantly effective as measured by a 50% reduction in Y-MRS entry scores and a decrease of Y-MRS scores of between 14 and 18 points compared to placebo responses of 8 to 10 points. In general, 45% to 65% of subjects improved on active medication versus 18% to 37% on placebo. The absolute treatment benefit (percentage of drug responders minus placebo responders) averaged 19% to 38%, and the number needed to treat (NNT) in successful trials in which drug was better than placebo varied from about 2.6 (high-dose aripiprazole and high-dose risperidone) to around 5 (low-dose aripiprazole and high-dose quetiapine). Side effects were usually greater for the high-dose condition without a correspondingly higher improvement. Asenapine, which is administered twice a day sublingually, was tested at low (2.5 mg), medium (5 mg), and high doses (10 mg). At the endpoint, YMRS responder rates for all 3 doses ranged 42% to 54% compared with PBO (28%). The 10-mg dose had the most robust separation from placebo on the Y-MRS in the clinical trial.

There had been small trials of lithium in children for many years, but none addressing acute mania with a placebo control until relatively recently. The TEAM study, which randomized children to risperidone,

Telegram: @medical_k

www.konkur.in

lithium, or divalproex, had reported a lithium response rate of 35.6%. There was no placebo arm, but placebo responses in industry-sponsored trials are about 25% to 30%. Thus, lithium would not have beaten the placebo in that study. However, the Collaborative Lithium Trials (COLT), specifically designed to test the efficacy of lithium, found a 4.5-point difference on the Y-MRS scale at week 8 between lithium- and placebo-treated participants (p = .031). Even so, rates of response (≥50% drop in Y-MRS) did not differ significantly between lithium and placebo groups, respectively (37.7% vs. 28.6%, Robb et al., 2014).

Several anticonvulsants have an FDA treatment indication for mania in adults. Data for bipolar youth is less robust. An industry-sponsored trial with divalproex ER requested by the FDA, which was only 4 weeks in duration (the duration of adult trials), was negative; drug and placebo responses were 24% and 23%, respectively. Atypical antipsychotics outperform divalproex in clinical trials. In addition, where it was measured, the time to response for atypicals was shorter than for divalproex. Blood levels were adequate in both the industry-sponsored trial and in the "Treatment of Early Age Mania" study [TEAM]. In the latter study, a poor response likely was due to the >90% rate of comorbid ADHD. As noted below, comorbid ADHD is a predictor of poor treatment response.

Published trials of two other anticonvulsants in youth, topiramate, and oxcarbazepine, have not been found to be significantly better than placebo. There have been no published placebo-controlled trials of carbamazepine.

Correll and colleagues provide a meta-analysis with relative effect sizes of different classes of medication. Atypical antipsychotics for mania/mixed mania show a larger effect size than mood stabilizers (effect size [ES] 0.65, CI 0.53 to 0.78 compared to ES 0.20 CI 0.02 to 0.39), and a 50% reduction in Y-MRS entry score is seen in 50% to 70% of subjects compared to 20% to 37% on placebo. The NNT in successful trials where the drug was better than placebo varied from 3.8 to 5.3.

The presence of ADHD complicates and attenuates treatment response for youth with BP. Attempts to treat both conditions include one study in which mixed amphetamine salts were added to divalproex, decreasing ADHD symptoms in that group. In another study, children with bipolar disorder stabilized on a thymoleptic received varying doses of methylphenidate (MPH) and placebo. ADHD rating scale scores were significantly improved compared to placebo in the MPH-treated youth.

Telegram: @medical_k

www.konkur.in

MPH added to aripiprazole did not destabilize youth in a cross-over study (though ADHD was not significantly improved, either). Finally, a small open-label study of atomoxetine added to a mood-stabilized regimen for BP and ADHD found atomoxetine was effective in treating the ADHD, although 2 subjects out of 12 reported worsening mood at some point during the 8-week study.

Given the level of severity and impairment with which most children and teens begin a bipolar treatment study, the improvement, when it occurs, is noteworthy, but it often is not sufficient. Few data are available to predict treatment response. The use of more than one medication has increasingly become acceptable for treating mania/bipolar disorder in both adults and young people. In youth, there are three types of studies: (1) comparing two medications to one—for example, combined divalproex and quetiapine versus quetiapine alone; (2) adding one to another if the first drug does not work—for example, adding risperidone to lithium or divalproex; and (3) starting two together—for example, lithium and divalproex—and discontinuing one.

Although the types of adverse effects of medication are similar in children and adolescents, the frequency and severity may differ. For instance, weight gain with metabolic syndrome, especially in medication-naive patients, is significant. Unlike other antipsychotics, aripiprazole is associated with a reduction in prolactin. However, it also may cause a dose-dependent increase in extrapyramidal symptoms. Risperidone, olanzapine, and quetiapine may increase prolactin and cause more weight gain than aripiprazole. Asenapine is very sedating and also may cause dysgeusia and oral hypoesthesia because of its sublingual administration.

Cases of polycystic ovaries secondary to divalproex may be of particular concern in young people. Similarly, disinhibited behavioral responses to many types of central nervous system medications seem to occur more often in children and perhaps slightly less so in teens. This is of particular relevance to antidepressant use, where misinterpreting the side effect of activation as a manic episode may result in withholding helpful medication and prescribing unnecessary treatments. Indeed, the DSM-5 revision has attempted to prevent that error by stating that the activation is a manic episode if it continues after withdrawal of the medication and beyond the medication's physiologic effects.

Prevention of Relapse

Telegram: @medical_k

www.konkur.in

Children and adolescents with bipolar disorder appear to have higher relapse rates and more episodes over the course of a year than adults. Regarding relapse prevention for mania, there is some suggestion that three medications, aripiprazole, lamotrigine, and lithium, may increase the time to relapse for mania. Beyond these reports, it is prudent to assume that medications that stabilize a child with BP should be continued for at least an entire school year while a child is in school. The AACAP Practice Parameter suggested 12 to 14 months. In cases in which it has taken a long time to stabilize the child and in which there is clear evidence from symptom monitoring that treatment has been effective, it may be wise to continue the treatment until the child has improved function, academically, socially, and within the family. The decision to continue medication treatment or not should be assessed annually. In cases in which treatment response is more tenuous and side effects more troublesome, longer maintenance is more difficult to support.

Treatment of Bipolar Depression

Treatment of bipolar depression in young people has received relatively little attention. Even in adults, only three medications (olanzapine/fluoxetine combined [OFC], quetiapine, and lurasidone) have FDA-approved indications for bipolar depression; two of those, OFC and lurasidone, are approved in youths aged 10 to 17 years. Other studies in young people consist of two open trials—one of lithium monotherapy in hospitalized adolescents with bipolar depression and one using lamotrigine alone or with other medications in outpatient adolescents. Symptoms declined in both studies. In the absence of placebo-controlled studies, and given the high placebo response in depression studies in youth in general, the treatment utility of these medications in youth remains to be demonstrated. Moreover, the adolescent samples studied had considerably more subthreshold manic symptoms (Y-MRS scores were 12 or fewer) than in the adults, whose Y-MRS scores were 2 or fewer. Thus, it is not even possible to extrapolate intelligently from adult data.

Of the placebo-controlled studies, one used flexibly dosed OFC (6/25 to 12/50 mg), which demonstrated superiority to placebo (effect size of 0.46), and the other used lurasidone (mean dose 33.6 mg/day). It had a similar effect size (0.45). Both have been approved by the FDA for the acute treatment of bipolar I depression in patients 10 to 17 years of age. Neither

Telegram: @medical_k

www.konkur.in

short- nor long-acting quetiapine has demonstrated efficacy compared to placebo in bipolar depression in children or teens.

There is a modest if anecdotal, literature on the efficacy of electroconvulsive therapy (ECT) in mood disorders in teens. The reader is referred to the AACAP's ECT Practice Parameter on its indications and contraindications.

Psychosocial Treatment

Psychosocial interventions (1) target the recognition of future episodes before they progress too far, (2) enhance treatment adherence, and (3) address environmental stressors that act as possible precipitants to further episodes, (4) help parents and children manage mood dysregulation, and (5) improve the quality of family relationships. There are a number of empirically supported psychosocial interventions. These include multifamily and individual family psychoeducation, family-focused therapy for adolescents, child- and family-focused CBT for younger children, dialectical behavioral therapy for adolescents, and collaborative problem solving. Each emphasizes the importance of psychoeducation and destigmatization, as well as increasing parental collaboration and empowerment by reducing parent self-blame for "causing the disorder." Other components include helping parents to distinguish between normative developmental behavior and bipolar symptoms, taking proactive steps to decrease the risk of relapse, developing tools for effectively managing emotional arousal, improving family communication skills, and teaching adaptive problem-solving strategies.

FUTURE DIRECTIONS

Developments in neuroscience and genetics, as well as longer-term treatment and follow-up studies, will undoubtedly help to advance the understanding of this complex and disabling disorder, in particular its relation to other psychiatric disorders such as ADHD, conduct disorder, developmental disorders, and psychotic disorders. It is hoped that such advances can shed light on the etiology and underlying pathophysiology, including the identification of dysfunctional brain circuits that may underlie pediatric mania and progress toward mechanistically informed treatments.

51 Anxiety Disorders in Children

51.1 Obsessive-Compulsive Disorder in Childhood

ADAM B. LEWIN, PH.D., A.B.P.P., AND JOHN PIACENTINI, PH.D., A.B.P.P.

Pediatric obsessive-compulsive disorder (OCD) is a chronic neuropsychiatric condition associated with broad impairments in functioning. Over the past two decades, OCD in childhood has garnered increased attention, given heightened public and professional awareness of substantial upward revision of the prevalence of this disorder in youth. Advances in functional neuroimaging, genetics, neurosurgery, neuropsychology, and psychoneuroimmunology have contributed to a better understanding of etiologic factors contributing to the pathogenesis of OCD in childhood. Concurrently, randomized controlled trials and subsequent meta-analyses from multiple research groups have established individual- or family-based cognitive behavioral therapy (CBT) with exposure and response prevention (E/RP) and selective serotonin reuptake inhibitors (SSRIs), alone or in combination, as first-line treatments for OCD in childhood. Despite promising interventions, OCD remains a chronic and disabling disease which

Telegram: @medical_k

www.konkur.in

can lead to marked social, academic, and familial dysfunction as well as increased risk for depression, self-harm, substance use, and poorer quality of life in adulthood. For individuals who do not benefit from available treatment, further refinement of treatment approaches remains paramount to diminish suffering and impairment while increasing the likelihood that youth with OCD can maintain relatively normal lives. Because many youth do not receive treatment due to lack of access to child psychiatrists and psychologists trained in evidence-based intervention, improving availability of care is another key goal.

DEFINITIONS

OCD is characterized by the presence of recurrent obsessions or compulsions that are distressing, time consuming, or debilitating. Obsessions are defined as recurrent, persistent, and intrusive thoughts, ideas, impulses, or mental images that are experienced by the individual as distressing and as a product of one's own mind (to differentiate them from thought insertion). These thoughts or ideas frequently generate (or are associated with) feelings of anxiety, tension, disgust, or aversion. Table 51.1–1 lists common obsessional fears. Compulsions are purposeful, repetitive behaviors or mental acts that typically function to neutralize, prevent, or reduce anxiety. Table 51.1–1 also listed common compulsive behaviors. Often, compulsions are performed in response to an obsessive thought or according to some other rigidly applied rules. Although compulsions function to mitigate distress or anxiety or to prevent some dreaded event, they are clearly excessive or are not realistically connected with the triggering stimulus (e.g., tapping three times to prevent illness after someone in the room coughs). While obsessions and compulsions are often ego dystonic and are often recognized by children as senseless or exaggerated, such insight is not required for the diagnosis of OCD in childhood. Otherwise, symptoms of OCD in childhood resemble those seen in adults.

Telegram: @medical_k

www.konkur.in

HISTORY

Early examples of childhood-onset OCD, consisting of case descriptions, date back to the late 19th century. In 1895, Sigmund Freud described an 11-year-old child with obsessions. Subsequently, the French physician Pierre Janet provided the first description consistent with OCD in childhood in his 1903 report on a 5-year-old boy. In the first half of the 20th century, descriptions of clinical samples and generalizations emerged. In 1942, L. Berman extracted clinical information on 62 children with possible obsessive-compulsive neurosis out of a case registry of 3,050 cases. In 1955, Louise Despert described more than 60 cases of children with "obsessive-compulsive neurosis," noting a male preponderance, children's recognition that their symptoms are abnormal and unwanted, and the tendency to attempt to conceal their symptoms from treatment professionals and others. Leo Kanner's (1962) textbook of Child Psychiatry contained descriptions of childhood OCD and the consequences of social isolation and family accommodation.

In 1965, Lewis Judd provided descriptive criteria for the diagnosis of OCD in children that closely resembles the current diagnostic criteria, including the requirement of significant impairment in functioning. Reports as recent as 1973 implicated parental withdrawal of attention as a critical causal factor of childhood OCD. However, by the 1980s, the notion that OCD was a neurobiologic disorder with possible childhood onset became more commonplace. Further, findings from the Epidemiologic Catchment Area (ECA) study indicating most adults with OCD report an onset of the disorder during adolescence prompted increased awareness of the disorder in childhood as well as research in this area. Programmatic work in the 1980s under the direction of Judith Rapoport and her group at the National Institute of Mental Health provided the basis for the first systematic studies of epidemiology, phenomenology, and treatment of childhood- and adolescent-onset OCD as well as fundamentally dismissing any notion that the emergence of OCD in youth was unusual or unexpected. The Pediatric Obsessive-Compulsive

Telegram: @medical_k

www.konkur.in

Disorder Treatment Study (POTS) emerged as the plenary multimodal treatment trial in 2004.

Table 51.1–1.
Common Symptoms of Pediatric Obsessive-Compulsive Disorder Obsessions

Obsessions
Concerns with dirt, germ exposure, fears of illness, disgust
Fears of harm befalling self or others
Need for symmetry, order, exactness, completeness
Need to save or hoard
Excessive moral, religious, or sexual concerns
Compulsions
Cleaning rituals
Checking
Repeating behaviors
Ordering or arranging
Confessing, reassurance seeking

COMPARATIVE NOSOLOGY

Diagnostic criteria for OCD have remained relatively constant over the past three editions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM). The fifth revision (DSM-5) published in 2013 defines the following features of OCD: (1) recurrent obsessions or compulsions; (2) obsessions or compulsions cause marked distress, are time consuming (take more than 1 hour per day) or cause significant impairment in functioning; and (3) obsessions and compulsions not due to the presence of another mental disorder, substance, or other medical condition. The DSM-5 further includes specifiers to code degree of insight and to indicate whether the individual has a history of a tic disorder. The 10th revision of the *International Statistical Classification of Diseases and Related*

Telegram: @medical_k

www.konkur.in

Health Problems (ICD-10) provides a description of OCD that is similar to the DSM-5.

EPIDEMIOLOGY

Although estimates vary, studies suggest lifetime prevalence for OCD in children between 1% and 3%, indicating that OCD is more common than previously thought and as common in youth as in adults. Sample age may explain some of the variability in these estimates. Older adolescents yield prevalence rates between 0.53% and 4.0%, whereas estimates for school-aged children remain lower. In fact, a large prevalence study from the United Kingdom showed an exponential rise in rates across age groups (5 to 7, 8 to 10, 11, 12, and 13 years). Another recent community sample found a prevalence rate of 3% for “clinical” OCD, defined as symptoms severe enough to cause distress and interference in functioning. The most accepted 6-month prevalence rate is between 0.5% and 1% of the general pediatric population. Of note, rates of OCD in late adolescence make it more common than panic disorder, schizophrenia, and bipolar disorder.

Mean age of onset for pediatric OCD is between ages 6 and 11. Onset age appears bimodal and varies by gender with a male preponderance in cases of prepubertal onset with an initial peak of incidence around puberty and subsequently in young adulthood. The gender distribution becomes roughly equivalent during adolescence. It is currently believed that up to 80% of adult OCD cases have an initial onset during childhood. Children with an early onset of OCD (below age 7 years) are also more likely to be male and to have a family history of OCD in comparison to children with later onsets, suggesting that genetic factors may play a role in development of early-onset cases. Referral bias may account for the underrepresentation of minorities and youngsters from lower socioeconomic strata in clinical samples of OCD youth, as epidemiologic studies with adult samples have not replicated this pattern.

Telegram: @medical_k

www.konkur.in

Table 51.1–2.
Comorbid Diagnoses in Pediatric Obsessive-Compulsive Disorder

Diagnosis	Frequency (%)
Anxiety disorders	26–70
Mood disorders	11–62
Tic disorders	11–26
Attention deficit hyperactivity disorder	16–20
Disruptive behavior disorders	9–19
Autism spectrum disorders	3–7

The occurrence of OCD in childhood may be somewhat higher than reported given the secrecy that children often display in reporting embarrassing thoughts and behaviors. In addition, limited insight into the abnormality of their symptoms (and linking OCD symptoms to potential impairment), parent inability to recognize OCD symptoms, and the lack of awareness about the availability of efficacious treatments may contribute to underdiagnosis. Therefore, it is reasonable to assume that many childhood cases of OCD remain undetected.

Comorbidity

In childhood, psychiatric disorders co-occurring with OCD is the norm rather than the exception. For example, in an analysis of 70 clinical cases of youth with OCD, 84% carried at least one additional Axis I psychiatric diagnosis. It is estimated that as many as 50% of pediatric patients with OCD have two or more co-occurring diagnoses (Table 51.1–2). The most common comorbid disorders include other anxiety disorders, depressive disorders, tic disorders including Tourette syndrome, attention deficit hyperactivity disorder (ADHD), and disruptive behavior disorders. Individuals also commonly report sensory abnormalities. Major depressive disorder,

Telegram: @medical_k

www.konkur.in

while rare in younger children with OCD, increases in prevalence over the course of adolescence and into adulthood.

ETIOLOGY

Neurobiologic Factors

Although the cause of OCD remains unknown, multiple neurochemical, neuroanatomical, and immunologic etiologic theories have been proposed. Clinical descriptions of OCD associated with Sydenham chorea (SC), tic disorders, traumatic brain injury, encephalitis, and Huntington chorea have helped to solidify the broad concept of the disorder as brain based and presumably reflecting impaired striatal functioning. Though the neurocircuitry and neurochemistry involved in OCD symptomology has been better clarified using in vivo brain techniques and evaluation of responses to psychoactive medications, there continues to be a need to further refine etiologic models of the condition.

Neurochemical. Dysfunction of the central serotoninergic neurotransmitter system continues to be a suspect in OCD symptomology. Primary support for this premise is the observed efficacy of SSRIs and altered sensitivity to acute administration of 5-hydroxytryptamine (5-HT) agonists, as well as from results of preliminary studies of 5-HT synthesis. Young patients with OCD have presented with reduced platelet (3H) imipramine binding; conversely, those OCD patients with higher (3H) imipramine binding at baseline differentiated responders versus nonresponders to SSRI treatment.

Research also suggests the involvement of the dopaminergic neurotransmitter system. This may be especially relevant to childhood OCD, given the increased rate of comorbid tic disorders. Clinically, administration of psychostimulants appears to worsen obsessions and compulsions. Conversely, the coadministration of dopamine antagonists with SSRIs may augment the beneficial effects of these agents. However, direct assessment of the dopamine system remains unstudied in children, including a lack of

Telegram: @medical_k

www.konkur.in

controlled administration of dopamine antagonists. Further, animal studies suggest that excessive glutamatergic output from the cortex to the striatum is associated with repetitive movements. Human studies in children with OCD have reported correlations between striatal glutamate with OCD symptoms and the drop in striatal glutamate with both SSRI medication and exposure-based CBT. In sum, available neurochemical models suggest the possibility of several neurotransmitter abnormalities associated with OCD.

Neurostructural. The pathogenesis of pediatric OCD is characterized by abnormalities in the prefrontal–basal ganglia circuits, specifically frontal–striatal–thalamic–cortical (FSTC) circuit disruption. This premise is supported by imaging studies of OCD, co-occurrence with other disorders with presumed basal ganglia disruption, as well as neuropsychological studies. Volumetric analyses using both magnetic resonance imaging (MRI) and computed tomography (CT) approaches have revealed that treatment-naive children and adults with OCD have smaller basal ganglia segments than adults. For example, reduced globus pallidus volume and gray matter volumetric abnormalities in the anterior cingulated gyrus have been found in pediatric patients with OCD compared to healthy controls. Higher hippocampal volumes and abnormalities in white matter coherence have also been found in child OCD, with greater white matter irregularities linked to increased OCD severity differences compared to healthy controls.

Treatment-naive children appear to also have large thalamic volumes. Thus, it has been hypothesized that children with OCD display abnormalities in normal developmental remodeling of neuronal structures affecting integration, response inhibition, gating/cognitive control, and processing. Positron emission tomography (PET) suggests dysfunction in FSTC circuitry, with studies showing increased glucose metabolism in the orbitofrontal cortex, ventral striatum, right caudate nucleus, and anterior cingulate gyrus, at rest and in response to symptom provocation. Orbitofrontal and caudate metabolic rates are highly correlated, suggesting that interconnecting loops are freed from usual inhibitory influences and

Telegram: @medical_k

www.konkur.in

reverberate. Disruption of affective/reward processing loops and cognitive control loops have been linked to OCD, and differential development of these systems may be expressed in OCD course and presentation. Recent studies of child OCD suggest that differential development of FSTC circuits and various interconnectivity may explain differential symptom expression (e.g., a finding suggested hypoconnectivity of cognitive control circuity in early-onset cases).

The observations that both medication and behavioral therapies reduce orbitofrontal and caudate blood flow validate the importance of these brain regions in OCD pathogenesis. Paradoxically, lower baseline orbitofrontal glucose metabolism predicts better response to pharmacotherapy. Imaging also suggests the frontal–limbic–basal ganglia system may mediate OCD symptom expression, demonstrating a wider interaction of cognitive and emotional circuits. Specifically, symptom provocation appears to activate paralimbic regions as well as insular, anterior temporal, and amygdalar regions.

Neuroimmunology. Significant attention has focused on the triggering of OCD-like symptoms following group A beta-hemolytic streptococcal infections (GABHS), similar to OCD symptoms observed in SC. These infection-triggered cases of OCD have been coined pediatric autoimmune neuropsychiatric disorders associated with streptococcus (PANDAS) and are believed to represent an autoimmune process related, if not identical to, that associated with rheumatic fever (RF) and SC. (It is noteworthy that patients with RF and SC both display higher frequencies of obsessions and compulsions versus comparison groups, and up to one-third of patients with SC meet research criteria for the diagnosis of OCD.) Immune activation leads to the inflammation of the basal ganglia and disruption of the cortical–striatal–thalamic–cortical (CSTC) function. This acquired basal ganglia dysfunction may result in choreiform movements, tics, obsessions, compulsions, and hyperactivity. PANDAS are characterized by abrupt childhood onset and episodic or saw-toothed course. Relations between the size of the basal ganglia nuclei and OCD symptom severity have been observed

Telegram: @medical_k

www.konkur.in

using MRI. Similarly, small sample studies of immune-modulating treatments (intravenous immunoglobulin G [IgG] and plasmapheresis) have been associated with improvements in OCD patients with suspected PANDAS. However, these interventions remain experimental, and efforts to establish markers of PANDAS have been inconclusive. In addition, the proportion of child OCD cases potentially attributable to streptococcal infection remains unknown. Additional research into PANDAS is warranted. Although the association between GABHS infection and OCD remains debated, evidence-based psychopharmacologic (e.g., SSRIs) and behavioral (e.g., CBT with E/RP) approaches for treating OCD symptoms in cases with suspected PANDAS should still be strongly considered. Positive titers and exposure to GABHS does not imply an atypical ideological influence; nor does a reduction in OCD symptoms following antibiotics. Formal PANDAS diagnosis should include a sophisticated evaluation of history/course, testing, and exam. Multidisciplinary consultation is recommended prior to experimental, high-risk interventions.

More recently, the term PANS (pediatric acute-onset neuropsychiatric syndrome) was coined to characterize cases with similar clinical presentations as PANDAS but without link or presumed cause with GAS infection. Similar to PANDAS, PANS requires abrupt/dramatic/overnight onset of OCD symptoms, and severe and acute onset of at least two of the following: anxiety, emotional lability, irritability/aggression, developmental regression, academic deterioration, sensory sensitivity, or somatic symptoms (including sleep disturbance, enuresis, or urinary frequency). Similar to PANDAS, diagnosis is not straightforward and even putative PANS caseness does not negate potential benefits of CBT or SSRIs nor necessitate the need for experimental interventions. Diagnosis of PANS/PANDAS is not straightforward and there are no definitive tests; evaluation requires careful multifaceted assessment of medical and psychiatric histories and titers alone are not indicative of diagnosis. As a result, the number of patients with confirmed PANS/PANDAS is significantly lower than the number presenting for treatment or requesting immunologic treatment for these symptoms.

Telegram: @medical_k

www.konkur.in

Youth with PANS/PANDAS can benefit from evidence-based psychopharmacology (including antidepressants and antipsychotics) and CBT, but adjustments may be needed, or side-effect profiles may vary.

Family Genetic, Behavioral, and Cognitive Factors

Family Genetic. OCD is a heritable disorder—the familial nature in most cases of OCD is well recognized. Monozygotic twins have a higher OCD concordance rate (0.52) compared to dizygotic (0.21). A meta-analysis of studies exploring familial patterns of psychopathology in relatives of subjects with OCD has documented a fourfold increased frequency of OCD in first-degree relatives of OCD probands (8.2 vs. 2.0 from control families). Rates of OCD among parents of youngsters with OCD range from 17% to 19%. A 2005 review of twin studies suggests 27% to 65% heritability rates for OCD (including nonpediatric onset). In addition, subclinical features of OCD (usually defined as typical symptom constellations without the level of interference required for formal diagnosis) are higher among family members with OCD (e.g., reported in 52% of parents). In fact, relatives of probands with early-onset OCD exhibit even higher rates of OCD and tic symptoms. Analysis of family patterns of OCD finds support for subclinical OCD as an intermediate phenotype that shares similar genetic risk factors.

The relation between OCD and tic disorders, including Tourette syndrome, has emerged from family studies. Tic disorders and some cases of OCD appear to share some susceptibility factors, leading to arguments that OCD may be an alternative expression of the risk factors underlying tic disorders. Some suggest an autosomal dominant model of inheritance with incomplete penetrance. In other words, the phenotypic expression varies in expression from OCD symptoms to tic disorders.

Data from twin and family studies suggest that OCD may be transmitted in families, but specific genes for the disorder have not been identified. Findings from the multisite Obsessive-Compulsive Genetic Association Study (OCGAS), the largest such study to date

Telegram: @medical_k

www.konkur.in

including 1,065 families/1,406 patients with OCD, failed to identify single nucleotide polymorphisms at genome-wide significance. Investigators posit that larger samples are needed to identify genes associated with OCD. Preliminary findings suggest OCD is polygenetic and likely arises from a large number of diverse genes. Candidate gene studies have yet to produce replicable, significant genes culpable in OCD. The neuronal glutamate transporter gene (*SLC1A1*) has the strongest support, with some findings implicating the serotonin promoter variant (*5-HTTLPR*). Definitive copy number variants associated with OCD have not been identified and, to date, OCD-specific genetic markers remain to be found.

Behavioral Factors. Hobart Mower's two-factor conditioning theory provides a behavioral explanation for OCD symptoms. Via classical conditioning, a neutral stimulus (or event) becomes conditioned to elicit distress because of its association with an unrelated aversive (or feared) stimulus. Fear can be conditioned to both mental events (e.g., blasphemous thoughts) and physical stimuli or behaviors (e.g., a "contaminated" object, items perceived as dangerous, driving, eating). Subsequent to the acquisition of the conditioned fear, rituals develop to reduce or avoid distress. These rituals (or compulsive behaviors) persist and become excessive because they temporarily ameliorate the distress associated with obsessive thoughts via operant conditioning (specifically, a negative reinforcement paradigm). In other words, the escape from/reduction of anxiety associated with performing a compulsive behavior or ritual results in an increased likelihood of the ritual being used in future instances of anxiety.

However, specific traumatic events responsible for the conditioned response are rarely identified. In addition, behavioral theories do not adequately explain the acquisition of obsessive fears. Regardless, these behavioral theories are useful for understanding the maintenance of many OCD symptoms and provide the foundation for behavioral intervention.

Telegram: @medical_k

www.konkur.in

Cognitive Factors. The cognitive perspective of the etiology of OCD posits that OCD results from the interpretation of intrusive thoughts rather than the frequency or content of these cognitions. If intrusive thoughts are interpreted in such a way that an individual perceives responsibility for causing or failing to prevent harm, obsessional patterns develop. Attempts to neutralize intrusive thoughts (or obsessions) via motor or cognitive rituals, avoidance, and reassurance-seeking behavior prevent the disconfirmation of the patient's fears and facilitate the proliferation of anxiety. The most common cognitive misinterpretations include thought–action fusion or the tendency to equate thought with action (e.g., thinking something bad is the same as doing it), and exaggerated responsibility for potential untoward consequences of inaction (e.g., "If I don't wash my hands and someone gets sick as a result, then it's my fault."). However, the specificity of these misinterpretations to OCD, especially in children and adolescents, remains unclear.

Similar to behavioral theory, cognitive theory does not adequately explain the etiology of symptoms. It is likely that cognitive misinterpretations and reinforcement theory (see above) maintain and expand OCD symptoms in individuals with biologic propensity for OCD development.

DIAGNOSIS AND CLINICAL FEATURES

Presenting problems among children and adolescents with OCD generally resemble the adult presentation. However, compared to adults, children are more likely to deny impairment due to obsessions and compulsions. Children may also be somewhat less likely to consider their OCD symptoms excessive, perhaps due to lower levels of cognitive awareness. Children do not need to recognize their symptoms as senseless or unrealistic for diagnosis to be assigned; the level of insight varies considerably related to a child's developmental level. Unlike most adults, children might not report symptoms to be ego dystonic. However, children are typically willing to discuss distress from family conflict arising from their rituals (e.g., chronically running late, excessive need for reassurance, time

Telegram: @medical_k

www.konkur.in

burden on parents, disruption of siblings functioning) or interference in schoolwork resulting in dropping grades. Overall, most children are quite open in describing their symptoms and seek assistance in better managing the illness.

Although comorbidity is the rule rather than the exception in childhood OCD, the content of the obsessions and compulsions cannot be better explained by a co-occurring Axis I disorder. Examples include self-deprecating ruminations associated with depression, obsessive concern with appearance in body dysmorphic disorder, hair pulling in trichotillomania, and fears of harm befalling a loved one in separation anxiety disorder. Similarly, the symptoms also are required not to be substance induced or due to the influence of a medical condition. The range of obsessions and compulsions experienced in childhood is similar to that of adults with OCD, although children are more likely to engage in compulsive reassurance seeking and involve family members in their rituals. Most children with OCD have both obsessions and compulsions; pure obsessional illness is rare in this age group. In fact, most childhood cases of OCD involve multiple obsessions and compulsions (mean number of four current compulsions and four current obsessions in one report). Compulsions in the absence of anxiety-related or otherwise distress-inducing obsessions may occur in (mostly younger) children, who often describe their rituals as being performed in response to an irresistible urge or an otherwise vague sensation (the “just-right” phenomena). The absence of reported obsessions in these cases may be due to underdeveloped awareness or ability to articulate these thoughts or result of a misdiagnosed tic disorder. Specific types of symptoms (e.g., touching/tapping/rubbing) may change with age, but the number of symptoms generally remains constant.

The most common obsessions in childhood include fears of contamination (e.g., dirt, exposure to germs, toxins, contracting an illness), fears of harm befalling self or others (e.g., becoming aggressive, failing to prevent harm), need for symmetry or exactness, hoarding or saving concerns, and excessive moralization or religiosity. Obsessions also may manifest as excessive guilt, self-

Telegram: @medical_k

www.konkur.in

doubt, or other forbidden thoughts. Common compulsions involve cleaning/washing rituals, checking, repeating behaviors (touching, tapping, rubbing), counting, ordering/arranging, avoidance, doubt/indecision, confessing, seeking reassurance, and slowness. The content and type of obsessive and compulsive symptoms may change over time. OCD is also stress sensitive, and many children experience acute symptom exacerbations during times of psychosocial stress or change (e.g., attending a new school, moving to a new home, death of a family member).

Similar to adult OCD, family members are commonly drawn into the child's OCD symptoms through the provision of reassurance to the child, modification of family routines as a result of the child's symptoms, or even actual participation in the child's compulsive rituals. Such accommodation can negatively impact the family environment and lead to increased levels of family conflict and negative emotional reactions toward the affected child. Accommodation has also been associated with increased feelings of depression and anxiety on the part of the accommodating family member (typically mothers).

Given the typically strange and senseless nature of many OCD symptoms, many children and adolescents will attempt to camouflage their rituals. It is not uncommon for children with OCD to be able to inhibit their rituals for short periods of time to avoid detection (e.g., in class). Not infrequently, teachers, peers, and even parents remain unaware of the child's OCD for months or years, only becoming aware of the problem after the child can no longer control the symptoms or becomes too overwhelmed to cope.

DIFFERENTIAL DIAGNOSIS

Developmentally Normative Rituals and Superstitions

Benign habits, transitory superstitions, or mildly excessive thoughts are not uncommon during childhood. In certain phases of early childhood, rituals or superstitions may be utilized by a child to manage new or stressful situations (first day of preschool, separating

Telegram: @medical_k

www.konkur.in

from a parent) or achieve a sense of proficiency. For example, a child may require a particular bedtime ritual or demand to wear a particular item of clothing. These normative rituals usually fade by the time of entry into formal schooling and are rarely associated with distress, significant interference with activities, or overlap in content with typical obsessions or compulsions. The absence of functional impairment differentiates mild, age-appropriate superstitions and habits from obsessive-compulsive symptoms.

Other Anxiety Disorders

Despite the presence of preoccupation and worry about issues related to their fears, children with other anxiety disorders typically do not engage in compulsive behaviors to reduce their anxiety. The content of the worry can also be useful in differentiating syndromes. Pediatric patients with generalized anxiety disorder (GAD) present with heightened anxiety relating to their health and safety, the safety of others, and their future. The content of these symptoms, although exaggerated, is grounded in everyday matters (finances, health, grades, safety) as opposed to the unusual or even bizarre content of obsessive worries. Behavioral analogs to compulsions are rare besides the requests for reassurance from others to reduce anxiety. Patients with social anxiety have fears of negative evaluation and extreme scrutiny by others. Again, fears are, by definition, excessive but typically not bizarre. Rituals are rare, although avoidance of feared situations is common. Similarly, the content of fears expressed by children with separation anxiety disorder is, by definition, confined to themes of separation or fears of harm to self or loved ones. Besides avoidance of separation, other behavioral features or rituals are absent from the presentation.

Tic Disorders, Including Tourette Syndrome

Children and adolescents with tic disorders typically display phonic or motor tics that occur frequently and may appear behaviorally similar to compulsive actions, particularly more complex tics. Tics are differentiated from compulsions as usually being avolitional and not

Telegram: @medical_k

www.konkur.in

preceded by precipitating obsessional thoughts. However, some patients describe their tics as partially volitional in that tic expression is triggered by, and leads to relief from, an uncomfortable premonitory sensation, a functional relationship identical to that between obsessions and compulsions. The content of tics is unlikely to be as purposeful as common compulsions (e.g., washing, arranging), although complex tics may also involve repetition, for example, tapping or touching something a specific number of times. It is noteworthy that there is substantial overlap between tic disorders and OCD in childhood; symptoms of each are not uncommon, and both diagnoses may be warranted.

Autism Spectrum Disorders

The term autism spectrum disorder (ASD) comprises children from a wide range of intellectual (and adaptive) functioning. Pervasive and stereotypic behaviors (including pragmatic language) are characteristic of ASD. In contrast with OCD, perseverations lack an association with anxiety; indeed, ASD perseverations or stereotyped behaviors may contain sought-after or pleasurable topics. Similarly, the stereotyped behavior may be elicited by excitement or frustration or may serve to manage stimulation and is generally not associated with preceding intrusive thoughts or impulses. Obsessions may be described, but they are generally better characterized as idiosyncratic interests accompanied by marked perseveration and no awareness of the disinterest of others (or the excessiveness of their focus). Examples include ordering, arranging, sequencing, and preservative speech. It is not uncommon for parents to report a child appearing “driven” to engage in their “compulsions,” especially younger children. Although OCD can overlap with ASD (6% to 20% of patients with OCD are estimated to have ASD traits), the distinction can usually be made by establishing the developmental context of the behaviors.

Psychotic Disorders

Telegram: @medical_k

www.konkur.in

The differential diagnosis of OCD from incipient psychosis in youth can be challenging. The fixed nature of bizarre or unusual obsessions can have delusional qualities and resemble schizophrenic symptomology. Although OCD-related obsessions and compulsions may appear bizarre, insight is usually preserved, and common themes are often evident. Children with OCD are typically aware that symptoms are products of their own mind (i.e., not thought insertion). OCD can usually be distinguished from schizophrenia by the absence of other symptoms, including formal thought disorder and hallucinations, and by the ability to engage in reality testing. In severe cases of OCD, reality testing may be challenged, and the boundary between obsession and delusion may be difficult to distinguish. OCD and psychotic disorders, though rarely, do co-occur.

Illness Anxiety Disorder (formerly Hypochondriasis)

If the distressing thoughts are exclusively related to fears of having a serious medical condition based on a misinterpretation of bodily symptoms, a DSM-5 diagnosis of illness anxiety disorder should be considered instead of OCD. Behaviorally, persistent need for medical evaluation and reassurance is not uncommon. However, if the preoccupation with illness is accompanied by rituals (e.g., washing, avoidance, checking based on the concern about contracting, exacerbating, or spreading illness to others), then a diagnosis of OCD may be appropriate.

COURSE AND PROGNOSIS

OCD, with onset in childhood, is a chronic condition characterized by substantial morbidity. Follow-up studies suggest that 43% to 68% of youth diagnosed with OCD continue to meet diagnostic criteria for the disorder up to 14 years after identification. A recent meta-analysis found that the remission rate may be as high as 62% (52% to 72% within the 95% confidence interval), with shorter duration of income being linked to better outcomes. Worse outcomes at follow-

Telegram: @medical_k

www.konkur.in

up were predicted by poor initial treatment response, a lifetime history of tic disorder, and a parental Axis I psychiatric disorder. The literature lacks long-term controlled treatment studies, and most follow-up data are from extant treatment trials following only a few months posttreatment. Further, this literature is complicated by multiple confounding variables, including treatment type, comorbidity, age or age of onset, and access to follow-up care. In sum, despite promising treatments for youth with OCD, long-term data are scarce, and there is considerable room for improvement with existing interventions. Early intervention appears to be critically important.

Even with remission following treatment, children with a history of OCD or subclinical OCD symptoms should continue to be monitored for relapse in symptoms. Likewise, relatives (siblings) of patients with OCD should be monitored closely and considered for treatment with the emergence of subclinical symptoms, even in the absence of more severe or impairing symptoms.

TREATMENT

Currently, there are two approaches supported in the research literature for pediatric OCD: CBT with E/RP and pharmacotherapy with SSRIs. According to the American Academy of Child and Adolescent Psychiatry, CBT or CBT with concurrent pharmacotherapy using an SSRI is considered the first-line treatment for pediatric OCD. Multiple controlled trials, meta-analyses, and systematic reviews support these indications and add further support for combined behavioral and pharmacologic approaches in more severe cases. Behavioral approaches are overwhelmingly preferential for parents (75% of parents prefer CBT only compared to CBT + SSRI, with the disparity increasing among parents of children under age 9). Recent data suggest both the robustness and durability of CBT. Overall, treatment methodology is improving for youth with OCD. The goals of treatment are now conceptualized as striving to achieve and maintain remission.

Telegram: @medical_k

www.konkur.in

Cognitive Behavioral Therapy with Exposure and Response Prevention

The efficacy of CBT in children has been demonstrated in numerous open trials and at least six controlled trials. Indeed, treatment response rates in the extant CBT trials were quite high, ranging from 57% to 90%. One meta-analysis of 20 studies and 1,293 participants yielded an effect size of 1.21 and relative risk of improvement versus comparison intervention of 3.93. Unlike pharmacotherapies (for which relapse is not uncommon when medication is discontinued), treatment gains from CBT commonly endure after therapy is completed. Strikingly, the Nordic Long-term OCD Treatment Study (NordLOTS) trial found at 3 years post treatment 90% (N = 242) of youth were responders (73% in remission). Importantly, CBT with E/RP for OCD is distinguished from other "talk therapies," including role-play–based, supportive, insight-oriented, relaxation, psychoanalytic, and psychodynamic therapies, which have no supported efficacy in the extant literature. Several treatment manuals outlining CBT with E/RP for children and adolescents are available. They consist of exposure (placing the patient in situations that elicit anxiety related to their obsessions), response prevention (deterring the compulsive or ritualistic behaviors that may serve to reduce or avoid anxiety from occurring), and, in some cases, cognitive therapy (training the patient to identify and reframe anxiety-provoking cognitions). In light of the chronic nature of OCD and potential for return of symptoms following completion of acute treatment, cognitive interventions also focus on teaching management, acceptance, and/or tolerance of anxiety and distress. The first step of treatment is psychoeducation about OCD and E/RP. It is important for the child and parents to understand the rationale for exposure to fear and restraint from anxiety-reducing compensatory behaviors. Next, a "fear hierarchy" is developed rank ordering symptoms. Following this, patients are systematically exposed to the feared situations (least feared first) while being instructed not to engage in their ritualistic behavior. Over repeated exposures, the associated anxiety can dissipate through the process of autonomic habituation.

Telegram: @medical_k

www.konkur.in

In addition, when the feared consequences of not ritualizing fail to occur, the patient's heightened expectations of harm disappear, reducing anxiety even further. In addition, inhibitory learning techniques, including prolonged exposure and a focus on disproving expectations that feared outcomes will occur (*my obsession will come true if I refrain from my rituals*), may also enhance treatment outcome.

The format and intensity of CBT with E/RP are variable. Studies suggest that weekly outpatient CBT for child OCD is equivalent in efficacy to intensive CBT. It is recommended that treatment of child OCD be conducted in vivo and in the context of the family in order to promote generalization. There is also support for telehealth-based ERP. In addition, CBT targeting OCD may also improve other anxiety and depressive symptoms.

In addition to E/RP, adjunctive cognitive strategies are utilized with pediatric patients. However, younger children and those with impaired cognitive functioning receive fewer and less sophisticated cognitive components to treatment due to developmental and cognitive limitations. A child's age, cognitive functioning, and insight into the nature of their OCD are paramount in determining the direction of treatment, as an introduction of cognitive components of therapy depends on the child's developmental level and insight.

In addition, children's rituals frequently involve parental and family participation. Moreover, E/RP requires significant out-of-session practice for understanding and extinction of OCD symptoms. Many children are unwilling or unable to complete the necessary "homework" from therapy on their own (perhaps due to anxiety, lack of motivation, or distraction). Thus, substantial parental involvement appears warranted, especially for younger children. Family treatment should include significant psychoeducation about OCD as well as mechanisms of E/RP. Parents may benefit from observing techniques presented by a skilled therapist so that they can assist their child with exercises in a supportive, noncoercive approach. In addition, this can help parents to correctly extinguish ritualistic behavior and disengage from OCD rather than scold/react/blame.

Telegram: @medical_k

www.konkur.in

Studies suggest family-based CBT is effective for youth with OCD symptoms as young as age 3.

Table 51.1–3.
Medications and Dose Ranges for Pediatric Obsessive-Compulsive Disorder

Medication	Typical Dosage (mg/day)
Fluoxetine (Prozac)	10–80[a]
Sertraline (Zoloft)	50–200[a]
Fluvoxamine (Luvox)	50–300[a]
Paroxetine (Paxil)	10–60[a]
Citalopram (Celexa)	10–40[b]
Escitalopram (Lexapro)	5–20
Clomipramine (Anafranil)	50–200[a]

[a]Mean doses as per the American Academy of Clinical Child and Adolescent Psychiatry 2012 Practice Parameters, based on randomized controlled trials.
[b]FDA has issued some warnings for the use of citalopram in excess of 40 mg.

Pharmacotherapy

The efficacy of pharmacotherapy for OCD in pediatric populations has been demonstrated in several controlled trials with serotonin reuptake inhibitors (SRIs) and SSRIs. Table 51.1–3 lists medications and dose ranges for pediatric OCD.

Clomipramine. Clomipramine, a tricyclic antidepressant, is the most researched SRI in the treatment of pediatric OCD. In a double-blind, 8-week, placebo-controlled study, 60% of pediatric patients showed significant improvement. Patients treated with clomipramine reported a 37% mean reduction in OCD symptoms compared to 8% for the placebo group (with an effect size approaching 1.0). In another 10-week controlled trial, a significant difference was found between clomipramine and placebo, with 75% of pediatric patients

Telegram: @medical_k

www.konkur.in

showing at least moderate improvement. Other research found that clomipramine was superior to the noradrenergic reuptake-inhibiting tricyclic antidepressant desipramine. This crossover trial found that 64% of patients who initially received clomipramine during their first treatment showed relapse of OCD symptoms during desipramine treatment. Overall, a 2003 meta-analysis of pharmacotherapy trials in children identified clomipramine to be significantly superior to SSRIs in reducing OCD symptoms. Nevertheless, the risk profile, adverse effects, and required electrocardiogram and blood-level monitoring associated with tricyclic antidepressants (e.g., antiadrenergic, anticholinergic, and antihistaminergic adverse effects) are of concern with clomipramine. Thus, clomipramine is relegated to a second- or third-line treatment choice for children and adolescents and should not be used until sufficient trials of CBT with E/RP, two or more SSRIs, and combination CBT with SSRI therapy have been attempted.

Selective Serotonin Reuptake Inhibitors. Several placebo-controlled trials have demonstrated the efficacy of SSRIs. In a 20-week, double-blind, placebo-controlled trial of the SSRI fluoxetine in children and adolescents with OCD, 44% reductions in OCD symptoms were reported. A 13-week controlled trial also demonstrated the efficacy of fluoxetine, with 55% of patients treated with fluoxetine rated as much or very much improved. Another 16-week, placebo-controlled trial of fluoxetine in children reported that 57% of patients demonstrated significant improvement. Several open trials also present favorable findings for the use of fluoxetine for pediatric OCD.

Data also support the use of the SSRI sertraline for the treatment of pediatric OCD. A 12-week, multicenter, randomized, placebo-controlled trial of children and adolescents with OCD found that 42% of patients receiving sertraline were rated as much or very much improved. Further, in a 52-week, open-label extension of the previous study, 71% of children (aged 6 to 12 years) and 61% of adolescents (aged 13 to 18 years) demonstrated 25% decreases in OCD symptoms and were rated as much or very much improved.

Telegram: @medical_k

www.konkur.in

More recently, another multisite, randomized, controlled trial found that 21.4% of pediatric patients entered clinical remission following a 12-week course of sertraline.

Finally, controlled trials have found the SSRIs fluvoxamine and paroxetine to be efficacious and well-tolerated treatments for children and adolescents with OCD. A 10-week, multicenter, placebo-controlled trial of fluvoxamine found a 42% response rate. A 10-week, placebo-controlled trial of paroxetine for pediatric patients with OCD found that 61% of patients responded to the medication. In an open-label trial of paroxetine for pediatric OCD (N = 335), 71% of patients demonstrated clinical improvement.

Overall, clinically significant reductions in OCD symptomology have been documented in children and adolescents using SSRIs, including fluoxetine, sertraline, fluvoxamine, and paroxetine, with a relatively minimal side-effect profile (as compared to clomipramine). Based on these findings, SSRIs are the consensus first-line medication for pediatric OCD. Although there are no controlled comparisons between these medications in children, research suggests that SSRIs are equally efficacious in children, and the specific choice should be based on the patient's medical history, concomitant medications, and adverse events. Poor clinical response to one SSRI is not necessarily predictive of failure with other SSRIs, suggesting adequate trials of multiple SSRIs may be indicated before augmentation. In addition, significant clinical response is unlikely within the first few weeks of taking an SSRI; generally, 10 to 12 weeks at adequate dosage is necessary to fully evaluate the efficacy of the medication.

It is noteworthy that on October 15, 2005, the U.S. Food and Drug Administration (FDA) issued a black box warning for antidepressant medications to alert health care providers to an increased risk of suicidality (suicidal thinking and behavior) in children and adolescents being treated with these agents. In light of this warning, increased attention to symptoms of depression among pediatric patients being treated with antidepressant medications appears warranted. This should include a formal assessment of suicidal ideation prior to and throughout the course of pharmacologic

Telegram: @medical_k

www.konkur.in

treatment. An implication of this warning, combined with strong research support for CBT with E/RP, suggests attempting an adequate trial of the CBT prior to pharmacologic intervention. Notably, a recent large-scale Scandinavian study suggested that for CBT nonresponders, continued CBT was as effective in comparison to SSRI augmentation. Meta-analyses suggest other considerations: Adding CBT to current SSRI treatment may be effective for non- or partial responders. Sertraline and fluoxetine may be superior to fluvoxamine. SSRI activation is more likely for youth with OCD versus SNRI activation, suggesting SNRIs as a second-line psychopharmacologic option for youth who become activated on SSRIs.

It is also noteworthy that the FDA issued an advisory regarding the use of paroxetine in children and adolescents (June 19, 2003), recommending that paroxetine not be used in the treatment of major depressive disorder. Although the FDA did not comment on the use of paroxetine for OCD in pediatric patients, one in every five children and adolescents with OCD has co-occurring depression. Overall, activation, disinhibition, and possible worsening of suicidal thoughts associated with SSRI or SRI exposure may be a special concern in depressed children and certainly demand caution and careful monitoring. Activation may be more common in younger children, especially when on higher SSRI doses. For these reasons and given the availability of other safer and effective pharmacologic options, paroxetine should not be considered a first- or even second-line treatment for OCD in children and adolescents.

Current FDA approval has been granted for four medications for pediatric OCD use: sertraline, fluoxetine, fluvoxamine, and clomipramine, although the minimum approved age varies by the compound. The most frequent SSRI side effects include nausea, insomnia, headache, and asthenia. During clinical trials, the inability to tolerate treatment due to side effects was reported in 15% or less of cases.

Other Treatments

Telegram: @medical_k

www.konkur.in

In pediatric cases that are unresponsive to CBT and trials with multiple SSRIs, pharmacologic augmentation may be considered. There is growing support for SSRI augmentation with atypical antipsychotics for refractory OCD in adult patients. For example, an 8-week, double-blind, placebo-controlled trial performed to determine the efficacy of risperidone augmentation in adults with treatment-resistant OCD found a 40% response rate. In addition, two recent meta-analyses of off-label use of neuroleptics (including haloperidol, risperidone, olanzapine, and quetiapine) in adults with OCD suggest that initial findings from open trials, controlled trials, and case studies are promising despite a need for substantial further research, especially in youth. Lithium carbonate and buspirone augmentation have generally not been efficacious augmentation strategies for treatment-refractory OCD in adults but may ameliorate depressive symptoms. Thus, augmentation may also be the case in children with comorbid conditions; for example, a tic disorder may require the addition of an α_2-agonist or neuroleptics. In sum, unlike the adult literature, there is a paucity of empirical data supporting augmentation strategies for pediatric OCD. In addition, significant undesirable side effects should be considered prior to prescribing neuroleptics and benzodiazepines in children.

www.konkur.in

Kosey is an 11-year-old male of Middle Eastern ancestry from a Southeastern urban community. He lives with his parents and older brother. Kosey originally presented to his advanced practice provider with new-onset obsessive-compulsive symptoms. The parents described their son as a perfectionist. Even as a young child, he would need to know the routine, was highly sensitive to certain sounds and textures, and frequently apologized for seemingly normal behaviors (e.g., dropping a toy, coloring outside of the lines). He would worry about his own performance, health, and safety. He was always questioning adults to ascertain, “Am I doing this right?” or “You’re not angry at me?” In addition to questioning, Kosey would always check over his homework, chores, and personal details (e.g., appearance) very carefully. However, approximately 6 months ago, more unusual and atypical behaviors developed. Kosey would rewrite homework assignments six or seven times, shredding papers if he had to erase the slightest mistake. He would change his clothes several times per day, stating that items “got dirty” when there was no evidence of any need for cleaning. His parents noticed a pile of his previously favorite sports jerseys and expensive athletic shoes stashed in the attic. When questioned, Kosey claimed they were “contaminated” and could not be worn again, despite any indication of soiling. He became late for school and activities, locking himself in his room for extended periods before leaving the house. He was evasive when questioned about this behavior but stated, “There are things I need to do to make sure things will be okay.” He later clarified that he would repeat a sequence of prayers and sayings in his head until “they felt just right,” and he could subsequently go out of the house. He refused to go to school on days he would need to change for physical education, confessing to his parents that he worried he might be “gay” (despite no signs of beginning puberty). Whereas Kosey’s elementary school teachers had tolerated tardiness and late assignments, given his history of being a stellar student, his middle school teachers did not accept

late work and reprimanded him for being late. Consequently, his grades were plummeting. At the same time, his extracurricular interests appeared to be diminished, and rituals replaced the time he had spent on age-appropriate activities. Fights were erupting between Kosey and his parents because Kosey's rituals made his mother late for work, and both parents grew tired of their son's increased need for reassurance.

There was no history of OCD in Kosey's immediate family. However, his father had a history of untreated "anxiety," and his mother had suffered from "postpartum panic." His brother also struggles with panic. His uncle had been diagnosed with Tourette syndrome, and his grandmother was described as extremely "compulsive and ritualistic." Kosey's problems had never been mentioned to a health care professional before. For years, his parents felt they were just idiosyncratic aspects of his personality. Moreover, he had been functioning well, and there was no evidence of distress, except when his parents were not available to provide reassurance. Symptoms spiked during the COVID-19 pandemic, with extensive worries about contaminated packaging, air, and risks of infection and death to his family. They presented for treatment, given Kosey's increased distress and impairment. It was recommended by his nurse practitioner that he begin on 50 mg of sertraline (his mother had responded well to sertraline). Kosey's parents wondered if PANDAS was a consideration, given the spike in symptoms when Kosey's grandfather was hospitalized with COVID-19. They were reassured that PANDAS was unlikely a consideration given the long course of symptoms and lack of fluctuating course. They were reluctant to start medication but did so, given the difficulty in finding a clinical psychologist. His dose was gradually increased to 150 mg, but his parents were concerned that he was not responding, despite reading that it can take several weeks or longer for medication to work at therapeutic doses. Consequently, the family was referred to a board-certified child and adolescent psychologist in a neighboring city with expertise in child OCD. Kosey and his family presented for initial consolation with the clinical

Telegram: @medical_k

www.konkur.in

psychologist, who agreed that CBT with E/RP was indicated, and she reviewed the treatment model with the family. Kosey and his family participated in weekly sessions for about 12 weeks, focusing on exposure to his feared thoughts and prevention of ritualistic behavior in a systematic method. He was highly motivated, and most of the visits were conducted via televideo. Therapy was family based, emphasizing family-based in vivo practice of E/RP, generalization of exercises outside of session, and minimizing disruption to school. A hierarchy of feared symptoms was developed at visit two, and in vivo E/RP commenced at visit three.

After about 3 months of CBT with E/RP, Kosey reported an improved ability to manage his obsessive thoughts and to resist rituals. He reported decreased anxiety as well as urges to ritualize. His parents reported an improved understanding of OCD as well as how to react to his reassurance seeking (and other compulsive behaviors) to facilitate his recovery. The family understood the algorithm for intervening with future obsessions or compulsions as well as the potential need to resume CBT if symptoms resurged. The family chose to remain with the psychologist for a few additional sessions to address family conflict that had developed surrounding the OCD behaviors; at this time, his presentation became consistent with clinical remission. His family desired to discontinue medication but was advised to consult with a child and adolescent psychiatrist to discuss discontinuation versus continuance to best maintain remission.

51.2 Posttraumatic Stress Disorder in Children and Adolescents

JUDITH A. COHEN, M.D.

Two-thirds of American youth experience at least one potentially traumatic event (PTE, e.g., child abuse, domestic or community violence, disaster, accidents, medical trauma, war, or multiple/complex trauma). A third experience multiple traumas, increasing the risk of serious mental and medical health problems. Up to 10% develop full-blown posttraumatic stress disorder (PTSD); many more suffer from subsyndrome PTSD symptoms with equivalent functional impairments. New criteria for PTSD in DSM-5 increase attention to developmental and cultural manifestations of trauma symptoms. Genetic and psychobiologic factors also influence the development of PTSD. Recognition of the frequency with which children develop PTSD symptoms has led to improved strategies for assessing and treating traumatized children.

DEFINITION

PTSD is defined by developing characteristic features after exposure to trauma, that is, events involving a threat to life, safety, or physical integrity, experienced or witnessed directly by the child or affecting someone close to the child (criterion A). The clinical presentation varies, and not all children manifest emotional fear, helplessness, or horror as previously required. Children aged 7 years or older must have one intrusion symptom, such as recurrent trauma-related

Telegram: @medical_k

www.konkur.in

memories or dreams or intense psychological or physiologic response to trauma reminders (criterion B); one symptom of persistent avoidance of trauma-related stimuli (criterion C); two symptoms of negative alterations in cognitions such as persistent negative trauma-related beliefs or persistent posttrauma negative emotional state (criterion D); and two arousal symptoms (criterion E). The revised criteria include developmentally sensitive diagnostic criteria for children 6 years and younger. These children must have one intrusion symptom (criterion B), one symptom of avoidance or negative alteration in cognitions (criterion C), and two arousal symptoms (criterion D). The duration of symptoms must be more than 1 month and the disturbance must cause clinically significant distress or functional impairment.

HISTORY

Descriptive accounts of children traumatized by the London blitz during World War II, of the kidnapping and subsequent burial of children in their school bus, and of children exposed to a fatal schoolyard sniper attack were published by early child trauma pioneers. Subsequent empirical studies of children exposed to sexual abuse, peer suicide, cancer, burns, and terrorist attacks confirmed that increased levels of trauma exposure and lack of adequate social support strongly predict the emergence of PTSD and other psychological symptoms. The September 11, 2001, terrorist attacks, the Asian tsunami of 2004, and Hurricane Katrina have documented that peritraumatic panic, delayed evacuation, and perceived life threat to self or family members are significant risk factors for later PTSD development. In the past 25 years, a number of empirically rigorous randomized controlled trials (RCTs) have documented the superiority of trauma-focused psychosocial treatments over usual care for pediatric PTSD. Few pharmacologic RCTs have examined the treatment of pediatric PTSD.

COMPARATIVE NOSOLOGY

Telegram: @medical_k

www.konkur.in

PTSD was first officially recognized in 1980 in DSM-III. DSM-III-R was the first version to include representative items for childhood PTSD. Importantly for children, this version increased the number of avoidance or numbing symptoms needed to meet diagnostic criteria from one to three. DSM-IV further elucidated childhood variants of symptomatology. The development of an alternative algorithm for diagnosing PTSD in preschool children and growing research led to the new diagnostic criteria in DSM-5 for children younger than 7 years. Research documents that many do not respond with horror, fear, or helplessness supported the removal of this criterion in DSM-5. Other research led to including a new cluster for alterations of mood and cognitions in DSM-5.

EPIDEMIOLOGY

Surveys document PTSD prevalence rates in the general youth population of 8% to 9%, with another 14.1% reaching subclinical levels. More relevant are prevalence rates among trauma-exposed children, as by definition, PTSD is only possible in this population. Nonreferred samples of adolescents exposed to various forms of trauma have documented that 25% to over 90% develop PTSD, depending on the trauma experienced, time since exposure, and the assessment method used. Chronic traumas, such as ongoing child abuse, or traumas that result in disruption of family and the broader social support network, such as war or refugee experiences, tend to result in a greater risk of PTSD than acute traumas, such as natural disasters. Exposure to multiple traumatic events is associated with an increase in PTSD. Female gender also tends to predict a greater risk of developing PTSD as well as other mood and anxiety disorders. Furthermore, the above rates only include children meeting full diagnostic criteria; several studies have indicated that the majority of trauma-exposed children develop PTSD symptoms severe enough to interfere with functioning, even in the absence of a PTSD diagnosis.

Telegram: @medical_k

www.konkur.in

ETIOLOGY

PTSD is one of the few DSM disorders that require the presence of an etiologic agent (a serious traumatic event). Exposure factors also predict outcome with severity and frequency of trauma exposure, exposure to interpersonal violence, greater perceived life threat, death of a family member, greater peritraumatic panic, and delayed evacuation (if during a mass trauma experience), all predicting higher risk of developing PTSD. Nevertheless, not all children exposed to such events develop PTSD, so other etiologic factors must also be considered.

Biologic Factors

Female gender is a risk factor for developing PTSD. Children with pre-existing anxiety disorders are at increased risk of developing PTSD following trauma exposure, and a history of depression in first-degree relatives also predicts increased vulnerability to developing PTSD. Prior trauma exposure is a risk factor for developing PTSD upon exposure to a new trauma, with a greater number of traumas predicting a greater risk of the disorder. Recent studies have demonstrated that genetic risk factors interact with other risk and protective factors, such as social support, in determining whether trauma-exposed children will develop PTSD or will be resilient despite traumatic experiences. Numerous psychobiologic abnormalities have been found in children with PTSD, including complex alterations in hypothalamic–pituitary–adrenal (HPA) axis functioning, increased excretion of adrenergic and dopaminergic metabolites, smaller intracranial volume and corpus callosum area, as well as lower intelligence quotient (IQ) and memory deficits. In addition to these alterations, adults with PTSD have evidence of amygdala hyperactivity, medial prefrontal cortex underactivity, and decreased hippocampal volume. However, because of the paucity of prospective studies, it is unclear whether these findings are indicative of etiologic (causal) factors in the development of PTSD or the effects of PTSD on children's developing brains.

Telegram: @medical_k

www.konkur.in

Psychological Factors

Classical and operant conditioning are involved in the development of PTSD. Extreme stressors typically produce negative emotions (terror, anger, sadness) as well as physiologic arousal from the activation of the sympathetic nervous system (the “fight, flight, or freeze” response). Classical conditioning occurs when neutral cues that were present at the time of the trauma become associated or “paired” with the trauma to the extent that they, too, elicit these intense psychological and physiologic reactions. Operant conditioning occurs when the child learns to avoid trauma-related cues in order to reduce the likelihood of experiencing these distressing reactions. As avoidance behaviors are repeatedly reinforced, they may also generalize. New responses can be acquired through the pairing of exposure and inhibitory learning.

Children’s maladaptive cognitions are also relevant to PTSD development. Shame, self-blame, believing that one is undeserving of being loved, protected, or being treated well, or believing that others cannot be trusted are common maladaptive cognitions among children who experience interpersonal trauma. Such children may have difficulty differentiating between what was done to them (the traumatic experiences) and who they are (their identity). This has important implications for how such children’s trauma symptoms are manifested (i.e., in assessing complex PTSD symptoms as described below).

Social Factors

Many pretraumatic social factors, including lower socioeconomic status, economic deprivation, family dysfunction, parental separation or death, lower intelligence, minority racial or ethnic status, and family psychiatric history, have been found to predict a higher risk of developing PTSD. The absence of a strong social support network has been found to increase the risk of developing PTSD. Parental psychopathology has also been implicated as a risk factor in children developing PTSD following exposure to a variety of traumatic events. Thus, there is growing evidence that social factors may have a role

Telegram: @medical_k

www.konkur.in

in the etiology of this disorder. However, a recent study demonstrated that twins who had been sexually abused were at significantly greater risk of developing a variety of adverse outcomes than their nonabused twins, despite shared genetics and family environment. Social etiologic factors should, therefore, not be overestimated.

DIAGNOSIS AND CLINICAL FEATURES

Exposure to a Traumatic Event

To qualify for a diagnosis of PTSD, the child must have been exposed to a traumatic event that consisted of direct personal experience; witnessing an event in person; learning about the trauma of a close family member or close friend (in the case of death, the event must have been violent or accidental); or experiencing repeated or extreme exposure to aversive details of the traumatic events (but not only through media descriptions). A number of qualifying traumatic events are listed in DSM-5, which specifies that in the case of child abuse, there does not have to be a threat of physical violence or injury (e.g., genital fondling without penetration would qualify).

Re-Experiencing

The child must have at least one persistent intrusion symptom related to the traumatic event. Children may have recurrent, involuntary, and intrusive thoughts, memories, images, or body sensations reminiscent of the traumatic event. In young children, this may take the form of repetitive play in which traumatic themes are present (e.g., sexually abused children may repeatedly re-enact inappropriate touching in their play). Children may have recurrent distressing dreams about the event, or in the case of younger children, there may be frequent frightening dreams without any recognizable content. Children may have dissociative reactions; these may include periods when they act or feel as if the event were reoccurring in the present moment (a flashback). In young children,

Telegram: @medical_k

www.konkur.in

trauma-specific re-enactment may occur (e.g., sexually abused children may insert objects into their own or other children's private parts or otherwise recreate abusive acts perpetrated against them). Children may experience intense psychological distress or physiologic reactivity when exposed to triggering events, people, or situations that remind them of the original traumatic event (e.g., children who witnessed a drive-by shooting may become agitated or have difficulty breathing when they hear thunder or a backfiring car). These reminders may be highly idiosyncratic to individual children.

The above criteria also apply to diagnose PTSD for children 6 years or younger, but in these children, spontaneous and intrusive memories might not appear distressing. It may not be possible to ascertain that the frightening content of dreams is related to the traumatic event.

Avoidance and Numbing

The child must experience persistent avoidance of stimuli associated with the traumatic event and numbing of general responsiveness, as indicated by one of the following symptoms. Children may avoid or make active efforts to avoid memories, thoughts, or feelings about or closely associated with the traumatic event. They may avoid or make efforts to avoid external reminders (e.g., discussions about the traumatic event or people, places, situations, or activities that remind them of the trauma). For example, after the sudden death of a loved one, children may refuse to say the name of the deceased or insist that others not do so.

In order to diagnose PTSD for children 6 years and younger, one or more symptoms representing *either* persistent avoidance of trauma-related stimuli *or* negative alterations in cognitions and mood associated with the traumatic event must be present.

Negative Alterations in Cognition and Mood

Children may be unable to recall one or more important aspects of the traumatic event (dissociative amnesia). Children may have persistent, overly negative beliefs about themselves (e.g., "No one

Telegram: @medical_k

www.konkur.in

loves me"); others (e.g., "I can't trust anyone"), or the world (e.g., "Nothing is safe"); or maladaptive cognitions about why the trauma happened (e.g., "I should have known he would hurt me") leading to distorted self- or other-blame. Children may develop negative emotional states such as shame, guilt, anger, sadness, or fear that persist after the traumatic event. Children may have diminished interest or participation in their normal activities, for example, not wanting to play with friends (social withdrawal) or participating less in the classroom. They may feel detached or estranged from others (e.g., feel that no one understands them; affiliate with deviant peers) or may experience diminished capacity to feel emotions, especially warm interpersonal emotions (e.g., children may say, "I don't feel like I love anyone anymore.").

In order to diagnose PTSD for children 6 years and younger, one or more symptoms representing *either* persistent avoidance of trauma-related stimuli *or* negative alterations in cognitions and mood associated with the traumatic event must be present.

Arousal and Reactivity

The child must also experience persistent symptoms of arousal and reactivity that were not present prior to the traumatic event, as evidenced by at least two of the following. Children may have increased irritability and angry outbursts, with little or no provocation; these may be expressed as aggression toward others (and are often misdiagnosed in children as externalizing behavior disorders). They may have reckless or self-destructive behaviors (e.g., self-injury, substance abuse, reckless driving, or unprotected sexual activity). They may exhibit hypervigilance (e.g., children may ask their parents to check several times every night to be sure that all the doors are locked) or exaggerated startle reactions (e.g., jumping whenever the telephone rings or a pencil drops in the classroom). Children may have difficulty concentrating or completing tasks, which may impair academic performance. Children may have trouble falling or staying asleep, or may have restless sleep, whether or not they have trauma-related dreams.

Telegram: @medical_k

www.konkur.in

The above criteria also apply to children 6 years and younger, except that these children do not typically exhibit reckless or self-destructive behaviors.

Duration, Types, and Clinical Features

These symptoms must be present for at least 1 month and must be accompanied by significant distress or impairment in an important area of functioning. PTSD with dissociative symptoms should be specified if the child meets the above criteria and experiences persistent or recurrent depersonalization or derealization symptoms that are not attributable to substance abuse. If the onset of symptoms does not occur until more than 6 months after the traumatic event, the diagnosis is PTSD with delayed expression. “Complex PTSD,” “complex trauma,” and developmental trauma disorder have been suggested to represent the complexity of symptoms existing in children experiencing repeated, interpersonal traumas involving attachment disruption. Such children have severe dysregulation of affect, behavior, cognitive, attachment, perceptual, and biologic domains that result in marked functional impairment. It is not clear whether the new DSM-5 PTSD criteria will more adequately describe these complex problems or whether a new diagnosis will be required. The International Classification of Diseases, 11th Edition (ICD-11) conceptualizes this as two distinct disorders, PTSD and Complex PTSD.

PATHOLOGY AND LABORATORY EXAMINATION

Although several alterations in the laboratory, neuropsychologic, and neuroimaging tests have been reported in children with PTSD, there is currently no laboratory or other test that can reliably distinguish children with PTSD from other children on an individual basis.

DIFFERENTIAL DIAGNOSIS

Telegram: @medical_k

www.konkur.in

Assessment of pediatric PTSD is complex and beyond the scope of this article. PTSD symptoms overlap and co-occur with several other psychiatric conditions. Acute stress disorder (ASD) occurs and is resolved within the first month after traumatic exposure. Children with less significant trauma-related adjustment symptoms may be diagnosed with an adjustment disorder. Several diagnostic criteria of PTSD overlap with those of anxiety disorders and major depressive disorder. For example, recurrent intrusive thoughts are a hallmark of obsessive-compulsive disorder, while avoidance of social situations, social withdrawal, and tantrums are characteristic of social phobia. The specific content of these thoughts or fears may clarify that they are not trauma-focused. However, because children frequently do not disclose traumatic experiences unless specifically asked, it is important for the assessing clinician to inquire directly about traumatic exposure whenever children present with anxiety-related symptoms.

In a similar manner, irritability, feelings of emptiness, decreased interest in normal activities, sleep disturbance, psychomotor agitation, inappropriate guilt, and decreased concentration are all symptoms shared by PTSD and major depressive episodes. Distinguishing between these two disorders may be particularly difficult in children with avoidance symptoms that prevent them from discussing the traumatic event. Careful history-taking is essential in determining whether the child's symptoms are trauma-related and to what extent the child meets the criteria for either or both diagnoses. Children with traumatic bereavement are particularly likely to meet partial or full criteria for both disorders.

Children and adolescents presenting with substance use disorder may have a past history of trauma that is either covert (never disclosed) or minimized by the child or assessing clinician. Accurately identifying PTSD in such children may be critical to their optimal treatment, as standard substance use interventions do not contain important elements of trauma-focused treatment. If such children are using drugs or alcohol to self-medicate trauma-related symptoms, it is unlikely that their substance use will improve without adequately addressing these symptoms.

Telegram: @medical_k

www.konkur.in

Additionally, PTSD may coexist with or be misdiagnosed as behavioral disorders such as attention-deficit/hyperactivity disorder (ADHD) or conduct disorder. Particularly in younger children who are less able to verbalize their anxiety, PTSD-related irritability, sleep difficulties, and difficulty concentrating may present as classic ADHD. Eliciting a history of trauma exposure and evaluating the timing of these symptoms may be important in distinguishing these disorders.

PTSD can mimic medical conditions such as hyperthyroidism, seizure disorder, caffeinism, migraine, asthma, or side effects from prescription or nonprescription medications.

Symptoms of complex PTSD (severe affective, behavioral, relationship, and cognitive dysregulation) may resemble those of bipolar disorder. Particularly if such children are avoidant of disclosing a trauma history, they will likely be diagnosed with bipolar disorder rather than PTSD. Since first-line treatments of these disorders are very different (medications for the former; psychotherapy for the latter), it is crucial to always inquire about children's trauma histories and assess their symptoms from a trauma-informed neurodevelopmental perspective.

Psychotic symptoms may occur in up to 20% of children with PTSD; flashbacks or other intrusive phenomena must be distinguished from true hallucinations or substance-induced disorders.

COURSE AND PROGNOSIS

The natural course of childhood PTSD has not been adequately determined. Based on the available studies, it appears that while PTSD symptoms spontaneously remit in some children, they persist for years or even decades in many others. There is also growing evidence that trauma-focused treatment significantly alters the natural course of pediatric PTSD. Studies have documented continued remission of PTSD 2 years posttreatment in children who received trauma-focused cognitive-behavioral therapy (TF-CBT).

The prognosis for children with untreated PTSD has become a matter of increasing concern since research has documented the

Telegram: @medical_k

www.konkur.in

numerous psychobiologic abnormalities associated with this disorder, and the severity of some of these (decreased intracranial volume, decreased corpus callosum area, and lowered IQ) is directly correlated with the duration of symptoms. Growing evidence that childhood sexual abuse is predictive of adult suicidality, as well as depression and suicidality in the offspring of such victims, also suggests a poor prognosis for unresolved PTSD in childhood. This emphasizes the importance of identifying symptomatic children and providing effective interventions early in the course of this disorder.

TREATMENT

Children with PTSD receive many treatments, but the effectiveness of most of these interventions has not been evaluated. To date, trauma-focused psychotherapies have the most empirical evidence of efficacy for treating pediatric PTSD. Although several selective serotonin reuptake inhibitors (SSRIs) have been shown to effectively treat adult PTSD symptoms, two RCTs have failed to show superiority to a placebo in traumatized children. Similarly, although open trials of adrenergic agents have had promising results, two RCTs have failed to show the superiority of propranolol to a placebo in treating pediatric PTSD. During the COVID-19 pandemic, treatment for children with PTSD quickly transitioned to being provided almost entirely via telehealth. Two studies have found that when trauma-focused psychotherapy is provided via telehealth, children experience equivalent outcomes with lower attrition than when treatment is provided in typical clinic settings.

Psychotherapeutic Treatments

Cognitive-Behavioral Therapies. Currently, TF-CBTs have the strongest evidence for resolving child PTSD and associated problems. TF-CBT has been found in 23 RCTs to be superior to other active treatments or comparison conditions in decreasing PTSD as well as depressive, anxiety, cognitive, behavioral symptoms, and functional impairment in traumatized children. TF-

Telegram: @medical_k

www.konkur.in

CBT has been tested in youth who have experienced sexual trauma, domestic violence, terrorism, disaster, war, traumatic grief, and multiple and complex trauma in multicultural cohorts in the United States, Europe, Africa, Asia, and Australia. TF-CBT is typically provided over 12 to 25 treatment sessions. Its core components are summarized by the acronym PRACTICE: *Psychoeducation* about the child's traumatic experiences and responses; *Parental or caregiver inclusion* in treatment, including a parenting skills component; *Relaxation skills,* which are individualized for each child and parent; *Affective* modulation skills; *Cognitive* coping techniques (connections between thoughts, feelings, and behaviors are taught and practiced); *Trauma narration and processing*, consisting of carefully calibrated efforts to encourage the child to describe increasing details about the traumatic event and to identify and process inaccurate or unhelpful thoughts related to the traumatic event; *In vivo mastery* of trauma reminders, in which children with overgeneralized avoidance and fear develop graduated mastery of these through calibrated exposure to the feared stimuli; *Conjoint* child–parent sessions in which optimal communication is emphasized and practiced; and *Enhancing safety* and future developmental trajectory, in which the child develops and practices effective strategies for maintaining personal safety. A stepped-care TF-CBT model has been found to be noninferior to standard TF-CBT for improving young children's PTSD symptoms and for addressing cost and access issues for some families. Neuroimaging data suggest that changes in brain functioning are correlated with improvements in PTSD symptoms during TF-CBT treatment. A group CBT model for school settings, Cognitive Behavioral Intervention for Trauma in Schools (CBITS), has been tested in schools and found to be effective in reducing PTSD and depressive symptoms. Other CBT-based treatments, such as the UCLA Trauma/Grief Program for Adolescents and a child adaptation of Narrative Exposure Therapy, have also been tested with positive results among refugee or war-exposed children. Cognitive-based therapy for single-incident traumas also has been found to be effective.

Telegram: @medical_k

www.konkur.in

Eye movement desensitization and reprocessing (EMDR) utilizes exposure and cognitive reprocessing interventions with bilateral eye movements. EMDR has been adapted for children and tested in two well-designed studies. A recent study comparing EMDR to TF-CBT found that both treatments were equally effective and efficient at improving children's PTSD symptoms, with TF-CBT being superior for improving comorbid psychiatric symptoms.

Psychodynamic and Attachment-Based Therapies. Child–parent psychotherapy (CPP) is an attachment-based treatment of trauma-exposed infants and preschool children and their primary caretakers. CPP has been tested in one RCT for preschoolers exposed to marital violence and found to be superior to case management in improving these young children's PTSD symptoms and in their mothers' PTSD symptoms. CPP includes the following components: Providers begin by providing developmental guidance or psychoeducation about the child's behavior and how it may be understood in light of normal development and changed through simple behavioral interventions. If needed, additional interventions are added to help the parent to understand the child's behaviors and enhance child–parent attunement. These may include behavior management, cognitive reframing, and processing, developing a joint narrative of the child and parent's traumatic experiences, and interpreting the child or parent's behaviors, emotions, and past experiences.

Psychopharmacologic Treatments

RCTs of sertraline (Zoloft), D-cycloserine, and propranolol (Inderal) have failed to show significant differences from placebo in improving pediatric PTSD. While open treatment trials have demonstrated clinical improvement in child PTSD symptoms following the use of adrenergic blocking agents (guanfacine [Tenex], clonidine [Catapres]), a dopamine antagonist (risperidone [Risperdal]), or an opiate (morphine [Roxanol]), none of these medications have been tested in well-designed double-blind, randomized trials.

Telegram: @medical_k

www.konkur.in

Pharmacologic treatments thus lack evidence for treating pediatric PTSD. Children who have comorbid psychiatric conditions for which effective pharmacotherapy is established should receive the appropriate psychopharmacologic treatment of those disorders; it is not yet known whether such treatment will also impact favorably on coexisting PTSD symptoms.

Biologic Treatments

Since dysregulation of the HPA axis is generally found in both children and adults with PTSD, the use of a corticotropin-releasing factor (CRF) antagonist has been suggested as a potential intervention for preventing this disorder from developing or in reversing PTSD symptoms once they are present. This intervention has not yet been tested in children or adults.

C was a 15-year-old girl referred to treatment following hospitalization for a suicide attempt. From 6 to 12 years old, C had been sexually abused by her paternal grandfather. C disclosed the abuse to her parents at 12 years old, who were supportive; however, a week later grandfather committed suicide. The following year, C came out about being gay to her parents and close friends, who were supportive. Her parents thought C was doing well until the suicide attempt. In the hospital, C disclosed the following: Since coming out, C experienced worsening physical, sexual, and verbal abuse in school related to her gay identity but kept this from her parents. During the current school year, C was repeatedly sexually assaulted by three male peers who threatened to kill her younger brother if she disclosed the abuse. Guilt (she "froze" during these episodes and did not say "no" or fight back) and negative self-cognitions led to the suicide attempt.

During the initial evaluation, C reported intrusive thoughts and nightmares about sexual abuse and her grandfather's gory suicide. C tried unsuccessfully to push these images out of her mind. She acknowledged maladaptive cognitions, including that she "deserved to be raped for killing my grandfather" and that she was "a terrible person." She endorsed sleep disturbance, increased startle, irritability, and sadness. She scored 58 on the UCLA PTSD reaction index (RI), consistent with very severe PTSD, and 20 on the beck depression inventory (BDI), consistent with a major depressive episode. During the assessment and treatment, the therapist also used strategies from the Family Acceptance Project (https://familyproject.sfsu.edu/) to evaluate behaviors that C's parents demonstrated related to C's sexual orientation, and how they could expand these in order to further support and advocate for C. These strategies are described in the TF-CBT LGBTQ Implementation Manual (https://www.tfcbt.org/tf-cbt-lgbtq-implementation-manual/).

C and her parents attended 23 sessions of TF-CBT. Twenty of these were individual sessions (half of the session was spent

Telegram: @medical_k

www.konkur.in

with C and half with parents); three sessions were conjoint child–parent sessions in which the family met together. During the stabilization phase (11 sessions), C and her parents learned about trauma reminders (e.g., the threat of sexual assault would serve as a trauma reminder for C in light of her history of sexual abuse), trauma impact (e.g., fight, flight, freeze, and trauma impact on affect, behavior, biology, cognitions, relationships, and perceptions), as well as a variety of coping skills for trauma reminders. C and her parents reported that this helped them to make sense of C's response to the rapists as a trauma response and was "a huge relief" for C. Although parents and C reported that parents were "supportive" of C's sexual orientation, through further psychoeducation and parenting skills, they became more aware of specific supportive behaviors they could engage in to show this support to C (e.g., encouraging her to have LGBTQ friends over, not allowing others in their family to make verbal slurs about LGBTQ individuals, and actively advocating for her with other family members, at school, and in their faith community, etc.). As her parents used these strategies, C reported that she felt more supported and happier at home. C preferred using visualization and the cognitive triangle (changing thoughts in order to change feelings and behaviors). She carried a notebook with her and practiced changing her thoughts whenever she had a negative feeling. She found that this was very helpful and, when paired with visualization, enabled her to reduce her distress level significantly in most situations. C's parents were very upset at the school for failing to protect C from harassment and physical assaults at school, and with C's agreement, they investigated other schools that C could attend. The therapist worked with parents to become more effective advocates for C in school, their extended family, and the community. C reported that this also contributed significantly to reducing her distress level.

During the trauma narrative phase (7 sessions), C developed a detailed description and cognitively processed her personal trauma experiences. Through this process, her understanding

Telegram: @medical_k

www.konkur.in

and cognitions about these experiences changed substantially. She identified how her grandfather manipulated her into worrying about her parents' response if she disclosed it and contributed to her self-blame for his suicide. Her new cognitions were that only the perpetrators were responsible for the abuse, her grandfather chose to kill himself rather than face up to prison, and she did not deserve to be hurt for any reason. During this process, C also made the decision that she wanted to go to a different school because "they didn't protect other gay kids and me the way they should have." Her parents actively advocated for this change and helped to find an alternative school. They also prepared a brief response letter to C's narrative stating their regret for not knowing about the abuse and bullying and how they would be more actively supportive in the future.

During the integration and consolidation phase (5 sessions), C shared her narrative with her parents and engaged in safety planning with them. This included how C could protect herself from bullying going forward and how her parents could also advocate for her. C made the transition to her new school successfully and found this to be a more supportive environment. C and her parents addressed healthy sexuality together and in individual sessions, and C reflected on her future hopes and plans. At the end of treatment, C's RI score was 15, and BDI was 10 (both normal).

FUTURE DIRECTIONS

1. Evaluating DSM-5 diagnostic criteria for children ages 7 to 17 years, particularly those with complex trauma, to determine whether the new criteria adequately describe the complex difficulties of these youth or whether an additional diagnosis is needed.
2. Developing and testing effective treatments for children who have PTSD in the presence of comorbid psychiatric disorders.

Telegram: @medical_k

www.konkur.in

3. Evaluating the relative efficacy of pharmacologic treatments for pediatric PTSD, alone and in combination with psychotherapy.
4. Developing a biomarker for pediatric PTSD and other effective neurobiologic tools for assessing pediatric PTSD.
5. Developing effective dissemination strategies for training community therapists in evidence-supported treatments for children with PTSD, including making these treatments usual care by embedding evidence-based treatments into routine graduate school training for counseling and social work students.
6. Developing and testing the use of social media applications for screening and treating pediatric PTSD. Given the large number of children who have PTSD, some will never reach mental health providers, but most have access to electronic media.

51.3 Separation Anxiety, Generalized Anxiety, and Social Anxiety

Benjamin N. Schneider, M.D., Ruben G. Martinez, Ph.D., and Tara S. Peris, Ph.D.

Fear and worries are a common and expected part of healthy child development. For most children, these worries are short lived and limited in the impairment they bring, and they track to developmental status. Among younger children, fears may focus on the dark, monsters, or strangers, whereas for older children and adolescents, fears may focus on friends, school, or decision making. These developmentally appropriate worries wane naturally over time as new experiences and skills overshadow them. Although transient fears and worries are a natural and necessary part of child development, for some youth, they will persist and bring a level of impairment that requires clinical attention.

The three most common pediatric anxiety disorders—separation anxiety, generalized anxiety, and social anxiety—share the same

Telegram: @medical_k

www.konkur.in

underlying construct of diffuse, future-oriented worry that is often focused on unknown threats. They have significant symptom overlap, are highly comorbid with one another, and show similar familial relationships and continuity with adult anxiety and depressive disorders. For these reasons, the three disorders are often grouped together as they are in this section. The three anxiety disorders are described separately in this chapter to highlight core constructs central to diagnosis; however, treatments are discussed for the disorders as a group, given the significant overlap in approach.

Anxiety disorders comprise the most prevalent class of mental health problems among youth, affecting up to one in three individuals by the time they reach adulthood. Children with anxiety disorders have an early onset and a persistent or recurring course with high levels of short- and long-term impairment. In addition to being comorbid with one another, anxiety disorders are often comorbid with nonanxiety disorders. Fortunately, there are highly effective psychosocial and pharmacologic treatments for these disorders. Current challenges include the identification of treatment methods to optimize outcomes and address co-occurring emotional and behavioral problems and the wide-scale dissemination and implementation of evidence-based treatments.

SEPARATION ANXIETY DISORDER

Definition

Separation anxiety disorder is characterized by excessive and developmentally inappropriate fear of catastrophic separation, avoidance of such separations, and irrational beliefs about the consequences of being apart from a caregiver (Table 51.3–1). Attachment figures are usually parents but may also be siblings, grandparents, or other caregivers or for adults, children or spouses. Whereas developmentally appropriate separation anxiety typically presents around age 6 months and declines between ages 2 and 3 years, children with separation anxiety disorder have either persistent and worsening or new-onset separation anxiety in the

Telegram: @medical_k

www.konkur.in

school-age years (i.e., ages 6 to 12 years). This section differentiates between developmentally normal separation anxiety in infancy and toddlerhood and separation anxiety disorder in school-aged children.

Comparative Nosology

Separation anxiety disorder appeared initially in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) and was classified as an anxiety disorder of childhood or adolescence. Although it was subsequently categorized in the DSM-IV as a “disorder usually first diagnosed in infancy, childhood, or adolescence,” separation anxiety is currently classified in the DSM-5-TR as an anxiety disorder. Since first introduced, the diagnostic criteria for separation anxiety disorder have been modified in four ways, along with modified wording in DSM-5 (continued in DSM-5-TR) to capture symptom presentation in adulthood. Unlike earlier versions, the DSM-5 does not require onset prior to age 18 and recognizes that some adults report onset after age 18 years. The minimum duration was increased from 2 weeks in DSM-III to 4 weeks in DSM-IV and subsequent versions, and DSM-5 specifies at least 6 months in adults to avoid overdiagnosis of transient fears. Also, evidence of serious distress or impairment was added for diagnosis starting in DSM-IV. Finally, recurrent excessive distress about (1) anticipated or (2) actual separation was collapsed into one symptom in DSM-IV, and thus the symptomatic threshold for separation anxiety disorder was reduced from three of nine symptoms in DSM-III-R to three of eight symptoms in DSM-IV and currently in DSM-5-TR.

Telegram: @medical_k

www.konkur.in

Table 51.3–1.
DSM-5-TR Diagnostic Criteria for Separation Anxiety Disorder

Telegram: @medical_k

www.konkur.in

A. Developmentally inappropriate and excessive fear or anxiety concerning separation from those to whom the individual is attached, as evidenced by at least three of the following:
   1. Recurrent excessive distress when anticipating or experiencing separation from home or from major attachment figures.
   2. Persistent and excessive worry about losing major attachment figures or about possible harm to them, such as illness, injury, disasters, or death.
   3. Persistent and excessive worry about experiencing an untoward event (e.g., getting lost, being kidnapped, having an accident, becoming ill) that causes separation from a major attachment figure.
   4. Persistent reluctance or refusal to go out, away from home, to school, to work, or elsewhere because of fear of separation.
   5. Persistent and excessive fear of or reluctance about being alone or without major attachment figures at home or in other settings.
   6. Persistent reluctance or refusal to sleep away from home or to go to sleep without being near a major attachment figure.
   7. Repeated nightmares involving the theme of separation.
   8. Repeated complaints of physical symptoms (e.g., headaches, stomachaches, nausea, vomiting) when separation from major attachment figures occurs or is anticipated.

B. The fear, anxiety, or avoidance is persistent, lasting at least 4 weeks in children and adolescents and typically 6 months or more in adults.

C. The disturbance causes clinically significant distress or impairment in social, academic, occupational, or other important areas of functioning.

D. The disturbance is not better explained by another mental disorder, such as refusing to leave home because of excessive resistance to change in autism spectrum disorder; delusions or

Telegram: @medical_k

www.konkur.in

hallucinations concerning separation in psychotic disorders; refusal to go outside without a trusted companion in agoraphobia; worries about ill health or other harm befalling significant others in generalized anxiety disorder; or concerns about having an illness in illness anxiety disorder.

Epidemiology

Epidemiologic studies show the lifetime prevalence rate of childhood and adolescent separation anxiety disorder is at least 4%, with peak onset between 7 and 9 years of age. Separation anxiety disorder is more common in childhood than in the preschool years or adolescence and is the most common anxiety disorder in children under the age of 12. Although the peak age of onset is in middle childhood, preschool children can be diagnosed with separation anxiety disorder (range from 0.5% to 10.5%) and can be distinguished from children with developmentally normal separation anxiety. Children with separation anxiety symptoms who do not meet diagnostic criteria are very common, with reported rates as high as 50%. Community studies suggest that girls are more likely than boys to meet criteria even in the preschool years, but clinical studies find the disorder to be equally common in girls and boys.

Etiology

Although the exact cause of separation anxiety is unknown, genetic, early temperamental, and family or environmental variables have all been associated with early-onset anxiety disorders. Although genetic factors likely play a significant role, early experiences, many of which are family-based, may play an important role in the onset of childhood anxiety disorders. Methods to sort the various contributions of genetics, temperamental and biologic vulnerabilities, and family or environment are often confounded. However, it is likely that genetically based, temperamental, or biologic vulnerabilities

Telegram: @medical_k

www.konkur.in

predispose affected children and their parents to interact in ways that either protect children from or predispose children from developing an anxiety disorder. For example, children with separation anxiety raised by a presently anxious parent may differ in outcome from children with separation anxiety raised by parents whose anxiety is well controlled. Although in both situations, the child and the mother share genetic, temperamental, and biologic vulnerabilities, the effect of the child's anxiety on the affected (and treated) parent and the affected (and treated) parent's impact on the child may account for significant differences in both short- and long-term outcomes.

Twin studies provide perhaps the greatest evidence for the role of biologic and environmental factors (shared and nonshared) in the etiology of childhood anxiety disorders. Although historically both genetic and environmental factors have been implicated in the etiology of childhood anxiety disorders, a large well-designed study of 6-year-old twins suggests significant genetic influence for the separation anxiety phenotype. The heritability estimate for separation anxiety was high, 73%, with the remaining variance attributed to nonshared environment, suggesting genetic effects on separation anxiety are substantial and more significant than environmental effects. Another investigation of the role of genetic and shared environment effects in a sample of twins and siblings over time reported that the influence of genetic effects increased and shared environmental effects decreased with age. Finally, newly emerging data suggest that the psychobiologic trait of CO_2 hypersensitivity may increase risk for separation anxiety (and supports a proposed genetic association between separation anxiety and later-onset panic disorder).

Behavioral inhibition (BI) to the unfamiliar, characterized by fear, withdrawal, and avoidance of unfamiliar situations or things, is considered a temperament vulnerability in infants and toddlers that predicts anxiety disorder outcomes in later childhood. BI is usually assessed using observational methods in laboratory settings for children aged 9 months through 6 years. Approximately 10% to 15% of children are thought to display BI and longitudinal outcomes,

Telegram: @medical_k

www.konkur.in

suggesting young children with BI are more likely than uninhibited children to exhibit clinical levels of multiple anxiety disorders including separation anxiety upon long-term follow-up. In cross-sectional studies, BI is associated with a range of anxiety symptoms and disorders in youth, and it has traditionally been considered a vulnerability that lacks specificity for any childhood anxiety disorder. However, longitudinal data found BI to predict *social anxiety disorder (SAD)* in middle childhood, but not other anxiety disorders.

Parental psychopathology is also highly associated with childhood anxiety disorders. Multiple pathways are operative in linking parent and child well-being. Parents and children may share the same genetic or temperamental vulnerability. Anxious parents are likely to model anxiogenic thoughts and behaviors that are readily adopted by their children. Bidirectional influence may also be operative inasmuch as anxious youth may pull for adults in their environment to maintain proximity and support. Regardless of the mechanism, children of parents with an anxiety disorder are up to five times more likely to be diagnosed with an anxiety disorder. More specifically, parental panic disorder and major depression are associated with an increased risk for separation anxiety disorder in children.

Longitudinal studies examining the role of infant–mother attachment in the development of childhood anxiety often used the Ainsworth Strange Situation to assess attachment and then follow children over time. In multiple studies, children with an anxious or resistant attachment during infancy were more likely to develop anxiety disorders than were securely attached infants. Although infant temperament or maternal psychopathology may affect attachment behavior, cross-sectional assessment of attachment status appears to be the more important factor in determining the presence of anxiety disorders at longer-term outcome.

Several decades of research identify a common set of parenting behaviors found among parents of anxious youth. These include high levels of symptom accommodation, parental intrusiveness, overprotection, and psychologically controlling behavior in the child's daily activities. Such anxiety-enhancing parenting approaches are thought to promote dependency and reduce the development of

Telegram: @medical_k

www.konkur.in

autonomy. Controlling and overprotective parenting may contribute to the development of anxiety by preventing the child from having a range of experiences that foster broad and complex coping skills. Furthermore, parental overprotection may communicate to the child that the world is a dangerous place, introducing a chronic and pervasive response bias. Parents may also support anxious behavior by encouraging anxious cognitions and avoidance in their children or children may mimic anxious cognitions and behaviors modeled by their parents.

Diagnosis and Clinical Features

The defining feature of separation anxiety is excessive and persistent worry about harm befalling an attachment figure (e.g., parent getting into car accident, spouse becoming ill or dying) or oneself (e.g., getting lost, being kidnapped, having an accident) upon separation. Symptoms may include avoidant behaviors such as refusal to go to school or work, sleep alone, or be without the attachment figure, in order to minimize separation and to reduce distress. Other common symptoms include nightmares with references to separation, and physical symptoms such as stomachaches or nausea in response to possible or actual separation. DSM-5-TR requires three of eight symptoms, a duration of 4 weeks in children and adolescents, and corresponding functional impairment. The diagnosis can be made in adults who are typically excessively concerned about their spouses or children and symptomatic for at least 6 months.

At home, children with separation anxiety frequently shadow their caregivers. They often are reluctant to be in any room alone and may not want to sleep alone in their bedroom. These children often request a parent to fall asleep with them or find their way to their parent's bed at night. They are uncomfortable staying with babysitters and may call or text parents frequently. In public, children with separation anxiety stay close to their caregiver and prefer to sit on their lap or be in physical contact. They are reluctant or refuse to attend birthday parties, sleepovers, camps, and extracurricular

Telegram: @medical_k

www.konkur.in

activities if the attachment figure is not present. Somatic complaints, especially gastrointestinal (e.g., stomachaches, nausea) and cardiovascular (e.g., pounding heartbeat, light-headedness) are commonly reported, particularly before other anxiety-provoking separations. Children may show their separation anxiety distress with tantrums or becoming panicky or oppositional when anticipating separation.

At school, the child may make repeated requests to call their parents to check in or visit the school nurse with physical complaints. When children experience anxiety at school they may become restless and fidgety and be so preoccupied that they are unable to attend to classroom work. Separation anxiety disorder is also a common cause of school refusal and may result in frequent tardiness or high numbers of school absences.

Younger children, in comparison to adolescents, with separation anxiety disorder tend to report a greater number of symptoms and more nightmares with separation themes. Some older children and adolescents with separation anxiety may not present obvious impairment or distress, as their parents and school find ways to accommodate the child's fears to decrease their distress.

As separation anxiety not only affects the child, disruption of family life or parent stress may result from accommodating and managing the child's anxious and avoidant behavior. It can be helpful in the assessment to attempt to quantify the amount of accommodation and to ascertain what the anxiety severity would be if the parents did not offer ongoing accommodation around the child's anxiety.

www.konkur.in

Posey is a 9-year-old Latina female living with her biologic parents and sister in a large metropolitan region. She presents for care with her mother, who reports that Posey has rarely, if ever slept in her own bed. Posey's difficulty sleeping in her own bed is disrupting family life as evidenced by parents who are losing sleep and coparenting/family conflict that has increased. At a recent slumber party, Posey began to complain of a stomachache, asking her host to call her mother to take her home. She reported being embarrassed that she had to leave her friend's house, but that she "needed" to be with her parents. Upon interview, Posey reports that she worries about the safety of her family ("something bad" happening to her parents) and that when she does not sleep near or with her parents, she has nightmares that someone will "break in and hurt them." She reports associated difficulty sleeping, and a near-constant level of stress when not in the presence of both parents. Both parents describe her as clingy and note that she needs them to stay present at extracurricular activities like soccer and piano.

Differential Diagnosis

Separation anxiety disorder can be distinguished from developmentally normal separation anxiety based on its onset or increasing severity in the school-age years, the duration of symptoms, and the degree of impairment or distress or need for parental accommodation.

Separation anxiety should also be differentiated from other emotional and behavioral disorders. Children with separation anxiety, generalized anxiety, and obsessive-compulsive disorder (OCD), all have concerns about harm. Children with separation anxiety worry about events that lead to being apart from an attachment figure. Children with generalized anxiety are more fearful of the actual event such as a dog bite, lightning striking, or getting sick than the impact on separation. Children with OCD have repetitive intrusive and senseless thoughts of harm befalling them or their loved ones if they

Telegram: @medical_k

www.konkur.in

do not complete a ritual. Children with separation anxiety may have social avoidance (e.g., parties or school) similar to children with SAD, generalized anxiety disorder (GAD), OCD, or even post-traumatic stress disorder (PTSD), but the rationale for the avoidance will differ for each of the disorders. Children with separation anxiety may be described as panicking upon separation or anticipation of separation, but the panic is distinguished from spontaneous panic attacks that characterize panic disorder.

Finally, children with separation anxiety may exhibit defiance, irritable or labile mood, and explosive behavior when presented with a situation that involves separation. These behaviors or moods should be distinguished from oppositional defiant disorder, which involves more general patterns of argumentativeness and misbehavior, and from bipolar disorder, which has prominent elevation in mood, decreased need for sleep, grandiosity, and increased goal-directed activities.

Course and Prognosis

The course of separation anxiety is not consistent for all children. Multiple rigorous prospective studies suggest that the majority of children with separation anxiety improve with time. Indeed, some appear to spontaneously remit while some see symptoms and impairment gradually wane. For others, separation anxiety symptoms persist over time and transfer to other close relationships. In still other cases, symptoms of separation anxiety resolve but are replaced with symptoms of another anxiety disorder. In some cases of separation anxiety, affected individuals may see symptoms evolve into more adult patterns of anxiety or depression. Prospective, longitudinal studies including both community and high-risk samples have found that those meeting DSM-IV criteria for separation anxiety disorder were at an increased risk of developing subsequent panic disorder with agoraphobia, specific phobia, GAD, OCD, pain disorder, and alcohol dependence, even after controlling for the risk of parental psychopathology. Other meta-analyses indicate an

Telegram: @medical_k

www.konkur.in

increased risk for all anxiety disorders, but less evidence for elevated risk for depression and substance use.

SOCIAL ANXIETY DISORDER

Definition

SAD, also called social phobia, is characterized by excessive, persistent, and impairing anxiety about potential embarrassment or catastrophic humiliation in social or performance situations. The worry may be restricted to a specific performance situation such as fear of being negatively evaluated during an athletic or musical performance. However, SAD is more commonly generalized such that worry about being scrutinized or embarrassed occurs across a range of activities and situations.

Comparative Nosology

SAD (social phobia) first appeared in DSM-III, with minimal alterations in subsequent editions. One impactful change from DSM-III to DSM-IV was the removal of the diagnosis of avoidant disorder. Avoidant disorder was classified as an anxiety disorder of childhood or adolescence, and characterized by fear and avoidance of strangers resulting in significant impairment in peer relationships. Concern about the overlap between the two disorders and the continuity between childhood avoidant disorder and adult SAD resulted in the removal of avoidant disorder as a diagnostic category in DSM-IV. In DSM-5 (continued in DSM-5-TR), there is no longer a requirement that individuals over age 18 must recognize their fear as excessive and unreasonable; instead, the anxiety must be out of proportion to the actual threat posed by the event after taking into account sociocultural factors. Whereas the 6-month duration was limited in DSM-IV to individuals under age 18, this criterion now applies to all ages. Finally, unlike DSM-IV, there is no longer a specifier for “generalized” but there is a specifier for “performance only” in DSM-5-TR.

Telegram: @medical_k

www.konkur.in

Epidemiology

Social anxiety is a common anxiety disorder, with a cumulative incidence of 11%. Prevalence rates have increased over time, likely because of the removal of the avoidant disorder diagnostic category from DSM-III to DSM-IV; that is, youth who were once characterized with avoidant disorder are now diagnosed with SAD, resulting in increased prevalence rates. According to data from the National Comorbidity Survey Replication Adolescent Supplement and the Early Developmental Stages of Psychopathology Study (EDSP), the 12-month prevalence for adolescents is 5.2% to 8.2%. The lifetime prevalence of social anxiety is 9.5% for females and 4.9% for males. Like generalized anxiety, the prevalence of SAD increases with age, possibly reflecting changes in cognitive and emotional development (i.e., the capacity for self-evaluation and self-consciousness).

Age of onset for SAD is during adolescence. The average age of onset in epidemiologic studies is between 10 and 16.6 years and varies depending on the sample studied and the strategy for determining retrospective reports for the age of onset. According to the EDSP which involved a community sample of 3,021 individuals aged 14 to 24 years, the incidence of DSM-IV social anxiety was greatest among those aged 10 to 19 years.

Etiology

Similar to both separation anxiety disorder and GAD, factors that contribute to the development of SAD include genetics, temperament, and family variables. Twin studies are useful in distinguishing between environmental and genetic influences. There are many discrepancies in the literature regarding the contributions of genetic and environmental influences because of differences in measurement (i.e., rating scale vs. psychodiagnostic interviews), informants (i.e., self vs. parent reports), and criterion (i.e., symptoms vs. severity vs. clinical diagnosis). However, the literature is consistent in showing that anxiety disorders are heritable and that both shared and nonshared environmental factors also play a role. Concordance rates for anxiety disorders including SAD are higher for

Telegram: @medical_k

www.konkur.in

monozygotic twins than dizygotic twins (34% vs. 17%). Familial transmission is also evident by studies showing a high concordance rate of social anxiety among first-degree relatives. Overall, studies investigating genetic transmission find evidence for an inherited propensity toward anxiety in general rather than for a specific type of anxiety.

As discussed earlier, BI is a temperamental construct characterized by increased physiologic reactivity and avoidant behavior in the face of novel or challenging stimuli. Inhibited children have greater sympathetic activation than uninhibited children, evidenced by higher and more stable heart rates and greater heart-rate acceleration under stressful and novel conditions. Many studies support the existence of a specific link between BI and social anxiety. Both longitudinal and retrospective studies show that toddlers with BI assessed by observational or questionnaire methods are more likely than uninhibited children to exhibit social anxiety as adolescents. In a recent prospective longitudinal study, 215 children assessed for BI were assessed for psychiatric outcomes in a 5-year follow-up at a mean age of 9.6 years. Structured diagnostic interviews revealed that BI present at age 4 or 6, but not at age 21 months, predicted social anxiety. BI was not associated with other specific anxiety, mood, or behavior disorders. In another study, adults from a clinical sample provided retrospective reports of childhood inhibition, and those with the highest levels of inhibition also had the highest levels of clinical SAD. It is important to note that less than 50% of toddlers and young children characterized as behaviorally inhibited go on to develop SAD. Similarly, children who are considered shy or have shy temperaments most likely do not develop SAD. Thus, BI is considered a manifestation of a biologic predisposition that serves as a risk factor for anxiety.

Environmental variables such as parent–infant attachment and parenting behaviors also are associated with the expression of SAD. As stated in previous sections, retrospective and observational research shows links between insecure infant attachment and the development of anxiety disorders. One study examined 172 adolescents 16 years after participating in the Ainsworth Strange

Telegram: @medical_k

www.konkur.in

Situation test at age 12 months and confirmed that infants with insecure attachments were more likely to meet criteria for anxiety, including SAD. Adult parents with SAD may sponsor social isolation by discouraging opportunities for social engagement. They also provide information that has the potential to heighten anxious arousal.

Diagnosis and Clinical Features

The defining feature of social anxiety is excessive fear about being scrutinized in social or performance situations (Table 51.3–2). Although the same criteria apply to children and adults, some provisions are indicated for children. First, social anxiety cannot be limited to adult settings and must occur in peer contexts. Second, in children, the anxiety evoked by the social situation may involve crying, tantrums, freezing, or shrinking from social situations with unfamiliar people. Common fears related to social anxiety include public speaking, participating in class, initiating or participating in conversations, attending social events, and eating or writing in front of others. Fear of public speaking is considered the most commonly feared social situation; however, test anxiety is commonly feared among adolescents.

Table 51.3–2.
DSM-5-TR Diagnostic Criteria for Social Anxiety Disorder

Telegram: @medical_k

www.konkur.in

A. Marked fear or anxiety about one or more social situations in which the individual is exposed to possible scrutiny by others. Examples include social interactions (e.g., having a conversation, meeting unfamiliar people), being observed (e.g., eating or drinking), and performing in front of others (e.g., giving a speech).
   Note: In children, the anxiety must occur in peer settings and not just during interactions with adults.
B. The individual fears that he or she will act in a way or show anxiety symptoms that will be negatively evaluated (i.e., will be humiliating or embarrassing; will lead to rejection or offend others).
C. The social situations almost always provoke fear or anxiety.
   Note: In children, the fear or anxiety may be expressed by crying, tantrums, freezing, clinging, shrinking, or failing to speak in social situations.
D. The social situations are avoided or endured with intense fear or anxiety.
E. The fear or anxiety is out of proportion to the actual threat posed by the social situation and to the sociocultural context.
F. The fear, anxiety, or avoidance is persistent, typically lasting for 6 months or more.
G. The fear, anxiety, or avoidance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
H. The fear, anxiety, or avoidance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
I. The fear, anxiety, or avoidance is not better explained by the symptoms of another mental disorder, such as panic disorder, body dysmorphic disorder, or autism spectrum disorder.
J. If another medical condition (e.g., Parkinson's disease, obesity, disfigurement from burns or injury) is present, the fear, anxiety, or avoidance is clearly unrelated or is excessive.

Some differences have been noted with respect to the presentation of social anxiety among different age groups. Adolescents endorse anxiety across a broader range of situations and more avoidance compared to children; however, both groups experience similar levels of distress. In addition, adolescents endorse more cognitive symptoms of social anxiety that likely reflect their greater cognitive maturity compared to children. Poor social skills, however, are evident across all youth with SAD.

Infants and toddlers cannot meet DSM-5-TR anxiety diagnosis guidelines primarily due to developmental issues; however, many very young children exhibit higher than normal levels of social fear and associated distress. For example, some children have difficulties playing with new children, refuse to participate in playgroups and classes, play alone at parties or on the playground, and refuse to eat in restaurants or attend public events because of severe distress. Some pilot data reveal that children aged 18 months to 5 years can be diagnosed with a modified version of SAD and are more likely than their nonanxious counterparts to display high levels of shyness, inhibition, and to have anxious parents. Many preschool-aged children meet DSM-5-TR criteria for selective mutism which involves restricted speech in social situations due to high levels of fear and anxiety.

www.konkur.in

John is a 16-year-old Caucasian male who lives with his biologic mother in a suburban area. He presents for care after experiencing an “anxiety attack” when asked to answer a question in class last week. Upon interview, John reported that he was randomly selected by his teacher to answer a difficult math question, at which point he “locked up,” began breathing heavily, and refused to respond. Upon further interview, he reported that he never raises his hand in class because “if I get the answer right, people will think I’m a nerd, and if I get the answer wrong people will think I’m stupid.” He reports that similar worries (e.g., being seen as weak or stupid) have stopped him from trying out for the football and soccer teams, as well as the debate club. He reports having few friends outside of his childhood friends, and his mother tells you she is worried that he is missing out on the high school experience.

Differential Diagnosis

SAD can be distinguished from other disorders based on the predominant feature that fears center around the potential for embarrassment or receiving negative criticism. Although social anxiety and separation anxiety may both involve avoidance of social situations, the fear with separation anxiety is associated with concern about being apart from a caregiver and is not associated with potential humiliation or embarrassment. The generalized type of social anxiety is differentiated from GAD on the basis of the individual feeling humiliated or embarrassed in public rather than a more global worry. Also, children with GAD may worry about a host of social issues (e.g., friendships, performance, how others view them), but worries are not limited to social or performance situations. Although individuals with SAD may experience panic in the face of challenging situations, the fear and associated somatic and cognitive symptoms occur in response to specific situations and are not unexpected or uncued as they are in panic disorder.

Telegram: @medical_k

www.konkur.in

Social anxiety is also distinguished from selective mutism, which is characterized explicitly by a failure to speak in situations where speech is expected and has a much younger age of onset relative to SAD. Selective mutism is considered by some professionals to be a developmental variant of social anxiety.

Finally, it is important to distinguish SAD from developmentally normal fears. For example, it is not uncommon for children to be anxious about speaking in front of the class. However, normative anxiety does not result in significant impairment in functioning or clinically significant distress as with SAD.

Course and Prognosis

SAD that emerges by the early teen years is associated with progressive worsening or persistence of symptoms through early adulthood. Late adolescence is characterized by a waxing and waning course during which symptoms are exacerbated by social stressors. Factors associated with persistence of symptoms include early onset, more anxiety cognitions, severe avoidance and impairment, co-occurring panic, parental social anxiety and depression, BI, and harm avoidance.

Few individuals experience spontaneous remission; data from the prospective longitudinal EDSP study suggest a natural remission rate of 15.1%. Individuals with SAD withdraw from or avoid situations, limiting opportunities for optimal social, academic, and emotional development. Research shows that children with SAD are less socially skilled than their nondisordered counterparts, limiting their capacity to form intimate relationships with friends, family members, or partners. Symptoms and impairment at school may result in academic underachievement, including failure to graduate high school or pursue college. Disabilities in educational and social functioning may lead to demoralization and other emotional problems. Longitudinal studies show, for example, that SAD is consistently linked with increased risk for subsequent depression. Further, individuals with comorbid social anxiety and depression are at increased risk for suicidal ideation and suicide attempts.

Telegram: @medical_k

www.konkur.in

Several longitudinal studies find that SAD is associated with the development of substance use problems. For example, one prospective study based on a subsample of 816 individuals from the Oregon Adolescent Depression Project found that SAD is a unique risk factor for the subsequent onset of alcohol and cannabis dependence. Specifically, a lifetime history of SAD at age 17 was associated with 4.5 times greater odds of alcohol dependence and 6.5 times greater odds of cannabis dependence by age 30. Also, results from a different prospective study showed that youth with SAD were significantly more likely 4 years later to smoke cigarettes and have a higher rate of nicotine dependence than a control group.

GENERALIZED ANXIETY DISORDER

Definition

In contrast to separation and social anxiety, which generally have one anxiety-triggering experience (i.e., separation and social humiliation, respectively) or focal fear, GAD is characterized by excessive and uncontrollable worry about a diffuse set of events. These events are often future oriented and center on possible poor outcomes related to school, friendships, health, and world events. In addition, for many youths, generalized anxiety focuses on living up to an internal standard (in school, friendships, extracurriculars) that is difficult to meet. Symptoms of this disorder occur with frequency and are experienced as difficult to stop. In addition, affected youth may report poor concentration, restlessness, and irritability, but other symptoms include fatigue, sleep disturbance, or muscle tension. As with other anxiety disorders, generalized anxiety must cause marked distress, interfere with social, emotional, and educational functioning, and is not simply a reaction to recent stressors.

Comparative Nosology

Prior to DSM-IV, a diagnosis of generalized anxiety was reserved for individuals 18 years or older, and children with multiple fears and worries could be diagnosed with overanxious disorder. Overanxious

Telegram: @medical_k

www.konkur.in

disorder was characterized by excessive or unrealistic worry for a period of at least 6 months. Due to the poor reliability and validity of this diagnostic category and symptomatic overlap and continuity with adult generalized anxiety, overanxious disorder was incorporated into the DSM-IV GAD diagnosis. Research comparing cases diagnosed by DSM-III-R and DSM-IV criteria found that the change in terminology did not affect the characteristics of cases. Criteria remained unchanged for DSM-5 or DSM-5-TR.

Epidemiology

GAD is a common diagnosis in children, with a reported lifetime prevalence of 9.0%. Community samples of preschool children report a prevalence range of 0.5% to 6.5% for overanxious disorder or GAD. Based on data from two community epidemiology studies, the 3-month prevalence rate for GAD among children aged 9 to 12 is 1.4%. The prevalence for adolescents aged 13 to 18 years ranges between 2.3% and 5.0%. Whereas rates of separation anxiety decline with age, rates of generalized anxiety increase with age, with a mean age of onset of 8 to 9 years, and median age of onset of 12 years. Girls are twice as likely as boys to meet diagnostic criteria.

Pediatric GAD is commonly associated with other anxiety disorders and mood disorders. Data from the National Comorbidity Study—Adolescent Supplement (NCS-A) and Great Smoky Mountains Study (GSMS) found that up to 2/3 of affected youth met criteria for another anxiety disorder, and about half met criteria for a mood disorder. Preschoolers with generalized anxiety have the highest rates of comorbidity compared to preschoolers with other anxiety disorders. Few significant differences in rates and patterns of comorbidity across age and gender have been identified; younger children are more likely than adolescents to have separation anxiety as a comorbid diagnosis, and males are more likely than females to have an externalizing disorder as a co-occurring diagnosis.

Etiology

Telegram: @medical_k

www.konkur.in

Similar to the other anxiety disorders, both genetic and environmental factors contribute to the development of GAD. However, heritability estimates are lower for generalized disorder (approximately 30%), suggesting that environmental factors, both shared (e.g., uterine environment in the case of twins, exposure to common parenting in the case of siblings) and nonshared (e.g., personal traumatic experience, peer relationships), may have a more prominent etiologic role. Twin studies show that generalized anxiety may be better explained by additive genetic factors and nonshared environmental factors compared to shared environment factors. Low heritability estimates in twin studies and high familial rates of generalized anxiety suggest that increased rates in families may be more related to environmental factors. For example, parental anxiety, parenting approaches, or exposure to stressful life events may negatively affect childhood anxiety outcomes. Similarly, childhood anxiety may also impact parental or sibling anxiety as the child's anxiety may change the larger home environment.

Anxiety sensitivity is a temperamental or trait-like factor under genetic influence that is considered a risk factor for anxiety in general. It is characterized by a tendency to interpret physiologic symptoms as a sign that something harmful will result. Such factors, while not specific to anxiety, may predispose children in certain environments to become symptomatically more anxious and impaired. Similarly, an attentional bias toward threatening cues and a tendency to interpret ambiguous situations as threatening are associated with children with current anxiety disorder. Although such relationships cannot be considered causal, it is possible that such attentional biases coupled with environmental variables such as parenting influences (e.g., hearing information from a parent about the potential dangers of a situation) may ultimately shape anxiety-related beliefs and behaviors. Anxiety sensitivity has been related specifically to panic in adolescents and otherwise has been linked to anxiety in general.

Diagnosis and Clinical Features

Telegram: @medical_k

www.konkur.in

The hallmark feature of GAD is excessive worry that is difficult to control (Table 51.3–3). The threshold for diagnosis differs slightly for adults and children; adults are required to experience three of six associated symptoms, whereas children are required to have only one associated symptom. A diagnosis also requires the child to experience excessive worry more days than not for 6 months, the worry and associated symptoms must interfere with daily functioning, and the anxiety is not triggered by recent stressful events.

Telegram: @medical_k

www.konkur.in

Table 51.3–3.
DSM-5-TR Diagnostic Criteria for Generalized Anxiety Disorder

Telegram: @medical_k

www.konkur.in

A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).
B. The individual finds it difficult to control the worry.
C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms having been present for more days than not for the past 6 months):

   Note: Only one item is required in children.

   1. Restlessness or feeling keyed up or on edge.
   2. Being easily fatigued.
   3. Difficulty concentrating or mind going blank.
   4. Irritability.
   5. Muscle tension.
   6. Sleep disturbance (difficulty falling or staying asleep, or restless, unsatisfying sleep).

D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
E. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism).
F. The disturbance is not better explained by another mental disorder (e.g., anxiety or worry about having panic attacks in panic disorder, negative evaluation in social anxiety disorder, contamination or other obsessions in obsessive-compulsive disorder, separation from attachment figures in separation anxiety disorder, reminders of traumatic events in posttraumatic stress disorder, gaining weight in anorexia nervosa, physical complaints in somatic symptom disorder, perceived appearance flaws in body dysmorphic disorder, having a serious illness in illness anxiety disorder, or the content of delusional beliefs in schizophrenia or delusional disorder).

The vast majority of pediatric patients with generalized anxiety (75% to 80%) endorse physical symptoms. Common physical symptoms include headaches, tension, restlessness, gastrointestinal distress, and heart palpitations. Cognitive characteristics of generalized anxiety include negative thinking errors such as catastrophizing (i.e., expecting the worst possible outcome) or overestimation of the likelihood that something undesirable will occur. Generalized worries cover a range of everyday issues, such as being on time, upcoming activities, failure of loved ones or friends to meet basic expectations, or whether unexpected events (e.g., inclement weather) will change daily plans or schedules. Children and adolescents with generalized anxiety are often described as perfectionistic and overly sensitive. They are plagued by negative self-image, need for reassurance, and insecurities about competence, performance, and expectations about the future.

Telegram: @medical_k

www.konkur.in

Jesse is a 14-year-old Black female who lives with her biologic parents and two older siblings in a suburban area. She presents for evaluation with her biologic father complaining of stomachaches, fatigue, and attention difficulties. Upon further interview, her father reports that Jesse has “always been nervous,” and describes numerous domains about which she frequently seeks reassurance, such as whether her family will have enough food to eat and a place to live, the possibility of a natural disaster destroying their home, and whether her grades will get her into a good college. Though her parents provide reassurance related to these worries, she will ask multiple times. She has no history of attention issues and has always been an A student, but she recently has been having difficulty concentrating in class; she reports worrying about many things for most of the day, and that she “can’t stop” the worry. As a result, her grades have become Bs and Cs, which she reports has caused even more worry.

Differential Diagnosis

Worry associated with generalized anxiety has multiple targets that include worries regarding everyday life experiences. Therefore, it may be more difficult to differentiate generalized anxiety from normative anxiety experienced by all individuals. However, the overall amount of anxiety, poor anxiety control, the lack of amelioration with appropriate reassurance and support, and longer-term impairment associated with generalized anxiety differentiate it from normal worry.

Generalized anxiety can be differentiated from emotional disorders based on the greater number of anxiety triggers and the specific nature of the worries. Children with generalized anxiety are concerned with past and future experiences, physical health, weather, environmental changes, and unexpected events. They may appear to have similar concerns to children with separation and social anxiety but differ in important ways. For example, children with

Telegram: @medical_k

www.konkur.in

generalized anxiety may avoid going to school, not because of separation or social concerns but because of academic performance worries. That said, it is not uncommon for younger children with GAD to also be diagnosed with co-occurring separation anxiety and older children with co-occurring SAD. Individuals with generalized anxiety and perfectionism may superficially resemble those with OCD. For example, a child with generalized anxiety and concern about academic performance may routinely check over homework for accuracy or study material repeatedly for the purpose of improving the work product or getting it "perfect." In contrast, children with OCD know the work product is good or perfect, but experience doubt that their perception is accurate and then recheck for the purpose of rechecking. In addition, individuals with generalized anxiety may have recurrent uncontrollable worries that could be mistaken for obsessions; however, worries of GAD do not appear senseless, intrusive, or unwanted, rather they are described as powerful bona fide concerns and are usually tied to events or situations that would stimulate normal concerns. For example, normal children may worry about bad weather as it happens, GAD children will worry that bad weather may happen on a cloudless day, and children with OCD may worry that if they do not count to three in sets of three then a loved one may die in a weather-related incident.

Ruminations (i.e., recurrent depressive cognitions) are characteristic of depression and tend to regard experiences negatively and hopelessly. For example, repetitive thoughts such as "No one will like me no matter what I do" can be readily distinguished from "I need to be perfect for my teachers and parents" by identifying the depressive (ruminative) quality of the former and the perfectionistic (generalized anxiety) quality of the latter.

Course and Prognosis

Prospective and cross-sectional studies of youth suggest that GAD is an episodic or recurrent disorder and that prognosis is dependent on comorbidity and severity. Individuals with a comorbid diagnosis tend to have higher ratings of severity and functional impairment.

Telegram: @medical_k

www.konkur.in

Those with greater severity and psychosocial impairment at baseline are more likely to retain a diagnosis over time.

Like other anxiety disorders, GAD is considered a risk factor for the development of additional psychiatric problems over time. Specifically, generalized anxiety may lead to the subsequent development of anxiety disorders, substance use, depression, or behavior problems. The New York Child Longitudinal Study investigated the associations between anxiety disorders and later psychiatric disorders in 9- to 18-year-old children and adolescents. DSM-III overanxious disorder was related to subsequent major depression, SAD, and generalized anxiety. Whereas children with separation anxiety symptoms were less likely than other children to begin drinking alcohol and did so later than others, those with generalized anxiety symptoms were more likely than other children to begin drinking and did so earlier. Results from the GSMS found that DSM-IV generalized anxiety was associated only with later conduct disorder but did not predict anxiety or other psychiatric problems.

TREATMENT OF ANXIETY DISORDERS

Both cognitive behavioral therapy (CBT) and antidepressant medications are effective for treating youth anxiety disorders (e.g., GAD and SAD). Expert reviews of the literature and meta-analyses repeatedly affirm the evidence base for both interventions, whether administered alone or in combination.

The Child/Adolescent Anxiety Multimodal Study (CAMS) remains the largest double-blind, placebo-controlled trial for child and adolescent anxiety disorders. The CAMS compared the relative efficacy of CBT, sertraline, combination therapy (CBT plus sertraline), and placebo for n = 488 youth with GAD, separation anxiety disorder, and/or SAD. All active treatments were superior to placebo, and combination therapy led to significantly higher response rates than CBT or sertraline (81% vs. 60% vs. 55%, respectively). Remission rates (loss of principal diagnosis, loss of all anxiety diagnoses) ranged from 20% to 68% and followed the same

Telegram: @medical_k

www.konkur.in

patterns as response rates based on treatment condition. Factors associated with better response and remission rates in the CAMS included the absence of comorbid internalizing disorders, absence of SAD at baseline, lower baseline anxiety symptom severity, lower caregiver strain, nonminority status, and younger age. A recent paper using CAMS data goes further to suggest that youth with mild–moderate anxiety benefit most from CBT monotherapy, whereas those with more severe illnesses may be best served by beginning with combined treatment.

Beyond acute and short-term follow-up of anxious youth, there has been considerable interest in understanding how these youngsters fare over time, particularly when they have had the benefit of evidence-based treatment. To address this question, youth who participated in the CAMS trial were followed as part of a prospective longitudinal study as they entered early adulthood (Child/Adolescent Anxiety Multimodal Treatment Extended Long-term Study; CAMELS). On average, youth were recontacted approximately 6 years following their CAMS treatment and followed for another 4 years. Findings from CAMELS suggest that roughly 20% of youth treated in CAMS remained consistently remitted over time as they entered early adulthood. Roughly half exhibited a fluctuating course marked by intermittent relapse. The remaining 30% were chronically ill, with anxiety disorder evident at every time point. These findings speak to the persistent nature of anxiety and the need to consider models of care that integrate chronic disease approaches and use surveillance and booster sessions to maintain wellness.

Psychotherapy

Over 50 years of evidence support the effectiveness of exposure-based CBT for youth anxiety. Although there is variability across treatment protocols, they are generally linked by their focus on psychoeducation, emotion identification, somatic management techniques, cognitive restructuring, exposure tasks, and relapse prevention. Traditional individual child treatment typically involves 10 to 20 weekly treatment sessions, and numerous studies support the

Telegram: @medical_k

www.konkur.in

use of additional formats, including group, family, brief intervention, and telehealth administration. In this section, we provide a brief synopsis of the evidence base for CBT before shifting to focus on newer trends in psychosocial treatment research for anxiety.

A 2017 study reviewed 100 anxiety treatment outcome studies in children and adolescents. For symptom reduction, CBT (d = 1.19), exposure alone (d = 1.05), modeling (d = 1.42), CBT with parents (d = 1.25), educational interventions (d = 1.26), and CBT with medication (d = 2.37) garnered the most consistent symptom reductions. The review established individual CBT as the most highly supported treatment for improving functioning, with an average within-group effect size of d = 1.76. CBT with parent involvement (d = 1.99), CBT with medication (d = 2.04), and exposure (d = .96) were categorized as having good support and being probably efficacious. These moderate-to-large effect sizes and the durability of treatment effects over time support the conclusion that CBT is an effective treatment for anxiety disorders in children and adolescents. They are bolstered further by findings from a 2019 meta-analysis which included clinical trials from 1963 to 2016 and found a mean posttreatment effect size of Hedges g = .66.

Given the robust evidence supporting the use of CBT, more recent studies have focused on understanding the mechanisms underlying its effects. Research suggests that both cognitive restructuring and exposure practice offer particular benefits during the course of treatment, with the steepest clinical gains observed following the introduction of exposure. Higher doses of exposure practice, more variable distress when practicing, and greater mastery of exposure tasks are all associated with better clinical outcomes. Moreover, contrary to what many may think, exposure practice does not diminish the therapeutic relationship but, indeed, enhances it.

In addition to efforts to optimize CBT by isolating its central ingredients (exposure) and maximizing their effects (via contemporary models of fear learning and extinction), research has also continued to consider factors that affect CBT outcomes. Family dynamics remain central, given their common links to youth anxiety and the identification of well-specified targets (e.g., symptom

Telegram: @medical_k

www.konkur.in

accommodation, overcontrol). Research consistently suggests that family-focused treatment is efficacious for youth anxiety; however, its additive value beyond individual child treatment remains a subject of some debate. This is likely due to methodologic issues across studies, including if/how putative family mechanisms are specified, how interventions map to specific family targets, and whether measurement approaches allow for tracking of family change and mechanistic effects. Certainly, there is emerging evidence from separate research groups that parent-only interventions may be comparable to child-focused CBT for anxiety.

A few somewhat distinct approaches to treating youth anxiety merit mention. First, parent–child interaction therapy (PCIT), originally developed to treat externalizing problems in young children and to treat various early anxiety problems, has been modified and adapted with success for youth anxiety. This approach targets child symptoms by reshaping parent–child interaction patterns associated with the maintenance of child anxiety symptoms. This goal is achieved through the use of live, unobtrusive parent coaching, delivered through a bug-in-the-ear receiver from a therapist situated behind a one-way mirror. Recently, the first randomized controlled trial (RCT) was conducted to test the efficacy of a 9-week PCIT treatment for separation anxiety in children aged 4 through 8 years. At posttreatment, 73% of children assigned to PCIT no longer met the criteria for a diagnosis of SAD, and results were largely maintained at a 3-month follow-up visit. Preliminary efficacy studies of another PCIT adaptation, the Coaching Approach behavior and Leading by Modeling (CALM) Program, designed to target the full range of anxiety disorders affecting young children (GAD and SAD, in addition to separation anxiety disorder) suggest the promise and feasibility of this approach.

A separate approach has focused on CBT adaptations designed particularly for social phobia, recognizing that this particular condition moderated the outcome in the CAMS trial. In a comparative treatment trial, children and adolescents aged 7 to 17 years were randomly assigned to Social Effectiveness Therapy for Children (SET-C, a behavioral approach), fluoxetine, or placebo. Results

Telegram: @medical_k

www.konkur.in

revealed both active treatments to be superior to placebo in reducing social distress and behavioral avoidance and increasing general functioning. SET-C, however, was superior to fluoxetine on these outcomes and was the only treatment superior to placebo in terms of improving social skills, decreasing anxiety in specific social interactions, and enhancing ratings of social competence. Although both treatments are considered efficacious, SET-C provides an added benefit by enhancing social skills.

A third innovation comes in the form of efforts to expand access to CBT intervention. Computer-assisted treatments which combine computer-based sessions with online and phone contact with a CBT clinician have been developed. These include protocols such as BRAVE-ONLINE and Camp-Cope-A-Lot. Preliminary trials of these programs, including one RCT, suggest that computer-assisted and in-person CBT produce statistically similar clinical improvements. Given the initial promising findings and the capacity of computer-based CBT to increase treatment accessibility, these programs merit continued investigation. Separate from this approach, telehealth CBT has also gained traction, with preliminary evidence that it produces outcomes comparable to clinic-based care.

Finally, technologic advances are also being integrated into treatment with the goal of enhancing learning and generalization of treatment effects. One such modality uses virtual reality technology to facilitate graded, in vivo exposures. Within this approach, youth are immersed in virtual environments where they interact with clinician-operated avatars to practice socially challenging tasks (e.g., greeting peers, answering questions, and assertiveness skills). The preliminary acceptability and feasibility of this approach have been demonstrated, and further research will assess its efficacy as a stand-alone treatment and adjunct to traditional CBT.

Pharmacology

Antidepressant medications are the mainstay of psychopharmacology of pediatric anxiety disorders. We have grouped the disorders in this psychopharmacology section—as is not

Telegram: @medical_k

www.konkur.in

uncommon in research studies (see CAMS trial)—as the treatments are mostly overlapping. Where appropriate, we will highlight key differences between disorders.

In a recent meta-analysis of the impact of antidepressant dose and class on treatment response in children with generalized, separation, and/or SADs, antidepressant-related improvement occurred early in the course of treatment, with approximately 50% of the improvement seen at week 12 occurring by the fourth week of treatment.

SSRIs are considered first-line medications for this population due to the favorable treatment response (effect sizes greater than 0.8) and low side-effect profile identified in a number of single-site and multisite RCTs. Agents that have demonstrated efficacy include fluoxetine (Prozac), sertraline (Zoloft), escitalopram (Lexapro), paroxetine (Paxil), duloxetine (Cymbalta), venlafaxine (Effexor), and fluvoxamine (Luvox). There is some data to support the use of tricyclic antidepressants (TCAs), including imipramine (Tofranil), but given the higher potential side effect burden, these are less commonly used.

Despite the demonstrated efficacy of SSRIs for anxiety in RCTs, no SSRIs are approved by the U.S. Food and Drug Administration (FDA) for use with children and adolescents. Published trials specifically targeting generalized anxiety included one effectiveness trial with sertraline and two trials—one positive and one negative—with venlafaxine (Effexor), which were combined and published together. More recently, duloxetine was found to be effective in a large, industry-sponsored, randomized, placebo-controlled trial of children and adolescents 7 to 17 years old with GAD leading to the first FDA indication of any medication for a non-OC, non-PTSD anxiety disorder in children and adolescents.

There have been three studies that have assessed the efficacy of antidepressants in SAD—two industry-sponsored trials and one federally funded study. Venlafaxine extended-release preparation was found to be more effective than placebo in a large sample of children and adolescents (n = 293) aged 8 to 17 years. Paroxetine was found to be more effective than placebo in a large sample (n = 322) of children and adolescents aged 8 to 17 years. Finally, the only

Telegram: @medical_k

www.konkur.in

federally funded study that assessed an SSRI, fluoxetine, and found it to be more effective than placebo was the SET-C study described above.

Open-label follow-up studies of SSRIs suggest that youth who benefit acutely continue on a positive trajectory for up to 6 months. Further, since anxiety disorders tend to run a chronic course with associated impairment, longer treatment with medication may be justified to support the consolidation of initial gains and prevent the return of anxiety symptoms.

There is no clear data to determine how long to treat children with medication to maximally reduce the chance for a return of symptoms upon medication discontinuation. Therefore, making the decision when to discontinue medication is often determined pragmatically. Treatment for 6 to 12 months after remission in symptoms may provide extended benefit without undue burden and may offer an opportunity to reduce the chance for a return of symptoms after medication discontinuation. However, longer-term treatment may be necessary if children experience a return of symptoms when medication doses are missed or during known trigger points such as the start of school in the fall or after the winter holidays (separation anxiety), grade reports, or final examinations (generalized anxiety), or group activities at school or camp (social). Such tenuous symptom control suggests that continued treatment, dose increases, or more intensive psychosocial treatments be provided to stabilize the patient before considering medication discontinuation. For patients and families who choose to pursue a discontinuation trial, it is important to consider timing. For example, it may be ill-advised to try coming off a previously helpful medication during a time of likely anxiety triggers or when family or medical support is not available (i.e., start of school for separation anxiety or participation in performance activities for generalized or social anxiety).

Although adults with GAD may be treated acutely with benzodiazepines, there are few data to support the efficacy of this class of medications for youth. For example, a small double-blind, placebo-controlled randomized trial of alprazolam (Xanax) for the treatment of pediatric overanxious and avoidant disorders

Telegram: @medical_k

www.konkur.in

demonstrated no benefit of medication over placebo. More to the point, benzodiazepines have not been extensively studied for the acute or chronic management of anxiety in children, and while potentially useful at reducing the experience of anxiety, they may lead to both psychological and physical dependence and thus complicate treatment long term. Given the efficacy of SSRIs and other antidepressants for childhood anxiety, benzodiazepines should not be considered as first-line treatment. If used at all, benzodiazepines may be considered for short-term augmentation of antidepressants early in the course of treatment for some highly anxious children.

There is little evidence supporting the use of other medications such as antihistamines, α-adrenergic agonists, or antipsychotics for the treatment of childhood anxiety disorders; however, it is not uncommon to see patients clinically who are treated with such agents to address problems with insomnia related to anxiety. Combining other medications with SSRIs to address anxiety-related insomnia should only occur when antidepressants have been maximally adjusted upward and anxiety and insomnia persist. Then the use of sedating antidepressants is preferred to the use of antihistamines, α-adrenergic agonists, or antipsychotics.

Buspirone (BuSpar), a nonbenzodiazepine, nonantidepressant anxiolytic, is effective in studies of adults with GAD and was evaluated in a large, multisite, industry-sponsored RCT. Although the trial was not published, a report of the negative outcome of the study is available on the FDA website.

Overall, the best evidence supports the use of SSRIs in the treatment of childhood anxiety disorders. The value of the SSRIs probably extends across the class so that medication choice can be based on a number of factors, including evidence of efficacy in high-quality clinical trials, half-life, the risk for drug–drug interactions, any subtle differences in side-effect profiles, and patient, family, and provider preference. SNRIs are also commonly used, bolstered by the FDA indication for duloxetine. The TCAs, which can be effective, have not been consistently able to separate from placebo in larger clinical trials, so they should be considered only as an alternative for

Telegram: @medical_k

www.konkur.in

those who have not responded to SSRIs or SNRIs. The value of TCAs in attention-deficit/hyperactivity disorder (ADHD) may make them a second-line choice for children with anxiety disorders and ADHD.

Despite ample evidence for the use of SSRIs and SNRIs in pediatric anxiety disorders, there remains tremendous heterogeneity in response. Nearly two in five patients with anxiety disorders fail to respond to these medications. There is growing awareness that pharmacogenetic factors likely account for some of this variability. Drug-metabolizing enzymes change throughout development, and there is data suggesting that SSRI exposure may be significantly different in children than in adults given the same dose. Though the Clinical Pharmacogenetics Implementation Consortium (CPIC) has published a guideline including dosing recommendations for adults, the same is not yet available in pediatric patients. Larger pharmacogenomics studies in pediatric patients are necessary to build evidence-based guidelines for the use of such data in children and adolescents with anxiety.

Safety. The SSRIs as a class share a number of important side effects that include physical symptoms such as stomachache and headache and can also be associated with changes in behavior such as activation/disinhibition, insomnia, apathy, manic reactions, and the potential for suicidal behavior. Activation/disinhibition (and similar or related symptoms such as akathisia) are quite common in the pediatric population, with a 10% to 15% difference between SSRI and placebo groups. Activation often occurs early in the course of treatment—days after the initial dose or first meaningful dose increase (e.g., sertraline 25 or 50 mg; fluoxetine 10 or 20 mg), and goes away with medication discontinuation. It appears to be more common in younger children and those whose anxiety co-occurs with symptoms of ADHD, autism spectrum disorders, or other early developmental psychopathology. The SSRIs impact sleep in two ways: (1) activation can make it more difficult to fall asleep, and (2) SSRIs disrupt sleep architecture; hence users may recover from anxiety, may experience a restful sleep, but may sleep more lightly,

Telegram: @medical_k

www.konkur.in

and experience middle-of-the-night awakenings. At higher doses of the SSRIs, apathy may occur, leaving patients relatively free of anxiety but unmotivated or feeling disconnected from living.

One area of concern to prescribers of SSRIs in anxious children is the induction of a manic reaction that may herald a new and more severe course of illness. However, manic reactions in the acute phase and large-scale RCTs of the SSRIs are exceedingly rare (<1%). Indeed, rates of manic symptoms are low even in longer-term follow-up studies. The concern regarding a manic switch is probably greatest when the anxiety disorder is complicated by problems with impulse control or aggressive behavior suggestive of bipolar disorder. Differentiating a manic reaction from the activation side effect can be challenging but an important distinction. Misdiagnosing an activation side effect as a manic reaction may shift the prescriber away from the antidepressants to the use of antipsychotics and mood stabilizers, neither of which are particularly effective for anxiety disorders. Manic reactions can be differentiated by their presentation, time course of onset, and response to medication discontinuation. Manic symptoms include elevated and expansive mood, grandiosity, decreased need for sleep, and increased goal-directed activities, and symptoms are distinct from the irritability and impulsivity that are commonly seen with activation. Activation occurs early in the course of treatment; manic reactions occur later. With medication discontinuation, activation symptoms decrease in relationship to blood level, whereas manic symptoms may persist and require medication treatment to reduce symptoms.

Finally, the risk of suicidal behavior emerging or worsening during antidepressant treatment is probably the public's greatest concern. A recent meta-analysis suggests that the suicidal behavior risk difference between the antidepressant and placebo in a high-quality clinical trial is <1% with numbers needed to harm of >100 and the number needed to treat in high-quality RCTs in depression (NNT = 3–4 in NIMH-funded trials), OCD (NNT = 5), and the triad of anxiety disorders (NNT = 3). These data, the observed reduction in antidepressant use with the advent of a black box warning, and the subsequent spike in youth suicide gave rise to concerns that the

Telegram: @medical_k

www.konkur.in

black box warning may have had unintended negative consequences. While the black box warning on an antidepressant has not been changed, prescribers are regaining comfort in the use of the antidepressants.

The side-effect profiles of SNRIs are similar to the SSRIs but now include symptoms consistent with norepinephrine reuptake, including nausea, and the potential for initial worsening of anxiety (not activation per se), and for heart rate and blood pressure increases. The side-effect profile of TCAs is well known and includes prominent anticholinergic effects, dry mouth, constipation and urinary retention, and noradrenergic effects on cardiac function, elevated heart rate, and orthostatic blood pressure changes, and the potential for prolongation of important cardiac intervals including the QTc.

FUTURE DIRECTIONS

Issues that warrant further clarification pertaining to the treatment of youth with separation anxiety, generalized anxiety, or social anxiety include the identification of moderators of treatment outcome, identification of critical elements of psychotherapy that contribute to the outcome, questions of treatment sequencing, and whether youth who fail to respond to either medication or CBT as their first treatment will respond to the other treatment, strategies for enhancing outcomes and addressing treatment resistance, and elucidating long-term outcomes, particularly following medication treatment.

51.4 Selective Mutism

R. Lindsey Bergman, Ph.D., and Araceli Gonzalez, Ph.D.

Telegram: @medical_k

www.konkur.in

Selective mutism (SM) is a childhood behavioral disorder characterized by a persistent failure to speak in one or more specific social situations despite speaking in other situations. Although the syndrome was recognized as long ago as 1877, the disorder (earlier called elective mutism) did not appear in the *Diagnostic and Statistical Manual of Mental Disorders* until its third edition (DSM-III) in 1980. Current conceptualizations of SM emphasize the relationship between considerable social anxiety and the failure or extreme reluctance to speak. In addition, researchers continue to investigate the presence of speech or language anomalies as well as oppositional symptoms among children with SM. Although there has been increased interest related to SM recently, in comparison with many other childhood emotional or behavioral disorders, there is a relative lack of consensus on many issues related to the epidemiology, phenomenology, and treatment of the disorder.

DEFINITION

The DSM-5-TR defines SM as a consistent failure to speak in specific social situations where speaking is expected (e.g., to peers at school), despite speaking regularly in other situations. DSM-5 also specifies that in order for the diagnosis to be assigned, the lack of speech must interfere with achievement or communication, must last at least 1 month (beyond the first month of school), and must not be due to a lack of knowledge or comfort with the language required in a given situation. Finally, DSM-5-TR specifies that the lack of speech cannot be better accounted for by a communication, developmental, or psychotic disorder. Criteria for SM are similar in the *International Statistical Classifications of Diseases and Related Health Problems* (ICD-11).

HISTORY

In the 19th century, the term *aphasia voluntaria* was first noted in the psychiatric literature and was used to describe children who voluntarily chose not to speak in certain situations. Many other terms

Telegram: @medical_k

www.konkur.in

including voluntary mutism, speech phobia, suppressed speech, functional mutism, and speech avoidance have also been used to describe children who meet the current criteria for SM. The term *elective mutism* was first used in 1934 and appeared in DSM-III in 1980. Some believed that descriptors such as “voluntary” and “elective” that appeared in these early terms suggested a volitional choice to refrain from speaking, and possibly, an oppositional attitude. This attitude was also reflected in the DSM-III definition of elective mutism, which contained a reference to a “refusal” to speak in the definition of SM. In DSM-III-R, elective mutism was renamed SM, perhaps reflecting shifting conceptualizations of the disorder such that attention was more focused on social anxiety as opposed to oppositional or volitional aspects of the nonspeaking behavior.

COMPARATIVE NOSOLOGY

Consistent with the shifting conceptualization described above, SM was reclassified as an anxiety disorder in the current edition of the DSM (DSM-5) and its text revision (DSM-5-TR). In the DSM-IV, SM was included in the section Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence. In the DSM-5, disorders within that category were reorganized into different categories and SM is now included as an anxiety disorder. This reclassification of SM in the Anxiety Disorders section of the DSM-5 is a logical fit given growing evidence for the phenomenologic similarities between SM and social anxiety (see Etiology section). However, the nature of relationship between SM and social anxiety is complex and requires further research as discussed below. Other than the relocation of the SM diagnosis from Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence to the Anxiety Disorders section, the diagnostic criteria for SM are virtually identical in the DSM-IV and -5. Interestingly, a diagnosis of SM does not require the presence of fear or anxiety.

The disorder is called SM in the current (11th) edition of the ICD. In the ICD-11, SM appears in the section of Anxiety or fear-related disorders.

Telegram: @medical_k

www.konkur.in

EPIDEMIOLOGY

SM prevalence rates vary by study but have been generally below 1%. Few community-based prevalence studies have been published and the majority of this work was completed in European samples. These studies have yielded disparate findings due to different sampling strategies and definitions of SM. A U.K. study identified 0.69% of 4 to 5 year olds as completely mute (i.e., not speaking at all) at school. However, this rate dropped to 0.08% after approximately 8 months of school. Another survey, also in the United Kingdom, identified only 2 of 3,300 (0.06%) 7 year olds as selectively mute at 36 months of age. More recent investigations have focused on the school environment to investigate the prevalence of SM. Two Scandinavian surveys found teacher-reported rates of DSM-IV-TR SM of 0.18% and 1.9%, respectively, and another study with Irish primary school children aged 4 to 12 years also found a prevalence rate of 0.18. One U.S. study surveyed kindergarten, first-, and second-grade classrooms in an urban public school district and reported a DSM-IV-TR SM prevalence rate of 0.71% (16 of 2,256). A study in Israel yielded comparable results with a prevalence rate of 0.76. Another clinic-based study in the United States found a prevalence rate of 0.50% in a primary care clinic. These studies provide evidence that the point prevalence rate for SM is comparable to rates of other childhood psychiatric disorders, including obsessive-compulsive disorder (0.5% to 1%) and major depressive disorder (0.4% to 3%).

Overall prevalence does not seem to vary markedly by sex or race/ethnicity; however, there is evidence that slightly more girls than boys seem to be affected by SM, with an average reported female-to-male ratio of 1.2 to 1. There is some evidence to suggest that this gender difference may become more pronounced among older children. Although it is commonly reported that children with SM show significant symptoms from the age at which they spoke fluently, with the age of onset typically reported from 2 to 5 years old, SM is often not noticed until the time of entry into school. It has also been reported that immigrant and bilingual or language minority children

Telegram: @medical_k

www.konkur.in

are at higher risk of SM, and the prevalence of the disorder may be three times higher in these populations. However, this required further study, and it should be noted that SM must be distinguished from a nonverbal period that is sometimes observed in children during second-language acquisition.

ETIOLOGY

The conceptualization of SM has undergone a considerable shift in recent decades. At this point in time, evidence suggests that SM results from multiple developmental pathways involving the complex interplay of genetic, neurobiologic, temperament, and behavioral (e.g., avoidance) variables. Previously, it was often suggested that SM was related to a variety of conditions including oppositionality, trauma, or family neuroses. While a variety of psychological and developmental factors likely play a role, there is a general consensus that SM is closely related to anxiety, and social phobia in particular. Children with SM and/or social phobia tend to exhibit similar levels of nonverbal social anxiety, trait social anxiety, and cortisol reactivity to a presentation task. The body of work is consistent with a conceptualization that SM is a developmental variant or precursor of social phobia, rather than an extreme form of SM. Strong support for this position is derived from studies reporting that 69% to over 95% of children with SM also met criteria for social anxiety disorder. Similarly, family history data reveal an elevated rate of social phobia among parents of children with SM, and severity of children's SM symptoms may predict parents' diagnosis of generalized social phobia. Research regarding genetic risk of SM is in its infancy. One recent study examining genetic susceptibility factors for SM in families with social anxiety–related traits found evidence of increased risk of SM in individuals with a genetic variation in *CNTNAP2*, a gene implicated in various forms of language impairment. Notably, *CNTNAP2* has also been implicated in autism spectrum disorder (ASD). While SM and ASD may exhibit several phenotypic similarities (e.g., difficulties with social communication) and there is recent evidence for a potential shared genetic

Telegram: @medical_k

www.konkur.in

susceptibility, they are distinct conditions (further discussed below in Differential Diagnosis).

Evidence of a relationship between SM and social phobia also come from studies demonstrating several cognitive and behavioral similarities. Recent studies also noted similarities between SM and social anxiety in the content of their reported fears, such as fear of negative evaluation by others. Researchers and clinicians have also noted the resemblance between SM children and children described as shy or “behaviorally inhibited.” In fact, reluctance to speak is often considered to be a sensitive index of behavioral inhibition. Consistent with this is the finding that parents of children with SM rate their children as not responding well to new situations or handling transitions well, both widely considered to be fundamental elements of behavioral inhibition. Since there is evidence that the presence of behaviorally inhibited temperament is associated with increased risk of future anxiety disorders, it is possible that behavioral inhibition is an etiologic factor in the development of SM. By contrast, a small proportion of children with SM do not exhibit social phobia with regard to nonverbal communication and will engage in social interaction using gestures, facial expressions, body language, and other socially engaged behavior. Such cases raise questions about the nature of the relationship between SM and social phobia, suggesting that some individuals may experience anxiety specifically related to expressive language and not to social situations more generally. Some researchers have investigated the notion that the “nonspeaking behavior” of children with SM essentially should be seen as an emotion regulation strategy aimed to reduce anxiety around social interaction. Finally, additional evidence linking SM to social phobia comes from the finding that pharmacologic agents used to treat adult social phobia are similarly effective in the treatment for SM.

As mentioned previously, oppositionality and recent trauma are often cited as etiologic factors related to SM; however, studies utilizing systematic diagnostic procedures do not provide support for these relationships. In comparing children who met criteria for only social phobia to those with both SM and social phobia and those with

Telegram: @medical_k

www.konkur.in

no disorder, researchers found no significant differences on parental reports of oppositionality. Furthermore, mean scores for ratings of oppositionality were in the normal range for children with SM. Thus, findings suggest that the majority of children with SM do not present with clinically significant oppositional behaviors. However, 29% of children with SM were rated as meeting criteria for oppositional defiant disorder (ODD) by clinicians. Thus, a subset of children with SM may exhibit comorbid ODD.

Somewhat more confusing are conflicting findings related to the prevalence of communication disorders among children with SM and the association between developmental delay and SM. Several studies have examined possible deficits in auditory or speech and language processing in children with SM. In one study, a little over a third of children with SM displayed speech and language disorders, particularly articulation and expressive language disorders. In another study, children with SM were compared to children with an anxiety disorder and normal controls on measures of language, nonverbal working memory, and social anxiety. When compared to children with other anxiety disorders and healthy controls, children with SM had lower scores on language measures and deficits on tasks requiring them to remember verbal information. In another study, researchers found that children with SM did not exhibit deficits in visual memory, but they did show significantly poorer verbal memory than controls. Thus, some children with SM may exhibit meaningful deficits in speech and language processing. While the majority of children with SM do not exhibit speech and language disorders beyond the context of SM, it was recently purported that a subset of children with communication and language difficulties who are also behaviorally inhibited may become nervous to speak in new situations, which may in turn contribute to risk for SM.

Although some children with SM may experience language delay or dysfunction and deficits in speech and language processing, it is noteworthy that among researchers it is not suggested that these problems supersede social anxiety as a major contributing factor toward nonspeaking. Furthermore, although language delay or speech disorder may be more common among children with SM,

Telegram: @medical_k

www.konkur.in

these problems could be a result, rather than a cause, of the disorder. Finally, speech and language problems associated with SM are likely to be subtle and are exclusionary criteria for the diagnosis of SM when they cannot be ruled out as the cause of the lack of speech. Ultimately, however, it is important to note that many in the field believe that neurodevelopmental and language anomalies occur more frequently among children with SM than among children with other anxiety-related disorders.

DIAGNOSIS AND CLINICAL FEATURES

The primary symptom exhibited by children with SM is the failure to speak in some situations where speaking is expected despite speaking in other situations. The situation in which the child has no difficulty speaking is almost always in the home environment. In fact, some families of children with SM report that the child seems to be "overly" talkative at home. However, in severe cases, there may be some members of the household to which the child with SM does not speak. If a child who is presumed to have SM does not speak at all at home, there is reason to seriously question the diagnosis of SM.

Several studies indicate that the situation in which speaking is most commonly avoided is at school. Within this common pattern (speech at home, failure to speak at school), there is large individual variation in terms of speaking patterns among children with SM. In the school environment, children with SM more commonly fail to speak to adults (e.g., teachers) than to peers, although a lack of speech with peers is not uncommon. However, many children with SM have individually distinct and stable patterns regarding to whom they do, and do not, speak. For instance, there are often particular extended family members with which the child does not speak and others to whom they consistently speak. Some children with SM have little or no difficulty speaking with strangers, whereas others place strangers at the top of their hierarchy of people with whom it is difficult to speak.

The label of SM can be used somewhat broadly to describe children who are consistently reluctant to speak or display low

Telegram: @medical_k

www.konkur.in

frequency of speech. Although some argue that children who speak inconsistently, reluctantly, or with low volume do not, in fact, have SM, these speaking behaviors are relevant for the diagnosis of SM because children who completely fail to speak in some situations often speak inconsistently, with low frequency or volume, or reluctantly in others. For example, some children with SM may fail to speak at all in some situations and speak normally in others (e.g., home), while in other situations they might speak but not in a “normal” voice but whisper fairly readily. Also fairly common is the child who does not speak at all in some situations, but in other situations speaks in a “disguised” or odd voice that is mechanical, gruff, or baby like.

Given that SM appears to be so closely related to social phobia, it is not surprising that children with SM also have difficulty with nonverbal but socially relevant tasks such as eating in front of others, having their picture taken, and communicating nonverbally. When social anxiety symptoms not related to speech are present and meet criteria for social anxiety disorder, the additional diagnosis should be given. Even among those who are not also diagnosed with social anxiety disorder, children with SM are typically described as shy and self-conscious. However, it is important to note that not all children with SM are shy; although not typical, there are children with SM who present as outgoing, friendly, and eager to interact but only interact nonverbally (e.g., smile for the camera, raise their hand in class but not answer when called upon). This presentation has led some researchers to view SM as a type of specific phobia of speaking.

The following case exemplifies a common presentation of a child with SM.

Telegram: @medical_k

www.konkur.in

James is a 5-year-old Chinese American boy who lives with his biologic mother, father, and older sister. James's parents reported that he speaks normally at home but that he started to have difficulty speaking to adults and children at school upon entry to preschool. He continued to have difficulty speaking throughout his preschool year and has ongoing difficulty in kindergarten. At home, his parents report that he is extremely talkative and outgoing when he is around immediate family members and extended family members close to his age. At school, James does not speak to any of the adults but answers classmates with one-word answers and speaks only in a whisper. By his parents' report, James also exhibits extreme social anxiety, to the point of "freezing" in certain situations when attention was focused on him. He often watches other children playing from a distance, does not join in group activities, and does not participate in circle time at school. James's parents also report that he hides behind them when strangers are around and that he dislikes having his picture taken. At the time of his evaluation, James had not received prior treatment for SM or any other emotional or behavioral disorders. James was born in the United States and speaks fluent English and limited Mandarin. His parents speak to him in both English and Mandarin and he mostly responds to them in English. According to his parents, he developed normally with no delays and appears to have above-average intelligence. They also reported that James enjoys riding on his bicycle, singing, and art activities.

During initial evaluation, James hid behind his parents and failed to respond in any way to the intake clinician. James's parents reported that this behavior is typical of him when in a novel situation with new people, but that he might answer with one-word answers softly, communicate nonverbally, and make eye contact with people once he gets more comfortable with them. James's parents reported that he speaks spontaneously and fluently when he is at home with his family. They also reported that he can be quite animated, is a lot of fun, and is very

Telegram: @medical_k

www.konkur.in

talkative at home. James received diagnoses of SM (moderately severe) and social phobia (moderately severe). Behavioral treatment was recommended.

Behavioral treatment was initiated following the intake evaluation. Initially, the therapist played nonverbal games and engaged in nonverbal activities with James to help him feel comfortable in the session (e.g., coloring, blowing bubbles, hiding pennies, and giving nonverbal clues). Next, James and his mother were asked to create a list of easy, medium, and hard speaking situations and a list of small, medium, and large rewards. These lists then became the basis for assignments (and reinforcement) for speaking tasks that gradually increased in difficulty. In general, sessions included time with James and his mother together to review past and future assignments as well as time with James and the therapist alone.

When treatment began, James did not communicate at all verbally with the therapist. The therapist gradually increased rapport (via unstructured play) while having James try increasingly difficult tasks, such as first whispering to his mother with the therapist in the corner, then nodding yes or no in response to the therapist's questions, pointing, using a puppet to "talk for him," whispering to his mother while facing the therapist, and then subsequently responding verbally to the therapist. A successful technique in working with James was having him whisper to his mother while playing games with the therapist and then having his mother move a few inches away each time he was asked to respond to the therapist. As the whisper became more audible, the therapist was able to hear his speech and responded directly to the whisper (without waiting for his mother to tell the therapist what James said). James became more comfortable with the therapist hearing his voice, and he was slowly able to direct his speech toward the therapist. After three sessions, James consistently and spontaneously talked to the therapist. James received stickers for completing each speaking assignment, and after filling up "sticker charts," he received

Telegram: @medical_k

www.konkur.in

rewards (i.e., small toy, special activity with parent, or treat from the reward list).

James was also given assignments that involved both his teacher and classmates. These were implemented in a gradual fashion and included waving to the teacher, playing a game with his parent first in an empty classroom then while his teacher was in the classroom, leaving a phone message for the teacher, playing an audiotape of him saying “hello” to the teacher, whispering to his parent loudly enough for his teacher to hear, whispering “hello” to the teacher, and speaking “hello” to the teacher in a regular voice. Assignments also involved classmates and included playing games with his parent and one classmate, asking classmates questions about their favorite things (e.g., color, animal, and food), playing games with classmates without his parent, and play dates at home. After approximately 12 sessions, James spoke a complete sentence to a group of three classmates, spoke to his teacher directly, and answered a question aloud in front of the entire class.

During the last few sessions, which were tapered over several weeks, James’s mother took an increasingly primary role in assigning and following up on speaking assignments. James’s mother had him continue practicing talking assignments with extended family members and unfamiliar adults and children. James entered the first grade and, after only a few days, began regularly speaking to his teacher (both privately and in front of peers) and to most peers in class. Following the completion of therapy, James’s mother continued to monitor his speaking behaviors and to promote speaking in new situations by encouraging (and rewarding) James’s gradual successes with novel people and situations.

DIFFERENTIAL DIAGNOSIS

As discussed above, the current understanding of SM emphasizes that social anxiety underlies most selectively mute behavior. The

Telegram: @medical_k

www.konkur.in

resulting conceptual and diagnostic overlap between SM and social phobia complicates the clinician's determination of whether a child with SM also meets the criteria for the presence of comorbid social phobia. One of the most successful strategies for the clinician attempting to make this determination is to direct queries toward the presence of social phobia symptoms that do not involve speaking. For example, the presence of fear and avoidance of eating in public, having pictures taken, using public restrooms, or writing in front of others provide strong evidence for an additional diagnosis of social phobia in a child who meets the criteria for SM. Although some may perceive the child with SM to be oppositional, distinguishing SM from primary ODD is fairly straightforward in many cases. Most importantly, the child with SM is unlikely to engage in significant oppositional behaviors outside of the context of verbal communication. If a child who appears to have SM (failure to speak in certain situations despite speaking in other situations) also exhibits oppositional behaviors in a variety of situations, both diagnoses are given. For children whose failure to speak does not appear to follow a consistent pattern with regard to the situation and targeted individuals, appears primarily motivated by instrumental gains, and occurs in the absence of any other anxiety symptoms, it is possible that ODD rather than SM is the correct diagnosis.

There is a growing body of work examining similarities between SM and ASD. A few recent studies report a high degree of overlap in symptoms of SM and ASD, as reported in a retrospective review of medical records and parent reports on developmental and social communication scales. Additional research is needed to determine the between—group discriminative validity of existing measures of ASD among children with SM. Although children with SM can be misdiagnosed as having autism due to their lack of speech in the clinic setting, this diagnostic error can be avoided with a more thorough evaluation of autism-like features in children with suspected SM, with close consideration of (in)consistency of behaviors across settings. One study examined joint attention (one person's purposeful focus of attention with another person, often impaired in children with ASD) in children with SM, other anxiety

Telegram: @medical_k

www.konkur.in

disorders, and a control group. Findings indicated joint attention abilities in children with SM did not differ from the other groups in an unstructured free play condition, although children with SM displayed less joint attention than the other groups during structured tasks. Although this indicates some level of behavioral or psychological overlap between SM and autistic-like features, the context-specific display of behavior in children with SM is critical to distinguishing SM from ASD and may be more reflective of behavioral inhibition than autism-related behavior. Critically, the lack of speech associated with SM is, by definition, limited to certain situations, and evidence indicates that related behaviors that overlap with other diagnostic categories (e.g., poor joint attention) might also be limited to specific situations. However, the cognitive, language, and social communication difficulties of a child with ASD are present across settings. Similarly, the diagnostic criteria requiring that the child speak normally in some situations can often rule out a severe communication disorder.

Several studies have identified subsets or profiles of children with SM who also have mild or moderate levels of oppositionality. Although one may perceive some children with SM to be oppositional, distinguishing SM from primary ODD is fairly straightforward in many cases. Crucially, many children with SM may appear to be oppositional, almost exclusively around situations during which they are reluctant to speak but are being prompted to do so. If a child with a purported diagnosis of SM consistently exhibits oppositional behaviors in a variety of situations, both diagnoses are given. For children whose failure to speak does not appear to follow a consistent pattern with regard to the situation and targeted individuals, appears primarily motivated by instrumental gains, and occurs in the absence of any other anxiety symptoms, it is possible that ODD rather than SM is the correct diagnosis.

The DSM-5 criteria state that a child should not be diagnosed with SM if the failure to speak is due to a lack of knowledge of, or comfort with, the spoken language required. Researchers in the area of bilingual children with SM report that immigrant children and those learning a second language in their new country may be overlooked

Telegram: @medical_k

www.konkur.in

or misdiagnosed. Thus, the diagnosis of immigrant and language minority children can be difficult, and it is important to understand typical bilingual child development to diagnose SM properly. Many children learning a second language may go through a nonverbal or “silent period” due to the realization that their native language is not understood by classmates and teachers and that their skills in the new language are not sufficient. To diagnose SM in bilingual children and children who are acquiring a second language, it is important to know that bilingual children with SM exhibit a failure to speak in both their native and newly acquired languages in several unfamiliar settings and for an extended period of time (>6 months). Although a child learning a new language may not feel completely comfortable speaking a new language for several months, most children show no progression of speech as they gain mastery over their new second language, whereas a child with SM typically does not.

COURSE AND PROGNOSIS

SM appears to have an insidious onset, with most parents reporting failure to speak in some settings as a problem that was evident from the time their child began talking. However, most typically, the lack of speech outside of the home is not considered to be a problem until school entry. Although SM is generally considered to be a disorder that is difficult to treat successfully, at the same time, it is believed to spontaneously remit over time in a large majority of cases. Based in part on one study that found a large reduction in SM over a 6-month period (from the beginning to the end of the school year), it was believed that the disorder spontaneously remitted over time in a large number of cases and that in these cases, and that SM should be described as transient rather than persistent. This distinction has been refined somewhat based on a school-based study that revealed that although close to 30% of children with SM showed some improvement from the beginning to the end of a school year, as a group, the SM children remained significantly more symptomatic than matched unaffected peers.

Telegram: @medical_k

www.konkur.in

In a controlled long-term outcome study (mean follow-up period of 13 years), young adults with SM in childhood were compared to young adults with anxiety disorders in childhood and young adults with no psychiatric diagnosis in childhood. Researchers found that 18% of patients with SM in childhood showed only slight improvement in young adulthood, while the rest of the patients with childhood SM were found to be either markedly improved or totally improved in young adulthood. They reported a complete remission rate of 58%. Unfortunately, these data did not include comparisons related to variation in course with or without treatment. The only controlled treatment study that assessed youngsters 1 year following successful behavioral treatment reported that children maintained or improved upon initial gains when reassessed.

Although it seems intuitively useful to discriminate between transient and persistent SM and to assume that persistent mutism may be related to more severe impairment, this distinction requires further investigation. Similarly, there is no information related to ongoing difficulties that might result from even relatively short-term or transient SM. Given that there is little information regarding lasting consequences related to an early disturbance in verbal communication and that nonspeaking behavior is often conceptualized as a learned behavior that is reinforced considerably over time, it makes sense to target treatment toward younger, recent-onset youngsters. Additional support for the importance of early intervention (vs. delaying treatment to establish if SM will resolve spontaneously) comes from recent findings that age of onset, duration of SM, and age at treatment all predict treatment effect size. Specifically, young age and shorter duration of SM were associated with larger treatment effects.

TREATMENT

Although in the last 20 years, there has been an increase in the amount of research on SM, the majority of published data on the treatment of SM continues to rely on single-case studies and case series of markedly varying quality. In addition, studies reporting SM

Telegram: @medical_k

www.konkur.in

treatment outcomes tend to rely on small samples or single cases and do not identify diagnostic procedures, assessment or outcome methods, number of treatment sessions, or details of the treatment method. In spite of these limitations, the conviction that behavioral techniques are an essential component of treatment for SM is widespread. Recently, two small randomized controlled trials of behavioral treatment for SM were completed and supported the efficacy of such interventions compared to a waitlist control. Follow-up studies as long as 5 years posttreatment provide support for the durability of findings. In general, these and other published reports in the literature describing treatment efforts provide a solid basis for the development of behavioral treatments that include parent and school involvement in treatment. In addition to behavioral strategies, a small but growing literature provides support for the efficacy of a pharmacotherapeutic intervention (primarily the selective serotonin reuptake inhibitors [SSRIs]). In addition to a growing effort aimed at empirical validation of treatment for SM, recent efforts have also resulted in better instruments for the assessment of specific symptoms of SM. Instruments such as the Selective Mutism Questionnaire, a parent self-report measure of the affected child's lack of speech, and the School Speech Questionnaire, the companion teacher measure, are commonly used in the assessment of symptoms in both research and clinical settings.

Behavioral Treatment

Multiple published reports describe the successful utilization of relatively standard behavioral techniques such as contingency management, stimulus fading, systematic desensitization, negative reinforcement, and shaping for the treatment of SM. A combination of behavioral techniques is probably the most common and successful treatment approach. Behavioral approaches typically utilize a hierarchy or rank-ordered list of situations in which the child has difficulty speaking. Then, the child is guided to systematically engage in speaking-related behaviors (e.g., mouthing speech, making sounds, and whispering) in increasingly more difficult

Telegram: @medical_k

www.konkur.in

situations. Over repeated successful attempts, the associated anxiety dissipates through the process of autonomic habituation. In addition, when the feared consequences of speaking fail to occur, patients' heightened expectations of harm disappear, reducing anxiety even further. Typically, the child receives positive reinforcement (rewards) following attempts to engage in speaking-related behaviors to shape the child's behavior. There are also several reports of treatments utilizing somewhat unique self-modeling behavioral interventions, including audio and video editing techniques and, most recently, techniques utilizing enjoyable electronic applications on mobile phones and tablets.

A number of considerations serve to complicate the behavioral treatment of SM and to distinguish it from treatment for social phobia, a disorder to which it is closely related. These factors include the child's failure to speak (even to the therapist), the young age of most SM patients, and the need for significant school involvement in almost all cases. The young age of children with SM necessitates considerably more parental involvement in treatment than is typically recommended for other anxiety disorders.

Although not without exception, most children with SM do not initially speak to the treating clinician. Obviously, treatment approaches for SM need to consider the initial communication difficulties that are often present and include strategies for facilitating verbal communication with the therapist. The initial lack of verbal communication with the therapist is assumed to reflect the general anxiety underlying failure to talk in situations outside the home and is addressed accordingly. To promote speaking in the treatment setting, traditional behavioral techniques (shaping, gradual exposure, reinforcement) are first introduced within the session. Recent reports show that the use of mobile apps in treatment is successful at reducing the time it takes children to begin verbalizing during treatment, with many study participants speaking during the first treatment session. The authors posit that the success is due, in part, to the principle of systematic desensitization: that is, the fear associated with speaking is incompatible with the enjoyment associated with the use of the app.

Telegram: @medical_k

www.konkur.in

The SM child's failure to speak represents a somewhat unique challenge for others in the child's life, particularly parents and school personnel. Although difficulty in differentiating oppositional behavior from anxiety-related avoidance characterizes many child anxiety disorders, when failure to speak is involved, parents and others are particularly likely to attribute avoidance to oppositional motivations and to get frustrated and angry. In contrast, other reactions to nonspeaking include the tendency to accommodate the child's lack of speech and speak "for" the SM child, thus decreasing the necessity of independent communication. This tendency, along with other ways that nonspeaking may be reinforced, also needs to be addressed in the treatment of the disorder. Recently, proponents of parent–child interaction therapy (PCIT) have combined components of PCIT with more standard behavioral SM treatment to develop a treatment that teaches parents how to encourage and coach their children to increase speech while reducing accommodation relating to avoidance of speech.

Nearly all forms of youth anxiety involve school-related impairment to some extent. However, unlike SM, they do not typically revolve as extensively around the school environment. For this reason, a treatment that integrates school participation as a central component of the intervention is necessary for the effective treatment of SM. Most importantly, close rapport with school personnel that includes regular communication and support must be established to ensure the success of behavioral interventions in the school setting. Furthermore, treatment programs should include teacher education and training in the behavioral methods utilized for treatment. The utilization of teachers in the treatment of SM has been highlighted as a particularly cost-effective treatment approach. In the last few years, treatment programs have been developed that include an intensive group element that simulates the school environments while additionally providing treatment condensed over a few days. This approach also has the advantage of providing treatment over a reduced period of time to children who have to relocate to find clinicians experienced in the treatment of SM.

Telegram: @medical_k

www.konkur.in

Other Psychosocial Therapies

Although the most common accounts of successful psychosocial treatment for SM involve behavior therapy, there are descriptions in the literature of successful treatment for SM with play therapy, family therapy, psychodynamic therapy, and group therapy. Although most of these descriptions are flawed by their small sample sizes and failure to adequately describe the diagnostic or treatment intervention processes, it is noteworthy that descriptions of play, family, and group therapy all contain considerable emphasis on the use of behavioral interventions. In general, traditional psychotherapy aimed at addressing underlying intrapsychic conflicts or other interventions (including play therapy, art therapy, supportive therapy, and family therapy) not containing the behavioral elements described above have not been found to be effective for SM.

Speech and Language Therapy

As noted by the DSM-5, the criteria for SM include a caveat that the symptoms cannot be primarily due to a speech or language disorder. However, it is not uncommon for children with SM to also have some degree of speech or language difficulty that may exacerbate speech-related anxiety or self-consciousness. Although there is a lack of research on the efficacy of multimodal approaches, the combination of cognitive behavioral techniques and speech or language therapy can be quite effective for the treatment of children with comorbid SM and speech or language difficulties. In addition, even in cases without the significant contribution of speech or language dysfunction, the small, supportive group setting of auxiliary speech services found in many schools may provide a beneficial environment in which to implement the graded behavioral intervention approach described earlier.

Psychopharmacologic Treatments

Currently, there are no approved U.S. Food and Drug Administration (FDA) medications for the treatment of SM. However, several small studies suggest that SSRIs may be effective treatments for SM in

Telegram: @medical_k

www.konkur.in

children. This is not surprising, given the central role of anxiety in the phenomenology of the disorder. Results from a single double-blind, placebo-controlled trial of fluoxetine in children with SM indicated significant improvement in parent ratings of mutism and anxiety. Results from open trials and case studies have also supported the efficacy of various SSRI treatments. In addition, a large multisite study of fluvoxamine for the treatment of separation anxiety disorder, social phobia, and generalized anxiety disorder in children included several children with SM who appeared to benefit from this treatment. These results, along with the mounting evidence that SM is closely related to social phobia, have begun to establish SSRIs as an important treatment option for children with SM. However, given concerns about medication use in young children, medication is not the first option for many families. In practice, behavioral therapy, when practical and available, should be considered the first-line intervention strategy. In treatment-resistant cases, combination treatment (behavioral therapy plus medication) appears to be the strategy of choice.

Early-Onset Psychotic Disorders

Kaitlin Boyle, M.D., Linmarie Sikich, M.D., M.A., and Tara Chandrasekhar, M.D.

Positive psychotic symptoms such as hallucinations and delusions may be present in a number of child psychiatric disorders, including the primary psychotic disorders (schizophrenia and schizoaffective disorders) as well as more common disorders such as depression, bipolar affective disorder, severe anxiety, and posttraumatic stress disorder (PTSD). They can also occur in the context of medical illness such as delirium, or neurologic disorders, including seizure disorder, autoimmune encephalitis, genetic disorders, metabolic abnormalities, intoxication, and medication side effect. In addition, transient psychotic-like experiences, including sleep-related hallucinations and imaginary friends, may occur in young children with a mental age of fewer than 8 years who have no mental health problems. The diagnostic distinctions between these disorders are primarily related to the duration and context of the hallucinations and the presence of specific co-occurring symptoms.

Children and adolescents, as well as their families, who have primary psychotic disorders and affective disorders with psychotic features, are often devastated by these illnesses. These illnesses are frequently characterized by recurrent crises, interruption of normal developmental processes, a deteriorating course, and treatment resistance. Often the care of such youth requires extraordinary monitoring and advocacy by their parents, frequent hospitalizations, and multiple long-term interventions provided by mental health, educational, and social service agencies. Such care often incurs very high societal costs. However, many

Telegram: @medical_k

www.konkur.in

believe that if effective treatments can be identified and implemented early in the course of illness, this may translate to improved long-term outcomes. In addition, many researchers believe that it may be easier to identify the neurobiologic processes involved in the pathogenesis of schizophrenia and related disorders in affected youth because they have a more severe but clearly developmental form of the disorder that appears more strongly associated with genetic factors than adult-onset schizophrenia.

DEFINITION

Positive psychotic symptoms include hallucinations, delusions, other sensory and cognitive misperceptions, and bizarre or disorganized thinking and behavior including catatonia. Negative psychotic symptoms include flattened affect, apathy, avolition (difficulty making choices), poverty of speech, and poverty of thought content. Early-onset schizophrenia (EOS) is defined as schizophrenia with onset of clear positive symptoms prior to 18 years of age. Onset of schizophrenia prior to age 13 is referred to as very early onset or childhood onset. The diagnoses of psychotic disorders in children and adolescents are generally made using the same criteria as in adults.

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and its text revision (DSM-5-TR) requires that youth with schizophrenia, like adults with the disorder, have at least 6 months of positive or negative symptoms and significant social or occupational dysfunction or failure to achieve expected levels of social development. In contrast, The *International Classification of Diseases* 11th edition (ICD-11) requires only a month of symptoms and does not include any impairment criteria. In addition, many researchers believe that marked neurocognitive declines in executive functioning, general cognition, social cognition, and memory are a key feature of schizophrenia, despite not being included in the diagnostic criteria. Indeed these symptoms, not positive symptoms, seem most closely related to long-term functional outcome.

Schizophrenia spectrum disorders also include schizoaffective disorder and schizophreniform disorder. Schizoaffective disorder is defined by the prominence of psychotic symptoms, presence of significant periods of co-occurring major depression or mania, and psychotic symptoms present for at least 2 weeks in the absence of any mood symptoms.

Telegram: @medical_k

www.konkur.in

Schizophreniform disorder is defined by its short duration of psychotic symptoms (1 to 6 months) and generally evolves into either schizophrenia or schizoaffective disorder.

Major depression with psychotic features and bipolar affective disorder meets all diagnostic criteria for the respective affective disorder but also include positive psychotic symptoms that are present only during periods of affective disturbance. Key distinguishing features of these disorders and other disorders with psychotic symptoms presenting during childhood are presented in Table 52–1.

HISTORY

Schizophrenia has been reported to occur in children since the diagnosis was introduced by Emil Kraepelin. From the early 1900s to 1980s, the term childhood schizophrenia or prepubertal schizophrenia was used to refer to a range of severe psychiatric disorders presenting in youth including autism, leading to uncertainty about the diagnosis of research subjects during this period. In the 1970s, Israel Kolvin and colleagues conducted seminal work to distinguish between primary psychotic disorders and autistic disorder. Beginning with ICD-9 and DSM-III, autism has been recognized as a distinct disorder and schizophrenia has been diagnosed using identical criteria in youth as adults.

COMPARATIVE NOSOLOGY

The diagnostic criteria for schizophrenia and schizoaffective defined by the ICD-11 are similar to those of DSM-5-TR. ICD-11, published in 2019, only requires 1 month of symptoms to make the diagnosis of schizophrenia versus the 6 months required by DSM-5-TR. In addition, there is no functional impairment criteria as required in the DSM-5-TR diagnostic criteria. Jorge Armenteros and colleagues found a high rate of diagnostic agreement between DSM-III-R, DSM-IV-TR, and ICD-10 in hospitalized psychotic adolescents. Similarly, there is good agreement between the diagnostic criteria for major depression with psychotic features and bipolar affective disorder with psychotic features between ICD-10 and DSM-IV-TR. It is highly likely that the same level of agreement will be found with increased use of DSM-5-TR and ICD-11 criteria.

www.konkur.in

Table 52–1.
Disorders Presenting with Psychotic Symptoms in Children and Adolescents

Telegram: @medical_k

www.konkur.in

Disorder	Distinguishing Features
Early-onset psychosis (EOP)	Any of a number of disorders in which positive psychotic symptoms are a prominent feature.
Early-onset schizophrenia (EOS)	Schizophrenia with onset prior to age 18. ▶ Involves a change from usual functioning, typically within 1–5 years of diagnosis, often has negative and neurocognitive symptoms rather than just positive symptoms. ▶ Affective symptoms may occur but are not present for a substantial part of the illness. ▶ If patient also has an autism spectrum disorder, positive symptoms must include hallucinations or delusions. ▶ Impact on functioning may include failure to achieve developmentally expected social functioning or deterioration in social or occupational functioning. ICD-11 does not require impairment. ▶ DSM-5-TR requires symptoms to be present for 6 months, ICD-11 requires symptoms for only 1 month.
Schizoaffective disorder (SA)	▶ During a substantial portion of the psychotic illness, the affected individual also meets criteria for a major depressive episode, manic episode, or mixed manic/depressive episode. ▶ There are at least 2 weeks during the lifetime duration of the illness in which psychotic symptoms are present in the absence of any affective symptoms.
Schizophreniform disorder	▶ DSM-5-TR diagnosis reflecting schizophrenia criteria for at least 1 month but fewer than 6 months. ▶ Not included in ICD-11. ▶ Generally evolves into schizophrenia or schizoaffective disorders but may less frequently evolve into bipolar disorder.

Telegram: @medical_k

www.konkur.in

Early-onset schizophrenia spectrum disorders (EOSS)	▶ Includes EOS, schizoaffective disorder, and schizophreniform disorder with onset prior to age 18 and Very Early Onset Schizophrenia (VEOS) or Childhood Onset Schizophrenia (COS). ▶ At this point, there is no clear evidence that the treatment or prognosis of early-onset schizoaffective disorder is significantly different from EOS.
Major depression with psychotic features	▶ Youth describes clear depressed mood vs. numbness or apathy. ▶ Psychotic symptoms are only present if mood symptoms are present. ▶ Psychotic features are usually mood congruent. ▶ Formal thought disorder is not usually present.
Bipolar disorder with psychotic features	▶ Psychotic symptoms are only present if mood symptoms are present. ▶ There is decreased need for sleep rather than insomnia. ▶ Negative symptoms are absent.
Substance-induced psychosis	▶ Psychotic symptoms are limited to periods of substance intoxication or withdrawal. ▶ Psychotic symptoms did not precede substance use. ▶ Psychotic symptoms generally resolve within 7–30 days of abstinence.
Posttraumatic stress disorder (PTSD)-associated psychosis	▶ Positive psychotic symptoms relate directly to trauma and are not associated with other areas of life or random events. ▶ There are other symptoms of PTSD.
Anxiety-related hallucinations	▶ Positive psychotic symptoms are limited to periods of high anxiety. ▶ There are no negative symptoms or signs of a formal thought disorder.

EPIDEMIOLOGY

Telegram: @medical_k

www.konkur.in

There are a limited number of studies reporting on the population prevalence of rare positive psychotic symptoms (≤4) in children and adolescents. A meta-analysis of 12 studies involving a total of 24,103 youths from non–help-seeking samples described a median prevalence of brief psychotic symptoms of 9.8% among youths 11 to 21 years old. Prior studies have suggested that the prevalence of psychotic episodes decreases with age. Importantly, having such symptoms is associated with a threefold increase in one's current or subsequent risk for having any psychiatric disorder and about a fourfold increase in risk for a schizophrenia spectrum disorder. In contrast, population-based studies of childhood psychiatric studies in the United States, which generally rely on semistructured interviews administered by nonclinicians, do not report any cases of schizophrenia and bipolar disorder. However, one study examining all the youths who had sought mental health care at a regional hospital in Germany serving ~100,000 children found that only 3 between 6 and 10 years old (0.003%) were diagnosed with schizophrenia. In this same sample, the incidence of schizophrenia increased by about fourfold between 10 and 14 years to 13 of 100,000 (0.013%) and by another fourfold between 14 and 18 years to as much as 0.055%. These results are generally consistent with estimates from the National Institute of Mental Health (NIMH), suggesting the prevalence of childhood-onset schizophrenia is less than 0.04%. Further, at least 5% of individuals with schizophrenia (~0.05% of the entire population) report onset of illness prior to 14 years of age and up to 40% of those with schizophrenia have been estimated to become ill prior to 18 years of age.

The reports of persistent psychotic symptoms in clinical samples are much higher and increase with the restrictiveness of the clinical setting. In one outpatient pediatric mood and anxiety clinic, 2,031 children aged 5 to 21 years (mean age 14.3 years) were evaluated using a structured diagnostic interview. Nearly 10% had definite or possible psychotic symptoms. Among those with psychotic symptoms, 62% had depressive disorders, 24% had bipolar disorder, and 14% had schizophrenia or schizoaffective disorder. Inpatient samples of children with depression have reported that as many as 60% will have psychotic symptoms. It is clear from the available studies that the presence of persistent psychotic experiences alone does not equate with a diagnosis of a schizophrenia spectrum disorder and instead serves as a marker for a variety of mental health disorders.

Telegram: @medical_k

www.konkur.in

Given the greater prevalence of major depression and bipolar affective disorder in youth, it is likely that as many or more cases of pediatric psychosis will be related to affective disorders rather than schizophrenia. It appears that EOS and affective psychoses are more common in individuals with family histories of the respective disorders. EOS appears slightly more common in boys than girls, whereas major depression is much more common in female adolescents than in male adolescents. Both genders appear equally affected by bipolar disorder. A clear relationship with onset of puberty has not been demonstrated.

Clinicians should also be aware of potential racial disparities in the diagnosis of psychotic disorders. Studies have shown that African American patients are diagnosed with schizophrenia at a higher rate than White patients despite epidemiologic data suggesting similar prevalence rates. This highlights a very important issue suggesting potential clinician bias that needs to be recognized and addressed. A misdiagnosis can lead to many issues beyond not receiving the appropriate treatment.

ETIOLOGY

Schizophrenia is a syndrome presenting with varied symptoms and heterogeneous etiologies, almost all of which remain unknown. Schizophrenia is generally thought of as a neurodevelopmental disorder. Some researchers have speculated that multiple disruptions or “hits” to normal neurodevelopmental processes are required for schizophrenia to develop. Such disruptions might result from genetic vulnerabilities; intrauterine adversities as a result of famine, infection, or inflammation; or various environmental exposures later in life including severe psychological stress including trauma and exposure to drugs of abuse, particularly cannabis.

Disruption of normal neurodevelopmental processes, particularly those that involve maturation of the frontal cortex and its connections during the second and third decades of life have been repeatedly demonstrated in histopathologic studies. In adults, alterations in the morphology of specific subclasses of γ-aminobutyric acid (GABA)ergic interneurons and of the volume and synaptic density of pyramidal neurons that receive thalamic afferents have been repeatedly demonstrated. These differences suggest aberrations in the normal developmental processes of synaptic refinement and pruning. Further, subtle differences in neuronal connectivity,

Telegram: @medical_k

www.konkur.in

especially in the hippocampus and parietal, temporal, and frontal cortices, have repeatedly been identified in both histopathologic and imaging studies. These differences appear to lead to less efficient cortical processing as demonstrated by functional magnetic resonance imaging (fMRI). Given the correlation between these connections and cognitive function, such connectivity alterations may be a potential underlying mechanism of cognitive issues in schizophrenia.

EOS appears to be associated with more profound neurodevelopmental disruptions than adult-onset schizophrenia. Frequently individuals with EOS have social and attentional difficulties during early childhood. Many have evidence of autism spectrum disorder (ASD) or symptoms. Structural imaging studies have repeatedly demonstrated an exaggeration of the normal pattern of cortical volume loss that occurs throughout adolescence, with excessive and progressive reductions being especially prominent in the cingulate, temporal, and frontal cortices. Further, the magnitude of cortical volume loss has been associated with the severity of positive psychotic symptoms. In addition, studies of prodromal individuals, many of whom are adolescents, have shown that regional gray matter volume reductions, especially in these same regions are present before appearance of overt positive symptoms and progress during the first few years of the illness.

The heritability of schizophrenia has also been consistently demonstrated. However, the underlying genetic links are more complicated. The ability to perform genome-wide association studies has allowed for the detection of over 100 common independent loci that are significantly associated with increased risk for schizophrenia. These account for only a small increase in overall risk, leading many to argue that schizophrenia is a polygenic disorder. However, individuals with EOS are significantly more likely than those with adult-onset schizophrenia to have chromosomal abnormalities and DNA copy number variants, which individually pose a greater risk for schizophrenia. A prominent example is the 22q11.2 deletion associated with velocardiofacial syndrome (VCFS). Interestingly, many copy number variants also significantly increase the risk for other neuropsychiatric disorders, including ASD, intellectual disability, attention deficit hyperactivity disorder (ADHD), and epilepsy. Some argue that schizophrenia lies on a spectrum of neurodevelopmental disorders with the disorders listed above. Further, youths with EOS are at least twice as likely as individuals with adult-onset schizophrenia to have

Telegram: @medical_k

www.konkur.in

a parent with the disorder. Genetic abnormalities suggest the involvement of immunologic and neurodevelopmental functions.

Although multiple environmental factors have been associated with risk for schizophrenia, cannabis use has been of particular interest in recent years given that it may be modifiable. Several studies show a correlation between heavy cannabis use and psychotic experiences as well as higher rates of depression and anxiety. Use during adolescence has been linked with increased risk of psychosis as well as long-term cognitive deficits. Alterations to the endocannabinoid system by exogenous cannabinoids during the critical adolescent period potentially serve as the link between early cannabis use and increased risk for psychosis and cognitive effects.

DIAGNOSIS AND CLINICAL FEATURES

All types of early-onset psychosis are diagnosed using the same criteria as the adult forms of the disorder. However, the characteristics of specific symptoms often show important developmental characteristics that may be confusing for clinicians who infrequently work with pediatric patients. Hallucinations are frequently multimodal, with the affected youth seeing, hearing, and/or feeling the hallucinated being. Children will frequently name the hallucinated being, often using stereotypes such as “an angel,” “the devil,” or “a monster” or will refer to it on the basis of a physical characteristic such as “the red sweater guy” or “the man with no skin.” Youth very seldom complain about their hallucinations if not asked directly. Family members often are not aware of hallucinations but may endorse that the child asks about being called when no one has said anything. Delusions are seldom highly complex or systematic prior to age 16. Instead youth often report vague symptoms like “everyone is out to get me” or “people are laughing at me.” Often reports from collateral sources are needed to determine whether such reports are delusional or reality based. Frequently, youth with EOS present with nonspecific symptoms such as poor attention or increased aggression.

Onset of EOS is often insidious, occurring over a few years. In addition, premorbid symptoms such as being odd and socially isolated or having multiple (but generally mild) developmental delays in cognitive, motor, sensory, and social functioning are common and appear more severe than in adults with adult-onset schizophrenia. Thus, when assessing youth for EOS, it is important to ask about changes in functioning and behavior that

Telegram: @medical_k

www.konkur.in

have occurred over the past 3 to 4 years, to specifically inquire about hallucinations and delusions using language that the child understands, and to encourage the child to describe their experiences in detail using their own words. One should ascertain whether the child is in control of the phenomena, which is not seen with true hallucinations, or whether they can only moderate their own response to the phenomena. It is also crucial to determine the frequency and persistence of positive symptoms and associated negative symptoms. Finally, often, but not always, EOS is associated with a formal thought disorder.

Clinicians are frequently reluctant to diagnose EOS even when there is clear evidence of the disorder. Although the reasons for this are unclear, unfamiliarity with the developmental variations in symptoms, concerns about overlabeling, likely poor outcome, and stigma are frequently involved. However, failure to make the diagnosis when indicated may reduce access to appropriately intense interventions and relevant psychoeducational resources, increase the likelihood of treatment nonadherence, and result in hopelessness if the youth does not robustly respond to treatment. Further, longer duration of untreated psychosis has been consistently associated with poor prognosis in adult-onset schizophrenia. Notably, a review in 2016 found the mean duration of untreated psychosis to be 3.5× longer in EOS than in adult onset.

Particular attention should be paid to risk for suicide in patients with psychosis. People with schizophrenia have a significantly increased risk for suicide compared to the general population with some studies suggesting this risk is highest during the year after the first hospitalization and may be as high as 10% during the first decade of the illness. Vignette illustrating typical presentation of EOS:

Telegram: @medical_k

www.konkur.in

Jack was first brought to a psychiatrist at age 12 when his parents were divorcing. He was obviously upset, was doing less well in school over the past year, and had gone on a hunger strike for the past month because he thought it would make his parents get back together. His parents noted that he had always been somewhat socially awkward, had a limited number of friends, and seldom had extended conversations. He was treated with fluoxetine (Prozac) and psychotherapy. After about 2 months, he was eating normally and seemed less preoccupied with his parents' divorce. However, he would make frequent statements that he needed to protect his younger brother, because he did not trust his parents to take care of the brother. He also said he was trying to find a house where he, his brother, and his father could live together.

A year later, after his mother remarried, he became markedly more irritable and was frequently noncompliant with her requests. His mother reported that there were episodes in which he would suddenly become extremely upset with little or no provocation. For example, she described an episode when they were out walking and he suddenly jumped on her back, saying that she looked like a prostitute. On another occasion, when his stepfather had instructed his brother to wash a glass that had been left out in the living room, Jack became very upset and said he planned to beat his stepfather to death with a golf club while his stepfather was sleeping. Jack's band instructor noted that he frequently seemed preoccupied and sometimes seemed not to know what to do next. Between these episodes, Jack was frequently pleasant and engaged superficially with the family, but had very seldom seen his friends or left the house. He experimented with marijuana by himself three or four times and said it made him feel calmer.

When asked about the incidents with his mother and stepfather, Jack seemed minimally concerned and did not provide an explanation. During his psychiatric evaluation, Jack reported that he often felt extremely angry without really knowing why. He acknowledged some periods of confusion. When asked directly about ever hearing anyone or anything talking to him, he said that his legs often talked to him and told him what to do. He denied significant mood symptoms and described his mood in nondescript ways. He had some poverty of content. At times his speech was disorganized and hard to follow.

Telegram: @medical_k

www.konkur.in

Organic workup including MRI and electroencephalogram (EEG) was noncontributory. Family history was significant for a great uncle who had been odd, socially isolated, and had been hospitalized multiple times at the state psychiatric hospital.

Jack was started on an atypical antipsychotic and showed a remarkable improvement in his oppositionality and irritability. He also became more engaged with family members and his grandfather noted he was having conversations with Jack for the first time ever. However, Jack continued to have increasing trouble in school, particularly as he entered high school. Although his positive symptoms were well controlled, he was failing all but one class. It was unclear to what extent his difficulties in school were related to sedation from the medication or cognitive limitations. Cognitive testing showed he was now functioning in the low average to borderline range and had particular difficulty with abstract thought and problem solving. Reading achievement was grade appropriate but he was significantly behind in math. Several meetings with the schoolteachers were held and an individualized education plan was developed. However, he continued to have difficulty. Various medication changes were tried without significant change in his presentation. When the antipsychotic dose was lowered to try to reduce possible sedation, he became more irritable and had thoughts of beating his mother to death while she slept because she had removed his video games for 2 days as a punishment. His school program was changed from a college preparatory program to an occupational preparation program. He felt much less stressed by this but was unable to find and maintain work at a part-time job as required for graduation. He did not seem particularly concerned by this and had no specific plans for the future. His family was considering applying for disability so that he could maintain his insurance after he turned 18 and was trying to figure out how to more effectively structure his time. Eventually, he began treatment with clozapine (Clozaril) given the persistence of negative symptoms and vulnerability to positive symptoms when his antipsychotic dosage was reduced. He did well and has been able to remain out of the hospital since that time.

PATHOLOGY AND LABORATORY EXAMINATION

Telegram: @medical_k

www.konkur.in

The physical examination of youth suspected of having EOS should include a careful neurologic examination. If there is a focal neurologic finding or impairment of consciousness, structural MRI is indicated. However, the volumetric, spectroscopic, and diffusion tensor imaging abnormalities consistently reported showing differences in group comparisons within research studies are not of sufficiently great magnitude to be used for diagnostic purposes. If there is any indication of episodic psychosis in the absence of mood symptoms or excessive sedation or confusion following psychotic behaviors, an EEG should be obtained to rule out a seizure disorder. Exposure to illicit substances should be assessed with a urine toxicology screen. Blood work should include screening for thyroid abnormalities, electrolytes, complete blood count, liver function tests, ceruloplasmin, and urinary copper for Wilson disease, heavy metals, and serum organic and amino acids to rule out a metabolic disorder. Antibodies to nuclear proteins and other proteins associated with lupus, as well as those detected with autoimmune encephalitis panels, should be obtained from both plasma and cerebrospinal fluid (CSF). Autoimmune encephalitis should be specifically considered if the onset of psychotic symptoms is very sudden and if neurologic symptoms, including seizures, emerge at about the same time. A paraneoplastic antibody panel or ultrasounds looking for teratomas should also be considered if the autoimmune encephalitis panel is negative and the patient does not respond to standard antipsychotic treatment. Negative antibody tests do not rule out autoimmune encephalitis since it is likely that all relevant antibodies have not yet been discovered. In cases with concomitant neurologic findings, it may be appropriate to undertake a trial of immunomodulatory therapy. Graus criteria for autoimmune encephalitis include acute onset of symptoms, focal neurologic finding(s), new seizures, CSF pleocytosis or MRI suggestive of encephalitis, and reasonable exclusion of alternative causes. It is very important to consider potential medical etiologies as these are managed differently than a primary psychotic disorder. Table 52–2 describes the components of a medical workup.

Telegram: @medical_k

www.konkur.in

Table 52–2.
Medical Workup for First-Episode Psychosis

Initial Broad Workup		
-Physical exam, including neurologic exam CBC with differential -CMP with LFTs -TSH + free T4 -B12 + folic acid -HIV 1+2, syphilis -ESR/CRP	-Urinalysis -Urine toxicology screen	-MRI brain with/without contrast (mandatory if focal neurologic findings are present)
If episodic psychosis/sedation follows episodes/confusion: -24–48 hours sleep-deprived EEG	If acute/subacute onset, + neurologic findings: -ESR/CRP, ANA -Serum + CSF autoimmune encephalitis antibodies	Other tests to consider: -Serum organic and amino acids -Ceruloplasmin + urinary copper -Heavy metal screen -Karyotype + microarray

Genetic testing including testing for chromosome 22q11.2 deletion syndrome should also be considered, particularly if the youth has a dysmorphic appearance, any congenital abnormalities or learning disabilities, or other cognitive limitations. Approximately 25% of individuals with 22q11,2 deletion syndrome become psychotic during adolescence, with most experiencing schizophrenia. Since the incidence of VCFS is estimated at 1 in 4,000 live births, as many as 10% of individuals with schizophrenia may have VCFS (Fig. 52–1). Projective psychological testing may be useful in confirming suspected cognitive disorganization.

Telegram: @medical_k

www.konkur.in

However, failure to demonstrate psychotic disorganization during projective testing is not sufficient to reject the diagnosis. In addition, neurocognitive evaluation including intelligence quotient (IQ), auditory and visual memory, working memory, problem solving, processing speed, and attention measures may be useful in helping adapt academic expectations for individuals with EOS who often are expected to perform at the same level as prior to onset of their illness despite significant changes in their capabilities.

DIFFERENTIAL DIAGNOSIS

Misdiagnosis of EOS is a major concern. Factors that may lead to misdiagnosis include children's inherent difficulties in describing psychotic symptoms that are outside their normal experience, overinterpretation of transient psychotic symptoms, and the high prevalence of positive psychotic symptoms in child psychiatric disorders other than EOS. However, failure to recognize EOS when present may slow the implementation of appropriate treatments and worsen long-term prognosis.

Evaluation of a child or adolescent who may have psychotic symptoms should always include separate interviews of the child and their guardian with a focus on clarifying the child's developmental trajectory, changes in functioning, internal experiences elicited in a developmentally sensitive way, past exposure to trauma, and environmental stressors. Family history, including information about extended psychiatric hospitalizations and suicides, should also be obtained. The clinician can usually make an accurate diagnosis with attention to co-occurring symptoms, the time course of symptoms, and strict adherence to DSM-5-TR criteria. However, affected youth and their families should be educated that the diagnosis will be re-evaluated over time as additional information becomes available.

Schizoaffective Disorder

Like EOS, schizoaffective disorder is characterized by persistent positive and/or negative psychotic symptoms and functional decline or failure to realize expected developmental progress. However, during a substantial period of the active and residual phases of illness, the individual also experiences prominent mood symptoms that meet the criteria for a major

Telegram: @medical_k

www.konkur.in

depressive episode, manic episode, or mixed manic episode. Psychotic symptoms must be present in the absence of any mood symptoms for at least 2 weeks during the lifetime duration of the illness. If an individual is in the midst of their only psychotic episode and has had significant mood symptoms throughout, it may not be possible to distinguish between schizoaffective disorder and an affective psychosis. However, the presence of negative symptoms would increase the likelihood of a schizoaffective disorder. EOS with a secondary major depression may be distinguished longitudinally because the depressive symptoms are not present for a substantial period of the illness.

Major Depression with Psychotic Features

Individuals with major depression are generally able to describe their mood vividly rather than simply label it as depressed. In contrast, individuals with EOS may say they are depressed but instead describe a state of apathy and emotional numbing that reflects their experience of negative symptoms. Insomnia, failure to enjoy activities, social withdrawal, lack of motivation, cognitive slowing, agitation, suicidality, and psychomotor retardation may be seen in both disorders. Likewise, weight loss and decreased food intake may be seen in either disorder. However, in EOS, these symptoms are usually the result of delusional beliefs about the food or one's weight. Although mood-incongruent hallucinations and delusions may occur in major depression, they are not common.

Bipolar Affective Disorder with Psychotic Features

It can be extremely difficult to distinguish a mixed manic state from EOS or schizoaffective disorder because hallucinations, delusions, irritability, and agitation are common in all three disorders. The primary distinguishing factors are the presence of a decreased need for sleep and hypersexuality in bipolar disorder versus negative symptoms in the schizophrenia spectrum disorders. Youth with bipolar disorder, especially those who require hospitalization, appear to have greater numbers of varied psychotic symptoms than adults hospitalized with bipolar disorder.

Telegram: @medical_k

www.konkur.in

FIGURE 52–1. Features of chromosome 22q11 deletion syndrome (velocardiofacial syndrome [VCFS]). **A:** Demonstrates fluorescent in situ hybridization. One bright probe marks the end of each of the two chromosome 22s. Another probe, which binds to a marker within the typical large deletion in VCFS, is present on the upper chromosome 22 (noted with the larger *gray arrow*) but not on the lower chromosome 22 (noted with a smaller *white arrow*). **B:** Illustrates the facial features of three youths with VCFS. Note the elongated face, tubular nose with a wide nasal bridge, bulbous tip, and small lateral nares. Frequently individuals with the 22q11 deletion have low facial tone, small mouths, learning disabilities or mild mental retardation, and a variety of congenital malformations, especially of the heart and palate. A history of feeding problems in infancy is common.

Substance-Induced Psychosis

In substance-induced psychosis, positive symptoms are limited to periods of substance intoxication or withdrawal and are not better accounted for by a diagnosis of EOS, schizoaffective disorder, or affective disorder. DSM-5-TR notes that such symptoms should resolve within 1 month of discontinuing the substance, although in clinical practice, most substance-induced psychoses in youth resolve much more quickly (e.g., 7 to 10 days). If positive psychotic symptoms have been present prior to the onset

Telegram: @medical_k

www.konkur.in

of substance use or during periods of sustained abstinence from substances, one of the other psychotic diagnoses is more appropriate. In addition, one is much more likely to see negative symptoms in schizophrenia spectrum disorders than in substance-induced psychosis, although a decline in functioning is common in both. Comorbid substance use is common in older adolescents with EOS. Substance use, particularly cannabis use, appears to be both a precipitating and exacerbating factor. Nonetheless, many youths with EOS appear to self-medicate with drugs of abuse.

Autism Spectrum Disorders

Studies have demonstrated a genetic overlap between ASDs and schizophrenia. Many researchers also agree that the risk of developing psychotic disorders is increased within the ASD population compared to the general population. ASD and EOS are distinguished by their developmental course and the presence of hallucinations and formal thought disorder. Although ASD may not be diagnosed until late childhood, the onset of symptoms prior to 3 years of age is required to make a diagnosis. Such abnormalities may be present in individuals with EOS and schizoaffective disorder, but additional symptoms should present later in life that leads to the psychotic diagnosis. Although individuals with ASD may be concrete and rigid in their thinking and verbal responses, they do not exhibit a formal thought disorder. Further, in order to make the diagnosis of a primary psychotic disorder in an individual with ASD, there must be clear hallucinations or delusions and a change in the level of functioning.

Anxiety Disorders and Posttraumatic Stress Disorder

Transient hallucinations may occur in youth with severe anxiety disorders. However, these youths seldom experience negative symptoms and are less likely to experience delusions or a formal thought disorder. In individuals with PTSD, the psychotic symptoms are generally limited to reliving events that occurred during the trauma and to the perpetrator of the trauma or very similar themes. Hallucinations that are very detailed or specific to certain situations can also be an indicator of a trauma-related phenomenon. Data regarding the long-term course of individuals with these symptoms is lacking.

Telegram: @medical_k

www.konkur.in

Organic Disorders

The list of potential organic etiologic agents of EOS is extensive. Entities that must be considered include (1) delirium, (2) seizure disorders, (3) central nervous system lesions (e.g., brain tumors, congenital malformations, and head trauma), (4) metabolic disorders (e.g., endocrinopathies and Wilson disease), (5) autoimmune disorders (e.g., autoimmune encephalitis and lupus), (6) neurodegenerative disorders (e.g., Huntington chorea and lipid storage disorders), (7) infectious diseases (e.g., encephalitis, meningitis, or human immunodeficiency virus [HIV]-related syndromes), and (8) toxic encephalopathies (both substances of abuse and medications). Individuals should be specifically asked about the use of solvents, phencyclidine, hallucinogens, cannabis, stimulants (including street-acquired amphetamines), synthetic or designer drugs, corticosteroids, and anticholinergic agents. Also, it is important to examine for comorbid medical or developmental disorders that will likely impact the type and extent of psychosocial treatments required. For example, there is an increased risk of psychotic disorders associated with 22q11.2 deletion syndrome, which is also associated with significant learning disabilities.

Telegram: @medical_k

www.konkur.in

Emily, a 16-year-old girl with no previous psychiatric history, was brought to the emergency room due to a sudden behavioral change and suicidal ideation. A previously cheerful and accommodating girl, for the past 2 weeks, she had been increasingly irritable, moody, and easily frustrated. The day prior to presentation, she began endorsing suicidal ideation and expressing a belief that her thoughts were controlled by an external presence (whom she referred to as “the man”). She also reported that her eyes had been replaced by cameras that allowed her to see ghosts. She was admitted to an inpatient psychiatric unit, where she was agitated, pacing, and continuing to endorse hallucinations. Her physical examination was notable for ataxia and movement disorder (semirepetitive orofacial and limb movements). Routine labs (electrolyte, blood count, liver enzymes, thyroid function, and urine drug screen) were unrevealing. An EEG was grossly normal, and her brain MRI showed no evidence of mass lesion or midline shift. She was treated with risperidone in escalating doses with little benefit.

On hospital day 7, she developed increasing fluctuations in her blood pressure and pulse and then experienced a generalized tonic–clonic seizure. She was transferred to the intensive care unit due to worsening dysautonomia and central hypoventilation. Lumbar puncture results showed protein, glucose, neutrophils, and lymphocytes within the normal range. Though CSF anti-N-methyl-D-aspartate (NMDA) antibodies were negative, serum anti-NMDA receptor antibody panel was positive, increasing the suspicion of anti-NMDA receptor encephalitis as a cause of her symptoms. Imaging for an underlying tumor revealed an ovarian teratoma, which was surgically removed. She was concurrently treated with corticosteroids and experienced a gradual improvement in her psychotic symptoms and remission of her movement disorder. At a follow-up visit 3 months later, she had returned to school part-time. She denied psychotic symptoms but reported residual fatigue and impaired concentration.

COURSE AND PROGNOSIS

Subtle developmental symptoms are frequently present throughout childhood in individuals who have EOS. The onset of overt psychotic

Telegram: @medical_k

www.konkur.in

symptoms is frequently insidious, particularly in individuals younger than 15 years. In older adolescents, approximately equal proportions of youth have insidious and subacute onset, with rapid onset over the course of several days being rare. Rapid recovery from the initial episode appears rarer than in adult-onset schizophrenia. In contrast, many youths with EOS show improvement but continue to experience significant positive symptoms despite medication adherence for 2 to 5 years. The course tends to be chronic rather than episodic, as is reported in adult-onset schizophrenia. Further, there appears to be a significant decline in cognitive functioning during the 4-year period surrounding the onset of the illness. This cognitive decline appears to reflect both biologic brain processes and an interruption of normal development and learning. A recent study found that 30% of individuals with EOS attempted suicide over the first 10 years of illness, with one in six of those who attempted completing suicide. Suicidality was associated with more depressive symptoms and fewer negative symptoms in the first episode.

Long-term prognosis in EOS also appears worse than in adult-onset schizophrenia. A meta-analysis of 320 studies of outcomes in adult-onset schizophrenia found that about 40% of individuals had good outcomes, whereas about 60% had a chronic disabling course. In contrast, a number of studies have found that very few individuals with EOS (5% to 25%) experience good outcomes and that 75% to 80% have poor outcomes, with about half of those having an extremely poor outcome. Few live independently as adults (7% to 29%), participate in full-time education, or are employed in the open market (17% to 28%). Another study found that fewer (25%) individuals with psychosis complete high school compared to age-matched peers (84%). Treatment resistance may also be more common, although this has not been adequately studied. Figure 52–2 schematically illustrates the differences in the course between EOS and adult-onset schizophrenia.

TREATMENT

The treatment of EOS is multimodal and should include pharmacotherapy, family and patient psychoeducation and psychotherapy, and interventions in the community to support ongoing education and transition to employment when appropriate. The evidence is strongest for pharmacotherapy. A variety of traditional antipsychotics have

Telegram: @medical_k

www.konkur.in

demonstrated efficacy in reducing psychotic symptoms. A series of studies have compared various atypical antipsychotics to placebo in adolescents with EOS and have demonstrated considerable antipsychotic efficacy, frequently reducing the Positive and Negative Syndrome Scale (PANSS) by about 20%. In these studies, olanzapine (Zyprexa) has been demonstrated to be associated with the greatest acute weight gain and lipid changes. Risperidone (Risperdal) seems to have more moderate acute weight changes, and aripiprazole (Abilify) more limited acute weight changes but a greater frequency of akathisia. Extrapyramidal symptoms appear infrequent but do occur. Only a few comparative trials have been done. These studies have generally found that the various antipsychotics differ in their side-effect profiles but have few differences in efficacy. Specifically, midpotency traditional agents appear to have relatively little impact on weight, lipids, and glucose tolerance but are modestly more likely to cause moderate or severe extrapyramidal symptoms, including akathisia. Significantly, these symptoms are generally well controlled with the addition of anticholinergic medications or propranolol. There is also a strong body of work indicating that individuals with treatment-resistant EOS respond significantly better to clozapine than to haloperidol (Haldol) or olanzapine.

Telegram: @medical_k

www.konkur.in

FIGURE 52–2. The comparative course of early-onset schizophrenia (EOS) and adult-onset schizophrenia. Note the lower premorbid functioning of EOS, more insidious onset, and more chronic course with more limited periods of recovery.

There is much debate regarding the role of Electroconvulsive (ECT) in children and adolescents. Different regions of the United States have various rules and restrictions around the use of ECT in this population, often making it difficult for this modality to be considered. The evidence that is available is reassuring that ECT can be as safe and effective in the pediatric population as in adults.

Compared to the literature on adult schizophrenia, few studies of psychosocial interventions have been conducted thus far in EOS. However, both cognitive remediation therapy (CRT) and supported employment interventions show promise in improving the functioning of affected youth. A recent study found that clinically stabilized youth who received CRT experienced significant improvements in verbal memory and executive functions and modest improvement in daily living, adaptive functioning, and reduced family burden compared with controls. Most of these changes were maintained after 3 months. Similarly, a small

Telegram: @medical_k

www.konkur.in

Australian study of supported employment (Individual Placement and Support [IPS]) found that youth engaged in IPS gained significantly more jobs (23 vs. 4), earned significantly more money ($2,432 vs. $0), and worked for a longer time period (45 vs. 19 days). An overall positive vocational outcome (return to work or education) was achieved by 85% of the subjects, compared to 6% in the control group. Therapeutic interventions must focus on functional improvement in addition to symptomatic improvement in order to facilitate recovery. Targets of treatment include reduction in self-stigma and caregiver burden and restoration of self-esteem, self-efficacy, hope, and optimism.

Specialized first-episode psychosis programs have been developed to deliver multimodal care to individuals early in their course of illness. Often these programs include interventions incorporating medication management, cognitive behavioral therapy, family interventions, and work and/or school support services. Two-year outcome studies from the NIMH Recovery Aftern an Initial Schizophrenia Episode (RAISE) Early Treatment Program revealed significantly greater improvement in quality of life and symptom improvement versus care as usual.

FUTURE DIRECTIONS

Improving the recognition and timely diagnosis of early-onset psychosis will be important in reducing the disability and personal and societal costs associated with these debilitating illnesses. It will be important to further characterize the long-term course of EOS and other early-onset psychotic disorders, particularly with regard to neurocognitive and biologic outcomes. In addition, it is essential that psychosocial treatments such as cognitive remediation, social skills training, and supported education and employment programs are rigorously evaluated and manualized where appropriate. More effective and safe medication strategies are also required to provide the most effective and safest treatment for these highly vulnerable individuals. This will require both more comparative trials and more studies of long-term outcomes. The development of additional psychopharmacologic treatments, particularly those that are more focused on the neurodevelopmental processes that appear so prominent in EOS, is also essential. Finally, EOS also can serve as a more homogenous model for understanding the pathophysiology of schizophrenia and identifying key neurodevelopmental pathways in which to intervene.

Child Psychiatry: Psychiatric Treatment

53.1 Psychodynamic Psychotherapy (Child Psychiatry)

DAVID L. KAYE, M.D., AND MICHAEL SHAPIRO, M.D.

Psychodynamic psychotherapy (PDP), rooted in psychoanalytic theory and used interchangeably with psychoanalytic psychotherapy by most practitioners, has a long and storied tradition in child and adolescent psychiatry both in the United States and internationally. While for many years the backbone of child psychiatric theory and practice, it was under siege for much of the past four decades from different quarters. The ascendancy of neurobiologic approaches and understanding, third party payers' demands for briefer and less expensive treatments, and the public's demand for empirical support all contributed to the diminished influence of psychoanalysis. Despite this, psychoanalysis has remained a vibrant, and still the most comprehensive, framework for understanding psychotherapy and the human mind. In the last two decades increasing empirical support for PDP with adults, children, and adolescents has energized the

Telegram: @medical_k

www.konkur.in

approach. The groundbreaking review by Shedler, The Efficacy of Psychodynamic Psychotherapy, published in American Psychologists in 2010 was a landmark in establishing the efficacy of PDP with adults. Since then Leichsenring has published a recent systematic review (2015) that concludes that PDP is efficacious for a wide range of adult mental disorders. In 2012, the American Academy of Child and Adolescent Psychiatry published the first ever Practice Parameter for PDP with children. Two volumes of the Child and Adolescent Psychiatric Clinics of North America (January, April 2013) were devoted to PDP. Evidence-based, manualized approaches such as interpersonal therapy (IPT) and mentalization-based therapy (MBT) are based solidly in PDP principles. Further there has been a softening of the boundaries between psychotherapy treatments with inclusion of aspects of different therapeutic approaches now commonplace in child therapy.

Although the place of psychoanalytic psychotherapy within child and adolescent psychiatry has declined from the hegemony it once held, it has remained a primary framework for many practitioners and a psychotherapeutic foundation of many, if not most, residency training programs. In the past, it was often seen as a stand-alone treatment for child psychiatric disorders. In current clinical work, practitioners work pragmatically, flexibly, and in concert with other approaches, including family therapy, behavior therapy, cognitive-behavior therapy, psychopharmacology, and school interventions. Regardless of the approach, the understanding of patients stems from an overarching psychoanalytic framework. Psychoanalytic concepts also continue to be applied broadly to clinical work in residential or other intensive treatment milieus, social services, police, juvenile justice settings, and schools. In looking over his career Leon Eisenberg, a long-time critic of psychoanalysis, observed that:

> "Where I erred was in failing to appreciate the powerful and lasting contribution psychoanalysis made to psychiatry by teaching trainees to listen to patients and to try to understand their distress, rather than merely to classify them by some diagnostic algorithm, or snow them with drugs, or lock them away, or release them to homelessness. Basing care on what is unique to the individual patient is central

Telegram: @medical_k

www.konkur.in

to clinical competence, whether in medicine or surgery or psychiatry." (Excerpt from Eisenberg L. The past 50 years of child and adolescent psychiatry: a personal memoir. *J Am Acad Child Adolesc Psychiatry*. 2001;40(7):743–748. doi: 10.1097/00004583-200107000-00008.)

Far from a single and monolithic set of ideas, psychoanalysis encompasses a wide diversity. Disagreement exists about the nature of the mind, development, psychopathology, and treatment. Despite this, psychodynamically oriented practitioners share the following precepts:

1. The primary emphasis and focus of PDP are the individual's subjective, inner experience of self and others.
2. A primary value is the search for emotional truth. Seen as elusive and often hidden from ourselves, emotional honesty and truth is sought as an end unto itself. Through this pursuit and recognition, human beings have their best chances for a satisfying life.
3. A primary goal in treatment is self-acceptance and self-understanding through the instrument of a relationship. The primary "tool" of psychoanalytically informed therapy is the relationship between the doctor and the patient.
4. Unconscious mentation is critical to understanding patient's subjective experiences and relationship patterns. Unconscious affects, motivations, and process (including defense mechanisms) are accepted as critical determinants of normal and abnormal human behavior.
5. Behavior, emotion, and relationship patterns can be understood through the lens of psychic determinism. Human behavior has a logic of its own, happens for psychological "reasons," and is understandable through following a link of multiple impulses, affects, defenses, and their associated relational experiences. Often these links are unconscious and the work of therapy includes greater awareness of the impact of defenses and warded off emotions and wishes.
6. The child is the father to the man. Early experience in a child's life is critical in initiating important and enduring patterns in perceiving, thinking, feeling, and behaving that are carried

Telegram: @medical_k

www.konkur.in

forward in life via internalized beliefs, working models, assumptions, expectations, and attitudes (i.e., transference).

7. Treatment critically focuses on transference. Focusing on the here-and-now transference reactions of the patient are central to understanding the patient and promoting growth in the psychoanalytic process.
8. Treatment goals are focused on psychological growth broadly, not just symptom amelioration. For example, in child psychotherapy goals often include a return of the child to a healthy developmental pathway, including greater self-acceptance, self-awareness, and self-expression.
9. Emotional barriers ("resistance") to psychological growth or resolution of symptoms can be expected in the course of treatment.

HISTORY

The first psychoanalytic reference to child cases was Sigmund Freud's case of "Little Hans" in 1909. Although Freud was skeptical that children could be analyzed, in this case he provided supervision to Hans' physician-father, who successfully analyzed the 5-year-old boy's phobia of horses. A few years later Sandor Ferenczi reported his attempt to directly treat a child, but found that the child quickly became bored with the analytic process and wanted to return to his toys to play. It was not until a series of women psychoanalysts entered the scene that it became appreciated that play was the central medium of expression for children, and should be incorporated into work with those with emotional disturbance. Hermine Hug-Hellmuth, a teacher by prior training, was the first psychoanalyst to report the use of play in the treatment of children in 1921. She believed that treatment of children was primarily educational and limited in its goals.

By far, the major figures in the early development of psychoanalytic treatment of children were Anna Freud and Melanie Klein. Klein began to develop a technique for working with children while in Berlin in the early 1920s, and in 1926 moved to London,

Telegram: @medical_k

www.konkur.in

where she continued her work. She saw children as a cauldron of passionate drives (both aggressive and sexual) with rigid, harsh superegos. Her technique relied on equally powerful and direct interpretations of unconscious impulses. She appraised play as the equivalent of adult-free association and eschewed any role for parents in the treatment. Anna Freud, also a teacher by training, began her psychoanalytic training in the early 1920s and shortly thereafter formed a child psychoanalysis study group in Vienna. She viewed children as immature and undeveloped, necessitating a gentler and educative approach that was careful not to interpret too deeply for fear of overwhelming the child. She recognized work with the parents as difficult but necessary to further the development of the child and also to support treatment with the child. She saw the goals of treatment as being to return the child to their developmental path and not to effectuate a definitive or complete cure. In 1927, Anna Freud wrote the first book on child analysis, *Introduction to the Technique of Child Analysis.* The differences between Klein and Freud led to a confrontational Symposium on Child Analysis in May 1927. These “controversial discussions” brought points of disagreement into sharp focus, and this schism has persisted to the present day, albeit lessening in the recent past. The Kleinian school became dominant in the United Kingdom and South America, while the Freudian school held sway in North America.

Into this fray entered the analysts of the “independent school” in Great Britain in the 1940s, including Donald Winnicott, Wilfred Bion, and others associated with the object relations perspective. Starting in the Kleinian camp, they attempted to bridge the divide with the Freudians. Winnicott contributed enormously to the analytic understanding of child development and treatment, remaining perhaps the most well-recognized influence in the field. His rich body of work included an emphasis on the importance of the early mother–child relationship; the role of play, mirroring, and the establishment of the “holding environment” in healthy development and in analysis; the meaning of the transitional object; and the true versus false self.

Telegram: @medical_k

www.konkur.in

In North America an additional perspective was emerging, beginning with Kohut's work in the 1970s on the development of the self. This evolution has continued to the present with major contributions from interpersonal, relational, and intersubjective theorists. Harry Stack Sullivan, Robert Stolorow, Stephen Mitchell, Joseph Lichtenberg, James Fosshage, and Irwin Hoffman among others have been major figures representing these perspectives. All of these authors have written primarily about clinical work with adults, with a few current authors applying the concepts to work with children (e.g., Gary Landreth, Charles Schaeffer). These theorists have also been informed by convergences with infant and attachment researchers such as Daniel Stern, John Bowlby, Mary Main, and Mary Ainsworth. Rather than emphasizing the role of drives, defenses, resistance, conflict, and other traditional concepts these authors assert that the basic building blocks of mental life are relations with others upon which major psychic structures are built. This reflects a shift in the foreground from an intrapsychic focus to a relational field model, from objectivism to constructivism. Consequently there has been a shift in emphasis in treatment from *interpretation* to the *"co-creation of developmentally needed relational experiences"* (Jay Greenberg and Mitchell). Recently there has been a convergence of attachment, self-psychological, and relational perspectives. This is embodied by the work of Peter Fonagy, Mary Target, Efrain Bleiberg, and others who have written about the central importance of *mentalization*, or self-reflective function. This ability to read and understand the feelings, thoughts, and impulses associated with human behaviors is fundamentally dependent upon the establishment of secure attachments. In the past several years this has led to MBT, a manualized therapy approach that has been evaluated empirically primarily in adolescents. Even more recently neuroscience-based understandings have begun to be integrated into PDP with books such as Daniel Siegel's *The Developing Mind* and Delgado, Strawn, and Pedapati's *Contemporary Psychodynamic Psychotherapy for Children and Adolescents: Integrating Intersubjectivity and Neuroscience*.

Telegram: @medical_k

www.konkur.in

While clinical work with infants is beyond the scope of this chapter, a great deal of parent–infant psychotherapy has been based on psychodynamic principles. Psychodynamic theory has influenced the field beginning with Selma Fraiberg and early programs developed by Alicia Lieberman, up to present-day evidence-based treatments such as Parent–Child Interaction Therapy.

It should also be noted that the term “psychodynamic” was originally used to describe the ever-changing balance of mental and neurophysiologic energy intrinsic to humans’ inner life. This was contrasted with an approach that emphasized behavior, descriptive phenomenology, or anatomic structure. In this sense psychodynamic and psychoanalytic are not synonymous. In the United States there have been a number of influential writers who would be considered within this broad psychodynamic tradition, even though they were not psychoanalysts. These psychodynamic therapists (e.g., Frederick Allen, Clark Moustakas, Ann Jernberg, John Meeks, Virginia Axline, and more currently Charles Schaefer, Garry Landreth) have also had a major place in the history of child and adolescent psychotherapy and continue to influence current practice.

THEORETICAL ISSUES IN PSYCHODYNAMIC WORK WITH CHILDREN

Beginning from its earliest days child psychodynamic psychotherapists have recognized that there are developmental differences between child and adult patients. While the overarching theoretical precepts of PDP reviewed above hold, there are fundamental differences in work with children and adolescents as compared with adults.

Children Are Not “Little Adults”

Child patients differ in significant ways from adults. These differences are crucial in informing practice. First, children’s limitations in language, cognition, and experience must be taken into account to engage and sustain children in treatment. Because of

Telegram: @medical_k

www.konkur.in

cognitive and emotional limitations their understanding of the problem or the need for treatment is likely to be incomplete or inaccurate. Children tend to externalize problematic issues and have little ability to understand how therapy might help them now, let alone in the future. Further they have limited capacity for tolerating pain and anxiety, creating another barrier for keeping child patients in treatment. Meeting with a stranger who will meet and talk intimately with the child is certainly extraordinary, and may be confusing and threatening. For all these reasons the child therapist must *actively* engage, educate, and work with the child to create the secure space needed to establish a therapeutic alliance.

Another major difference is that children do not come to treatment at their own request. They are brought by their parents, often for reasons that are more of concern to the adults rather than the child. Further, the stigma associated with treatment is often difficult for children (especially adolescents, who are struggling to feel “normal” and “like other kids”). The reasons for treatment must be explored and explained in a way that is understandable and meaningful to the child. The rationale that engages the child may be different from the reasons the parents bring the child in.

Telegram: @medical_k

www.konkur.in

A 7-year-old boy was brought for treatment by working-class parents who were concerned about depressive irritability and argumentativeness, which had created great tension in the family. When seen individually the therapist asked the child about his understanding of why they were meeting. The child responded “I don’t know.” The therapist then asked why the child thought the parents had brought him, and he again avoided the question. Later in the interview the therapist returned to the issue while the child played out a puppet scene of different animals fighting. The therapist explored how the animals felt and the child said “sad.” As the play developed the therapist explored whether the child might also be sad. This seemed to resonate and the child nodded his head “yes” and went back to playing with the puppets. As the session closed the therapist suggested that in meeting together they might come to understand “why you feel sad and what we can do to help you feel better. How does that sound to you?” The boy looked up shyly and nodded his approval.

The Child Psychotherapist Must Recognize the Critical and Central Role of the Parents or Caretakers in the Child’s Life

In the early days of child PDP the child therapist would have no contact with the parents, while a social worker would meet alone with the parents. Over the years the importance of establishing and utilizing the relationship with the parents moved more to the foreground. Contemporary psychodynamic psychotherapists endorse that at a minimum the therapist must be able to sustain enough of a relationship with the parent(s) or caretakers to support the treatment of the child. The parents must be engaged sufficiently to bring the child to treatment, pay for the treatment, and withstand their own emotional reactions that may arise as the child changes. Further, a positive alliance with the parents can sustain a child patient through the usual feelings of reluctance to coming to treatment. Ideally the parents can be assisted in fostering sturdier

Telegram: @medical_k

www.konkur.in

attachment, boundaries, and mentalization. This all requires the psychodynamic child therapist to develop a solid working relationship with the parents while at the same time preserving a sense of confidentiality and trust with the child.

A 10-year-old girl was seen in twice-weekly psychodynamic psychotherapy. As the child left her sessions, her mother each time asked “how is she doing?” The therapist made a separate appointment with the parents to discuss these concerns further, while also exploring how the child felt about this meeting. The girl had concerns about “what they are going to say about me,” but assented with support and understanding from the therapist. After discussion with the parents it was agreed that the therapist would meet with the parents once every 3 weeks to discuss the child’s progress and current functioning, provide support and guidance to the parents, and monitor the parents’ anxiety. Once this plan was initiated, the mother’s anxiety seemed to lessen and she no longer waited expectantly after the sessions with her daughter. The therapist remains attuned to the impact of these meetings on the child patient and discusses with the child as needed.

The Child Patient Is Dependent on the Parents Materially, Physically, and Emotionally

This has profound implications and has led to the conviction, even among the most traditional child psychoanalysts, that therapeutic work with the parents is essential and necessary in working psychodynamically with children. Furthermore the ongoing interactions with caretakers have a continuing effect on the growth and progress of children in therapy. Because a child’s personality is unfolding and shaped strongly by continuing developmental experiences, the ongoing parent–child interactions have a “double-barreled” effect. They not only affect the child’s developing internal world of expectations, assumptions, and beliefs about self and

Telegram: @medical_k

www.konkur.in

others, but also then in turn impact on the child's exposure to future developmental experiences. By inhibiting or encouraging exposure to growth-promoting developmental experiences the ongoing parent–child interaction exerts a multiplier effect on the child. This observation strongly influences the overall aim of PDP with children, which, as initially articulated by A. Freud, is to restore the child to the path of normal development. Once back on track, normal development can then take over and provide the experiences needed for internal growth. From a psychological perspective the child's dependency also impacts the individual treatment directly. Adolescents, especially during the early teen years, are struggling mightily to separate from their parents and establish an independent sense of self (i.e., identity). As a result looking to and depending on another adult, like a therapist, can be fraught with complication and ambivalence. This can interfere with the establishment of a therapeutic relationship even when the adolescent recognizes a need for help.

Children and Adolescents Evoke Stronger Emotional Responses in Psychotherapist's Attempts to Help Them

As is known by anyone who has spent any time working in child mental health settings children evoke strong feelings in the therapists who work with them. This often results in desires to protect and rescue the child, especially when therapists observe here-and-now pathogenic interactions and traumatic experiences enacted by parents. At other times the child's behaviors can be exasperating, infuriating, and frightening. All of this results in feelings within the therapist that are generally much higher in intensity than those generated in adult work. This places a premium on the therapists' recognition and containment of their own emotional responses. While these reactions may be helpful clues in understanding the child's world, they can make for highly challenging work.

Telegram: @medical_k

www.konkur.in

Play Is the Central Medium for Communicating With Younger Children

Since its initial recognition by early psychoanalysts, play has been recognized as the critical in communicating with children in PDP. This is especially true for younger children whose language skills have developed to a limited degree and for whom play is their "natural" language. Older children are increasingly comfortable talking about their own inner states and by 9 or 10 may find playing "baby-ish." Whether or not to use play materials with an individual child must be determined on a case by case basis. Psychodynamic psychotherapists will encourage play by having a number of toys visible and accessible to the child. This helps to engage the child and conveys that the therapist is willing to meet them on "their turf" and create a safe space for talking about their problems. Much of the "talking" is done "in the displacement" of the play as opposed to the direct discussion that occurs in therapy with older adolescents and adults. Most therapists recommend a limited number of toys that allow for the symbolic expression of a wide array of affects and themes (e.g., doll house, dolls, puppets, animals, blocks). Art materials (drawing, painting, clay) and techniques (e.g., Winnicott's Squiggle Game), storytelling (e.g., Gardner's Mutual Storytelling Technique), and role playing are often incorporated into dynamic therapy. Therapists also may utilize structured games (e.g., checkers, chess) or therapeutic games (e.g., Talking, Feeling, Doing Game) in some circumstances.

As Winnicott has pointed out, play exists "in the space between" the inner world and external life, *between* patient and analyst. Play requires active participation from both the patient and the analyst. It is aimless and nonpurposeful; there are no social consequences. As such, play allows for the safe exploration of affects, conflicts, areas of concern, ideals, roles, and wishes. This accords play a self-healing effect in and of itself. Play is a forum for problem solving and experimentation. Play also offers a window into the inner life of the child. This allows for a deepening of the understanding of the child and may be the basis for targeted interventions. As Winnicott has

Telegram: @medical_k

www.konkur.in

written, when play is not possible then the work of the therapy is to help the child to be able to play.

Transference in Children and Adolescents Is More Complex Than With Adults

Much controversy has surrounded the concept of transference in work with children. Children's internal representational world is still being actively formed and altered by ongoing current interactions with parents and others. As such transference reactions, while organized to a degree, are still in flux. Nevertheless transference reactions occur ubiquitously in PDP as children enact the beliefs, assumptions, and expectations they are developing. These reactions are here-and-now examples of the prototypical interactions that are interfering with their growth and development. Interpretations of transference phenomena primarily address this here-and-now aspect ("perhaps the nervous feeling you have is because of some anger you are feeling") and much less so address genetic roots (i.e., interpretations about the child's reaction being connected to previous experiences with parents are less applicable with younger children). PDP focuses its greatest attention on these transference reactions, seeing this as the most powerful arena to help children gain flexibility and greater freedom in their understanding of themselves and their interactions with others. Psychodynamic work with children is made more complex because the child's transference reactions intersect with the parent's emotional needs and vulnerabilities. This can lead to divided loyalties between the child's desire for growth and the parent's needs. As in all PDPs countertransference reactions require the therapist to discern what belongs to their own psychological dynamics and that which is engendered by the child's behaviors. Countertransference reactions can be invaluable clues to understanding the child's transference reactions and warded off self-experiences.

Barriers to Change Exist Within the Child Patient (i.e., Resistance) and Within the Family System

Telegram: @medical_k

www.konkur.in

Resistance is a concept that originates in classical theory to describe the inevitable intrapsychic barriers to growth. Traditionally this is thought to derive from conflicts between the patient's ego, id, and superego. Subsequent theorists have conceptualized this differently. Some have understood these barriers as a striving for growth and attempt to master traumatic experience. Others have seen the terror and dread of changing and giving up familiar ways of seeing oneself and others as central. Still other contemporary theorists account for these impasses as a result of psychic deficits that arise from the absence of needed relational experiences and empathic failures. Resistance in this frame is further impacted by the therapist's ability in the here and now to provide these growth promoting experiences.

While resistance is typically seen as intrapsychic, there are also systemic barriers to change. As the child becomes less symptomatic and grows psychologically the parent's self-concept, parent–child or marital relationship may become challenged, likely due to the child's previous role as the identified patient in the dysfunctional system. This system can continue to create impediments to the child's progress and may require the therapist to attend and respond to the parents' anxiety about change.

A 16-year-old girl was seen in individual psychodynamic psychotherapy for generalized anxiety disorder and recurrent depression. As the teen's symptoms lessened and she developed greater confidence, she began to experiment with desires to move away from the orbit of family expectations and expressed interests outside the parents' expectations. This, in turn, stimulated the mother's criticism about the teen possibly "ending up like her father." This led to increased intra-martial conflict, revealing a longstanding issue in the marriage. The parents were not able to negotiate this in a more satisfactory way, and ultimately, they were referred to marital counseling for themselves. Without this forum for their own growth, the pressure on the child to inhibit their own growth would remain unchecked.

Telegram: @medical_k

www.konkur.in

There Is an Increasing Focus on Attachment, Mentalization, and Self-Regulatory Issues versus Oedipal Issues

Classical theorists have highlighted the central importance of oedipal issues in understanding both psychopathology and treatment. Early case descriptions appear to explain clinical phenomena almost entirely through this lens and treatment appears to hinge on adequately addressing through interpretation these oedipal issues consistently; triadic relationship patterns and issues of competition, sharing, sexuality, and rivalry are paramount. In contrast, contemporary theorists, no doubt responding to the major societal changes and vicissitudes of life in the 21st century, have instead placed the primary focus of understanding psychopathology and treatment to early parent–infant interaction, "basic trust," attachment, separation–individuation concerns, self-reflective process (mentalization) and self-regulation. While not disavowing a place for triadic issues this has prompted a major shift in emphasis to dyadic issues.

A 12-year-old boy is brought for treatment because of multiple fears, languishing academic performance and ambivalent attendance to household responsibilities. Toward the end of the psychotherapy, after the child had made much progress, his father had a relapse of substance addition. While the original symptoms could be understood as a reflection of oedipal issues (e.g., castration fear and guilt over hostile feelings toward a parent, leading to academic inhibition and fearfulness), contemporary theorists would emphasize the boy's real anxiety over the safety of his father, and the potential for guilt for hostile feelings toward a loved one with a chronic illness.

Interpretation Was Emphasized as the Central Determinant of Therapeutic Action in Classical Theory, But Contemporary Views Place More Emphasis on Attachment Perspectives

Telegram: @medical_k

www.konkur.in

While interpretation was seen in classical viewpoints as the central determinant of how psychodynamic psychotherapy works ("therapeutic action"), alternative explanations are now in ascendancy, namely the primary importance of a consistent and caring attachment figure. Classical analysts have emphasized the central role of interpretation and "making the unconscious conscious" in the treatment of children. Interpretations proceed from that closest to consciousness to those mental contents furthest away (i.e., unconscious). This is especially important with children. These interpretations may be directed toward defenses, wishes or intentions, or transference phenomena. Interpretations are traditionally made in a specified order, from the manifest level to what is unconscious: first affect or behavior, then defense, then impulse. In other words the analyst first would interpret the affect or behavior ("You appear to be feeling angry right now"), followed by the defense ("perhaps you are angry because you were disappointed that I did not remember your birthday"), and last the underlying impulse ("perhaps you were really hoping that someone would remember your birthday"). Timing of interpretations must be aligned with the patient's readiness and the state of the therapeutic alliance. Theorists differ in what they see as the primary impulses or fundamental motivators. Classically oriented analysts follow Freud's original drive theories and see sexuality and aggression as primary; contemporary analysts might emphasize self-cohesion, self-regulation, attachment, mastery and assertion as the most powerful organizers of motivation. Contemporary theorists hence would see therapeutic action as stemming from the provision of needed relationship experiences that allow for the development of a cohesive and vital self. Fonagy, Bateman, and others have attempted to bridge these views, attachment theory, and cognitive neuroscience by highlighting the goal of *mentalization.* Mentalization, or the self-reflective capacity, enables the child to perceive and process mental activity in the self and others. This allows the child to develop a model of the inner thoughts and feelings that underlie human behavior. Optimally this capacity develops out of the child's early attachment with parents who relate to the child as an

Telegram: @medical_k

www.konkur.in

intentional being with underlying thoughts, feelings, and intentions. As a result of these experiences the child is then able to understand other's behaviors and inner states. These theorists posit that this is the centerpiece of psychoanalytic work with children (and adults) and success depends on the degree to which this develops.

PRACTICAL MATTERS

Psychodynamic Psychotherapy With Children and Adolescents Can Take Differing Forms and the Principles Can Be Applied in Work With Individuals, Groups, and Families

Classically, child psychoanalysis involved seeing the child four or more times per week, lasting over a period of years. In this form psychoanalysis is rarely used currently, although there is some research to suggest it may have a place with particularly disturbed children (see Research section). PDP occurring once, or perhaps twice, per week over a period of months to years, is much more common in both private practice and public clinic settings, although it is increasingly difficult because of payment issues and the hectic pace of family life in the United States. The nationalized health systems in the United Kingdom and Canada continue to support such treatments widely.

While typically open-ended in length, there have been recent adaptations of brief, time-limited PDP to work with children. For example, MBT has been applied to work with adolescents, children, and families. Psychoanalytic principles have also been widely applied to adolescent and family group therapies.

As noted previously, psychoanalytically informed principles often are integrated into all treatment efforts with the child. Owen Lewis has delineated such a model of integrated treatment in which psychodynamic principles fundamentally inform the gamut of treatment interventions (e.g., behavior therapy, psychopharmacology, family therapy, and so forth). The more recent review by Malberg and Mayes (The Contemporary Psychodynamic Developmental Perspective) elaborates on this evolution.

Perhaps Even More Than in Work With Adults, the Therapeutic Frame and Setting Are Critical in Working With Children and Adolescents

Child therapy requires a dedicated office that can serve as a concrete reminder of safety, security, and predictability for the child. Using the same office for every session fosters these goals. Some analysts create special cubby holes or boxes for children to keep their particular toys, drawings, and so forth. This also serves to personalize the space for the child. The office should be neither so small that the child feels closed in, nor so large that the child is overwhelmed and overstimulated. An explicit therapeutic contract should be discussed with the child and parents. Children should not be forced to attend therapy although reluctance is not uncommon. Assent (vs. consent) is a more appropriate goal. It is generally recommended that therapy occur at the same time, on the same day of the week. This also strengthens the predictable frame necessary for successful work. All these ingredients contribute to establishing what Winnicott referred to as the “holding environment.”

Confidentiality Is a Particularly Complex Issue With Children and Adolescents

On the one hand, there is a clear need to maintain a sense of safety and security in order for the child to reveal their deepest worries, hopes, thoughts, and desires; on the other hand, therapists may perceive parents or guardians could be instrumental in making effective change if they were aware of such deep worries, thoughts and desires that a child or adolescent may forbid the therapist from sharing. In more serious situations, therapists have a legal and ethical obligation to safeguard the child’s welfare and may be required to break confidentiality. When issues of safety (e.g., suicidality) arise parents must be informed. At other times the involvement of child protective authorities may be needed, which in some situations may end the treatment. In any event the limits and extent of confidentiality should be carefully explained to both the child and parents at the beginning of treatment.

Working With Parents Is Essential in Psychotherapy With Children and Adolescents

As already noted parents are decisive players in PDP with children. Although there are times that the parents need to honor the necessary boundaries of treatment with the child, it is seldom appropriate that the parents are excluded from the treatment. Typically parents are included from the beginning to obtain the history and to begin to establish a working relationship that can sustain the treatment of the child. At the conclusion of the evaluation period it is helpful to explicitly review the assessment and establish a treatment plan with the parents. The analyst must reach concordance with the parents on the nature of this treatment contract from the beginning and may need to re-visit this throughout the course of treatment. Regular meetings with the parents (with or without the child) are routine parts of PDP. These ongoing meetings serve to maintain the working relationship, provide further information about the child, and create a forum for parent guidance or exploration of parental psychological issues that impede the child's growth. When it becomes apparent that the parent(s) are in need of their own treatment then referral is generally made to another therapist. Providing individual PDP to two members of the same family contemporaneously is discouraged due to the inherent conflict of interest and encroachment on confidentiality that may undercut the alliance with one or both persons.

CLINICAL CONSIDERATIONS

The Aims of Psychoanalytic Psychotherapy Are Ambitious

Psychoanalytic psychotherapy aims to go well beyond the relief of symptoms and/or greater coping or adaptation. With adults, the goals have been to seek a "cure," broadly improving the quality of life (i.e., "to work and to love"), and inoculating the patient from future stressors. In contrast, A. Freud first articulated the aims of child psychoanalysis as a return to the path of normal development.

Telegram: @medical_k

www.konkur.in

Subsequent analysts have emphasized the aims of increased mentalization, self-understanding, self-regulation, personality integration, self-expressiveness, self-esteem, flexibility, interdependence, capacity for intimacy, increased frustration tolerance, and capacity to play. It is assumed that reaching these goals in a “good enough” fashion will result in a diminution of symptoms as well as improved functioning in school, in the community, and with peers and family members.

The Indications for Psychodynamic Psychotherapy Most Likely Include Children and Adolescents With Internalizing Disorders

Indications for PDP have historically focused on the presence of certain strengths or loose categories of problems generally seen as due to intrapsychic conflict. Typically, indications have included those children with neurotic level disorders and sufficiently good internal and external resources such that the gains will be following sustainable termination of treatment. This situation rarely exists in clinical practice. Further, research has indicated that this group of children may benefit as well or better from less intensive treatment efforts involving the school, family, or community resources. At the same time, children with more severe disturbances often subsumed under the category of borderline conditions, may require an intensive effort such as psychoanalysis for effective results to be achieved (see the section on Research and Evaluation). Another way to look at indications is to consider the goals of the treatment. For example, if the goal is to understand one’s feelings, thoughts, and the connections between this inner world and the outer world of behavior (mentalization or self-reflective function), then PDP is likely to be helpful. Because PDP is now generally integrated with other treatment approaches, it is not necessary for this treatment to be all-encompassing but rather to aid in forwarding critical developmental processes.

Some Children With Externalizing Disorders May Be Helped With Family-Focused Psychodynamically Informed Therapies

Telegram: @medical_k

www.konkur.in

Regulation-focused Psychotherapy for Children (RFP-C) and Parent–Child Interaction Therapy targeting Emotion Development (PCIT-ED) are two examples of recent manualized psychotherapies targeting the emotional regulation of young children. This is an area of increasing research (see the section on Research and Evaluation), with the best results seen with modalities that include a heavy component of parent/guardian involvement. Historically, externalizing disorders have been considered a contraindication of individual PDP; the key elemental difference perhaps being the recruitment of parents/guardians to assist children in regulating their intense emotional outbursts.

There Are Some Children for Whom Individual Psychodynamic Psychotherapy Is Not Likely to Help or Is Contraindicated

Contraindications may include some children with externalizing problems, particularly when there are “callous-unemotional” features or when there is no comorbid internalizing disorder or an inability to restrain impulses consistently enough to play. Another group of children for whom there is little to justify this treatment would be children with more than mild intellectual disability, classical autism, many autism spectrum disorders, and traumatic brain injury (and other neurologic conditions) when receptive language abilities are substantially compromised. These may be relative contraindications as there may be focal psychodynamic goals even in some of these cases. Again, treatment for many of these individuals will be multimodal, and other treatment modalities may be more critical (i.e., school interventions for children with autism-spectrum disorders).

AN OVERVIEW OF THE PHASES OF TREATMENT

Beginning Treatment: Focusing on the Establishment of a Working Alliance

This requires not only creating a therapeutic ambiance for the child but also establishing a supportive, working relationship with the parents. The initial goal with the child is to create a playful,

Telegram: @medical_k

www.konkur.in

confidential environment in which they and the therapist can explore the world of the child's thoughts, feelings, and behaviors. In the beginning, some exploration and understanding of why the child is meeting with the therapist is useful, as well as an explicit clarification of the treatment frame and contract ("we will be meeting for 45 minutes every Tuesday at 4:00. This time will just be for us. We'll try really hard to meet every week"). It is also helpful for the therapist to explain to the child that they are "someone who meets with kids to help them with their feelings," "to see if we can understand you," "to help you feel better," "to help you understand how you feel and why you do some of the things that cause you trouble," and so forth. The gist of these comments is to explain the role of the therapist and to convey a steadfastly hopeful attitude to the child (and parents) through what will be inevitable ups and downs. For the playroom to acquire a "specialness" to the child, these messages must be communicated repeatedly. The ground rules also should be explained ("we will talk and play together during the time we are together. Anything is okay as long as no one gets hurt and nothing gets broken."). Of course, once the child begins to express themselves they will see what the therapist is "made of." This is the true acid test for the child. Only over time can the child get the sense that the therapy is not a punishment, that the therapist has hope for the child, the child can feel understood, and problems can be solved. For the most part, in the initial phase, the therapist keeps their comments and interpretations focused on the displacement of the play rather than making direct comments about the child's real-life situation. This initial launching typically takes a few weeks (in the healthiest children) to a number of months to achieve a secure working relationship.

Mid-Phase Treatment

This begins when the child has established a clear working alliance. The child has a familiarity with the frame of treatment, even though emotional upheavals may continue in the sessions. During this phase, the primary emphasis is on the "work" of therapy, that is, the

Telegram: @medical_k

www.konkur.in

slow and repetitive recognition of feelings, defenses, and their relationship to behaviors. Over this time, the same theme in a play session may occur for months at a time. The therapist continues to create with the child a sense of hope and comfort as increasing recognition and understanding of the child's inner world accrues. It is in this phase that the interpretation of prototypic problematic patterns and transference reactions occurs. The focus on the here-and-now reactions of the child with the therapist is especially fruitful, although much work continues to be done in the play displacement. Gradually in this phase, the child becomes more able to connect this displacement with their own life. Reconstructive statements linking current emotional or behavioral patterns with previous life experiences are generally not emphasized in work with children.

Ending Treatment

Optimally treatment ends when the child is free from symptoms, has made sufficient progress in psychological growth and maturity, and is back on track developmentally. In the real world, termination generally comes about for other reasons. Frequently termination occurs when partial improvement has been made and practical considerations (insurance, finances, transportation, moves, graduation) become paramount. Termination provides an opportunity for the child to focus on issues of separation, loss, and mourning. Paulina Kernberg has elegantly stated:

> "As the child approaches the end of her treatment, the same issues that brought her to therapy once again come to the fore: (1) Do they (the parents) care? (2) Does the therapist care? (3) Do I care for you (the therapist)? (4) Do I care for them (the parents)? (5) Can I care for myself? (6) Will you remember me? (7) Will I remember you?" (From Kernberg PF. *Children With Conduct Disorders*. copyright © 1991. Reprinted by permission of Basic Books, an imprint of Hachette Book Group, Inc.)

In the process of ending, it is important to include the child actively in setting a final date. In general, 6 weeks to 3 months is sufficient time to allow the child and family to concentrate meaningfully on these issues. Setting the date so that it does not coincide with other

Telegram: @medical_k

www.konkur.in

real-life endings (e.g., graduation, moving dates) permits the child and family to experience the fullest impact of the termination. During the ending phase, children frequently regress, with a recurrence of symptoms and defenses in the face of this stressor. Denial of the importance of the relationship by the child, parent, and therapist is not uncommon and should be understood as a reaction to the impending separation and loss. In the course of ending, the child should have an opportunity to explore and claim the gamut of feelings that inevitably arise: anxiety, guilt, anger, sadness, satisfaction, ambivalence, and so forth. This frees the child from developing defensive patterns to face the inevitable future losses of life.

Telegram: @medical_k

www.konkur.in

After 8 months of weekly psychotherapy, an 11-year-old girl's symptoms of perfectionism and severe recurrent abdominal pain had improved sufficiently that the child came in and stated that "I don't have pain! I don't need to come here anymore." She later added that "maybe I need help with boys." This led to a series of discussions about termination, which resulted in the setting of a final date 6 weeks hence. In the first meeting after the termination date was set, she revealed that she was able to comfortably talk with the therapist, unlike with her parents, with whom she felt she could not be open. The next week she became irritated by a comment from the therapist and said, "If I had known you would say that I would have left weeks ago!" She continued to talk about other separations in her life, especially the death of her grandmother. In the final sessions, she alternated between denial and recognition of her emotional reactions to the upcoming termination. She continued to discuss other endings, moves, and friends leaving. In the last session, she said: "Okay. I have something to say. I think I'll miss you. You helped me." To which the therapist responded: "Well, we have worked well together. And I will miss you too." She left the session knowing that she could make future appointments if the need arose.

RESEARCH AND EVALUATION

Claims of lacking an evidence base have been haunting PDP for decades. Because of psychoanalysis' emphasis on the fundamental uniqueness of each individual, single case studies were historically the preferred form of publishable research. These were typically reported as detailed narratives without the systematic or objectified approach typically taken in reports of behavioral or psychopharmacologic treatments. With the ascendancy of randomized controlled trials (RCTs) and meta-analyses, this traditional psychoanalytic approach has been widely seen as lacking.

Telegram: @medical_k

www.konkur.in

While there remains persistent criticism within psychoanalytic circles of the overvaluation of the RCT, there has been acceptance of the need for RCTs and meta-analyses involving PDP. RCTs are seen as necessary, but not sufficient, to establish a treatment as “evidence-based.” Patient values and preferences, outcome measures broader than symptom change, long-term outcomes, and clinician’s observations also are held as important factors as well. Its typical length, ambitious aims, the complexity of operationalizing goals, and the difficulty in manualizing the approach have been serious barriers to applying the RCT model to psychoanalytic psychotherapy.

Despite these concerns, there have been increasing efforts and positive results in evaluating PDP for children and adolescents, as well as adults. A more recent problem is that the evolution of psychotherapy has occurred in such a way that psychodynamic principles are increasingly integrated into more focal or modular treatments. For example, IPT is clearly rooted in psychodynamic principles and has been adapted to adolescents. Many other branded therapies, for example, Parent–Child Interaction Therapy, Mentalization-Based Treatment, Adolescent-Focused Therapy, Attachment-Based Family Therapy, and Regulation-Focused Psychotherapy, among others, have strong psychodynamic foundations. Further, the emphasis on the therapeutic alliance that began with psychoanalysis is now accepted as a key component for virtually all psychotherapy. Many of these treatment approaches have been investigated empirically, although they are not generally included in reviews of the traditional research base for PDP. Much of the literature on PDP has been conducted on small numbers of real-world patients with multiple diagnoses and with broad definitions of PDP. While the largest studies have been observational, there have been a number of RCTs sufficient to generate systematic reviews and meta-analyses. The largest empirical study of psychoanalytic therapy with children has been carried out at the Anna Freud Centre (formerly known as the Hampstead Clinic) by Fonagy, Target, Midgely, and others there. Following extensive searches and rigorous inclusion criteria, they identified over 30 primary studies that involved over 1,200 patients. This represents a significant increase

Telegram: @medical_k

www.konkur.in

in studies from 10 years ago but still must be considered limited, especially when compared to studies of other psychiatric treatments. Building on previous RCTs, meta-analyses, and systematic reviews, Midgely et al. in 2021 published their seminal “narrative synthesis” of the evidence base for PDP for children and adolescents, including over 120 papers representing over 80 separate distinct studies. The general conclusions are:

1. There is increasing evidence to support the effectiveness of psychoanalytic psychotherapy of children and adolescents, with both the quality and quantity of empirical papers in this field increasing over time.
2. Children with internalizing disorders, primarily depression and emotional disorders, tend to respond most favorably to this treatment modality. The treatment of these disorders has the most high-quality evidence and suggests that brief PDPs are just as effective as other psychosocial interventions, including cognitive behavioral therapy.
3. A number of studies support positive responses to PDP for eating disorders and the effects of trauma in children.
4. There are small but increasing numbers of RCTs focusing on anxiety disorders, and there already exist treatment manuals for PDP for treating children and adolescents with anxiety disorders.
5. There are small but increasing numbers of studies on emerging personality disorders, with several observational studies of the psychodynamic treatment of BPD published in the last 3 years. Mentalization-Based Treatment and Transference-Focused Psychotherapy, both of which were initially developed to treat BPD in adults, have been adapted for adolescents. MBT has shown promise for self-harm as an alternative to DBT.
6. Younger children show larger effect sizes than older children and adolescents, but a sufficient frequency of sessions must be achieved to produce positive outcomes.
7. The psychodynamic treatment of externalizing disorders has received less research attention and, in general, is seen as less effective. Despite this accepted wisdom, some studies show

Telegram: @medical_k

www.konkur.in

promising findings, particularly when the child also presents with some emotional difficulties. Young children with disruptive disorders are more likely to respond to interventions that lean heavily on involvement from parents and guardians if they are to respond.

8. There is low quantity but high-quality evidence that PDP may be helpful for adolescents with certain medical or physical conditions, such as diabetes, headache, and treatment adherence.
9. Children and adolescents with conduct disorders or psychotic disorders, receptive language disorders, and intellectual disabilities are also unlikely to respond to this form of treatment. Children with autism generally do not respond well to individual psychotherapy, although there is some evidence that there may be a place in the broader autism-spectrum group for approaches influenced by psychodynamic principles.

A range of methodologic limitations continues to abound, including small sample sizes, lack of or inappropriate control groups, and inadequate outcome measures. More high-quality research is still needed.

Following these findings, recent national guidelines have included PDP as recommended treatment for the two conditions with the most substantial evidence base; the UK NICE guidelines now include PDP as an evidence-based treatment for depression in children and adolescents; in 2015, the AACAP Practice Parameter for Eating Disorders included Adolescent-focused therapy as a recommended treatment in cases of anorexia nervosa when family-based treatment was not available or acceptable to the patient and family. While the empirical data supporting psychoanalytic psychotherapy with children is growing, larger-scale studies for additional targeted populations continue to be needed. At the same time, psychodynamic approaches will continue to be incorporated into other forms of therapy as the field continues to strive to find “what works for whom.”

Telegram: @medical_k

www.konkur.in

FUTURE DIRECTIONS

Psychoanalytically informed psychotherapy has a long tradition in child and adolescent psychiatry. Many practitioners over many decades have found this orientation extremely helpful for large numbers of child and adolescent patients. There now exists better empirical support for PDP for children and adolescents with certain conditions, including depression, trauma, eating disorders, anxiety, and personality disorders. More methodologically sound studies are needed and underway. There is still a need to understand those patients or clinical problems for which this technique is especially or uniquely relevant, its mechanism of action, and critical areas of technique. An increasing number of manualized psychotherapeutic modalities have incorporated elements of psychodynamic thinking and practice. This trend is expected to become more prevalent as the field moves to more targeted, individualized therapies.

However, as has been highlighted by Shedler and others, there is a uniqueness to psychodynamics that ultimately may not be able to be isolated in traditional research studies. The supposition that the core elements of psychodynamics can be isolated, pre-packaged, and scripted for randomized control trials so that any therapist picking up a manual will be able to fit that manual to an individual patient will be extremely challenging to test. Evidence-based medicine is inherently designed to eliminate confounding variables and things left to chance, but in doing so, it may also eliminate the individual differences and variations that are co-created by individual patients and therapists. As Shedler has said, it is perhaps these differences and variations, the “unique rhythms,” that are both eliminated in many randomized studies and yet also compose “nearly everything that matters.”

www.konkur.in

behavioral therapy (CBT) is a form of psychotherapy that combines behavior therapy and cognitive therapy into a broad approach composed of empirically based methods built on the fundamentals of social learning theory and experimental psychology. It is the treatment of choice for various mental health problems due to its efficacy. CBT is widely taught in various mental health training programs and is a mandated component of psychiatric residency training in the United States. CBT is a mandated first-line treatment in the United Kingdom for specific mental health problems such as anxiety, eating disorders, and depression.

HISTORY

CBT is best viewed as a multifaceted theoretical approach with a strong allegiance to the experimental method and a resultant set of techniques applied within a CBT formulation. The cognitive-behavioral approach is the convergence of distinct movements in the study and science of human behavior, including classical conditioning, operant conditioning, and the cognitive revolution. In the early 1920s, Ivan Pavlov's work demonstrated the processes of classical (otherwise known as respondent) conditioning and established the stimulus-response learning paradigm. Essentially, classical conditioning is a form of learning in which a neutral stimulus is repeatedly paired with a stimulus that elicits a reflexive response. In his classic experiment, Pavlov paired the neutral stimulus of a bell with food, a stimulus that naturally produces salivation. Eventually, the presentation of the neutral stimulus (bell) by itself elicited the conditioned response of salivation. This process is illustrated in Table 53.2–1. This work greatly influenced John B. Watson, who applied Pavlovian classical conditioning principles to understanding the origins of psychological disorders in humans. Known as the "father of behaviorism," Watson promoted the tenet that psychology should be concerned only with directly observable stimuli and responses and rejected any notion of unconscious and dynamic processes (i.e., mentalistic constructs) underlying behavior, including cognitive processes. Early laboratory research with animals

Telegram: @medical_k

www.konkur.in

demonstrated the acquisition of the fear response through classical conditioning learning trials.

Watson and colleagues demonstrated that fear reactions are also conditioned in humans who previously did not evidence such a reaction. In their classic experiment, Watson and Rosalie Rayner conditioned a fear reaction to a white rat in a young child named Albert. Initially, Albert played happily with the rat and showed no evidence of fear or avoidance of this animal. Next, the experimenters followed the introduction of the rat with a loud noise made in close proximity to the child, causing him to startle. The pairing of the loud noise (aversive stimulus) and the rat (neutral stimulus) in a sequence of trials resulted in Albert developing fear of the rat (conditioned response). Subsequently, not only did Albert become fearful of the presence of the rat, eventually his fear generalized to other white, furry stimuli, such as cotton balls. Inasmuch as this experiment demonstrated the process of Pavlovian learning principles in the etiology of psychological disorders, Mary Cover Jones demonstrated that one could eliminate human fear conditions in children through a similar learning paradigm that would foreshadow later methods of behavioral treatments for anxiety disorders. With Watson as her dissertation mentor, Jones used an approach involving the techniques of modeling and graduated exposure to treat 3-year-old Peter's fear of rabbits. Initially, Peter was exposed to observing other children playing happily with a rabbit (i.e., modeling), and, subsequently, while Peter was eating his favorite food, the rabbit was shown to him during a time when he was in a calm state. Gradually, the rabbit was moved closer to Peter until he was able to pet and play with it without experiencing fear (exposure). Although many will recognize Jones' work as straightforward examples of the basic behavioral procedures of modeling and graduated exposure, her approach to treating Peter was revolutionary at the time. In fact, it was decades before the techniques employed in Peter's treatment were systematically studied and identified as valuable therapeutic procedures.

Telegram: @medical_k

www.konkur.in

Table 53.2–1.
The Process of Classical Conditioning

Before conditioning	
Food (Unconditioned stimulus) →	Salivation (Unconditioned/reflexive response)
During conditioning	
Bell + Food (Neutral stimulus) + (Unconditioned stimulus) →	Salivation (Unconditioned response)
After conditioning	
Bell (Conditioned stimulus) →	Salivation (Conditioned response)

While Pavlov and Watson were experimenting with classical conditioning paradigms, Edward Thorndike of Columbia University was beginning pioneering work in understanding the processes of operant (instrumental) conditioning. Thorndike demonstrated that by changing the consequences of behavior, the occurrence of the behavior is either increased or decreased—that is, providing a reward after the occurrence of a certain behavior increases the probability of that behavior occurring again, whereas withholding the reward, over time, results in the decrease of the behavior. These principles, influencing the later work of Harvard psychologist B.F. Skinner and his students, are widely used today in therapy and educational settings, such as in parent education and training. A common example is that of a young child who throws a temper tantrum in response to being denied a treat. If the parent provides attention to the child through admonishing, coaxing, or giving in and/or providing the treat, the tantrum behavior is likely to occur again at the next instance of the child's being initially denied the treat. Note that the reward in this case is parental attention, regardless of whether it is the positive attention of coaxing or giving in or the negative attention of admonishment. In any case, the child gets the parent's attention. However, if the parent refrains from giving attention and ignores the child's crying and whining, the

Telegram: @medical_k

www.konkur.in

tantrum will stop and subsequent tantrums are unlikely to occur when the child is denied or frustrated. The child will learn that tantrum behavior does not result in positive outcomes. Skinner articulated fully the theory and principles underlying the process of reinforcement in his seminal tome “Contingencies of Reinforcement: A Theoretical Analysis.” This type of learning is central to parent management training (PMT), an empirically based treatment approach, and similar parent training programs. Change in child behavior (decrease in tantrums) is facilitated and enhanced through the simultaneous pairing of positive child behavior with parental attention, so parents are also taught to give attention and praise when their child behaves in acceptable and desired ways (e.g., “I like the way you are playing nicely with your sister”). The procedures of systematically ignoring undesirable behavior while systematically reinforcing desired behavior are known together as *differential reinforcement of other behavior.* Throughout the 1950s and 1960s the principles of operant conditioning were greatly expanded and researched by Skinner and other experimental behaviorists; eventually, this work moved from the laboratory analog studies of learning processes with animals to applied evaluations of the utility of operant procedures in the treatment of adult psychiatric inpatients. For example, Ted Ayllon and Nate Azrin introduced the first comprehensive token economy program at Anna State Hospital in Illinois. Despite initial resistance and skepticism from the hospital staff, the token economy resulted in significant changes in targeted behavior of inpatient adults with severe mental illnesses and disabilities. Token economy systems flourished in psychiatric settings and training schools and were adapted for widespread use in programs serving youth, such as hospitals, residential facilities, and schools.

The emergence of behavior therapy as a distinct field of study began in the 1950s, in part due to advances in the understanding of both classical and operant learning processes, and also because of a growing discontent with traditional psychoanalysis. A major goal of psychoanalytic treatment is for the patient to develop insight into their problems. *Insight* refers to the emotional and intellectual

Telegram: @medical_k

www.konkur.in

understanding and acceptance of one's problems and is a crucial step in achieving therapeutic benefit, and gaining insight is associated with uncovering the unconscious conflicts and motivations underlying the problematic behavior. The assumption of unconscious conflicts is a major premise of psychoanalysis that is rejected by the behavioral approach. The focus on achieving insight, along with the often inordinate length of time spent in psychoanalytic therapy, contributed to discontent with psychoanalysis. South African psychiatrist Joseph Wolpe, dissatisfied with his patients' progress in psychoanalysis, was among the founders of contemporary behavior therapy and moved its applications from experimental settings and institutions to more mainstream psychotherapy contexts. In the 1950s, Wolpe developed procedures of systematic desensitization and assertive training, directly stemming from Cover Jones' work with children in the 1920s. In each procedure, phobic and anxious patients are taught to replace fear reactions with deep relaxation and proactive communication behaviors, respectively. These procedures provided a more rapid therapeutic response than traditional analysis and proved to be more cost-and time-effective to patients. Very quickly, Wolpe's procedures were extended to individual and group therapy contexts and adapted for use in children and adults. Worldwide, behavior therapy was developed, advanced, and promoted by pioneers such as Wolpe, Cyril Franks, Hans Eysenck, Stanley Rachman, and Arnold Lazarus. As a field, behavior therapy took shape through the systematic study of behavioral principles and the testing of its methods in single-case and large research trials. In 1966, Franks became the first president of the newly formed Association for Advancement of Behavior Therapy (now the Association for Behavioral and Cognitive Therapies), the flagship professional organization whose missions remains that of promoting the development and dissemination of behavior and CBT therapy.

Radical behaviorists, steeped in the tradition of Watson, eschewed the study of cognition, in that thought processes were viewed as mentalistic constructs not readily observable or verifiable by others. From a purely behavioral perspective, directly addressing inappropriate or abnormal behavior will change any upsetting or

Telegram: @medical_k

www.konkur.in

inappropriate thoughts and feelings associated with the behavior, and, hence, direct access to thoughts is not necessary. During the 1960s however, the cognitive revolution began with the work of Albert Bandura, Aaron T. Beck, and Albert Ellis. The cognitive therapist takes a different view, espousing that, if one changes dysfunctional thoughts, change in functional behaviors will follow. The cognitive therapist assumes that thoughts are made observable through methods such as direct interviewing, self-report scales, journal or diary entries, and listing of thoughts. At Stanford University, Bandura integrated the principles of classical and operant conditioning with observational learning to formulate the tenets of social learning theory. Through observational learning, the process of observing the actions and reactions of others can effect a change in the behavior of an individual. In essence, observing the actions of others and their resulting consequences, without the individual needing direct experience with a situation, can shape the emotional and behavior repertoire of an individual. Of course, risk and protective variables interact with observational learning to shape behavior such that the temperamentally inhibited child may learn to respond with anxiety and withdrawal when watching the distress of a peer who is teased by the class bully, whereas the child with a more rambunctious disposition may focus on the behavior of the bully and learn to respond in similarly aggressive ways. This theory places critical importance on the role of cognitions in the development and maintenance of behavior, both normal and abnormal, in that cognitions involve thoughts, images, beliefs, expectations, memories, and attributions, among other simple and complex cognitive processes. In the bully example, the inhibited child may think, “oh no, that can happen to me and embarrass me.” This type of thinking leads to anxious withdrawal and fear reactions. Conversely, the more extroverted child may think, “It is fun making this kid cry and I want to do it next,” leading to imitation of the aggressive behavior. The response of the environment to either child’s response then becomes involved in the complexities of this learning paradigm to further influence the observational learning by either rewarding/accepting or punishing/extinguishing the particular

Telegram: @medical_k

www.konkur.in

response. The process of observational learning is the basis for concern expressed by parents and other concerned parties over violence depicted in television, movies, social media and video games and one of the reasons for parental ratings found in the media and music industry.

The cognitive revolution continued with the work of psychiatrist Aaron T. Beck at the University of Pennsylvania, who observed within the course of his psychoanalytic treatment of patients that certain problems were evident in the thoughts of depressed individuals and that traditional psychoanalysis did not allow for the direct confrontation of these thoughts. Beck's study of depressed patients revealed a certain negative triad of thoughts related to pessimistic views of the self, the world, and the future. Through the Socratic method of questioning the veracity of these thoughts, Beck was able to assist patients with gathering evidence to refute the thought and engage emotional and behavioral resources to counter the depression and increase healthy functioning. Cognitive therapy emerged from this work and became a mainstay in the treatment of a wide range of emotional disorders, including depression, anxiety, personality disorders, and, more recently, psychoses. Concurrent with the development of Beck's approach, psychologist Albert Ellis took note of the irrational beliefs guiding his patients and undermining their ability to proactively manage activities and stressors in everyday life. Ellis developed rational emotive therapy, which seeks to challenge certain core irrational beliefs such as "I must be loved by everyone" and "I must be perfect in my performance/relationships." According to Ellis, irrational beliefs are conditioned cognitive responses that serve to render an individual vulnerable to disappointment and failure and engender a sense of helplessness and eventual psychopathology. Both Beck's and Ellis' therapies integrate behavior principles and processes, such as behavioral exposure and behavior activation, to activate and challenge negative, irrational thinking. From these roots, the cognitive approach, integrated with behavior therapy in forming contemporary CBT, was expanded and adapted to meet the needs of children, adolescents, adults, and families to address a wide range

Telegram: @medical_k

www.konkur.in

of psychological and behavioral problems. Recent “third wave” influences on the practice of CBT reflect the integration of mindfulness and meditation principles found in dialectical behavioral therapy (DBT) as well as the acceptance and commitment therapy (ACT) focus on values and committed action. The foundation of the third wave approaches rests on the theoretical and empirical foundation of CBT.

THEORETICAL ISSUES

The value of CBT as an evidence-based and front-line treatment is ever-expanding and evolving. Since its inception and integration of the behavioral and cognitive movements, treatment packages such as self-instructional training, problem-solving therapy, harm reduction, behavioral family therapy, and behavioral couples therapy have been advanced. Problem-specific treatments have emerged and include the Coping Cat for childhood anxiety disorders, the Adolescent Coping with Depression Course, Brief Behavioural Activation for Adolescent Depression, CBT of Childhood OCD: It’s Only a False Alarm, The Incredible Years and Parent-Child Interaction Therapy for disruptive behavior in young children, Multisystemic Therapy for serious child and adolescent disruptive behavior and substance abuse, the Maudsley Approach for adolescent eating disorders, and the Unified Protocols for Transdiagnostic Treatment of Emotional Disorders in Children and Adolescents. All CBT protocols are based on the principles of social learning theory and several basic theoretical assumptions of CBT (Table 53.2–2). First, the cognitive-behavioral therapist does not assume that an underlying unconscious process or drive is fueling the behavior of any individual. Rather, the cognitive-behavioral therapist assumes that all behavior, whether adaptive and pathologic, is subject to conditioning principles, although there may be limits on learning due to constitutional constraints (e.g., intellectual capacity, physical limitations) or contextual constraints (e.g., dysfunctional home, depressed community settings, systemic racism or bias). As such, the therapist works with the patient (and

Telegram: @medical_k

www.konkur.in

with the parents in child cases) to examine samples of behavior across contexts to uncover the antecedents and consequences of behavior. The *ABCs of therapy* refers to the antecedents-behavior-consequence chains that serve to establish and perpetuate behavioral patterns. Rather than assume that an individual is predisposed to behaving in a certain way due to traits such as aggressiveness, introversion, or obsessiveness, the cognitive-behavioral therapist takes a more interactionist approach and assumes that the individual is interacting with the environment in developing response patterns to discrete and specific stimuli that may bear a resemblance to prior similar stimuli or experiences, thus shaping apparently trait-like responses. Through the process of CBT, behavioral antecedents and resultant consequences are identified and addressed within the treatment plan. The cognitive-behavioral therapist, based on empirical findings, applies procedures steeped in the principles of learning to change or modify the patient's behavior. Through a process of collaborative empiricism, the therapist and patient (including parents or caregivers in the case of dependent youth) specify clearly defined goals for treatment and establish a time frame for achieving subgoals and overall goals. The therapist and patient will then engage in a continual process of evaluating whether goals are achieved and, if not, examining impediments to change, including resistance, throughout the course of therapy. CBT is applied flexibly to meet each individual patient's needs. That is, techniques are adapted to be developmentally appropriate for a given age or cognitive level and otherwise adapted to meet the needs of an individual patient.

Telegram: @medical_k

www.konkur.in

Table 53.2–2.
Assumptions of Cognitive-Behavioral Therapy

Cognitive-behavioral therapy, relative to traditional psychotherapies, concentrates on behavior (this includes verbal behavior and covert behavior, such as thoughts, beliefs, memories, attributions, and images), rather than on some presumed unconscious underlying cause.
Cognitive-behavioral therapy assumes that maladaptive behaviors are acquired through learning in the same way that any behavior is learned.
Psychological principles, especially learning principles, are highly effective in changing and modifying maladaptive behavior.
Cognitive-behavioral therapy involves setting specific, clearly defined, and observable treatment goals.
Cognitive-behavioral therapy rejects classic trait theory—that is, the notion that an individual has an inherent predisposition to similar behavior in a wide range of situations.
The cognitive-behavioral therapist adapts the method of treatment to a patient's problem.
Cognitive-behavioral therapy is focused on the here and now yet does not neglect the past or history of the patient.
Cognitive-behavioral therapists place great value on the empirical testing of their assessment and treatment methods.

Contrary to popular belief, CBT does not ignore historical information. The patient's history, including parental and related family members' histories, are essential for understanding the original setting events and learned reactions comprising the etiology of the problem. However, the work of CBT is focused on the present maintaining factors that prevent healthy functioning and allow the persistence of the patient's problem. Thus, CBT is focused on the here and now, with emphasis on understanding the current reinforcement paradigm, allowing persistence of the problem and teaching new skills to promote adaptive behavior. Finally, scientific

Telegram: @medical_k

www.konkur.in

rigor, whether on a large-group scale or within the single-case approach, is highly valued by the cognitive-behavioral therapist. It is expected that the cognitive-behavioral therapist will be current with the empirical literature and apply the scientific method to their practice of therapy. Thus, within the clinical practice, each patient is regarded as an individual case study in which the therapist and patient again collaborate to test hypotheses of behavioral change and refine their techniques or approach to maximize the potential for therapeutic benefit.

TECHNIQUES

Techniques are not the essence of CBT, nor are they sufficient for the resolution of any clinical problem. A thorough understanding of the empirical bases and theoretical principles of CBT, along with appropriate training and experience, is a prerequisite to the development of competency to formulate a sound treatment plan and deliver CBT to persons in need. In addition, CBT is a very action-oriented approach focused on the here and now. It requires a directive rather than passive stance. Therapists must be ready to teach, model, guide, and reinforce the patient in working toward their goals. Cognitive-behavioral therapists are very active in treatment and often conduct sessions in vivo—that is, in the situations in which the child or adolescent may be experiencing distress. The cognitive-behavioral therapist should expect to make a trip to the school, home, or other settings in which the child has difficulty, as appropriate, with careful planning to maintain confidentiality while promoting therapeutic benefit. Moreover, certain disorders, such as the phobias and obsessive-compulsive disorder (OCD), require the therapist to model the handling or touching of phobic or feared objects such as dogs, insects, and potentially “contaminated” objects such as doorknobs or toilet seats. Cognitive-behavioral therapists take care to devise these in vivo experiences to be maximally beneficial to the child while minimizing risk.

Behavioral Assessment

Telegram: @medical_k

www.konkur.in

A classic phrase coined by Barrios and Hartmann in their review of CBT is that “behavioral assessment is the cornerstone of (cognitive) behavior therapy.” In essence, CBT is dependent on a carefully constructed and thorough functional analysis of the patient’s presenting problem. The functional analysis involves the use of appropriate assessment methodologies to uncover the relationships and conditions under which the patient developed and has maintained their problematic behavior (the ABCs defined earlier). Assessment in CBT involves multiple methods, multiple informants, and multiple time periods. Assessment involves multiple methods to capture the most useful and valid information concerning the patient and their functioning across a variety of contexts. Thus, diagnostic interviews, self-report questionnaires, diary forms, and behavioral observation techniques can all be used, given time and cost restraints. The use of multiple methods and multiple informants allows for data to be captured without relying on any one form of assessment or individual that may be subject to biases or limited in scope. For example, although children generally are able to report internal states with accuracy, younger children tend to report what is within their immediate experience, and, as such, even recent events may be distorted or inaccurately represented. In addition, the nature of some disorders may interact with youth report on any particular method of assessment. Adolescents with social phobia in general have difficulty admitting to this form of anxiety and tend to minimize or deny symptoms. In contrast, parents of youth with social phobia are able to identify and report the behavioral avoidance associated with the syndrome. Consider, for example the comparison of responses to questions from a diagnostic interview by a 15-year-old boy with social phobia and that of his parents (Table 53.2–3). Although the youth denies a lack of friendships and minimizes his social anxiety, the parents’ report establishes his isolation due to avoidance of social interaction and activities with peers. In this case, the youth may be unable to admit to the anxiety due to self-presentational demands; however, the parents are readily able to identify the specific behavioral contexts (after-school activities, mobile phone use) in which behavioral avoidance is apparent. This

Telegram: @medical_k

www.konkur.in

information, taken within the broader context of a diagnostic interview, will be compiled to establish a diagnosis and specify goals for treatment (e.g., engage in social activity outside of home and school; engage with friends on the phone or texting).

Behavioral assessment often involves obtaining samples of behavior through behavioral approach tasks. The behavioral approach task can be individually tailored for each patient or standardized for a particular disorder. Standardized behavioral tests for youth with social phobia involve giving a speech in front of a camera or a small, live audience. Youth with separation anxiety disorder may be asked to stay in the clinician's office while the parent is sent on an errand. The behavioral approach task allows the clinician to assess the behavioral limits of the patient. If the child refuses to attempt the task, important information about their initial reactivity and ability to manage anxiety is accessed. No child or adolescent is ever forced to attempt a behavioral approach task; rather, they are allowed to avoid or quit the task at any point. The behavioral approach task also provides information on how long the patient can stay in the situation and what methods make the situation better or worse for the patient. For example, children who fear the dark may be better able to sit in a darkened room with the use of a flashlight or with another person with them. These safety signals provide information about what coping strategies the child is using and whether the strategy needs to be refined or removed through treatment. The behavioral approach task also allows for access of specific cognitive, physiologic, and behavioral content by having the patient list their top six thoughts that occurred during the task, taking measures such as heart rate or respiration, and recording the length of time engaged in the task or how close the patient can be to a feared stimulus. Optimally, the real stimulus that is feared (e.g., separation situation, small animal, heights) should be used in a behavioral test for maximal effect. However, certain stimuli or situations are inherently difficult to create in a therapist's office due to confidentiality (e.g., social situations) or practical matters (e.g., airplane travel, heights), setting a limit on the ecologic validity of the stimulus and patient's experience. Virtual reality environments,

Telegram: @medical_k

www.konkur.in

found to be efficacious and of high utility in the assessment and treatment of adult psychiatric conditions, offer a promising medium for creating age- and developmentally appropriate situations that mimic real-world stimuli and scenarios for behavioral tests as well as for use in exposure therapy in youth. Overall, the behavioral approach task provides both qualitative and quantitative information to establish baseline functioning and evaluate the progress of treatment. Sample behavioral approach task situations for anxiety disorders are given in Table 53.2–4. These tasks can also be used in designing exposure situations during treatment.

Interview Question[a]	Adolescent Report	Parent Report
Do you worry about what other people think of you or that you may do something embarrassing in front of others and then they'll think badly of you? Do you worry about this social anxiety more than other kids your age?	Yes, I worry I'll sound dumb sometimes. But I don't think it's any more than anyone else. I don't think so.	He is always worried about what he says and often says he does not know what to say. He fights with us about this. We try to push him to go out and talk to people, but he's too shy. He won't speak up and he is anxious that others will think he's stupid or awkward. This is different than our other kids who are quite social.
Do you think you have the same number, fewer, or more friends than other kids your age?	About the same as other kids.	Fewer. Actually, we don't think he has any friends that we're aware of and hasn't had since elementary school.
How often do you see your friends outside of school? What kinds of things do you like to do with friends?	Well, not much, maybe once a month. There's not much to do and nothing's really going on. And I have a lot of homework.	He doesn't see anyone outside of school. He just stays in his rooms and plays videogames. He doesn't go to any parties or to school events. We feel like

Telegram: @medical_k

www.konkur.in

		we are constantly nagging him to go.
Do you text your friends to do things, or do you wait for them to reach out to you?	I text them back sometimes.	He doesn't seem to call or text anyone. We see our other kids always texting or on social media. Not him. One classmate called to get homework and even that was hard for him.

[a]Questions are modified appropriately when addressed to parent.

The use of multiple informants involves obtaining information from the child, parents, teachers, and, potentially, peers, other relatives, and former caregivers or therapists. The use of multiple informants addresses issues of responder bias while accessing the opinion of individuals who have experience with the child over a sustained period and in multiple contexts. Information gained from parents and teachers, for example, may reveal the occurrence of behaviors that are not likely to present in the therapeutic environment. However, reports from others may be limited by an inability to appreciate the antecedents or consequences of behavior and the inability to understand the child's internal dialogue or ideas. Critical to maximizing the use of the information gathered through behavioral assessment methods and the input of multiple informants is an understanding of role of inequalities related to social determinants of health (e.g., poverty/economic instability, housing and food insecurity, access to healthcare and resources, discrimination/racism). Structural racism and systemic bias continue to result in marginalized youth and families experiencing inequities and disparities leading to unmet or poorly administered mental health care. A comprehensive assessment needs be grounded in a competent and informed evaluation of the cultural and contextual

Telegram: @medical_k

www.konkur.in

factors affecting the child's strengths and impairments in functioning. This then allows for a personalized, culturally responsive conceptualization and pragmatic treatment plan. Failure to include and address culture and context in the assessment risks perpetuating the disparities experienced by the youth and family. Finally, assessment occurs throughout the course of CBT. The initial assessment is used to establish a baseline diagnostic picture and establish the limits of functioning and identify behavioral excesses, strengths, and deficits. The goals for treatment are defined through data accessed during the assessment, and specific treatment protocols or techniques are chosen based on the assessment results. Assessment continues throughout the course of treatment to track progress, continue to gather data in specific domains (e.g., daily ratings of anxiety or depression, number of social contacts, diary forms to elicit though patterns and beliefs), and inform the therapist and patient about treatment response.

Table 53.2–4.
Sample Behavioral Approach Tasks for Child and Adolescent Anxiety Disorders and OCD

Telegram: @medical_k

www.konkur.in

Social anxiety disorder: Reading aloud in front of the therapist and office staff, initiating a conversation with an unfamiliar person, sending a text to a peer, “liking” a social media post, dropping books in a crowded waiting room, asking for assistance from a store clerk, asking for directions to the restroom.

Selective mutism: Whispering to the parent in front of the therapist, speaking at a low volume/whispering to the therapist, asking a question in a normal voice to the therapist, speaking on the phone with a relative, leaving the therapist a voice mail, asking the teacher a question, calling and inviting a friend to get together, video talking with a friend or teacher.

Separation anxiety disorder: Staying alone in the therapy room for 10 minutes, staying alone in a darkened room for 10 minutes, parents leaving the child at the clinician’s office to run an errand, being dropped off at therapy and not knowing parent’s whereabouts, parent being late to pick up child at school.

Generalized anxiety disorder: Purposefully making mistakes on a homework assignment, being late for an appointment, reading an upsetting story online or watching an upsetting news clip about crime or world events, being told of unexpected changes to routines or plans.

Animal/insect phobia: Being in the same room with a caged animal, staying in the room with the animal on a leash, touching the animal, allowing the animal to roam free in the room, allowing the animal to interact freely with self.

Injections/doctor phobia: Entering an examination room, looking at the medical instruments, holding a syringe, allowing self to be examined by a physician, allowing needle to rest against skin.

Darkness phobia: Sitting in a dimly lit room with another person, sitting in the dimly room alone for 10 minutes, sitting in the room for an unknown period of time, sitting in complete darkness while holding a flashlight, sitting in complete darkness.

Obsessive-compulsive disorder: Touching “contaminated” objects (e.g., doorknobs, shoe soles), not washing hands, shaking hands with various office staff, saying “forbidden” words or thoughts

Telegram: @medical_k

www.konkur.in

aloud (e.g., “God is dead”), using “unlucky” or “bad” numbers on purpose.

Table 53.2–5.
Daily Diary for an Adolescent With Major Depressive Disorder During the Early Phases of Treatment

Column A What was happening? (stimulus)	Column B Mood Rating (0 = best, 10 = most depressed ever)	Column C What was I thinking?	Column D What did I do?
Parents were arguing.	8	This is miserable. I hate it here at home. Why don't they stop?	Went to my room and cried. Didn't eat dinner and stayed there all night.
Had an essay due in English class.	7	I can't think of anything to write about. There's nothing interesting to write. I can't do this.	Listened to music and lay in bed. Tried to write but couldn't. Watched some TV and then went to sleep.
Friends posting pictures while at a party I didn't know about.	5	No one tells me when there's something going on. I never get invited. I'm no fun and they know it.	Blocked all those people on social media. Didn't answer any of their texts when they tried to reach me. Felt like cutting myself.

Psychoeducation

Telegram: @medical_k

www.konkur.in

A core component of CBT for just about any disorder or problem is psychoeducation for the child or adolescent and parents. Psychoeducation typically begins in the first treatment session and is carried on throughout therapy. Developmentally appropriate information is delivered to the youth and parents concerning the nature of the disorder in question (e.g., addressing the proposed etiologic pathways and maintenance of depression) and the process and procedures of CBT. It is important for patients and parents to learn that certain emotions may be “charged up” or “cooled down,” given changes in the environment (being teased by a bully, getting an A+ on a difficult examination, canceling a picnic due to rain), physical state (e.g., hunger, fatigue), time of day or year (school holidays, final exams) and other internal and external factors. Individuals may be born with a predisposition or vulnerability to experience certain emotions more strongly and readily than others, and over time, by interacting with the wider environment, a person can develop a style of thinking or psychological bias to interpret things in a more emotional manner (the “negative filter”). Although these biases exist, children and parents are further taught that individuals can learn strategies to manage their emotional reactions to a large degree, either with or without the assistance of medications. Emotions are broken down into three components—the physical (e.g., tension, irritability, physical symptoms of anxiety and depression), cognitive (e.g., automatic thoughts, beliefs, cognitive distortions), and behavioral (e.g., actions, aggression, withdrawal, avoidance). The relevant cognitive-behavioral techniques and principles tied to each component are offered as the ways in which the child will learn to recognize the triggers of their emotional reactions and use appropriate coping strategies effectively to manage the emotion and situation. Parents are also given specific information to address any gaps in their understanding and expectations for normative child development.

Column E Which dispute handles can I use?	Column F What is my Rational Response?	Column G New mood rating based on evidence and realistic thoughts	Column H What is my action plan?
How often do they argue? Is this the worst thing that could happen? What are they usually like together?	Mom and dad are loving to each other, and all couples disagree and argue at times.	3	Focus on what they are usually like together. Sit with the family for dinner and, if the time is right, let them know I was upset hearing their argument.
How many times have I written an essay? How likely is it that I wont be able to think of anything if I try? Do I have to do this all at once?	I've prepared for class and read all the material, so I do have ideas to use in this essay. I still have 4 days to get this finished and that gives me plenty of time to work on this.	3	I will review my notes from class and make an outline for the essay. After a short break for a snack, I will begin to prepare the content of the essay. If I get this done tonight, I can rest and finish tomorrow.

Telegram: @medical_k

www.konkur.in

How important is this particular party to my social life? Am I jumping to conclusions that no one tried to tell me about it? Do I have all the facts?	This is just one party and I've been invited before to others. With multitasking school, part time job and my social life, I'm going to miss things here and there.	2	Breathe and use my calming skills, and be proud of myself for not cutting. Reach out to my closest friends and ask if they had a good time. Make plans to get together for lunch and some fun.

Psychoeducation also involves the introduction and training of the child and parents in self-monitoring. Structured diary forms are often used to guide the monitoring of triggers to emotional states (both "positive" and "negative") and rating of the intensity of emotion (e.g., from 0 to 10). Monitoring sets the stage for later tracking of cognitive and behavioral responses that become the focus of other treatment components. A sample monitoring form for an adolescent with depression is shown in Tables 53.2–5 and 53.2–6.

Somatic Management Techniques

The vegetative and physiologic symptoms accompanying anxiety and depression are addressed through structured relaxation and exercise assignments. Deep diaphragmatic breathing and progressive muscle relaxation training form the mainstay of techniques used to dampen anxious or aggressive arousal and increase a child or adolescent's ability to control their unhelpful or inappropriate responding. Mindfulness exercises may also be introduced to teach children and adolescents strategies for nonjudgmental awareness of their bodies. Prescribed exercise regimens involving dancing, walking, bicycling, pilates, yoga, playing

Telegram: @medical_k

www.konkur.in

team sports, and engaging in similar physical activities are geared toward behavioral activation to reduce fatigue and increasing stamina and energy in the depressed adolescent. Nutritional counseling and sleep hygiene methods are also used as indicated to address concomitant problems such as eating and sleep disturbance accompanying the internalizing disorders.

Cognitive Interventions

The goals of cognitive interventions are to build on psychoeducation and provide corrective information concerning the presenting problem while systematically uncovering and refuting the automatic thoughts and schema that drive the youth's emotional distress. Automatic thoughts are discrete, rapid, and often context-specific thoughts that vulnerable individuals treat as fact about themselves, the world, and their future. All individuals have automatic thoughts each day. Typical automatic thoughts for youth with anxiety and depression are listed in Table 53.2–7. Cognitive restructuring involves identifying these thoughts through the use of diary forms, employment of Socratic questioning in the therapy room, and then developing rational responses based on actual evidence for the thoughts to assist with their emergence in everyday life. Apps have also been developed and disseminated to assist youth in monitoring and challenging thoughts in the moment. In effect, patients are taught to treat the thoughts as hypotheses, not facts. The therapist then guides the patient in planning home-based behavioral experiments to test whether the thoughts are true through the process of gathering evidence to either accept or refute them. Dispute handles, also shown in Table 53.2–7, are questions used to examine the evidence for the thought and guide the child or adolescent toward considering alternatives to their negative biases.

Telegram: @medical_k

www.konkur.in

Table 53.2–7.
Typical Cognitive Distortions and Dispute Handles for Youth With Anxiety and Depression

Cognitive Distortions

I'm not as smart as other kids.
I don't know what to say to others.
I'm not as attractive as others.
No one wants to hang out with me.
They think I'm a geek because I was nervous giving that oral report.
What if I do something stupid?
Nothing will work out for me.
This is the worst situation anyone could ever be in.
I know I'm going to fail.
If I don't ace this test there's no point in trying anymore.
I should have done better.

Dispute Handles

Am I 100% sure that ____ will happen?
Do I have evidence that ____ will happen?
How many times has ____ happened before?
Is ____ really so important that my whole future depends on its outcome?
What is the likelihood that ____?
Does ____'s opinion reflect that of everyone else?
Do I have a crystal ball?
Am I responsible for this entire conversation?
What is the worst that could happen?
What can I do to cope/handle the situation?

Depending on the age and cognitive developmental level of the child, cognitive interventions can be simplified or rendered more complex. Young children and those who are more concrete in thought processes can be presented with a simple cue to "stop and think" when experiencing strong emotions such as fear or disappointment. A picture of a stop sign or favorite cartoon character

Telegram: @medical_k

www.konkur.in

holding up a stop sign may suffice to teach the child to resist the negative emotion and engage in proactive coping. Emotive imagery is a technique by which the child's favorite superhero or character provides "guidance" in managing the difficult situation. For example, a 7-year-old boy with separation anxiety disorder might be taught to imagine how Spider-Man's parent was late in picking him up from school. The therapist would coach the child to imagine Spider-Man handling each situation and then have the child imagine himself in each situation, with Spider-Man "standing by" in the image and assisting the child with coping strategies, such as deep breathing and thinking realistic, helpful thoughts. Older children are often provided acronyms to remember a series of steps in cognitive restructuring: Feeling frightened? Expecting bad things to happen? Actions and attitudes to help me cope with this situation. Results on how the situation turned out and how I handled it and reinforce myself for trying. Homework in cognitive restructuring involves the use of additional columns in the diary for (see Tables 53.2–5 and 53.2–6). These forms are reviewed in session, whereby the therapist and patient evaluate each step of the restructuring process and work through plans to overcome challenges and reinforce success experiences.

Exposure/Behavior Change Techniques

In the anxiety disorders, behavioral exposures are used to provide systematic success experiences while managing difficult situations and refining cognitive restructuring skills. Anxiety is partly maintained by avoidance of or escape from challenging situations, and thus the child does not gain experience to refute anxious thoughts and learn that the feared negative outcomes are unlikely to occur or can be managed. A child with separation anxiety disorder tries to avoid, at all costs, the experience of being away from loved ones for fear that something terrible will happen to result in permanent separation. By avoiding separation situations, the child maintains a focus on the catastrophic fear and does not learn that the feared negative outcome is highly unlikely. Moreover, avoidance prevents the child

Telegram: @medical_k

www.konkur.in

from learning that, when adverse or less-than-desirable or expected events occur, such as a parent returning home late from work, the event is independent of the child's fear and avoidance behavior. Exposure directly addresses the fear and avoidance partly through the process of habituation, by which the anxiety response naturally dissipates during the exposure. Exposures also provide opportunity for inhibitory learning, in which the child can learn that catastrophic feared events did not occur and new beliefs about potential outcomes come to inhibit previous beliefs. The child concurrently gains experience with coping and interacting with the feared stimulus or situation. Exposure is usually conducted in a stepwise manner of introducing increasingly challenging situations. Flooding, which is not recommended for young children or those with more severe anxiety levels, involves having the patient confront a situation that provokes the highest levels of anxiety and stay in the situation until the habituation occurs. Exposure may be imaginal or in vivo but is typically arranged hierarchically for children, from least to most challenging. Role plays with the cognitive-behavioral therapist may be included in preparation for exposures; however, they do not substitute for exposures. During imaginal exposure, the therapist may construct scripts about anxiety-provoking situations and ask the child to listen to the scene as if it were really happening. As the child's subjective anxiety decreases, scenes of greater intensity are presented in succession. In contrast, in vivo exposure involves having the child actually engage in the feared situation. Again, when the child reports tolerable levels of anxiety, the situation may be enhanced to produce a greater challenge to the child and require a new level of cognitive and behavioral coping. In contrast to situational exposures, interoceptive exposure involves inducing the sensations of panic through certain exercises and activities that cause physiologic responding, such as tachypnea, tachycardia, palpitations, diaphoresis, and paresthesias. Again, these exposures are designed to break the fear of internal sensations of anxiety and increase tolerance for normative changes in body functioning. Recent experimental studies indicate that habituation may not be necessary to reduce anxiety, but rather, exposure may assist in the

Telegram: @medical_k

www.konkur.in

learned tolerance of expected anxiety reactions that would previously have resulted in avoidance. For example, learning to tolerate the discomfort of dental procedures, the arousal accompanying asking someone for a date, and other situations that are inherently challenging to anyone, can result in improved functioning and quality of life, and reduced anxiety overall. In all types of exposures, children are encouraged to use their somatic management skills, as well as cognitive restructuring. Use of safety signals may be allowed for less challenging exposures, but systematic removal may be necessary for increasing exposure potency and testing potential feared outcomes.

Behavioral activation tasks are structured experiences planned for youth with major depression or persistent depressive disorder. The reinforcement theory of depression asserts that low rates of contingent reinforcement contribute to depressed mood and anhedonia and set up a cycle by which withdrawal behavior occurs and, thus, the youth is even less likely to engage in or have access to reinforcing events. For example, withdrawal from team sports, procrastination in homework assignments, and loss of interest in self-care may occur over time in depressed adolescents. By withdrawing from the team, social reinforcement and contact with peers comes to halt. Withdrawal also may have transactional effects on the teen as peers may disengage and taper contact in response, thereby further reinforcing potential distorted beliefs about themselves. Procrastination leads to a sense of dread and failure in school activity, and the drop in self-care compounds the youth's negative self-image. The result is a systematic decrease is positive reinforcement and corresponding increase in negative feelings about the self. In CBT, the therapist surveys the youth for activities that may bring social reinforcement, success (self-efficacy or accomplishment), or pleasant feelings (e.g., relaxation). Typically, monitoring of mood occurs concurrently with the monitoring of these activities to provide feedback to the youth that engaging in such activity that the youth is likely to attempt, setting up parameters for engaging in the activity, and self-monitoring and processing the outcome of the event. Planned activities increase in type and

Telegram: @medical_k

www.konkur.in

number as treatment progresses, with the goal that the youth will assume the responsibility of planning these activities and that they will again become a natural and fixed part of their behavioral repertoire.

Parent Involvement in Treatment

Parents and family members are often inadvertently drawn into the cycle of negative affect accompanying the internalizing disorders. Family members may provide reassurance or reinforce escape and avoidance as a way of calming the anxious child or protecting the child from becoming upset and anxious. In depression, parents may take over tasks the adolescent is unable to complete due to anhedonia and vegetative symptoms, such as doing the teenager's homework or other compulsory acts. The intention of the parents is to prevent the child or adolescent from becoming even more anxious or depressed and, thus, to allay the distress experienced by their child. Unfortunately, although well intentioned, these parent behaviors are incorporated into vicious cycles of continued anxiety or withdrawal. In CBT, parents are provided a model of negative affect and education about the proposed etiologic mechanisms and maintenance of these states. The therapist and parents collaborate to examine maintaining variables in the child's environment and family system, to develop plans to change parental behaviors when necessary, and to rearrange contingencies in the immediate environment to foster the child's recovery. For example, in selective mutism, usually another child or family member will speak for the child and reinforce the child's mutism. The parents of adolescents with social phobia order for their adolescent in restaurants, speak to teachers on the adolescent's behalf, and have fewer expectations for their adolescent's social life. Parents of depressed youth may fear worsening the child's depression by challenging or encouraging participation in activities and thus prefer to "leave well enough alone." Parents are often taught to be good CBT "coaches" for their child. In essence, parents are taught to ask questions (use the Socratic method) to guide their child in arriving at a coping/action

Telegram: @medical_k

www.konkur.in

plan rather than providing an answer for the child. Much like a good coach, parents are taught to provide opportunities to practice the skills learned in CBT while refraining from judging the child. Reinforcing and praising the child's effort at coping, no matter how small, is essential for parents to learn in CBT. Parents are also taught systematic skills to ignore certain child behaviors (e.g., whining, refusal to speak, irritability) and to reinforce with positive attention those behaviors that approximate the goal behaviors. Parents are also trained in the use of contingency management procedures that may involve setting specific goals and contracts, such as "If Jonathan sleeps alone is his bed until 7 a.m., he gets 15 minutes of extra iPad time after school." The goal of contingency management procedures is to rearrange the reinforcement paradigms in the child's environment such that the child receives contingent positive reinforcement for appropriate behavior—in some cases, this may be stickers, small treats, or special privileges—whereas reinforcement is removed or withheld when inappropriate behavior occurs. These procedures also provide structured and, if necessary initially, scripted opportunities for parents to attend to positive behaviors and to effectively communicate this reinforcement. Cognitive-behavioral therapists do not advocate the use of punishment, which has been found to be ineffective in maintaining long-term behavioral change, in addition to being ethically unacceptable.

There are a few guidelines and caveats when planning the level and type of involvement of parents in the child or adolescent's therapy. First, the greater the distress and impairment for the child, the more likely it is that the parents are needed to reinforce the treatment program in the home environment. This is especially indicated in cases involving school avoidance behavior, in which the parents must rearrange contingencies in the home and actively work in cooperation with the school and therapist to promote attendance. Second, externalizing disorders or other complex comorbid conditions tend to fare better in CBT with parent involvement. Third, younger children have been found to respond better in acute treatment when parents are actively incorporated into the treatment

Telegram: @medical_k

www.konkur.in

plan. Fourth, the developmental goals of adolescence involve forming independent self-identity and behavioral skills; thus, parent involvement should take this and other developmental issues into consideration. Finally, in cases in which parental psychopathology or marital or family discord is present, the involvement of the parents may hinder rather than help the child's progress in treatment. In these cases, involvement of the unaffected parent or minimal parent involvement may be indicated, with referrals given as appropriate for concurrent marital or family therapy, parent management training, and individual parent therapy.

Relapse Prevention

As treatment draws toward a close, the therapist begins the process of transferring the responsibility for continued progress from the therapist to the child. That is, specific strategies and techniques are used to consolidate gains, reinforce coping skills, generalize gains to a wide range of contexts, and bolster the child's sense of self-efficacy. In the initial phase of relapse prevention, treatment sessions are moved to a biweekly and then monthly schedule to allow the child time to practice skills on their own and decrease reliance on the therapist. By identifying upcoming events or changes in the child's life (e.g., starting school, moving to a new neighborhood, facing developmental challenges calling for increased independence), the child is encouraged to develop a coping plan for each event and to plan their self-guided exposures in advance of the event. Hence, if a child is changing to a new school, plans to visit the school and meet the teacher or some peers are encouraged, and cognitive restructuring is completed for any negative thoughts or expectations that may occur. Similarly, booster sessions can be planned for anticipated tough times (e.g., the start of school, before annual examinations) to reinforce coping skills and assist with transitions. Throughout treatment, therapists can work with parents and children to incorporate technology to optimize coping. For example, deep breathing or mindfulness exercises can be recorded on smartphones, or coping reminders can be set for a specific date or

Telegram: @medical_k

www.konkur.in

time to encourage regular practice or situation-specific coping. In addition, smartphone applications and websites are available that provide age-appropriate CBT support (e.g., Kids Feelings App; Camp Cope-A-Lot). Finally, the child's diaries, workbooks, and journals from treatment become excellent relapse prevention aids for the child to refer to after the end of treatment. Photos taken during exposures or behavioral activation tasks that illustrate the child's accomplishments are pasted into these journals, bookmarked on the child or adolescent's smartphone, or put on posters in the child's room to reinforce gains. Finally, the Coping Cat program for anxious youth advocates the development of "commercials" by which the therapist and child produce a recording that incorporates all of the skills acquired during treatment. The child is the "star" of the recording and is shown as if teaching others how to overcome a problem. Commercials can also be produced in the form of comic strips, short books, poems, and other creative methods that inspire the child. Whatever the form the commercial takes, the child can refer to it for relapse prevention purposes and to reinforce gains. A resource for parents' "Do's and Don'ts" can also be generated for the parent component of relapse prevention. Table 53.2–8 presents a summary of the CBT components reviewed here.

CLINICAL ISSUES

Indications

CBT is indicated for the treatment of a range of disorders of childhood and adolescence, including anxiety and mood disorders, attention-deficit/hyperactivity disorder (ADHD), oppositional defiant disorder, conduct, and oppositional disorder, habit disorders, OCD, PTSD, substance abuse, eating and feeding disorders, and parent–child discord, in addition to other conditions and behavioral disturbances. CBT is generally accepted as the first-line treatment for a range of disorders in childhood, with a combination treatment of CBT and medication preferred for more intractable or complex cases.

Telegram: @medical_k

www.konkur.in

Limitations

Child or adolescent-focused CBT may not be the treatment of choice in situations involving extensive parent–child discord or marital problems. In such cases, as noted previously, the preferred course of treatment would involve family or marital therapy. The level of training and experience of the therapist typically limit the effectiveness of CBT, and, despite the widespread dissemination of CBT manuals and workshops, partially trained or inadequately trained therapists are no substitute for specialists in CBT. Hence, families and referral sources must be fully informed as to the degree of expertise in CBT of the therapist and adjust expectations accordingly. Similarly, the motivation and adherence to the treatment plan demonstrated by the patient and family may limit CBT. The therapeutic relationship, contrary to popular belief, is of critical importance to the cognitive-behavioral therapist. Thus, the cognitive-behavioral therapist will work to establish trust, positive regard, openness, and collaboration with the patient and family, no matter how rapidly a course of treatment is planned, to facilitate treatment progress.

Complications

Incomplete assessment and failure to fully uncover the antecedents and consequences of behavior may result in complications in therapy. It is not unusual for younger children or those who have successfully avoided phobic stimuli to underestimate their true level of fear. Hence, exposure may be too complex or overwhelming for a child, requiring the therapist to break the situation down into smaller, more manageable parts. Therapists who allow a child to escape or prematurely end an exposure session before adequate habituation and processing of the exposure can reinforce the anxiety and escape. Thus, it is essential that enough time is allotted for an exposure session and that the parameters of the exposure be clearly and fully examined with the child or adolescent. CBT does not purport to teach positive thinking but rather to teach optimistic,

Telegram: @medical_k

www.konkur.in

realistic, and coping-focused thinking. As such, exposure to less-than-ideal situations and outcomes is a part of treatment.

Contradictions

CBT is a flexible set of techniques and approaches that has been effectively applied to a wide range of child and adolescent disorders. There are no known contraindications for the use of CBT in young people.

CASE EXAMPLES

Telegram: @medical_k

www.konkur.in

SOCIAL ANXIETY DISORDER

James was a 15-year-old boy in a single-parent, middle-class home and enrolled in the 10th grade of a public school. His mother sought evaluation and treatment for him for a longstanding history of “shyness” and anxiety in social situations. The evaluation revealed social anxiety disorder as the primary disorder in an adolescent who was temperamentally inhibited since early childhood. James had a great fear of making mistakes, looking foolish, and otherwise being the focus of attention when performing academic tasks or simply trying to engage in conversations with peers and teachers. At the same time, James was forthcoming with the evaluator and revealed that he knew he had always been attracted to other boys but did not act on his attraction for fear of rejection due to being gay. Also, he had not told his mother or other close relatives or friends of his sexual orientation. These concerns led him to feel dysphoric more days than not, as “I can’t even be my true self.” James was motivated for treatment and reported that he wished to make friends and feel more comfortable opening up and being himself with other people, and be more confident in social situations. Consequently, James was treated with cognitive-behavioral group treatment for adolescents with a social phobia —a 16-session course of treatment combining psychoeducation, cognitive restructuring, social skills, behavioral exposure, relapse prevention, and four sessions of parent involvement. James was initially quiet in the group; however, as treatment progressed, the other group members encouraged his interactions, validated his feelings, and expressed unconditional and nonjudgmental positive regard for him, resulting in James fully engaging in the therapy. The therapists designed social interaction exposures geared toward his engaging in conversations at school, volunteering to speak in class, making mistakes in front of others, and attending school-related social activities (e.g., clean up in the public park, car wash) where he would need to have

Telegram: @medical_k

www.konkur.in

conversations with others. A self-identified key goal for James, and among his most challenging homework exposures, however, was talking with his mother about his sexual orientation. The therapist role played various ways this could go—from his mother being accepting and open to her questioning whether he was confusing his feelings with a “phase.” Although he was prepared for a less-than-desired outcome with his mother, in actuality, she expressed relief that he had “finally” come out to her (“A mother knows these things”), and she encouraged their making plans to seek outlets for greater support and connection for him and for her to know how best to support James. He considered the school and peer-based exposures successful and subsequently went on to other social events and increased his class participation and engagement with school-based activities. In this case study, the importance of exposing youth to a range of potential outcomes for a given personal or social situation was crucial to James’s trust in the therapy and therapists and belief in the credibility of treatment. Moreover, he was appropriately prepared through behavioral exposure and practice to handle what could have been an awkward and discouraging situation.

Table 53.2–8.
Summary of the Main Components of Cognitive-Behavioral Therapy

Telegram: @medical_k

www.konkur.in

Component	Focus/Goals	Associated Techniques
Psychoeducation	Provide corrective and accurate information about the nature of the disorder or problem in question.	Didactic instruction, self-monitoring (diaries, journals), assigned reading
Somatic management techniques		
Anxiety-related	Target autonomic nervous system arousal and related physiologic symptoms.	Breathing retraining (deep diaphragmatic breathing), relaxation training (progressive muscle/cue-controlled/applied relaxation), meditation, exercise
Depression	Plan behavioral activation tasks involving increase in activity to counteract negative, vegetative symptoms.	Exercise- and employ-related physical, social, mastery, and pleasurable activities
Sleep hygiene	Restructure sleep cycle through scheduling of awake activities and self-soothing activities to promote healthy and restful sleep.	Set tasks and guidelines geared toward decreasing arousal and promoting relaxation prior to bedtime; decrease/extinction of arousal activities such as exercise or

Telegram: @medical_k

www.konkur.in

		use of stimulants (caffeine) in close proximity to bedtime.
Cognitive restructuring	Identify maladaptive (automatic thoughts, schema, irrational beliefs) thoughts, beliefs, and images and challenge thoughts with realistic, coping-focused thinking; in children, uncover “unhelpful self-talk” and replace with coping-focused self-talk (“coaching”).	Monitor thought processes through the use of diaries, apps, or questionnaires to reveal thinking styles, identification and labeling of automatic thoughts; teach rational disputation of automatic thoughts using realistic evidence and problem-solving steps.
Exposure/behavior change techniques	Systematic exposure to avoided situation(s) to provide experience with using cognitive restructuring and other deficient skills (e.g., social skills, problem-solving skills, conflict resolution, affect regulation).	Imaginal exposure, in vivo exposure, gradual or massed (more intense) exposure to anxiety-provoking situations; in depression, use of behavioral activation tasks or behavioral experiments to counter negative and self-defeating behaviors and gather evidence to refute depressive ideation.

Telegram: @medical_k

www.konkur.in

Reinforcement techniques	The systematic application or withdrawal of stimuli to either increase desired behavior or decrease undesirable behavior.	Patient earns reinforcement through behavioral contracts, level programs, or parent-, therapist-, and/or school-administered contingency management programs; reinforcers can include tangible items (stickers, money), social reinforcers (praise, positive attention, elevation in status), or desired activities (free time, computer/videogame use, extended curfews); time out from positive reinforcement is the removal of the individual from a reinforcing situation for a set period; punishment, which is the application of a noxious or undesired stimulus, does not result in long-term behavioral change and is not
Positive reinforcement	Provide a desirable stimulus (praise, attention, tangible reward) after a desired behavior to increase the probability of the behavior occurring again.	
Negative reinforcement	Remove an undesirable stimulus after the production of a desired behavior to increase the probability of the behavior occurring again.	
Punishment	Apply a noxious stimulus after an undesirable behavior to decrease the probability of it occurring again.	

Telegram: @medical_k

www.konkur.in

		recommended for use by child behavior therapists.
Relapse prevention	Focus on consolidating cognitive-behavioral therapy skills and generalizing treatment gains over time; decrease reliance on therapist and others (e.g., parents, spouse) for managing problems.	Fading of sessions (from weekly to biweekly), role reversal (patient acts as therapist for a session), planned booster sessions.

SELECTIVE MUTISM

Anna was a 5-year-old girl from an intact middle-class family referred by her kindergarten teacher due to selective mutism. Anna was described as always having been a shy child who was behaviorally inhibited. Although she would speak and interact with immediate family members, she would withdraw and become quiet around peers and strangers. When she started preschool, she did not speak to her teachers or any school personnel and also began to withdraw from speaking around extended family members at holidays and parties. She also experienced distress about separation from her mother, who would generally respond to her and make requests for her. The school had also allowed her to nod and use nonverbal cues to communicate her preferences, and she was not required to read aloud or speak in front of her peers. She occasionally played and engaged with peers on the playground and was otherwise pleasant and friendly. During the evaluation, it was revealed that Anna enjoyed eating Skittles as a treat. Treatment was designed to provide an incentive for speaking through the delivery of a contingent reinforcer of high value, the Skittles. Hence, Skittles became available only in the school and therapist's office and, temporarily, were not available in her home. The therapist enacted a process of graduated shaping of communication behaviors—first nonverbal and then vocal noises—and trained the teachers to do the same. Skittles were kept in full view of Anna at all times during the initial phase of treatment, and when she was "caught" gazing at the package, the therapist or teacher would prompt her for acknowledgment that she wanted the treat. Pointing, looking, and nodding in their direction resulted in receiving two Skittles. While in session, the therapist would also leave the room while she and her mother were left to play; if the therapist returned and she continued to vocalize or speak, she would receive additional reinforcement via Skittles. Next, the therapist and parent spent time "making noise" with objects (e.g.,

Telegram: @medical_k

www.konkur.in

rattling keys, pressing telephone buttons) and then with their mouths (e.g., animal sounds, silly sounds), and Anna was prompted to join in and make similar sounds to receive the Skittles. Finally, prompts to ask for the Skittles were enacted, first with an “Ssss,” then the full word, and finally the full sentence/question (e.g., “Can I have a Skittle?”). This shaping procedure took three extended-length sessions and collaboration, along with telephone consultation with her school teachers. In addition to treat requests, Anna was increasingly reinforced for additional situations on her fear and avoidance hierarchy: making eye contact, saying hello to neighbors, ordering her own food in a restaurant, purchasing her own Skittles from a drug store, singing in the park, etc. The treat was faded over time—that is, delivered on a variable ratio schedule of every three to eight times that she spoke to promote further speaking and decrease the association with the treat. As a part of their relapse prevention plan, Anna’s parents were reminded to allow or prompt Anna to speak for herself in various pre-identified possible situations.

Telegram: @medical_k

www.konkur.in

OBSESSIVE-COMPULSIVE DISORDER

Ayana was a 13-year-old girl with a family history of anxiety and mood disorders. Her parents brought her to treatment due to recurrent obsessions involving contamination and germs and corresponding compulsions by which she had her parents overcook her food, check her food for contaminants, and wash her hands repeatedly to the point of their becoming raw and bleeding. The evaluation revealed a fear that, unless her parents checked her food for bugs or germs, the meal was contaminated, and she would get sick and die. Hence, after cooking it, her parents had to pull apart her food physically and examine it to her satisfaction, which could take upward of 1 hour for each meal. This caused much distress and family discord. In addition, Ayana washed her hands repeatedly after opening a door, using a cell phone, tying her shoelaces or putting on or taking off her shoes, or touching any object that she deemed dirty. First, Ayana, her parents, and the therapist mapped her OCD and constructed a hierarchy based on her compulsions, rituals, and avoided situations (from the least upsetting, checking food prepared by her mother, to the most upsetting, touching something that was wet and slimy and then touching her mouth). The process of exposure and response prevention was introduced in combination with a contingency reinforcement plan for Ayana's completion of "brave challenges." Systematically, the therapist had Ayana first engage in imaginal exposure to a scene (e.g., "You watch dad take a bite of his medium rare burger, then you imagine taking a bite of a medium rare burger with the red juice oozing out. You realize it is not super well done, and they did not check it for germs.") until her anxiety dropped to minimal levels. This usually occurred after 20 to 30 minutes. Next, in vivo exposures were gradually introduced, by which foods were introduced with "contaminants" in them (e.g., putting pieces of uncooked rice into the burger to mimic "grit"), phasing out the parents' checking of meals as well as her own checking

Telegram: @medical_k

www.konkur.in

behaviors. As treatment progressed, Ayana learned that her feared consequence of becoming sick was not likely to occur. Washing rituals were addressed by having her touch items with various substances coating them and then touching her face and mouth. At first, she was asked to delay washing her hands over increasing time increments and then to resist for larger blocks of time. Importantly, it was critical to address some of Ayana's mental ritualizing thoughts regarding when she would be next able to wash her hands. Treatment occurred over a 14-session program, with some sessions including extended time to allow for exposure and response prevention to occur. Her parents were taught to assist her with these exposures in the home and refrain from engaging in her rituals or accommodating them (e.g., removal of antibacterial sanitizing gels). They were also provided coaching scripts so as not to engage in disputes over meals. Relapse prevention plans were enacted to expand her range of food choices and situational contexts (cafeterias, food stands, restaurants) for exposure. By the end of treatment, Ayana was eating without the need for checking and with minimal to no anxiety, and her handwashing had decreased to within the normative range of daily washing.

GOALS OF TREATMENT

In the abstract, the overall goals of CBT are to increase an individual's freedom of choice—that is, to free the individual from the confines of a disorder which removes the opportunity to make decisions and choices for one's self out of personal preference and which, instead, determines an individual's choices as a result of fear, depression, anger, or other emotional constraints. The goals of CBT are symptom relief, education about the nature of one's symptoms, vulnerabilities, and patterns of behavior, and the teaching of adaptive, coping-focused, realistic, and optimistic behavior (cognitive and overt) to maximize the person's potential, prepare them to meet the challenges of everyday life and improve their quality of life.

Telegram: @medical_k

www.konkur.in

ETHICAL ISSUES

CBT is a safe, tolerable, and effective treatment for a range of behavioral health problems, with increased efficacy linked in some clinical studies to more seasoned and well-supervised therapists. The main risks of CBT may lie within exposure-based treatments, which are associated with temporary emotional discomfort when confronting feared situations. Contrary to the myth that exposure may result in adverse reactions (e.g., unrelenting anxiety, psychosis, breach of therapeutic alliance), any discomfort and boundary issues in conducting exposure can be skillfully and carefully managed by the experienced therapist. When conducting exposure in community (in vivo) settings, such as schools, parks, and playgrounds, therapists need to be mindful of confidentiality concerns and take precautions to minimize compromising the patient's right to privacy.

RESEARCH AND EVALUATION

CBT is considered the "gold standard" psychosocial treatment approach with more empirical support than any other psychosocial intervention. Efficacy in the treatment of childhood internalizing and externalizing disorders through a number of controlled, randomized trials, including combined trials of medication and CBT. Long-term follow-up of youth treated for anxiety, OCD, or depression suggests maintenance of treatment gains, in addition to further improvement over time. It is incumbent on clinical trial researchers in CBT to test this approach in youth presenting with variations in cognitive and developmental functioning, comorbidity patterns, and various environmental adversities to test the effectiveness of therapy programs in mental health service settings. Further research is needed to evaluate treatment algorithms, discontinuation procedures, and pretreatment factors that predict the maintenance or relapse of treatments over the long term. The critical issue faced by today's clinical scientists involves moving treatments from the laboratory to the community. This rests on the collaboration and cooperation of clinical scientists, clinicians, patient advocates, and

Telegram: @medical_k

www.konkur.in

consumers for critical feedback to flow in multiple directions to adapt and adopt evidence-based treatments in community settings.

53.3 Group Psychotherapy

MARGO L. THIENEMANN, M.D.

Group therapy is the counseling, guidance, or training of children and adolescents involving interactions of three or more members that has the potential for reciprocal influence. Empirical support for group therapy for children and adolescents is growing. In 1997, Matthew J. Hoag and Gary M. Burlingame published a meta-analysis of the 56 English-language studies of child group therapy that used randomization or matching in their experimental designs. Compared to wait-list or placebo control, group therapies helped to a moderate degree (effect size 0.61, range –0.04 to 2.99). More recent studies have addressed specific populations, as discussed below.

Group interventions for children and adolescents can be categorized by goals, therapeutic processes, duration, and population served and may be referred to as *psychotherapy groups, psychoeducational groups, support groups,* and *self-help groups.* Delivering therapy via groups may be better than individual therapy for addressing specific illnesses or may more effectively address treatment issues such as motivation for change or the need for social reinforcement of learning.

HISTORY

Therapists have been describing group treatments for children for approximately 100 years. Early in the 20th century, adolescents met for psychodrama groups in Vienna. In the 1930s, *activity group therapy* developed. In these groups, children played among therapists who used nonverbal, noninterpretive interactive strategies to effect “ego repair.” After World War I and during the Depression, when delinquent youth needed constructive supervision and

Telegram: @medical_k

www.konkur.in

resources, and manpower was short, adolescents were treated in groups. After World War II, understaffed military hospitals in the United States and England used groups to deal with psychiatric casualties. The 1960s saw the emergence of encounter groups, the community mental health movement, antiestablishment groups, and increased tolerance in society for talking openly about one's feelings.

Today, groups are used frequently and ubiquitously. Psychotherapy, support, psychoeducational, and self-help groups may be found in all human service facilities, including schools, hospitals, clinics, and on the internet. Conceptual understanding and beginning clinical skills of group therapy are listed among the required core competencies for child and adolescent psychiatrist training, according to the Accreditation Council of Graduate Medical Education (ACGME), though Pollock and Kymissis noted that few training programs include adequate training in group psychotherapy.

Environmental factors have shaped these historical trends. Pollock and Kymissis, discussing the future of adolescent group therapy in 2001, posited that theoretical and clinical developments, training opportunities, scientific research, economics, social change, and public and professional attitudes all influence the type, quality, and availability of group therapy. Psychoanalytic theory informed early groups, which aimed to use group interactions to recapitulate family interactions. Developmental theory, considering the peer group's role in identity formation, pointed to using the group for adolescents' therapy. The development of learning theory and cognitive-behavioral therapy (CBT) has led to problem-focused, time-limited group interventions.

Societal changes and economic factors have increased the appeal of group interventions. According to Miffitt, the current health care climate of high demand and limited resources makes the group therapy format cost-effective and fiscally responsible. Due to the developmental tasks of adolescence, which include identity formation and development of the concept of self through peer relationships, peer approval, and belongingness, group modalities are perhaps especially useful for pre-adolescent and adolescent children (paraphrased from Miffitt, 2014). Today, many group

Telegram: @medical_k

www.konkur.in

therapies have been researched, and as all evidence-based therapies require treatment manuals, the practitioner will have access to guidance.

Some factors serve as potential obstacles to the use of group psychotherapies. Managed care, because of group therapy's potential cost-effectiveness, initially provided an incentive for increasing the use of outpatient group therapy. Despite increased societal comfort with self-disclosure, therapists and patients may reject group therapy, considering it diluted and less effective. Perhaps, as has been the case for pharmacologic, individual, or other treatment modalities, research will demonstrate that specific group therapies for specific problems administered by specifically trained individuals help, and the interventions may gain adequate support for dissemination.

THEORETICAL ISSUES

Therapeutic Power of the Group

Gathering individuals together for therapy may help them more than working with them alone. Existential psychiatrist Irv Yalom published The Theory and Practice of Group Psychotherapy, in which he described factors that make psychological treatment in groups especially effective. Yalom listed the instillation of hope, universality, imparting of information, altruism, corrective recapitulation of the primary family group, development of socializing techniques, imitative behavior, catharsis, the addressing of existential factors, cohesiveness, and interpersonal learning as factors leading to change. In children and adolescents, the use of the group to address developmental issues may also be an advantage.

Hope. In groups, children can meet other children with similar troubles. As they see peers overcome obstacles and actively addressing problems, they can develop hope that they, too, can help themselves get better. Families may gain hope; a parent of an unmotivated anxious child remarked that seeing other children

Telegram: @medical_k

www.konkur.in

tackling their anxieties gave her hope that her child would be able to do so. Similarly, in multi-family groups, parents often remark that seeing other children improve behavior-wise gave them hope that their families could also begin to function in a healthier manner.

Universality. Children with psychiatric disorders frequently feel they are “weird,” “crazy,” or “losers.” Getting to know peers with similar issues can lessen the pain and reduce the erosion of self-esteem that comes with having a mental health disorder. Adolescents are in the midst of exploring and consolidating their identities during the time that a number of major psychiatric illnesses begin to manifest themselves. Having the opportunity to interact with others with similar difficulties can help teenagers integrate having a psychiatric illness into a broader sense of self. In a recent pilot study by Straub et al., reviewing the most positive evaluations of their time-limited cognitive-behavioral group for teen outpatients, the most positive elements identified by participants were being with other adolescents and feeling comfortable in the group. By seeing others in the group, teens can come to see a disorder as only one of many aspects of themselves.

Imparting Information. Children learn together at school, on teams, and in families. In group therapy, children can learn about the course and characteristics of their disorder. In addition to presenting live examples, the group format is suited to psychoeducation via leaders’ instruction, educational videos, and structured learning activities. When the child teaches and helps other members, their learning is reinforced. Following the Coping Cat anxiety protocol model, members of one adolescent group treatment for obsessive-compulsive disorder (OCD) ended the group by making a didactic video. The group members delighted in their educational video, which taught about the etiology, symptoms, treatment, and impact of OCD. They watched it repeatedly and shared it with their families.

Altruism. Supporting others in the group is gratifying and a positive coping mechanism. Altruistic actions can boost one’s sense

Telegram: @medical_k

www.konkur.in

of well-being and self-esteem and help to defend against upsetting feelings. Children and adolescents in group therapy often make thoughtful suggestions to other members. One study of adolescents participating in cognitive-behavioral group therapy reported that most participants tried to help their peers to design behavioral interventions in every session.

Corrective Recapitulation of the Primary Family Group. Through examining psychodynamic processes and addressing treatment resistances, the group format can provide a wealth of opportunities for addressing family conflicts. In a group setting, children develop transference relationships with leaders and peers. Providing a safe, constructive atmosphere in which maladaptive interpersonal patterns are addressed and reworked may provide group members a chance to work through dynamic conflicts originating in the family.

Development of Socializing Techniques. Yalom stated that all therapy groups help patients develop social skills. Social deficits, social dysfunction, and isolation are prominent concerns for children with psychiatric disorders (including those with pervasive developmental disorders), learning disorders, attention-deficit disorder, other externalizing disorders, and social anxiety and depressive disorders. Groups allow patients to practice new skills and receive feedback from professionals and peers in real-time. In one controlled group therapy study of girls without friends, girls in the treatment group did learn to approach peers and begin conversations. Reinforcement and criticism from peers may be the most meaningful feedback for adolescents.

Imitative Behavior. Seeing how others behave greatly influences what children and adolescents do. Children in groups observe other children working on solving problems like theirs. Group leaders often demonstrate strategies, like social problem-solving and conflict resolution, as ways to deal with these. Many group protocols call for role-playing and rehearsal of skills. Sexually abused children

Telegram: @medical_k

www.konkur.in

practice acting assertively, and impulsive children practice entering an ongoing conversation successfully. In the pilot study by Straub et al. examining a CBT group for depressed teens, participants reported that they felt understood by and comfortable with the group leaders and rated their advice as helpful. Imitating effective behaviors modeled by leaders whom children respect and peers with whom children may identify effectively teaches functional behaviors.

Catharsis. Group therapy can allow one to express one's distress in the presence of individuals who can truly understand one's suffering. Although catharsis provides some relief, catharsis alone is insufficient for change. Members of one adolescent trichotillomania treatment group noted that talking at support groups had helped initially but left them feeling dejected after hearing about others' experiences. They felt more hopeful when they could learn new tools with which to address their behaviors.

Existential Factors. In the trichotillomania group just mentioned, one member openly expressed hopelessness and refused to address her hair-pulling. The other group members challenged her stance, urging her to take responsibility for attempting to change her behavior. Unwilling to take charge at that time, she left the group. Issues of personal responsibility will change, loneliness, and demoralization frequently emerged in the context of group therapy, which provided a rich format in which to discuss these universal existential concerns. Adults in one substance abuse group rated the group's ability to address existential issues as its most powerful component.

Cohesiveness. The experience of being part of something, being self-revelatory *and* accepted, and working together feels good and can improve children's motivation to work in therapy. When children and adolescents are secretive about their disorders, they may have a sense they do not belong anywhere. In a group, they can enjoy a sense of closeness when they can be open about their troubles, are accepted, and are understood. A study by McConachie et al.

Telegram: @medical_k

www.konkur.in

investigating group therapy for anxiety in children with autism spectrum disorder found that the most helpful strategies were learning alternative coping strategies, sharing experiences, and feeling accepted.

Interpersonal Learning. By working in the here and now of relationships in the group sessions, individuals have an opportunity to address dysfunctional interpersonal difficulties. The group can be a safe place to develop and practice healthy ways of interacting. For example, in a mentalization-based therapy group, teens are often encouraged to discuss when they find other participants' behaviors confusing or distressing so that the behaviors can be understood and improved.

Developmental Factors

Each stage of development has its tasks. Younger children's egocentric focus differs from preadolescents' yearning for same-sex soul mates and from adolescents' empathic, individuating, and affiliative capacities. Understanding the developmental needs and capacities of a set of children or adolescents is necessary for designing and enacting a successful group therapy intervention. A parent-only, group cognitive-behavioral intervention for children with anxiety disorders was used to take advantage of the collaborative working relationship between school-age children and their parents (and of the benefits of parents working together at their common stages of parenting). Aronson delightfully discussed ways in which adolescent developmental issues are addressed in a paper, "Where the Wild Things Are." In it, he likened the journey of Maurice Sendak's Max trying on his new identity—affiliating with peers, individuating, and returning with a new relationship to his family—to psychological processes occurring in adolescent group therapy. Whether the group is a cluster of same-age peers or contains a range of ages, the group interaction can foster developmental stage-appropriate maturation.

Other Factors

Telegram: @medical_k

www.konkur.in

Most geographic areas have an inadequate number of psychotherapists, and most individuals have little surplus money for psychotherapy. The group format uses therapist resources in a lower-cost way to provide care that otherwise might not be available due to a lack of resources.

TECHNIQUES

Gains made in symptom resolution and psychosocial development in groups can result from general therapeutic factors and from learning specific information and skills. Before discussing specific diagnoses and problem-focused interventions, this subsection reviews general technical issues.

Selection of Patients

Number. A typical group contains 6 to 10 members—a size large enough to allow for a rich exchange but small enough to prevent members from being neglected. Having enough at the outset ensures against depletion due to dropouts and absences. Sometimes, goals call for a smaller or larger group. In one treatment study, aggressive young boys practiced coping with being teased. Because of the intensity of the intervention and the potential for strong emotions and behavioral acting out, the interventions were done in triads. On the other hand, Meezan and O'Keefe studied a large-group format used to address abusive and neglectful caregivers and their children. Two or more members of at least two generations of each family met with five to seven other families and four therapists. More change (including a reduced incidence of child abuse and improved child behavior) occurred in the families in the intervention group than in a control group using an individual family treatment. The authors believed that families improved more because they met families who had "been there" and other families who motivated them and encouraged them to change. Families felt that compared to feedback from therapists, feedback from other families was easier to take and helped them the most.

Telegram: @medical_k

www.konkur.in

Describing an inpatient community group of 18 severely disturbed and conduct-disordered boys between the ages of 11 and 16 years, another author remarked that although maintaining structure and creating a safe environment presents a challenge with a large group of disturbed children, the larger group was powerful and a good choice for reluctant participants and those limited in their capacity to share their thoughts and feelings.

Age and Sex. Participants' age defines the nature of the interactions and the structure of the intervention. Some investigators have included children of different ages and have found that members benefit from the interesting modeling and teaching opportunities provided by the family-like grouping. Most often, groups are composed of children at similar developmental levels (e.g., 8 to 12 years and 12 to 18 years). When patients are of elementary school age, mixed-sex groups are often appropriate, especially for the younger grades. For this age group, games and activities can be fun while they facilitate interactions and learning. As the children age, they can tolerate a format increasingly focused on verbal interaction. Children in preadolescence prefer same-sex peers and can be distracted and inhibited by members of the opposite sex. Adolescents enjoy and can use mixed-sex groups again. Mixing highschool–aged adolescents with younger ones may expose the younger children to topics with which they are not comfortable.

Gathering Group Members

Difficulty gathering a cohort of patients at once can impede the initiation of group work. Wood and coworkers studied a group format for treating adolescents who deliberately harm themselves. Sixty-three adolescents who had intentionally injured themselves were randomly assigned to either group therapy along with routine care or routine care alone. The group format was chosen for both clinical and administrative reasons: because poor peer relationships and impaired problem-solving were thought to be amenable to group

Telegram: @medical_k

www.konkur.in

intervention and because group therapy was hoped to decrease the use of individual therapy and train a team of therapists for dealing with self-harm. The authors advanced the field by writing a manual describing necessary complex psychotherapeutic techniques. The manualized therapy—a developmental group psychotherapy—included a variety of techniques, including problem-solving, CBT, positive corrective therapeutic relationships, dialectical behavior therapy (DBT), and psychodynamic group therapy. After the assessment, six acute sessions were followed by long-term group therapy, which was open-ended. Group members could join the groups at any time. The themes of acute sessions included relationships, school problems, peer relationships, family problems, anger management, depression and self-harm, hopelessness, and feelings about the future. While the group therapy did not reduce levels of depression or suicidal thinking, participation in the group (the median number of sessions was 8; the range was 0 to 19) did lead to a change in the incidence of deliberate self-harm and the use of other therapy resources. Those who had more group sessions were less likely to harm themselves again, whereas those who had more individual sessions were more likely to repeat self-harm. This study is interesting not only for the clinical outcome but also for a model for running a continuous group, adding newcomers after a six-session lead-in.

Excluding Patients

Certain individuals in group therapy may undermine the process to the extent that, although the individual might benefit from participating, their detriment to the group calls for exclusion. Particularly in adolescent groups, individuals who actively use drugs may disrupt the group by showing up under the influence or reveling in escapades. When this does not serve the group's goals, these individuals should be excluded. Fragile children and adolescents may experience the group as unduly stressful, thus contraindicating their participation. Most group protocols exclude actively suicidal or psychotic individuals, who may monopolize the leader's attention,

Telegram: @medical_k

www.konkur.in

upset other members, and require the leader to leave the session to appropriately triage the patient. On the other hand, crises and decompensations are part of the territory of treating mentally ill children and adolescents. Witnessing the therapist compassionately and competently handle a troubled peer may be reassuring to a group member. Including an unwilling "captive" member in a group could drag the group down in a mutinous way or, skillfully handled, highlight issues of motivation and personal responsibility for each member.

Investigating the importance of carefully selecting members (considering such factors as level of acting out or ego development), Johnson and Gold sorted 34 latency-aged boys into four groups based on a measured leadership quality score. Groups met weekly for 20 sessions. All group-treated boys improved in popularity ratings and leadership. The authors remarked that the therapist's ability to match techniques to the characteristics of the group members was more important than group composition.

Parents

Parents spend many more hours with their children than the therapists can and are able to influence their children by teaching, shaping, and modeling. A growing literature supports including parents in group interventions, often in parallel parent groups and sometimes as a sole intervention. A University of Michigan group tested the effects of a child-only, child-plus-mother, and waiting-list intervention for children who had witnessed intimate partner violence. The children in the child-only group participated in a 10-week group therapy aimed at increasing their knowledge about families and family violence, managing their emotions, and managing interpersonal conflict. The separate mothers' group taught the mothers about the influence of violence on children's development and worked to improve parenting and disciplinary skills. The child-plus-mother therapy was the most effective in improving externalizing behaviors, with gains continuing after the group ended. When sexually abused children aged 3 to 12 (n = 617) were treated

Telegram: @medical_k

www.konkur.in

using group therapy with a concurrent parent group, it was found that children who participated in the group improved significantly in their symptoms, which included somatic complaints, interpersonal difficulties, psychological state, and behavioral problems. These children were less likely to be revictimized or become sexual offenders, particularly when the parents also attended the group. Parents are an important resource for the reinforcement of skills and psychoeducation taught in groups.

Setting

Group therapies for children typically take place in the clinic or school. The advantages of clinic-based groups include confidentiality and coordination of care. The more available school setting offers the specific advantages of convenience for the children, opportunities for developing friendships with schoolmates who are accessible, and the potential for doing primary prevention work. Some social skill group therapies based in clinics have improved socializing with group members, but results have failed to generalize to school peers. Conducting social skills groups in the schools increases the chance for generalizability of skills. At the time of this writing, most school and clinic work was performed online due to COVID sequestration. Over time, the effectiveness of this distance therapy will be researched and more understood.

Therapist

The effective group psychotherapist understands child development, psychodynamic concepts, characteristics of the child-targeted psychopathology, and facility with the therapeutic intervention. In addition, the therapist needs knowledge of factors particular to groups. The therapist must foster a climate of security, tolerance, and acceptance for differences in feelings and behaviors; be able to control the tensions and anxiety levels in individual group members within acceptable limits; and control group phenomena such as bullying, scapegoating, monopolizing, and instigating. Groups benefit from therapists who are flexible and playful, can regress without

Telegram: @medical_k

www.konkur.in

becoming a peer, have the ability to provide structure in an authoritative (not authoritarian) manner, and provide a good co-therapy relationship. The group therapist must be aware of and contend with their countertransference to the group and its members. As with all countertransference reactions, the therapists' anxiety and resistance can be used to further understand the group process. By analyzing one's countertransference, one can alert oneself to possible enactments. Group resistance may reflect the therapist's own anxiety.

Co-Therapist Relationship

Having more than one therapist expands the capacity for simultaneously processing multiple members' reactions and allows more efficient administration of the group. Having a co-therapist also provides back-up in the event a leader is absent. The co-therapist relationship has been likened to a marriage or sibling relationship: It takes a cooperative, complementary partnership that must withstand multiple potential stressors. Often, co-therapists are individuals with unequal training and experience. The pair must withstand group members responding to them as a parenting duo and/or mentally assigning them good therapist/bad therapist roles. Throughout the therapy session, co-therapists must negotiate the dips and turns of members' (and their own) emotions in front of the group. Witnessing how co-therapists problem-solve together provides the group's child and adolescent members with an opportunity for modeling and recapitulation of the family. The co-therapist relationship requires a respectful, egalitarian stance in which therapists are open to processing their interaction and their reactions to the group. Unfortunately, due to declining reimbursements, co-therapy is becoming less feasible in community settings.

Tools

Creative group therapy tools range from simple games to video interventions and can facilitate the therapeutic process. One author described a low-tech approach—a variation of pass the parcel, in

Telegram: @medical_k

www.konkur.in

which a package is passed around the group for each member to remove a layer of wrapping and answer the question written on it.

Heiman and Ettin used a variety of interesting techniques in a therapy group for sexually abused girls. They began with a puppet-making exercise included to promote disclosure and build group cohesion. Girls built puppets in dyads and used them to introduce each other and as a supportive “friend.” Girls named the group in the second session, a task that began their working together as a group and set the stage for them to take ownership and define the goals of the group. Other tools included a board game that asked questions about specifics of abuse, a coloring book about girls’ rights and bodies, a collage project about girls at different ages used to facilitate a discussion of appropriate sexual behavior at different ages, letter writing to perpetrators to express strong feelings, and throwing into the trash drawings and writings symbolizing things they would like to put into the past.

A group for sexually abused boys made a group flag, which required creativity and compromises that led to group solidarity. This same group rolled a “feelings cube,” which directed them to describe a situation causing a certain feeling, act the feeling out, or answer questions posed by group leaders and members. They made and photographed clay figures portraying their abuse. Each of these tools was chosen to help the girls and boys confront and process difficult issues.

Videos can facilitate learning and discussion in groups for children. Prevention films for sexually abused children can be used to teach self-protection skills. Films of social vignettes can provide a take-off point for discussion and role playing for social skills groups. Watching the video stories together is an efficient teaching medium and provides a shared experience from which discussion can flow in a lively way.

Activities can also serve to introduce levity that promotes camaraderie and communication. In DBT groups, games are often used to enforce mindfulness techniques such as observing one’s feelings and radical acceptance. In one activity, members choose a favorite from a bowl of mixed candies. Then they are asked to pass

Telegram: @medical_k

www.konkur.in

the favorite to the person on their left and mindfully eat the new piece of candy. In a mentalization-based therapy technique, teens are encouraged to “play the doctor” using a stethoscope and dressing in white coats to empower themselves in discussing what they think may be going on in the minds and hearts of other family or group members. Similarly, playing freeze tag where participants “freeze” showing how they look when feeling a certain emotion can help teens understand the concept of the “opaque mind” and illustrates that they can only guess at what goes on in another’s mind. Role play is yet another effective tool to promote perspective taking and communication.

In the era of social media, creating original video recordings can be an exciting developmentally appropriate and available tool. For instance, to consolidate knowledge of information and skills acquired in one anxiety group, members chose to make an instructional video. In one report, therapists introduced a continuously recording video camera to a group to spark group interest when it was waning. They observed that the camera’s eye acted as both an additional group member and as a transference object.

Food, obviously symbolically and physically nurturing, may be included in group therapies for practical and therapeutic reasons. Children coming to the clinic after school may be hungry and feeding them may help to improve their attention. Some treatment protocols use a snack break to allow practice in a less structured socializing for socially phobic or impulsive children. Others use food as reinforcement for specific behaviors. The group therapist must decide whether the distraction caused by food is a reasonable cost for the gained therapeutic benefit.

Length of Intervention

The rate of improvement is greatest in early therapy sessions. With increased emphasis on cost containment and measuring outcome, most recent group therapies are scheduled to last only between 8 and 12 sessions. Therapeutic factors may also call for time-limited work. Formally dividing time into phases like introductory/group

Telegram: @medical_k

www.konkur.in

forming, working, and consolidation/termination phases may help with focus and momentum. This is not to say that longer interventions are not beneficial. For some children, more sessions are needed before there is significant improvement, still others benefit from more time for reinforcement of learning and perhaps taking on of leadership roles.

Group Rules

For individuals to feel safe in taking the risks necessary for change and for therapists and group members to serve multiple individuals' needs, groups need rules. Developing a set of rules is usually a group activity early in the intervention. Fairly universal rules include those regarding confidentiality, personal safety, attendance, not coming to the group while intoxicated, and respecting others. Deblinger notes that the use of praise, reflective listening, selective attention, positive reinforcement, and negative consequences such as time-out may improve focus in more unruly groups. While, at first glance, prohibiting socializing with other group members outside of sessions may seem unnecessary, it has proven consistently to be an important rule. For example, after members of a structured adolescent cognitive-behavioral group met with each other outside of the group, one member left the group, uncomfortable with feeling pursued by the other and others felt left out. Members of a trichotillomania group requested permission to use instant messaging on the internet to seek support from each other when they had urges to pull. Although most felt that this was helpful, some eventually desisted, feeling that boundaries were impinged on.

Family Involvement

Families may be involved in group therapies for children and adolescents in a variety of ways: they may be included with the children in the session (multifamily group), in parallel parent groups, with families included in parts of each session, certain sessions, or not included at all. Childhood anxiety disorder researchers have examined the role of family involvement in treating anxious children.

Telegram: @medical_k

www.konkur.in

One study compared outcomes of group therapy in three conditions: parent-and-child parallel group therapies, a child-only intervention, and a parent-only intervention. Its authors found that, although all groups improved, those children in the parent-and-child parallel group intervention used new coping strategies more actively outside of the group. Barrett and coworkers included parents in group therapy for anxiety disorders because the parents were at increased risk for having anxiety disorders and because the therapists believed that family interactions play a major role in the development of children's anxiety. They randomly assigned 79 children to group CBT, group CBT with family involvement, and wait-list control. The family component encouraged parents to reinforce courageous behavior and ignore excessive complaining and anxious behavior and it taught them communication and problem-solving skills to deal successfully with their children's emotional upsets and anxieties. After treatment and 1 year later, those in the combined-treatment group had a better outcome than those in the child-only condition (95% diagnosis-free vs. 70%).

Similarly, in a recent multi-center randomized controlled trial by Scholten et al., parent involvement in group therapy for children with chronic illnesses did reveal additional positive effects on parent-reported internalizing, child-reported externalizing, information seeking, and social competence, when compared to the child-only arm. Parental involvement also appeared to contribute to durability of improvement.

Process in the Structured Group

Group therapies increasingly use structured and manualized treatment protocols. Critics and skeptics of manualized treatment fear that therapy from a manual will be stiff and "cookie-cutter." Kendall, who developed the first manual for treating childhood anxiety disorders, the Coping Cat, noted that the therapist cannot be a "cookbook" therapist but must have a sound understanding of the theory behind the intervention and adequate flexibility and creativity to use the tools in a way that suits the needs of each patient.

Telegram: @medical_k

www.konkur.in

Manuals and outlines of therapy interventions inform and guide but do not control the group therapist. The therapist will lose effectiveness and opportunities to help if they ignore psychodynamic forces and other resistances to treatment. In an article on group therapy for sexual abuse patients, Heiman and Ettin stated that group dynamics and collective process do not disappear even within a highly structured psychoeducational group. If group members' affective reactions are not monitored and the collective dynamics are not acknowledged, then the group curriculum may have little impact. Especially in a group of adolescents, joining is crucial to promote learning. In some cases, the group process can act to disrupt the viability and stability of the group. For example, if a group member decides that a game or activity is silly, it may be difficult to have the rest of the group participate. At times, it may be necessary to pull such an individual out of the group to explore their reasons for disagreement or isolation and encourage rejoining. Group processes can be harnessed to maximize therapeutic impact. By responding to the messages underlying children's behaviors, rather than suppressing them, an opportunity exists to respond and transform the function of children's actions and maximize the efficacy of structured activities.

CLINICAL ISSUES

Indications

Group therapy should be considered if the child or adolescent has a condition for which there is evidence that group therapy is effective. This subsection provides descriptions of empirically supported group therapy interventions for specific pediatric populations. Rather than being an exhaustive review of all reported studies, it presents examples of treatments with support to describe the treatment elements and factors that made group therapy the choice. For some children, group therapy alone may be sufficient, whereas others require concomitant pharmacologic, individual, or family intervention.

Telegram: @medical_k

www.konkur.in

Addiction, Substance Abuse. Many interventions for substance abuse are in use, many with little empirical support. Exposure to a credible peer: the type of peer who could be a negative influence under other circumstances, but, when seen in the therapy where each has a goal of not using may be helpful through positive modeling, positive reinforcement, and an alternative peer group.

The mutual self-help groups, Alcoholics Anonymous (AA) and Narcotics Anonymous (NA) may be a cost-effective option for supporting treatment gains for some substance-abusing adolescents; one study reported a decrement in health care costs over 7 years of 4.7% for each session attended! While a number of researched treatment programs have up to moderate effect sizes, the rate of relapse is high. Participation in AA and NA improves abstinence and recovery in a dose-dependent way. Research suggests that general group elements, including meeting others with similar troubles, learning from others' experiences, receiving encouragement, hope and support are powerful contributing factors. In a review, Nash notes that initially, adolescents gain most from participation with same-age peers, with peers improving the likelihood of engagement. Later, adolescents have been found to improve more in groups that also include older members. Research has elucidated particular potential barriers for adolescent participation in 12-step groups: adolescents may not see substance use as a problem due to short duration of use and the feeling that they do not need help. Adolescents' developmental need for autonomy may not mesh with accepting powerlessness against a problem; limited insight and enjoyment of substance use may not align with considering lifelong abstinence. Finding peer role models may be important to buy-in and continuing participation. For instance, Kelly and colleagues followed 160 adolescents at intervals for 8 years (84%) after an in-patient stay for substance abuse. They found that a high initial program participation dropped consistency over the 8 years. Those who attended most were with those with more episodes of alcohol intoxication and those who felt they had a problem with alcohol. Those attending most frequently during the first year had significantly better outcomes over the 8-year duration

Telegram: @medical_k

www.konkur.in

of the study. Those who perceived that they could use alcohol in moderation attended fewer groups and were consistently less abstinent. The data suggested that in adolescents with substance abuse, attendance at one or two AA meetings per week increased abstinence and that attending at a frequency of three times per week was associated with *complete* abstinence. The authors speculated that the mutual self-help group model succeeds because it may help maintain motivation, provide a new social context of sober peers, enhance coping skills and improve self-efficacy. Nash summarized, "Though not the only model for post-treatment recovery support, research to date suggests that similar to adults, adolescents' involvement in 12-step groups predicts improved AOD use outcomes, and greater participation (i.e., frequency, duration, and extent of involvement) predicts abstinence and SUD remission better than attendance alone."

With the internet being one of the most commonly used methods of communication and entertainment (and, in COVID sequestration times, school) internet "addictions" are emerging among adolescents. There have been growing concerns that online video game play may be addictive and invite people to escape from their problems or daily responsibilities. Snodgrass and coworkers sought to explore some of these concerns using the online game World of Warcraft (WoW), played by groups of people regularly, simultaneously, internationally, and day and night. They also investigated online gamers' motivation, looking at the factors of achievement, social connectivity, and immersion factors that tend to foster problematic play in the online worlds. "Achievement" refers to competitiveness drawing players deeper into game, where they spend more time online than they might wish. "Social connectiveness" refers to getting drawn into communities or associations that also demand more of their time. "Immersive play" refers to players who not only temporarily escape but more persistently or maladaptively avoid real-world problems. Researchers conducted 30 formal interviews and 252 people participated in a web survey. Results showed that subjects' online play could be a source of distress in their lives. They also showed

Telegram: @medical_k

www.konkur.in

that players lacking high levels of offline success (i.e., good job, high income, having a good social network of family and friends) may attempt to compensate by playing excessively and players *with* high levels of offline success are less likely to overplay. Players who experienced dissociation (losing track of the real world while immersed in the virtual world) were more likely to have problematic play. Playing multiplayer WoW to gain a sense of social connectiveness correlated with such dissociation and problematic play. While WoW group interaction can be problematic when players, who dissociate too fully and lose themselves in the virtual world of WoW, use it as a primary social outlet, thereby risking more problematic behaviors both online and offline.

Du and colleagues used a school-based, multimodal cognitive-behavioral group therapy to treat internet addiction in adolescents. Fifty-six adolescents aged 12 to 17 (with their parents and teachers) were randomly assigned to group therapy or a control group. Group CBT involved 6 to 10 students participating in an eight, 1.5-to-2-hour session group CBT run by two child and adolescent psychiatrists simultaneously with parent group therapy. Teachers attended workshops that included didactics, discussion of cases, and role plays. Groups focused on recognizing and managing one's feelings, fostering healthy family communication, strengthening relationship skills, using the internet in a healthier way, controlling one's impulses, recognizing when behavior is becoming addictive, and coming up with ways to stop addictive behavior. Parents also learned skills to improve emotional awareness and behavior, communication, problem-solving techniques, and managing adolescents with internet addiction. After the intervention, and 6 months later, the intervention group demonstrated better time management skills. As well, the treatment group showed large effect sizes for improvement in anxiety which is important, as anxiety is often associated with internet addiction and emotion and behavior regulation.

Aggression/Conduct Disorder. Children who are aggressive and have conduct disorder have social difficulties, especially in frustrating circumstances. Concerned that parent training for oppositional

Telegram: @medical_k

www.konkur.in

defiant and conduct disorder did not help all families or generalize to school, Wester-Stratton and coworkers designed a social skills and problem-solving training protocol (Incredible Years: Dinosaur Curriculum) for children between the ages of 4 and 8 years. The investigators used the group as a supervised place to practice social skills. Ninety-nine children with the diagnosis of Oppositional Defiant or Conduct Disorder were randomly assigned to a control condition or a group intervention that included directly taught social skills, problem solving, and anger management. Groups of five or six children met weekly for approximately 6 months. Children in the treatment condition watched videotaped vignettes of children coping with stressful situations. They discussed the vignettes and collaborated to practice a repertoire of acceptable solutions and coping skills. They also discussed feelings they had about troubles caused by their own behaviors. To enhance motivation, attention, and learning and provide a developmentally appropriate milieu, therapists used puppets, cue cards, coloring books, small reinforcements, group activities, and games. The treatment group demonstrated more significant clinical improvement in conduct problems as rated by parents and teachers. Those gains were persisted at 1-year follow-up. The authors noted that many of the children made their first good friends in the group therapy and postulated that intervention might be even more effective if delivered in the subjects' actual peer setting.

In response to a paucity of resources for treating conduct disorder in South Africa and in the hope that group cognitive-behavioral treatment could help children and adolescents with conduct disorder to respond more appropriately to social situations, a group of investigators designed and studied a 12-week intervention program. An occupational therapist and a psychology student were trained and supervised by an experienced adolescent group therapist. The sessions included: (1) an overview of rules, expectations, and rewards; (2) teaching problem solving/decision making; (3) impulse control, response gap thinking; (4) assertiveness training; (5) requesting behavior change; (6) reward session; (7) empathy, perspective taking; (8) sex differences, interactions, relationships; (9)

Telegram: @medical_k

www.konkur.in

sex education video, relationships; (10) norms, values, role models; (11) giving compliments; and (12) closure. Parents of treated and control subjects were invited to six sessions of parent behavior management training. The treatment group showed significant improvement in defiance, physical aggression, and delinquent aggression posttreatment and at 6 months, whereas the control group demonstrated improvement only in defiance and a remarkable increase in truancy. The authors noted that this brief intervention using community workers showed promise as a sustainable intervention.

Attention-Deficit/Hyperactivity Disorder. Although the Multimodal Treatment Study demonstrated that stimulant medication is the treatment of choice for uncomplicated attention-deficit/hyperactivity disorder (ADHD), children with greater difficulties may require additional psychosocial interventions to optimize function. Willis and colleagues summarized that socially, children with ADHD are often disruptive and/or developmentally inappropriate, act impulsively and in a self-centered way, and are less sharing, turn-taking, and cooperative than other children. They also demonstrate deficits in social cognition, perspective taking, and social problem solving—all of which may alienate peers, who may see them as immature, intrusive, and/or inept. Moreover, children with ADHD do not realize these things; peer relationships may represent their greatest impairments.

Hinshaw and coworkers designed a CBT intervention for boys with hyperactivity, including peers for practicing social skills. An initial study compared outcomes for a group CBT intervention for boys between the ages of 8 and 13 years treated with methylphenidate or placebo. A second study compared the treatment on a daily basis in the context of an intense summer program with a psychoeducational intervention. In each, the boys were first taught problem-solving strategies: (1) define the goal or problem, (2) generate multiple solutions, (3) consider the outcome of the various solutions, and (4) choose and operationalize a behavior. In groups of 3, the boys first practiced applying these problem-solving strategies to a series of

Telegram: @medical_k

www.konkur.in

academic and fine-motor tasks; then they applied them to interpersonal problem vignettes. Practicing recognizing signs of anger, rehearsing strategies for dealing with provocation, and then maintaining self-control while experiencing planned provocation in the form of teasing from group peers and group leaders improved significantly in the group intervention and with medication, significantly more than the psychoeducation only subset.

Post hoc analysis suggested that children who had more experience seeing peers model coping behaviors in the group benefited most.

Pfiffner and McBurnett randomized 27 children with ADHD to receive an 8-week group social skills training—with either a parent group and teacher feedback, or wait-list control. A group format was selected so children could practice newly learned social skills and receive social reinforcement from peers. Children reported on their behavior points earned during the week, pooled their points for a group pizza party, role-played specific social skills with immediate peer feedback on performance, and shared fun activities. Evaluation after several months supported the utility of social skills training, with or without parents' and teachers' involvement. The authors noted that strong group reinforcement in a stimulating, developmentally appropriate program led to significant improvements in social skills and problem behavior.

Hoping to improve chronic management of ADHD, a larger (71 subjects in 3 clinics completing) controlled study compared a monthly group therapy intervention with a computerized clinician decision support system, the Child Health Improvement through Computer Automation (CHICA). CHICA promotes clinicians' adherence to clinical care guidelines for ADHD. Up to nine families per group participated in a 60-minute group discussion followed by a 30-minute medication visit, with parents and children in separate, simultaneous sessions, scheduled at the end of the day. The authors randomized treatments to sites, acknowledging the system-level changes necessary for personnel and scheduling. The parent group intervention included psychoeducation about ADHD, educational advocacy, and positive parenting strategies; the child intervention

Telegram: @medical_k

www.konkur.in

also included psychoeducation and reflection on ADHD's impact, and what they saw as strengths and challenges for themselves. Compared to those in individual therapy with therapist participation in CHICA, families in the group improved in measured outcomes: they attended more visits over 12 months, experienced better parental emotional health, had fewer challenges related to misbehavior, reported significant improvements in child functioning at home and more time for themselves, other siblings, and routine household activities. Unfortunately, children receiving individual intervention reported a significant drop in mean emotional health. Bauer and colleagues, in this extension of earlier work, concluded that, especially with nearly half of children with ADHD being managed in primary care, group intervention in the familiar primary care clinic may carry less stigma and serve as an effective adjunct to competent medication management, filling a gap between primary and specific mental health care services.

Willis and colleagues, in a recent review of studies of stand-alone social skills training for children with ADHD, while expressing concern about the degree of current studies' rigor, still suggested that parent training is beneficial. They noted that the most powerful elements included emphasizing to parents that they, as parents, have important roles as their children's social skill educators and peer relationships coaches. Reviewers also endorsed the concept of simultaneous parallel parent and child sessions and recommended maximizing opportunities for positive peer interactions, even making friends. The review suggested that targeting the child's natural peer group to increase inclusiveness of the child outside the group setting (such as at school) would help.

Anxiety. Avoidance, social isolation, and difficulty with social skills are significant troubles for most anxious children and adolescents. An opportunity for direct exposure to peers, practicing social interaction, and receiving social support and reinforcement make group therapy a theoretically attractive treatment modality for anxious youth.

Telegram: @medical_k

www.konkur.in

In 1998, Barrett reported the results of a CBT group for anxious children and their families. The manual-based treatment focused on providing children and families with skills in managing anxiety and avoidance, problem-solving, and mutual family support. Posttreatment and 12 months later, 65% of children in the child-only group, 85% of those in the group with family involvement, and 25% of the wait-list control group were free of diagnosis. Silverman and coworkers also compared a group intervention for anxious children and their parents to a wait-list control group. They considered the disadvantages of group therapy—dampening of the therapist–child relationship, overly taxed therapist resources, and possible negative modeling—along with possible advantages. Sixty-four percent of the treated subjects versus 13% of the wait-listed subjects were free of their primary diagnosis posttreatment. At 6 months, 79% of the treated group no longer had their primary anxiety diagnosis.

Beidel compared a combined 12-week group and individual treatment for latency-age social anxiety disorder with an active control condition—the Test Busters study skills protocol. The treatment condition consisted of child and parent education about social anxiety, social skills training, peer generalization experiences, and in vivo exposure. In the group social-skills training component, children learned about greetings, starting conversations, maintaining conversations, listening and remembering skills, skills for joining groups, positive assertion, negative assertion, telephone skills, using instruction, modeling, behavioral rehearsal, corrective feedback, and homework. Immediately after the social skills training session, the anxious children joined a group of not-anxious peers for a 90-minute “fun” unstructured group activity (such as bowling or in-line skating). Each week, the children met individually with the therapist to engage in exposure activities, practicing a single task, such as reading aloud in front of others. In this treatment, investigators thoughtfully combined two forms of group intervention and an individual session. The first part allowed for economic use of resources for teaching and an opportunity to practice skills in a structured session. The second part, an unstructured group activity, included non-affected peers and provided an opportunity to expand on and generalize the skills in a

Telegram: @medical_k

www.konkur.in

more challenging situation. The individual exposure session allowed for customized, individual, symptom-driven intervention. At the end of the group, 67% of those in the treatment condition and 5% in the study skills condition no longer met diagnostic criteria for social anxiety disorder—with gains maintained at 6 months.

A Cochrane Database of Systematic Reviews of CBT for anxiety disorders in children and adolescents in 2015 reviewed 41 studies of adequate quality with a total of 1,806 participants. It concluded that CBT is significantly more effective (60%) than no therapy (waiting list, 16%) in reducing symptoms of anxiety in children and young people. Group, individual, with and without parent therapy formats were indistinguishable in their outcome. CBT was found no more effective than other "active therapies" such as psychoeducation, other supportive interventions, bibliotherapy, and treatment as usual. This suggests that group therapy for childhood anxiety is as effective as other active interventions, and it may offer the advantage of lower cost. It also points to the need for a better understanding of what makes treatment effects more durable.

Bereavement. Universality may be an especially powerful therapeutic factor in groups gathered to deal with loss. Pfeffer and coworkers used manual-based group therapy to assist children after the suicide of a parent or sibling. Families of children between the ages of 6 and 15 years were contacted within 3 weeks of the suicide death of a parent or sibling and were randomly assigned to receive or not receive intervention. Children with psychiatric diagnoses were excluded. The intervention consisted of ten 1.5-hour weekly group sessions of two to five children within 3 years of age of each other, with simultaneous parent groups. The children's curriculum consisted of offering psychoeducation about death and its permanence, identifying feelings of grief, defining what suicide is, and discussing why people commit suicide. Children's groups discussed preventing suicidal urges and presented problem-solving skills. The therapy facilitated expressions of grief and promoted identification with the positive aspects of the deceased. Parents learned about childhood bereavement, learned to help their children

Telegram: @medical_k

www.konkur.in

express their grief and discuss the suicide, learned to identify morbid reactions in the children, and learned to promote children's healthy functioning. The parents' grieving was also supported. Children in the therapy developed new supportive relationships. They showed greater reductions in anxiety and depression than did the nonintervention children.

Depression. Group therapy is among the most empirically supported therapies for adolescent depression. A large study compared group CBT, group CBT with families, and a wait-list control group and three intensities of follow-up care for depressed adolescents. One hundred and twenty-three adolescents with major depression were randomly assigned to 16 sessions of group CBT, group CBT, plus nine sessions of a parent group or a waitlist. Mixed-gender groups of up to 10 adolescents met for 2 hours twice weekly for 8 weeks. The therapy used a manual and workbooks and taught skills of mood monitoring, improving social skills, increasing pleasant activities, decreasing anxiety, and depressogenic thoughts, and improving communication and conflict resolution. In the parent condition, parents reviewed the adolescent course content and met once per week and twice jointly with the adolescents. Posttreatment, 67% of treated and 48% of wait-listed subjects were diagnosis free. Neither parental involvement nor booster sessions made a significant difference in the measured outcome.

Hypothesizing that treating depressed Latino youth in groups would be successful, researchers recently compared group and individual CBT and interpersonal therapies (IPTs). Authors considered that Puerto Rican cultural value placed on *personalismo* (preference for personal contact in social situations) and *familismo* (placing the interest of the family over the individual) would be served in the group therapy format. Analysis of outcome favored CBT over IPT, which may have resulted from its increased structure and directiveness (consistent with *respeto*) and found results to be similar in the individual and group formats.

Stallard and coworkers designed a clinical and cost-effective study of classroom-based CBT for depression in high-risk adolescents. Of

Telegram: @medical_k

www.konkur.in

the 5,030 students that were asked to participate, 1,064 adolescents aged 12 to 16 years old were considered high risk and were randomized to a CBT group, the usual school curriculum: Personal, Social, and Health Education (PSHE) delivered by teachers, or an attention control group (the usual school PSHE with two additional facilitators). This study examined whether these preventative interventions for depressive symptoms could be both clinically effective and cost-effective. All three groups showed decreased depression scores with no significant differences between groups. Because it required trained therapists, classroom-based CBT was not shown to be cost-effective compared to the teacher-administered groups. The study did suggest that a preventive school-based group intervention could decrease adolescents' degree of depressive symptoms.

Internet-based interventions may be useful in decreasing social isolation, which may contribute to depression. Van der Zanden et al. studied a treatment that involved groups of six or fewer people aged 16 to 25 in 90-minute chat-room therapy sessions. Participants were randomly assigned to this online cognitive-behavioral group course known as Master Your Mood (Grip op Je Dip) and a wait-list control group. The therapy focused on restructuring thinking patterns by recognizing one's unproductive, unrealistic thoughts and transforming them into more helpful, realistic thoughts. Performance of daily activities and mood monitoring were also done. Reductions in depression and anxiety and an increased sense of mastery were seen after intervention and at 3-month and 6-month follow-ups.

A functional MRI study by Straub and colleagues found alterations in the strengths of brain area connectivity after only 5 sessions of group psychotherapy for 19 depressed adolescents. Compared to controls, after therapy, depressed adolescents demonstrated a change in functional connectivity consistent with their clinical improvement; conductivity changes were consistent with decreased rumination and self-referential processing and increased cognitive control.

www.konkur.in

Suicidality, Self-Harm, Borderline Personality Disorder Traits. DBT is the first well-established, empirically supported treatment for decreasing repeated suicide attempts and self-harm in youths.

Two independent randomized controlled trials with diverse samples of 250 self-harming youths have demonstrated that DBT is effective in reducing self-harm in adolescents. Recently, McCauley and colleagues in Washington State, California, Pennsylvania, and Texas compared two manualized therapies: Dialectical Behavioral Therapy and Individual and Group Supportive Therapy (IGST), each of which employ individual and group elements, with adolescents at high risk for suicide. DBT aims to teach patients skills and encourages the employment of those skills. The DBT intervention is comprised of weekly multifamily group meetings and daily patient diary cards for teaching DBT skills, weekly individual sessions to reinforce engagement and skill use, up to seven family sessions, weekly therapist team consultation, and 24-hour brief crisis coaching. DBT uses mindfulness and CBT skills to enhance emotion regulation, distress tolerance, and building a life worth living. IGST is a manualized supportive therapy that considers “thwarted belongingness” as a suicide risk factor; IGST emphasizes acceptance, validation, and feelings of connectedness and belonging. IGST contained the same therapeutic intervention types (minus diary cards) as DBT.

173 adolescents who had attempted suicide, had self-harmed more than 3 times, rated high on suicidal ideation, or had more than 3 diagnostic criteria for borderline personality were randomized to DBT or IGST, then treated for 6 months, and followed up for 1 year. The authors postulated that the DBT treatment’s greater family involvement, with all learning coping skills, may have been responsible for its advantage.

Eating Disorders. Outpatient group therapy for eating disorders (EDs) has hardly been examined. Heinicke and colleagues did complete a study of manualized group therapy for girls who identified themselves as having disordered eating, using a self-help manual, My Body, My Life: Body Image Program for Adolescent Girls, in

Telegram: @medical_k

www.konkur.in

which subjects were asked to read and complete contained activities each session. The intervention consisted of six weekly group sessions facilitated by a trained therapist and postintervention sessions at 2-month and 6-month follow-ups. Seventy-three adolescent girls were randomized to the intervention group or delayed treatment. The 28 girls who completed the intervention showed improvements in body dissatisfaction, disordered eating, and depression postintervention and at 2-month and 6-month follow-ups.

Many individuals with EDs participate in group therapies in the context of residential ED treatment programs, which generally have large effect sizes on ED pathology. Group therapies may include daily process groups, topic-focused groups on ED symptoms, creative arts therapy, nutritional counseling, trauma, and substance use-focused therapy groups, group exposure for food, body image (e.g., mirror exposure), and co-occurring emotional problems. Detangling the effects of group therapy from individual therapy and other aspects of residential treatment seems very difficult. Thompson-Brenner and colleagues worked to implement the Unified Protocol for Transdiagnostic Treatment of Emotional Disorders (UPTTED) at 2 residential and 14 partial hospitalization sites, following 616 patients (mean age 26 +/– 11 years) with anorexia nervosa, bulimia nervosa, and ED not otherwise specified over 3 years. Transdiagnostic approach elements include motivation enhancement, mindfulness and emotion awareness, cognitive appraisal and reappraisal, addressing maladaptive avoidance, developing interoceptive awareness, and emotion exposures. After the implementation of UPTTED, individuals improved significantly in experiential avoidance, anxiety sensitivity, and mindfulness. Groups assessed before and after UPTTED was instituted had large positive effects on depression and ED symptoms at discharge, with postimplementation UTM patients showing larger reductions in ED and depressive symptoms and pre-UTTED patients worsening at 6 months follow-up. Length of stay had a significant positive effect on symptoms, experiential avoidance, anxiety sensitivity, and mindfulness. This study adds to the literature in its effort to examine

Telegram: @medical_k

www.konkur.in

the effects of residential treatment in a systematic way and to address psychopathology using an accepted transdiagnostic psychotherapy.

Gender Identity Issues. Choosing group therapy to address shame and isolation, Rosenberg used supportive group therapy as a component of treatment for children with gender identity issues. In a case report, she described her regimen of individual plus group treatment for working with 12 children and their parents. All but one child had comorbid symptoms of anxiety, inattention, and social isolation. Each of the children had been taunted and derided. The child group component of treatment was proposed to help self-esteem through the experience of universality. In the parent group, parents expressed relief to talk openly, for the first time, about their children. They shared their experiences and fears that their children might be harmed physically, emotionally, or by sexually transmitted illnesses. They were coached on ways to interact assertively with school personnel, friends, families, and neighbors and on how to access resources. The author reported that the children made significant clinical improvements in comorbid symptoms. The author of this 2002 study noted, “None of these children abandoned their stereotypically cross-gender interests, but they added gender-syntonic interests. All of the children in treatment for several months or more begin to express acceptance of their biologic gender.” A recent World Professional Association for Transgender Health Standards of Care notes that 6% to 27% of prepubertal children who were referred to clinics for assessment of gender dysphoria had dysphoria that persisted into adulthood.

Menvielle and Tuerk also reported the benefits of a group for parents of non–gender-conforming children. In the monthly parent support group, therapists focused on child themes and parent themes. Discussions focused on reducing the polarity of gender-based interests (girl stuff vs. boy stuff), communicating acceptance of the child’s thoughts and feelings about gender and interests, setting limits on behaviors that invite trouble, facilitating peer relationships, dealing with bullying, and discussing the possibility that

Telegram: @medical_k

www.konkur.in

the child will be homosexual as an adult. Parent-focused themes included helping parents to grieve, developing coping mechanisms for dealing with embarrassing situations, and learning to intervene when necessary in social and school situations. The authors noted that the group helped to destigmatize the nonconformity for parents and that humor helped the group to build cohesiveness and reduce tension, elicited compassion, and provided insights.

Improving Adherence to Medical Regimens in Chronic Illness. Parents of children with chronic illnesses must deal with many demands: attending to their sick children, dealing with insurance and the health care system, continuing to work their jobs, caring for the rest of their families, and struggling with their own emotions. In New Zealand, investigators developed and tested a Strong Parents–Strong Children 6-week group intervention to help parents to manage these stresses and learn practical skills for accessing services. Parents learned to plan time for themselves, address catastrophizing cognitive distortions, and use relaxation techniques. They practiced strategies for obtaining and sharing information from relevant health professionals and maintaining family life and social contacts with the goal of handing off aspects of illness management to the child when developmentally appropriate. Parents who participated in the group perceived themselves as more effective and more able to manage stress and perceived the family as more cohesive, less anxious, and better able to cope than those on the waiting list.

For some adolescents, adherence to life-saving medical regimens is poor. Some preliminary studies suggest that treating adolescents in groups together with parent or “treatment buddy” involvement may help. Viner and colleagues compared a measure of diabetes control (hemoglobin A1c) in adolescents who elected group therapy with that in adolescents who were assessed but declined therapy. The intervention consisted of motivational enhancement therapy, analysis of strategies that help (solution-focused therapy), and a parallel parent group. Those treated in group therapy improved in glucose. A “treatment buddy” model also led to improved antiviral medication

Telegram: @medical_k

www.konkur.in

regimen adherence in a pilot of a group intervention involving adolescents; nearly all participants increased adherence to medication, as well as other important health behaviors.

Obsessive Compulsive Disorder. Recent years have seen the development of a number of centers offering intensive group-based CBT with family involvement for children with OCD. An intensive outpatient program for children with OCD and social anxiety disorders at McLean engages children in group psychoeducation, unstructured group snack time, and group exposure therapy, where participants work on their particular exposures 4 days per week. Other weekly sessions include exposure therapy in a public setting, a caregiver guidance group, and a multifamily group. Six patients participated per group meeting for a minimum of 4 weeks, after which children and their parents reported that children's functioning had improved at school, at home, and in social environments.

Youth with severe OCD are also treated within residential treatment programs. In one, Rogers Memorial, patients participate in 27 hours of exposure therapy per week alone and with staff, with process groups and school on weekdays, and experiential therapy groups several times per week. An examination of outcomes found that participation in the program (average 78 days) was associated with improvement in OCD and depressive symptoms. Anecdotally, a number of participants have reported that meeting and living with other adolescents with OCD was significantly helpful to them.

Posttraumatic Stress Disorder/Sexual Abuse. Group therapies are widely used to treat individuals who have been traumatized by molestation or other events. In an Indonesian community plagued by poverty and a decade of armed violence between religious groups, Tol and colleagues introduced a 15-session school-based intervention administered in schools by volunteers with no formal mental health training. The manualized CBT protocol included 18 group sessions, with an individual pull-out session to establish a stimulus hierarchy at week 10. Elements included an overview, information gathering, group rules, relaxation training, anger

Telegram: @medical_k

www.konkur.in

management through problem-solving, examination of self-talk and cognitive restructuring around PTSD, the introduction of a narrative about the trauma, imaginal and in vivo exposure, confrontation of PTSD-induced dysfunctional beliefs, summary, and graduation party. Subjects treated with trauma-processing activities, cooperative play, and creative-expressive elements improved and maintained improvement over 6 months in measurements of posttraumatic stress disorder (PTSD) symptoms and hope in the setting of continued environmental conflict and stress. Girls showed greater improvement than boys. The authors concluded that a classroom-based intervention could be an appropriate approach to target large numbers of children with stress-related symptoms, in which the start dates but not the psychometric assessment dates were staggered. The authors hoped that such time-limited manualized treatment might help in situations of severe natural or human traumas.

British investigators Trowell and coworkers randomly assigned 71 symptomatic, sexually abused girls between the ages of 6 and 14 to participate in either 30 sessions of manualized, focused, weekly individual psychoanalytic therapy or 18 sessions of manualized psychoeducational and psychotherapeutic group psychotherapy (hours spent in therapy were comparable). In the individual psychoanalytic therapy condition, play materials were provided, and topics to be addressed were designated in the manual, but the topics were addressed as they arose, and each was covered. The group topics were prearranged with notebooks, task sheets, and play material. Time was also allowed to address the relationships between the girls and their relationships with the co-therapists, and this was linked to past and current relationships, losses, and disruptions. The outcome was measured posttreatment at 1 and 2 years. Individually treated subjects had significantly greater improvements in PTSD symptoms. Each treatment led to improvement in general functioning and in anxiety and depressive symptoms.

Deblinger and coworkers performed a randomized comparison study of group supportive versus group CBT for young children who had been sexually abused and their mothers. The interventions

Telegram: @medical_k

www.konkur.in

aimed to improve the adjustment of the children by helping them to learn to communicate their feelings, identify inappropriate touching, and learn abuse response skills. In the children's support group, the material was presented in a didactic format. The children's CBT format was interactive, using a workbook, role play, behavioral rehearsal, and joint parent–child exercises. In groups parallel to the children's, the parents were randomly assigned to cognitive-behavioral group therapy or support groups. In the CBT condition, parents were assisted in coping with their emotional reactions to the abuse and their children, taught about effective communication with their children in general and about sexual abuse, and provided behavior management skills. The support group was run with a manual guiding the therapist with skills of active listening, unconditional positive regard, reflecting feelings and empathy, and providing information about group dynamics. The magnitudes of effect sizes for changes posttreatment and at 3 months for children and mothers who participated in the CBT groups were large on most measures. For the support group subjects, the effect sizes were medium. Parents in CBT expressed greater satisfaction with the therapy. Children in the cognitive-behavioral groups (which used interactive behavioral methods) demonstrated greater knowledge and retention of body safety skills.

In the specific context of child sexual abuse, group psychotherapy might be considered a "treatment of choice" because of its impact on the negative effects of sexual abuse: isolation, stigma, and self-esteem. The group format can foster a sense of belonging among peers and help overcome the element of secrecy, which is a common component of child sexual abuse. Group and individual treatments of sexually abused children and adolescents have now been found to be equally efficacious, finding that the adjusted expense of individual therapy is 64% more than group treatment formats. However, a 2016 Cochrane review of child therapies and adolescent therapies for PTSD with a variety of traumas found that the evidence for psychological therapies versus treatment, as usual, was low overall for longer-term outcome but found that the effectiveness of CBT in decreasing PTSD symptoms was moderate

Telegram: @medical_k

www.konkur.in

in the short term. The review found no difference in the change of symptom scores between group and individual therapy. As with most psychotherapies, well-designed studies with well-defined populations looking for moderators of change are needed.

Social Skills. Group treatment settings provide obvious opportunities for learning and practicing social skills. Children and adolescents with various disorders may have impaired ability to perceive important aspects of social intercourse, deficient knowledge of what to do to interact effectively, and/or ineffective means of being with others. Social skills have been reported to improve using therapy in groups for children and adolescents with autism spectrum disorder, aggression, or ADHD.

Kolko and coworkers described one model that illustrates the use of many child group therapy components. Targeting social perception, knowledge of social rules, and peer group behavior in hospitalized boys with ADHD and conduct disorders, compared outcomes of three times per week, 5-week group social skills training with social activity group participation. Fifty-six boys were assessed by self-report on assertiveness and loneliness, by staff reports on social problems and social acceptance by peers, and by peers on popularity. The subjects were rated on 15 role-plays for competence and on behavioral observations that detailed social involvement, gaze, physical space, appropriate voice loudness and inflection, using openers and compliments, making assertive requests, responses to provocations, and appropriate play. In each session, group rules were read, the last lesson was reviewed, and questions were asked to assess retention. Skills training was accomplished by reviewing and rating videotaped role plays of situations handled correctly and incorrectly. Incorrectly played situations were correctly role-played, discussed, and then rehearsed in the group. Points earned in the unit's token economy were recorded in the group. Outside the group, a "Secret Agent" awarded stars when the group members were caught appropriately putting the skill learned into action.

Telegram: @medical_k

www.konkur.in

However, the Cochran Database in 2019 reviewed 25 randomized trials of social skills treatment programs involving 2,690 participants. Each study had methodologic issues. Analysis revealed that by teacher report, the main outcome variable, social skill training did not improve social skills, emotional competencies or general behavior compared no social skills training. The authors found no adverse effects of the therapy but did note possible improvement in ADHD in those treated.

A meta-analysis of group social skills interventions for children and adolescents with autism spectrum disorder noted that while many studies have been published, the formats, subjects, measures, and durations varied. The effect sizes of included randomized, controlled studies were small according to parents, observers, and teachers and large by self-report. Gates and colleagues observed that learning about particular skills and actually using them are two different things. They recommended that providers work to provide opportunities for practicing the skills in real-life situations.

The same year the above review was published, a randomized controlled study of a social skills group training was published. Olsson and colleagues recently reported the results of a randomized, controlled multisite (12 sites) study of 296 youth engaged in a 12-week intervention for youth with autism spectrum disorder. The manualized SSGT KONTAKT is described as follows: it “aims to improve social interaction and communication skills, social motivation, awareness of self and others, problem-solving capacities, and self-confidence. The program applies elements of cognitive-behavioral therapy (CBT), computer-based cognitive training, behavioral activation, psychoeducation, observational learning, and parent involvement through various mandatory, recurring, and variable treatment formats. Training sessions focus on understanding social rules and relationships, initiating social overtures, developing conversation skills, identifying and interpreting verbal and nonverbal social signals, managing conflicts, and developing social communication strategies. The teaching formats include individual goal identification, group discussions, social and role play, emotion-processing training, group activities, and tailored

Telegram: @medical_k

www.konkur.in

homework assignments aiming to facilitate the generalization of skills to everyday life. Elements such as group discussions and role plays are applied more among the adolescents in the variable parts of the training, whereas more playful elements are used in the children's group." Authors reported a small to moderate effect size in autism symptoms and adaptive function in female adolescents compared to standard care, according to parents unblinded to the treatment group. Authors urged that work to improve social skills training is needed, perhaps by adding strategies to improve motivation, focus, and developmental relevancy, along with a longer intervention, is important. The protocol encouraged flexibility within structured sessions. Flexible elements included social interaction games, role play, group discussion, group discussions, pantomime games, and computer-based affect recognition games focused on the recognition of emotions in human faces and eyes. In this pilot study, the youth showing the most improvement included those with higher IQs and higher initial levels of communication difficulties.

A meta-analysis of group social skills interventions for children and adolescents with autism spectrum disorder noted that while many studies have been published, the formats, subjects, measures, and durations varied. The effect sizes of included randomized, controlled studies were small according to parents, observers, and teachers and large by self-report. Gates and colleagues observed that learning about particular skills and actually using them are two different things. They recommended that providers work to provide opportunities for practicing the skills in real-life situations.

Terrorist Attacks. In the 9/11 terrorist attacks, at least 6,000 children lost a parent, and many others developed PTSD. Group psychotherapy served as a place where children could put their experiences into words and play, find support, and begin self-repair. Scheidlinger and Kahn made several observations during their group work with children after 9/11. They used play, drawings, and discussion questions with elementary school–aged children to help them to express their feelings and fears. Play was especially important for traumatized children aged 4 to 8 years, helping them to

Telegram: @medical_k

www.konkur.in

describe their experiences. Expressing feelings and thoughts in the group setting allowed other group members to share their experiences and relate to others, a significant step toward building trust and unity within the group. The clinicians observed that traumatic events can continue to affect processes of social and mental development, and they emphasized the importance of making effective interventions like group therapy available in events with global impact.

Haen described a two-phase group therapy intervention for children directly affected by 9/11. Many children felt alone and feared for their safety. It was imperative that a safe environment be provided for the children to minimize the sense of isolation they often felt. The first phase of group therapy aimed to develop trust, safety, and security and included work toward psychoeducation and connecting to one's support system. The second phase was designed to provide an open forum to address and discuss distortions and misconceptions developed by the children after 9/11. When children blamed themselves for the loss of their parent(s), work focused on correcting cognitive distortions. To facilitate the second phase of group therapy, Haen used play, art, and other nonverbal tools to communicate feelings and thoughts. In one example, drama therapy allowed group members to role-play and alter endings to traumatic events. In some cases, they were able to prevent imagined disasters. These tools helped participants to accept and cope with losses and improved the perception of security and safety for young clients.

Limitations of Group Therapy

When nonbehavioral approaches such as nondirective and psychodynamic models are used, meta-analysis found that group therapies demonstrate a smaller effect size. In group therapy, the therapist is constrained in their ability to attend to specific individual troubles and has less flexibility in a crisis. Gathering sufficient group members may prove difficult for individual practitioners.

Telegram: @medical_k

www.konkur.in

Training

Running group therapies requires more organization up front: Enlisting co-therapists and patients, locating facilities, establishing a mutually acceptable meeting time, obtaining materials for the participants, coordinating communications, obtaining insurance authorization, and much more. The cost of training therapists to administer empirically supported therapies (which is of course most desirable) can be large and present a barrier to adopting them in clinical practice. Crome and colleagues modeled analysis of costs of adding a CBT intervention using psychologists. Considering direct and indirect costs as well as the opportunity cost of lost income during training, they predicted that at the lower end, reading manuals and attending workshops might cost $9,000, while the upper level reached $55,000; the largest expense was the missed income during training. While the field wants to move toward using the most evidence-supported treatments available, authors expressed concern about scalability.

Complications

A patient's ability to discuss emotional issues and be vulnerable practicing new skills in a group is dependent on their feeling safe and respected. When confidentiality is breached, when occurrences of disrespect are inadequately processed, or when individuals feel physically unsafe or threatened by interaction outside of the group, the group is counter-therapeutic. Adequate therapist training and supervision, careful screening of patients, and close attention to the group rules and process may guard against these occurrences.

Choice of Treatment

Each group therapy aims to ameliorate symptoms and promote psychosocial growth. The rationale for choosing to provide therapy in a group format must be that group therapy either has evidence to support its choice or has qualities that make it theoretically suited to address the patient's individual problems.

Telegram: @medical_k

www.konkur.in

ETHICAL ISSUES

As implied previously, group therapy, although possibly cost-effective, should not be prescribed with that sole consideration in mind. It is properly used as one tool of many in the armamentarium of psychotherapists when evidence supports its use or, lacking other more empirically supported therapy, theory provides a rationale.

RESEARCH AND EVALUATION

As delineated by the ACGME Program Requirements for Graduate Medical Education in Child and Adolescent Psychiatry ACGME-approved focused revision: June 13, 2020; effective July 1, 2020, those treatments possessing empirical support should be identified, developed, disseminated, and used. A bustling movement is growing to develop well-established treatments. Doubtless, group therapies for children and adolescents will be among those whose use will be supported, but as the reader may surmise, more work needs to be done to establish which interventions, and which elements of interventions, work best for whom in well-designed, multisite, controlled studies.

The author would like to acknowledge Drs, Sonal Rana and Nicole Quiterio for their contribution to this chapter in a previous edition and Abby Miller for her help in manuscript preparation.

53.4 Family Therapy

JOHN SARGENT, M.D., AND NEHA SHARMA, D.O.

Telegram: @medical_k

www.konkur.in

Family therapy represents an organized, well-developed, and variable set of interactions with family members that addresses mental health and substance use problems that affect them. It also has been used to assist with recognized relationship problems, including communication difficulties and difficulties occurring within spouse and parent–child relationships. (In this section, “parent” refers to any adult with custody of the child and responsibility for the child’s well-being and development.) Tenets of family therapy can also be used to address conflicts among colleagues and family members including those that are created by implicit bias, racism, and discrimination.

These interventions take advantage of the importance of family relationships to individuals and the willingness of individuals to alter their behavior and thinking to help family members. Family therapy theory and practice are based on a range of ideas and ideologies (Table 53.4–1) and are oriented to respond to a wide range of problems. The therapist’s responsibility is to appreciate the nature of the problem, develop a shared appreciation of the problem with family members, and collaborate with the family to develop the best overall adaptation of family members, including ameliorating the manifestations and effects of the problem.

www.konkur.in

Table 53.4–1.
Family Tasks as Child Development Unfolds

Telegram: @medical_k

www.konkur.in

Infancy

- Ensuring parental availability
- Ensuring resources to enable parental caretaking
- Providing support to parents when stressed
- Providing education about infants and parenting
- Encouraging balance between jobs of adult and parent, especially during times of transition

Preschool Children

- Enabling parents to respond to separation/individuation efforts of the child
- Encouraging parental consistency in discipline and limit setting
- Supporting positive parent–child connections based on individual nature of the child and the child's competencies
- Encouraging play, use of fantasy, and creativity in the interactions between parents and child
- Encouraging child's relating ability with other children and with other caretaking adults

School-Age Children

- Ensuring parental consistency in understanding, accepting, and being available for the child
- Developing rule-based behavioral expectations and consequences for the child
- Encouraging the child's competent engagement with school, friendships, and community activities
- Gradually assisting the family in developing a consistent, positive, and hopeful appreciation of the child
- Encouraging the child's independent perception of and participation in family life

Adolescence

- Assisting the parents with adolescent problems that require rules, consequences, and consistency
- Encouraging parental figures in assuming a supervisory role with children, with parents willing to allow for experimentation and learning, although also establishing essential rules

Telegram: @medical_k

www.konkur.in

Encouraging the adolescent's voice and role in family life, as well as their competency and involvement in extrafamilial experiences

Assisting the parents in encouraging self-direction, self-definition, integrity, and values in adolescent children

Assisting parents with refocusing on important aspects of their lives as they separate from their children

Table 53.4–2.
Assumptions of Family Treatment

Family therapy is an integral part of the practice of child and adolescent psychiatry.

Child and adolescent emotional and behavioral difficulties always affect family life and relationships.

Family relationships always affect child development, emotional status, and behavioral capacity.

Adaptation of the child and adolescent with psychopathology to the family is always a goal of treatment and requires change on the part of the family, accommodation by the child when possible, and consideration by treating professionals.

The family can always be a source of understanding, support, and healing for children and adolescents.

The family should agree to, participate in, and assist in directing all mental health interventions at all levels of care.

Family involvement in all treatment should be defined and structured to achieve family goals and facilitate achieving goals for the child with psychiatric difficulties.

Various therapeutic interventions and classes of interventions can be used to achieve these goals.

Family interventions address problems that have neurophysiologic and genetic elements and have developed in relation to unique environmental occurrences. Interactional responses often naturally occur that reinforce the problem. Family members are also

Telegram: @medical_k

www.konkur.in

emotionally affected by their relatives' difficulties, leading to a further mismatch between family members' needs and others' behavior. A child may be identified as the patient while the family struggles with a poor marital relationship or with parental mental health concerns. Family therapy is much more interested in the solutions to problems and improvement in the overall well-being and functioning of the family than in the etiology of the problem. This leads to a future-oriented focus of treatment and also suggests that assessment is carried out in a manner that is engaging and therapeutic. Often, family members are frustrated and frightened, and often their interactions are unproductive and repetitive, reinforcing and maintaining the problems. Therapy occurs through the interventions of the therapist and the relationships they develop with family members and with the family as a whole. The therapist's behaviors are intentional and carefully chosen and carried out to facilitate engagement, mutual care, support, and a resolution of problems that the family is experiencing. The therapist also appreciates that improving family relationships and interactions often leads to improved overall functioning, which can become mutually reinforcing and self-perpetuating. Family therapy is a treatment approach strongly supporting social justice, equity, and opportunity for all family members.

This section focuses on the use of family assessment, family interventions, and family therapy to address the problems that families have with their children's development (see Table 53.4–1), emotions, cognitions, and behavior. It is based on the premise that the practice of child and adolescent psychiatry always involves interacting with and understanding family interactions and functioning, and always involves engaging the family in the treatment and monitoring process (Table 53.4–2). At the core of family work, there is acceptance of each family's cultural and social values. The section includes case examples demonstrating the range of applications of family therapy with diverse families, as well as the various forms that family treatment may take. Tables reviewing these significant models of family therapy (Table 53.4–3), the theoretical foundations of family therapy (Table 53.4–4), specific treatment

Telegram: @medical_k

www.konkur.in

approaches for common child mental health problems (Table 53.4–5), and unique family treatment approaches to differences in family composition, family history, and the culture and ethnicity of the family (Tables 53.4–6 and 53.4–7) are included. Family distress brought on by the effects of racism, discrimination, and exclusion is universal target of family treatment.

Telegram: @medical_k

www.konkur.in

Table 53.4–3.
Varieties of Family Therapy

Telegram: @medical_k

www.konkur.in

Psychodynamic

- Assumptions and Major Concepts
  - Family relationships are based on previous parent–child relationships of each parent.
  - Difficulties arise from developmental arrest, current interactions and projections, and current stressors.
  - Improvements develop through the process of family members gaining insight into problematic relationships from the past.
  - Therapy consists in shared exploration of past relationships and current distortions and role confusions.
  - Therapy also encourages the development of mutual appreciation of the needs and limits of family members.
- Major Theoreticians and Practitioners
  - Nathan Ackerman
  - James Framo
  - Ivan Boszamenyi-Nagy

Experiential/Existential

- Assumptions and Major Concepts
  - The family is a developing organism, and the goal of therapy is to encourage the growth of the family and its members through the process of therapy.
  - This process is best supported by encouraging expressiveness, openness, and communication within the family throughout the therapeutic encounter.
  - The family is responsible for its solutions; the therapist is a facilitator who encourages growth and confronts stagnation.
- Major Theoreticians and Practitioners
  - Carl Whitaker
  - Virginia Satir

Intergenerational/Bowenian

- Assumptions and Major Concepts
  - The family is an emotional relationship system, with the goal of relationships to promote engagement, foster differentiation, and avoid fusion.

Telegram: @medical_k

www.konkur.in

- In conflictual situations, engaging a third party (triangulation) stabilizes the family system.
- Individuals marry partners at the same level of differentiation, leading, at low levels of differentiation in married couples, to severe personal and relationship difficulties.
- Therapy is aimed at clarifying current relationships, promoting individuation, resolving current conflictual interactions, and working through intergenerational and introjected difficulties and patterns of behavior.

Major Theoretician and Practitioner

- Murray Bowen

Structural

Assumptions and Major Concepts

- Focused on current organization of the family as demonstrated through repeated patterns of interaction.
- Particularly attentive to how the family's organization promotes or inhibits task performance, especially child rearing.
- Analysis of interactions allows the therapist to determine the nature (distance vs. closeness) and the flexibility of family relationships in relation to task performance.
- The therapist promotes interactions in sessions to determine family relationships and then intervenes in those interactions to introduce greater flexibility, alternative patterns and structures, and more effective task performance.
- Enmeshment (ineffective closeness) and disengagement (excessive distance), as well as rapid fluctuations between extremes, are manifestations of dysfunctional family relationships when associated with significant symptoms in a family member.
- This form of family therapy was developed to respond to child and adolescent emotional and behavioral problems and is particularly effective in those situations.
- The therapist is both the director of therapeutic action and participant in the process of therapy.

Major Theoretician and Practitioner

Telegram: @medical_k

www.konkur.in

Salvador Minuchin

Systemic/Strategic

Assumptions and Major Concepts

Symptomatic behavior is embedded within the patterns of communication and relationships in a family.

Ineffective attempts at solutions to problematic behavior become part of the pattern also and thus part of the problem.

The therapist is responsible for developing and prescribing tasks and behaviors that disrupt usual patterns of interaction while strengthening other, more productive patterns.

The therapist maintains a stance of neutrality and distance with respect to the family as whole and individual members.

Specific methods of questioning designed to elicit information about family relationships (circular questioning) are used; posing hypotheses, reframing, externalizing blame, and the use of positive connotation are common techniques.

Major Theoreticians and Practitioners

Jay Haley

Cloé Madanes

Mara Selvini-Palazzoli and colleagues (Milan group)

Cognitive-Behavioral

Assumptions and Major Concepts

Concepts of learning theory—conditional contingency, reinforcement, extinction—explain problematic behavior and identify therapeutic interventions.

Sessions are entirely problem- and solution-focused in the present.

Skills training is emphasized throughout treatment; homework, record keeping, and between-sessions tasks are used regularly.

Therapy is aimed at changing both cognitions and behavior and uses new cognitions among family members to direct and evaluate behaviors.

Telegram: @medical_k

www.konkur.in

- Particularly useful for managing mild to moderate disruptive behaviors in children and adolescents, focusing treatment on parent skills training.

Major Theoreticians and Practitioners

- Gerald Patterson
- James Alexander

Telegram: @medical_k

www.konkur.in

Table 53.4–4.
The Theoretical Foundations of Family Therapy

Telegram: @medical_k

www.konkur.in

General Systems Theory

The whole is greater than the sum of the parts.

Actions that affect one part of a system affect the whole.

Each part of a system is in a constantly changing relationship with all other parts.

Cybernetics

Interaction among family members is circular and continuous, with each behavior being the effect of one behavior and the cause of another.

Circular causality encourages attention to pattern of interactions and feedback between behaviors and relationships.

Communication Theory

All behavior is communication (both actions and words); behaviors define the nature of the relationships among family members.

Structural Theory

Relationships are structured in a hierarchical, potentially developmentally oriented fashion.

The structure of a family can only be determined by noting the patterns of interaction among family members.

Structures are functional or adequate insofar as they provide for the achievement of family goals.

Social Constructionist Theory

Each individual constructs or makes sense of their experience from their perspective.

Therefore, many different interpretations of a set of circumstances may be simultaneously true.

Families, therefore, must and do develop shared constructions of their situation.

The constructions may become unsatisfactory when problems or changes require interaction with systems (health care, school, extended family, community agency, etc.) that have alternative constructions of events.

Psychodynamic Theory

Telegram: @medical_k

www.konkur.in

Early experience is formative in defining who people are.
The capacity for projection and projective identification can seriously inhibit the flexibility, resilience, and growth of relationships.

Attachment Theory

Affect regulation occurs within close relationships.
Secure attachment facilitates social relationships and the ability to know and communicate about mental states.

Over the last 20 years, manualized family therapy treatments have been developed and identified as evidence-based treatments through randomized, controlled trials. These treatment approaches have been developed for specific child and adolescent disorders, such as traumatic stress, substance abuse, anorexia nervosa, and conduct disorder.

PROCESS OF FAMILY THERAPY

Engagement

The key to successful family treatment is successful engagement of the therapist with the family and with family members. This process requires that the therapist possess the skills of connecting with more than one person at the same time and making each person feel understood, comfortable, and cared about. Engagement conveys the therapist's hope for the family's successful future and their belief that with effort, patience, mutual care, and concern, changes can occur and that a successful future can be realized. Family therapy in whatever fashion is always a creative act, an act of vision. The therapist's connection with the family and its members is based on their assertion of the meaning and value of this family. Through the acceptance inherent in engagement, the therapist works to create a context of safety that promotes greater flexibility in the interactions of family members and greater possibility that the situation can be accepted and improved. In addition to warmth, curiosity, hope, and vision, the therapist must be able to hold and act on opposite ideas:

Telegram: @medical_k

www.konkur.in

that the family possesses strengths and has difficulties, that the family is doing the best it can, and that the family needs to change, and that the family and its situation are unique and also resemble other families in their connections to each other, their concern for each other, and their wish that every other family member have the best life possible.

The therapist also engages with the family as an entity. By acting in a manner that reflects the therapist's belief in the integrity of the family, family members can begin to relax, see each other differently, and behave in a manner that reflects their interest in membership in their family and their commitment to its well-being. The therapist asks about the family's history, culture, rituals, and beliefs; respects what they hear; and treats the family as an entity in which they believe in and cares about. This helps the family members to come together, work together, and change the ways in which they treat each other. In doing this, family members begin to understand that relationships can improve, conflicts can be dissolved, and mutual understanding and mutual support can develop. Through successful engagement with individual family members and with the family as a whole, the therapist creates a solid foundation for family change and symptomatic improvement.

Safety

Throughout the engagement and assessment process the therapist's first responsibility is to ensure the safety of the child, the family members, and others in the community, as well as their safety. In some families aggressiveness is a part of their interactions, emotions may run high when disappointments, hurts, and conflicts have occurred, and family relationships may feel and at times be unsafe. Thus the therapist must be attentive to signs of the possibility of violence, aggressiveness, abuse, and suicidal behavior. If there is concern about safety, consideration of hospitalization or involvement of human services or the justice system must be considered. The therapist's role is to work with the family to decide together on the level of care necessary to promote the safety of all while also

Telegram: @medical_k

www.konkur.in

beginning treatment in a manner that ensures the safety and connection of all. The therapist creates a safe space where family members can speak to and listen to each other and where hurts and disappointments can be spoken about, and reconnections can be achieved. The therapist can establish ground rules for sessions and, if concerned, meet with family members individually to ensure a commitment to self-control and mutual respect in treatment and ultimately throughout family life. The quality of the therapist's engagement with the family and their presence, integrity, and his belief in their vision of successful resolution of problems are crucial in leading the family to the changes needed to ensure nonviolent family life. This sense of safety also leads to a space for advocacy when needed for issues of equity and justice.

Assessment

Family therapy is based on an ongoing assessment of the child's problem and family life. It is important for the therapist to recognize that the assessment is part of the therapeutic process. Assessment is completed in an interactive manner that is based on the therapist's interest in the family's strengths and individual capacities and interests, as well as the therapist's professional responsibility to appreciate the family's problems. The therapist, connected to the family in the treatment system, elicits a discussion about the questions the family has about their child and the concerns and issues the family experiences in their life.

Telegram: @medical_k

www.konkur.in

Table 53.4–5.
Family-Oriented Treatment Approaches for Specific Clinical Problems

Telegram: @medical_k

www.konkur.in

Psychosis

- Ensure appropriate diagnostic evaluation, accurate diagnosis, and adequate antipsychotic treatment.
- Psychoeducational treatment model is very helpful, providing education about the disorder, outlining family roles in treatment, and providing guidelines about how to respond to crisis and specific problems.
- Efforts at reducing blaming and intensity of affective expression within the family are often helpful.
- Ensuring family collaboration with the treatment approach, especially concerning communication with professionals, medication, vocational training, and work and placement, is extremely helpful.
- Parent support is an important aspect of treatment.

Depression

- Ensure that all involved recognize and accept the child's depressed mood.
- The therapeutic orientation should include attention to building attachments and connections, reducing personalized criticism, and building support among family members.
- Building individual competence is essential.
- Cognitive-behavioral strategies are most effective.
- Setting limits to deal with acting out, personal irritability, and poor academic performance is often helpful.
- Special attention should be paid to parental psychiatric problems.
- Psychopharmacology should be integrated within the therapeutic approach.

Anxiety Disorders and Phobias

- Collaboration in treatment reduces the power of the child's fears and vulnerability.
- Cognitive-behavioral approaches with the family are helpful.
- Agreement about the expectations for the child, especially regarding fears, is necessary.

Telegram: @medical_k

www.konkur.in

- Distraction, relaxation, social skills assistance, and focus on building peer relationships all are helpful for the entire family to focus on.
- Recognition of temperament and the possibility of recurrence of worries during stressful periods often aid long-term outcome for the family.

Disruptive Disorders

- Attention-Deficit/Hyperactivity Disorder (ADHD)
- Agreement about diagnosis is essential.
  - Education concerning the various aspects of ADHD is helpful.
  - Family involvement in measuring and monitoring the results of behavioral interventions and psychopharmacology is helpful.
  - Parent support groups can help long-term adaptation.
  - Specific plans for impulsivity, reactivity, and aggressiveness are helpful.
  - Independence, self-regulation, self-organization, and personal responsibility are goals of treatment.
  - Special attention should be directed to developing the strengths, competencies, and self-esteem of the ADHD child and the family as a whole.
- Conduct Disorder
  - Collaboration among parents and all involved professionals and agencies is essential.
  - Responsibility and accountability for the child are primary goals of treatment.
  - Parameters of treatment must be explicitly stated.
  - Behavioral approaches highlighting consistency, expectable consequences, and predictable responses to transgressions are the cornerstone of treatment.
  - Plans must be made for responses to violence and other serious problems.
  - Impulsivity in treatment should be avoided; treatment must be consistent, continuous, developmentally oriented, and

Telegram: @medical_k

www.konkur.in

focused on building successful adaptation of the child, as well as on reduced behavior problems.

Medication is to be used for specific target symptoms, and its use and effectiveness must be supported by all participants in treatment.

Substance Abuse

Agreement about avoiding substance use among all involved adults in necessary.

Family tolerance for affective expression usually needs to be expanded.

The family must also attend to comorbid problems, depression, learning problems, ADHD, and so forth.

The role of consequences and limits for substance use must be expressed clearly.

Parental substance use also must be addressed in treatment.

Family participation in mutual support groups (Narcotics Anonymous, Alcoholics Anonymous) is often very helpful.

Peer problems, legal difficulties, and relapses should be addressed directly with the family.

Eating Disorders

Structural techniques build family cohesiveness and a consistent approach to the disturbed eating behavior.

Simultaneous support for individuation and connection is necessary.

Cognitive-behavioral techniques assist in establishing consistency in family relationships, as well as in responses to eating disorder symptoms.

Family therapy offers an opportunity for dealing with gender issues, as well as concerns associated with control and perfectionism.

The age of the eating-disordered individual defines how treatment is structured; early adolescents respond best to family-oriented treatment; older adolescents and young adults respond better to family therapy approaches that they arrange

Telegram: @medical_k

www.konkur.in

and manage in conjunction with simultaneous individual therapy.

Abuse (Physical or Sexual)

Safety of the child is paramount.

Parents should collaborate with the therapist and social service agency staff.

A clear role for parents in the treatment process should be outlined, with specific expectations and consequences defined.

Parent training and skills building are helpful, especially if the unique contributions of the child to the family situation are highlighted and the parents have the opportunity to practice responses and receive praise and support when they demonstrate competence.

Honesty, clarity, and directness often reduce defensiveness and evasiveness on the part of family members.

As much as possible, the child should have a developmentally appropriate, active role in treatment.

Encouragement of verbal expression can be helpful in affect regulation and maintenance of consistent responses to behaviors among family members.

Academic or Learning Problems

The child's learning or academic problem must be defined to the satisfaction of parents and school professionals.

Parents assist with developing questions to be addressed through psychological, psychiatric, and educational evaluations.

Roles and responsibilities of parents, school professionals, mental health professionals, and the child should be clearly identified.

Specific educational and school-based goals should be set; these should be development of academic competency, self-esteem, and greater connection between the child and school.

Steady progress through school marks development and achievement and builds greater maturity.

Telegram: @medical_k

www.konkur.in

Other difficulties influencing learning (e.g., depression, anxiety, ADHD, and other disorders) need to be addressed simultaneously.

Telegram: @medical_k

www.konkur.in

Table 53.4–6.
Variations in Family Composition

Telegram: @medical_k

www.konkur.in

Single-Parent Families

- Recognize the strength, responsibility, burden, and stresses of the custodial parent.
- Support the independent competence of both the parent and the child.
- Encourage the parent's use of alternative caretakers and other modes of personal connection and support.
- Encourage the child's exploration of their relationship with the noncustodial parent.
- Assist with transitions that may occur with new relationships that the parent might develop.

Divorced Families

- Encourage parental collaboration in divorcing and parenting processes.
- Assist the independent emotional reactions of each family member to the separation and divorce process, including the recognition that this is a highly painful experience for children.
- Encourage the development of effective separate relationships between each parent and each child.
- Build strengths of sibling relationships.
- Assist the competency and expression of each child.
- Assist parents in collaborating in parenting tasks.

Grandparent- or Relative-Headed Families

- Recognize the effort and strength of the child-rearing adult.
- Encourage the child's emotional adaptation to not living with their biologic parents.
- Encourage effective limit setting and adult affiliation with the child in these families.
- Emphasize the child's competency and extrafamilial engagement and accomplishment.
- Support consistency in involvement of biologic parents to the greatest extent possible.

Adoptive Families

Telegram: @medical_k

www.konkur.in

Recognize that the child's problems may be associated with preadoptive phenomena.

Support with sensitivity the parents' emotional reaction to their child's difficulties.

Possible special attention to the child's background and special attributes.

Build connections among family members while dealing with the losses and separations associated with adoption.

Families with Same-Sex Parents

Similar strategy as adoptive families

Support parents to feel empowered and effective in their parental role.

Guide parents to differentiate between their personal childhood experience and their child's experience.

Build connections in the community such that family members feel welcomed and accepted.

One can view the process of assessment in child-oriented family therapy as the iterative development of an imagined video of the child and family at home, their relationship with the child's school, and their presence in their community. This understanding appreciates not only the child's symptoms and abilities, but also the interactions within which those symptoms and strengths are embedded. Thus, symptoms—either those that are spontaneous or those that are reactive—are viewed within the interactions that precede them and those that follow them. One way to understand the patterns in which symptoms are embedded is to encourage interaction among family members in sessions and to be attentive to spontaneous interactions as they occur in sessions. Understanding these patterns provides the therapist with many possibilities for discussion and intervention.

Table 53.4–7.
Family Therapy Approaches: The Effects of Cultural Differences

Telegram: @medical_k

www.konkur.in

Cultural Differences and Family Worldview

- Worldview defines the relationship of a family to people, institutions, and objects.
- Cultural experience affects a family's worldview.
- Race, religion, and traditional position within the power structure also affect a family's worldview.
- These factors influence family relationships, family roles, and expectations of parenting, child rearing, and child development.

Examples of Cultural Considerations in Family Treatment

- White families: focus on individuals, use verbal expression, and distinguish between physical and mental factors.
- African-American families: focus on actions and behavior; realize that extended family is important, as are religion and church; also realize that history of oppression and racism affects relationships with institutions.
- Hispanic families: acknowledge bilingual background with intrafamilial differences in acculturation and language use; religion and extended family are important; respect for the family's heritage and background is very helpful in ensuring engagement in treatment.
- Asian-American families: recognize specific national origin; family, privacy, and saving face are central to family life; recognize intrafamilial differences in acculturation and language use.

Attending to Cultural Issues in Family Therapy

- Basic Values
  - Any family is a microculture.
  - The family's culture is necessarily a synthesis and amalgam of cultures.
  - Problems develop when the family experiences conflict internally between the cultures of the extended family or with external cultures, institutions, or systems.

Telegram: @medical_k

www.konkur.in

- The family is responsible for defining itself and its culture and for developing the most successful adaptation with other cultures.
- The therapist's responsibility is to support and facilitate that adaptation, recognizing (1) that there are many ways to be a family and raise children that are healthy and (2) that there may be issues that raise ethical concerns for the therapist, and in those situations further knowledge of the family's culture and consultation or supervision may be helpful.

Interactive Approaches

- The therapist must assume a stance of respect for and acceptance of the family as it is.
- The therapist should ask about the meaning of requesting mental health assistance for the family.
- Honest curiosity expressed in open questioning about how the family operates and how the family's cultural background influences its operation is essential.
- The therapist should refrain from judging the family, but rather should ask about how it achieves its goal.
- The therapist should avoid behaviors based on assumptions about a particular cultural background.
- The therapist should inquire about child-rearing practices in the family and responses to academic, emotional, behavioral, and social problems in the child as they reflect cultural beliefs and cultural expectations.

Clinical Approaches

- Specific responses to the child's symptoms and assistance with parenting skill need to be embedded within the therapist's and the family's understanding of cultural beliefs and expectations.
- Negotiation of the therapist's role and behavior should be based on the family's sense of their culture's expectations of professional behavior.
- The therapist can help the family to understand their cultural background as a method of helping the family to define and

Telegram: @medical_k

www.konkur.in

understand themselves and clarify their approach to therapy.

Explorations of culture assist the family in assuming direction and responsibility for treatment.

Discussions about respective cultural backgrounds and what those backgrounds mean can assist in conflict resolution and enhance the development of the children.

The therapist can assist the family in making accommodating measures with schools and other institutions based on cultural considerations.

The family and the therapist can also decide together on other questions to be answered through the treatment process. Intellectual concerns, educational abilities, and vocational aptitudes all can be evaluated if questions exist. Diagnostic questions and the use of psychopharmacology also can be discussed in a collaborative fashion with the family. The guiding issues are always: What are your questions? What are your goals? What of these alternatives do you want to do? The key to understanding this process is to appreciate several key principles:

1. Assessment results are impressions and not judgments.
2. All assessments of the family are hypotheses based on limited data and thus are subject to change.
3. Because interactions can change and are largely dependent on context, the therapist holds the belief that if the context changes, the interactions can change.
4. Any intervention represents a question: will this intervention be successful in achieving the goal? If not, a different intervention is required.

The process of developing a shared opinion of both the child and the family, including an appreciation of strengths and difficulties among members of the treatment system, is another opportunity for therapeutic intervention. There may be opportunities to discuss and resolve disagreements between caregivers about the child's capacities and problems. There may be opportunities, depending on

Telegram: @medical_k

www.konkur.in

developmental ability, for the child to participate in this discussion. The therapist supports the child's voice and expects the child to participate responsibly. As this process proceeds, the family's ability to negotiate effectively can be supported and reinforced by the therapist.

If other agencies or systems are involved with the family, especially in response to the child's problem, their representatives also will need to participate in the agreements about strengths and problems. This can be difficult, especially if the family has a history of conflict with these systems. The family may believe that a system with which they must be involved, such as the child's school, is treating the child ineffectively. The family will need the therapist's encouragement and potentially the therapist's coaching to be able to come to a collaborative approach with school personnel so that the child's education proceeds successfully. Similar negotiations will need to occur with the child protective system, the juvenile justice system, after-school programs, coaches, extended family, and church leaders, depending on who is involved with the child and what the child's needs, abilities, and problems are. At times the therapist will need to convene meetings of the family and those involved. The therapist, with the family's permission, may need to speak individually with the teacher, probation officer, and so on. These individuals may need to change their impressions of the child or family, and at times they may need to change the way in which they interact with the family. Supporting these new impressions is part of the therapist's responsibility for the success of their interventions. These changes become part of the therapeutic effort and goals for the treatment and become the focus of addressing implicit bias and social injustice when needed.

PROMOTING EFFECTIVE AND REWARDING PARENTING

Ensuring the safe and effective development of children is one of the main responsibilities of parents and caretakers. Caretakers need to

Telegram: @medical_k

www.konkur.in

recognize and provide structure to ensure an immature child's ability to grow and explore their world in a way that supports developmental change and newly learned skills. They also need to provide the love and care that encourages the growth of self-confidence and self-esteem while also reinforcing developmental gains. Caretakers must also be observant to note situations in which children may have the maturity to recognize and safely navigate them. Parenting provides the foundation for secure attachment including the availability needed to support the stressed child while also modeling effective emotion regulation. Through parenting children learn to recognize situations they cannot master and to ask for help and support when necessary. Family life changes as children mature and develop. Parenting approaches need to appreciate these changes and be adjusted and modified to respond to changes and growth in the child's aspirations and abilities. Parenting that included physical control of the child during toddlerhood will need to change to parenting based upon clear and agreed upon rules and consequences for a school aged child and then to more supervision that encourages judgment, impulse control, and the development of prosocial values during adolescence. Not only do parenting approaches need to change and transform in step with developmental maturation caretakers will need to be alert to situations that demonstrate lack of skills and regression and require parenting approaches more appropriate for less mature children.

Family therapy is very helpful in addressing parenting challenges in families. The therapist will need to appreciate the source of these problems which can be a mismatch between parenting approach and the child's developmental capacity, an inherent difference in the child impacting development and function, a lack of agreement or cooperation between parental figures or external stressors impacting parental ability to recognize or address the child's needs. Stress related to immigration and acculturation can further magnify these mismatches and differences between the parent and child. During acculturation, the child often gets accustomed to the new culture faster than the parent. This separation in the acculturation process can cause more conflicts in the family, also referred to as

Telegram: @medical_k

www.konkur.in

acculturative family distancing. Furthermore, the parents' added challenge of imparting culture to the next generation in isolation can make parents more rigid and less open to child's need to integrate two cultures. Thus, engaging and empowering parents to be effective in a culturally sensitive manner is an important target of family therapy. The therapist's ability to engage the parents and the child, appreciate the source of parenting difficulty and ensure the caretakers' trust and motivation often utilize all of the family therapist's skills in connecting, directing, and reinforcing new and effective behaviors in both caretaker and child. An accurate assessment, psychoeducation about children's difference, enactments during family sessions and a relationship of respect and regard with caretakers are important skills in enhancing parenting and building family competency and flexibility which in turn build family connections and affection.

Ensuring a Balance between Support and Limits in Parent–Child Interactions

One of the most challenging aspects of child-focused family therapy is developing an effective balance between, on the one hand, enhancing parent–child warmth, support, and the interactions that reflect secure parent–child attachment and mutual respect, and on the other, working to establish effective rules, supervision, and consequences for misbehavior and rule-breaking. This often requires skill, focused attention, and persistence on the part of the therapist. Because parental warmth forms the foundation of the mutual respect needed for effective discipline, the therapist's first task is to build that warmth. This often occurs at a time when parents feel betrayed, helpless, angry, and victimized. Parents may mistrust the therapist based on experiences of racism and health inequities within the health care system. An open discussion of these experiences and recognition of the impact of discrimination and difference upon the family can be extremely helpful in ensuring the partnership and relationship necessary for family therapy to be effective. At this point, it is the therapist's belief in the parents, in their love for their child,

Telegram: @medical_k

www.konkur.in

and in the possibility that they might help their child grow up safely and successfully that matters most. The therapist models warmth in their relationship with the parents. Compassionate understanding characterizes these interactions. Interactions that caringly convey the therapist's belief that the parents care for their child and believe in the child's future characterize the therapy. This must occur even if the child expresses skepticism or disbelief about the parents caring for them. As trust develops between the therapist and the parents, who know that the therapist believes that they care truly about their children, a wide range of interventions is possible. These include establishing parent interactions with the child aimed at understanding the child's disagreements with their parents in a nondefensive way and in a dispassionate fashion while establishing expectations for their child's behavior as well as consistent consequences for failing to meet expectations. In this process, the therapist helps the parents to deal with their disappointments with their child so that consequences are not vindictive and helps the parents appreciate that their child could want their approval and could wish to earn their regard. In this approach, parents understand and support their child's emotions, disappointment, frustrations, and anger while also holding firm expectations, limits, and consequences. In a sense, parents are feeling one way—frustrated and angry—and acting another way—calm and firm—while allowing the child to act one way—frustrated and angry—and expecting the child to feel another way—accepted and respected even while adhering to parental limits and appreciating parental involvement and concern.

Parents often want advice about establishing discipline and limits, especially in situations in which the child has a disruptive behavior disorder and defies parental rules and limits. This often represents a challenging therapeutic concern. Often in these situations there is a difference in approach between parental figures. Everyone is exhausted, hurt, frustrated, and angry. The parents will frequently claim that consequences do not work. Disrespect and defeat characterize parent–child interactions. In these situations the therapist might choose to meet alone with parents to help them to

Telegram: @medical_k

www.konkur.in

begin to work together, as well as to develop strategies to reinstitute effective limits. The therapist can help parents to prioritize their expectations and plan to establish one rule at a time. In the process the therapist can also help the parents to develop realistic expectations of their efforts with their child. The parents can receive validation of the experience of frustration and their sense of being betrayed by their child. As long as the parents hold on to their experience of being hurt by their child, it is very unlikely that they will notice small attempts at improvement on their child's part. They also will have difficulty holding to their expectations if the child becomes angry or has a temper outburst when a limit is imposed. In such frustrating situations, guided by the therapist, a parent can gain support from their partner that could result in decreased emotional intensity and improved ability to maintain positive expectations. Another frequent occurrence that can be discussed with the parents alone is the possibility that the child will act in a totally unaffected way when the limit is imposed, as if to say that the parents have no effect on the child. By discussing these possible scenarios, the therapist can help the parents prepare to institute appropriate limits in a planned and controlled manner. In these sessions the parents can practice talking with their child and maintaining firmness even if the child is particularly challenging. The therapist may also choose to meet alone with the child to see whether they have concerns that the therapy might resolve. Defiant, disruptive children and adolescents often want to be trusted and understood, and to have autonomy.

The therapist can help the child to receive parental approval if the child performs acceptably and gains autonomy in relation to their ability to act responsibly. When both parents and child are prepared, a session with all of them together can be held outlining the rules, expectations, and consequences. The child has the opportunity to ask for what they want, and the therapist can help the parents to promise the child the desired autonomy if the child abides by the rules and accepts the consequences. The consequences should be simple, easy to undergo, brief, and have some relationship to the transgression. The key to consequences is that they are meaningful but not onerous. Losing access to a cell phone or computer for one

Telegram: @medical_k

www.konkur.in

evening is a meaningful but transient consequence. If the parents and child form a committed relationship with the therapist, the therapist can then, with patience and time, bring them back together in an initially tenuous but gradually caring manner. Building understanding and trust, establishing a realistic plan for limits, and noticing small successes provides a pattern of improvement that all can recognize and believe in.

Engaging Families in All Levels of Care

Family members should be actively involved in decisions about treatment programs, levels of care and care delivered, and inception and discontinuation of treatment. This expectation helps the parents or caretakers develop monitoring, supervisory, and organizational skills that they might be lacking. Because the parents possess decision-making power, they must learn to understand their child, make the child's behavior make sense, and begin the process of accepting the child's differences. This can accentuate feelings of support and understanding, which may have been undermined by their responses to symptoms and their consequences. This is especially true in the case of families with children with disruptive disorders, in which difficulties in school or with the justice system may have felt hurtful and shaming.

The journey to get out-of-home services often results in parents feeling ineffective and disempowered. The purpose of family intervention is to empower parents to conduct effective parenting. Thus, family involvement is essential for children being treated in treatment programs such as hospitalization, day treatment, or residential treatment. For the home environment to reinforce positive behaviors and not reinforce negative behaviors, it is necessary for program clinicians and staff to be attentive to the interactive sequences of which the symptoms were a part and intervene with the family to alter those sequences so that the home environment is different when the child is discharged or the program ends. If discipline is problematic, parents can be consulted when program rules are broken and consequences are required. Parents can be

Telegram: @medical_k

www.konkur.in

informed by the child of successful experiences so that their praise is added to that of the staff. These successful experiences can translate into hope for change for parents. Parents can be expected to meet regularly to have a meaningful voice in treatment review, learning to develop realistic expectations of their child based on how the child is able to function rather than based on everyone's wishes about how they might function. It can be difficult at times to share power with parents, but with patience the staff can help the parents to feel empowered throughout the treatment program. If passes home are part of the treatment program, activities can be planned for the entire family that emphasize practice with new interactions at home prior to discharge.

FAMILY THERAPY FOR SPECIFIC PROBLEMS

Attention-Deficit/Hyperactivity Disorder

Families with a child with attention-deficit/hyperactivity disorder (ADHD) need to learn about the disorder, understand appropriate treatment, and support the development and functioning of their child. This requires that parents agree about the presence of the problem, agree to seek the help of a physician, and agree to have their child take medication if prescribed. It is also important for the parents to learn to be consistent with behavioral expectations and to appreciate and reinforce the child's strengths. Often, prior to diagnosis, the child may have experienced failure at school and rejection by peers and marked negative interactions at home. Family therapy after diagnosis of ADHD may be needed to help the family assist the child with these previous difficulties, and also to help the child to be more successful at school and with friends and to feel consistently accepted at home. Comorbidity with learning disability is common, and the family may need assistance with ensuring appropriate education for the child. ADHD often occurs in association with complex trauma in situations of abuse and trauma. Sometimes the concentration problems of the child are a manifestation of anxiety caused by trauma and sometimes the child

Telegram: @medical_k

www.konkur.in

has both ADHD and Complex PTSD. Therapeutic flexibility and accurate assessment are important aspects of family treatment. Transitions, including moving and changing schools, can be challenging. The family may also need assistance during the child's adolescence, particularly with impulse control, exposure to drugs and alcohol, and self-management as the child becomes a young adult. A chronic illness framework often is extremely helpful for families with children with ADHD.

Telegram: @medical_k

www.konkur.in

Jason was a 7-year-old boy who attended the second grade and who had been noted by his teacher to be extremely active in class and to have significant difficulty concentrating and following class rules. He especially had difficulty during unstructured time in school, both in the cafeteria at lunchtime and on the playground at recess.

When his teacher checked with his previous teachers from kindergarten and first grade, they stated that Jason had difficulties with his attention and activity level in both of those grades. Despite these concerns he was quite bright and had been able successfully to complete his grades and pass to the second grade. Jason's teacher invited his mother to come to school for a meeting after having sent home reports concerning his overactive behavior and his inability to finish his work.

At the meeting with Jason's mother, his teacher spoke about her concerns and suggested that Jason should undergo a psychiatric evaluation and might need medication to help him concentrate and manage his activity. His mother reported that she was also concerned about how active he was at home and how difficult it was to help him get ready for school in the morning or finish his homework in the afternoon.

Jason lived at home with his mother, stepfather, and 4-year-old stepsister. His parents had divorced when Jason was 3 years old, and his mother remarried his current stepfather 1 year prior to Jason turning 7 years old. Jason saw his biologic father on a regular basis and spent alternative weekends at his father's house. His father had also remarried, and Jason had an 18-month-old half-brother who lived with his father and stepmother.

Jason was seen by a child psychiatrist shortly after his mother and teacher met. The child psychiatrist believed that Jason was a child with ADHD and suggested to the mother that a trial of stimulant medication might be helpful for him. The mother was given rating scales to complete after Jason had started on the medication, along with written information about both ADHD and the stimulant that was prescribed for him.

Telegram: @medical_k

www.konkur.in

The child psychiatrist also recommended that there be a meeting of all four adults involved in Jason's life—his mother, stepfather, stepmother, and biologic father—so that they could talk together about Jason's difficulties and ensure consistent treatment. The goals of the meeting were to encourage regular use of the stimulant medication and to help everyone to understand the need for clear and focused directions, focused attention, follow-through on homework, and consistent discipline in both households.

The family attended this meeting. The psychiatrist noted that Jason's biologic father was concerned about the use of medication and asked about the risks and side effects of the medicine. Jason's stepmother was concerned that there was no way successfully to help Jason without medication. As the family talked together with the child psychiatrist, asking questions and gathering information, they came to the conclusion that the best approach was to institute a trial of stimulants. The trial was begun, and Jason's teacher reported to the family that he was much more able to focus his attention and manage his behavior in school. He was noted to have less difficulty during unstructured times in school and was also able to do better academically than he had previously.

The child psychiatrist also suggested that the family come back for a second meeting, after Jason had been on medication for 6 weeks, to review everyone's impression of Jason's progress. The child psychiatrist recognized that the biologic father and stepmother were now comfortable using medication for Jason. They agreed to follow through with the medicine and to help Jason manage his behavior better in their home.

Three years later, as Jason continued to do well in school on stimulants, during a routine medication review with the child psychiatrist, Jason's mother reported that his father was getting divorced for a second time. Jason tearfully admitted that he was very upset by this and that he was going to miss his times with his stepmother and younger half-brother.

Telegram: @medical_k

www.konkur.in

The child psychiatrist asked to speak to the father, who agreed to come for a session with Jason and talk with him about what was happening in his family. Jason's father agreed to help him have continued phone contact with this stepmother as the father and stepmother proceeded with their plans for divorce.

Six years later, Jason was old enough to obtain a driving permit. He had continued to take stimulants daily and had done well in school. He had grown up without significant emotional and behavior troubles and was eager to learn how to drive. Jason's father and mother had continued to meet with the child psychiatrist every 4 months to review Jason's medication and to check in with how everyone was doing. They were concerned about Jason driving. Jason was sure that he would be able to drive perfectly well even though he was known to be more impulsive and more disorganized than other teens his age. The child psychiatrist helped the family to discuss the privilege of driving. They decided that they would let him drive with one of them in the car and not let him drive after dark for the first several months that he was driving. They decided not to allow him to drive with peers until he had driven successfully for several months. This negotiation was difficult for Jason, but Jason's father and mother both felt very supported by the child psychiatrist. They were comfortable with their decision that Jason could learn to drive as long as he was monitored quite closely and supervised very carefully.

Oppositional Defiant Disorder and Conduct Disorder

The primary goal of family therapy for oppositional defiant disorder and conduct disorder in one or more children is the establishment of a warm and mutually respectful relationship between parents and child, which forms the foundation of effective limits, appropriate supervision, and responsible prosocial behavior by the child. Often the family situation is complicated by any or several of a variety of family risk factors. These include parental stress, parental psychopathology or substance abuse, criminality and incarceration,

Telegram: @medical_k

www.konkur.in

poverty, marked parental preoccupation with time-consuming work, or preoccupation with other children. Overcrowding, living in a violent community, and domestic violence also occur frequently. Negative coercive cycles often occur in the interactions between parent and child, in which the child is demanding and the parent becomes controlling, leading the child to seek attention through misbehavior and leading the parent to believe that only direct control will make the child behave appropriately. The child fails to learn self-control and self-direction, and the parent becomes gradually and insidiously disempowered and negative toward the child. As the child grows, the parent increasingly becomes hopeless about the child and begins to believe that the child will fail to grow up successfully. This results in parents feeling helpless and re-emphasizes that improvement must come from outside the family. Therefore, the parent hopes that something else will lead the child to develop responsibility and seeks placement of the child in residential treatment or in the juvenile justice system. This perspective localizes the problem in the misbehaving child, leaving the child feeling blamed and even more disconnected from their family.

Two forms of family therapy deal specifically with these issues. Parent–child interaction therapy is specifically designed to treat families with young (preschool) children with oppositional defiant disorder. Multisystemic therapy has demonstrated effectiveness for families with adolescents with delinquency who are involved with the juvenile justice system. Parent–child interaction therapy focuses on building the positive aspects of the relationship between the parent and young child. Through the therapist's praise, the parent relaxes and becomes more accepting and more openly caring toward the child. The parent receives the therapist's praise and care and passes that on to the child, leading to closeness, the experience of being understood and cared for, and warmth and attunement in the parent–child relationship. This also leads to improved cooperation between parent and child, greater compliance on the child's part, and, on the part of the child, much greater interest in the parent's praise and positive regard. Parent–child interaction therapy has been shown in more than 30 clinical trials to be effective for families with preschool

Telegram: @medical_k

www.konkur.in

children (between ages of 2 and 6 years) with oppositional defiant disorder. It has also frequently been requested by child protective services to improve parent–child relationships in situations in which mild physical abuse has occurred.

Multisystemic therapy has been shown to be effective in reducing recidivism and delinquency for children and adolescents in treatment trials and through follow-up. Trained therapists with very small caseloads help the parents to manage the stresses in their lives and supervise and set limits on their child. The therapist is available to the family consistently and the treatment is intensive, with three or four contacts with the family weekly over 4 months. The therapist builds family cohesion and encourages the child to identify and earn privileges by being responsive to parental direction. Rules are defined and consequences are specified early in treatment. Parents are expected to be available, observant, and consistent in monitoring their children. For this to occur, other difficulties that the family experiences need to be addressed through the therapy. This treatment is best suited to moderate delinquency and works best early in the course of delinquency.

Another form of family treatment for conduct disorder is parent management training. In this therapy, parents attend sessions without the child and learn and practice techniques of setting limits and imposing consequences. Most important in this treatment is helping the parents plan and practice how they will withstand the child's demanding and defiant behavior and how they will respond if the child's behavior becomes worse before it gets better (as is expected). In this treatment the therapist supports a united front among adult authority figures and builds mutual support among these authorities. Parental self-control is another goal of these parent-coaching sessions. The therapist needs to ensure that the parents learn the skills necessary to set effective limits and manage their lives at the same time.

Telegram: @medical_k

www.konkur.in

Isaac was a 4½-year-old boy who was brought to a child mental health clinic for evaluation of defiant, challenging, and difficult behavior. He had been referred by his pediatrician after his mother discussed his defiant and difficult behavior with the pediatrician during a regular checkup. The history also revealed that Isaac had been expelled from his preschool and had to be looked after by a neighbor in her house because of aggressive and difficult behavior at school.

When the clinician met with Isaac and his mother, Isaac appeared to be a well-behaved, quiet child who was able to focus his attention and play easily with the interviewer. However, it was noted that his mother was extremely negative about him, and was frustrated, angry, withdrawn, and sad. During the interview the clinician noted that Isaac's mother was exhausted, overwhelmed, and observably sad and irritable.

The more comfortably Isaac played with the clinician in his mother's presence, the more upset and withdrawn she became. She reported that Isaac's father had left before he was born and that she had an older, 8-year-old boy with developmental disability and cerebral palsy. That child was in special education classes. She lived alone with the children. She stated that she was estranged from her mother and that she worked as a cashier in a grocery store. The family lived in a small apartment in an impoverished area of the city, and the mother reported that at times it was difficult to have enough food for her, Isaac, and his brother to eat.

The clinician was struck by the poignancy of Isaac's mother's situation, by her isolation and lack of support, and by her level of exhaustion and sense of being overwhelmed. The therapist was also touched by Isaac's attention to his mother and his tendency to watch her and comfort her when she became sad during the interview. The clinician was attentive to and supportive of the mother, and during the interview she began to calm down and admitted to being depressed, sad, and lonely.

Telegram: @medical_k

www.konkur.in

Isaac and his mother arrived for their second session on time and both seemed eager to talk. The mother had noticed that Isaac was a little bit better behaved at home, and she seemed more relaxed and comfortable.

The therapist continued to support the mother and encouraged her to engage with Isaac in a game during the session. The therapist was warm, caring, and praising of the mother's efforts with her son. The therapist also recommended that Isaac and his mother have some regular time to enjoy each other's company during the week and suggested 15 to 20 minutes every day, during which their neighbor could look after Isaac's older brother. As Isaac received more attention from his mother at home, their negative interactions decreased. He seemed to relax and become less quick to anger, both at his babysitter's house and at his mother's house.

The clinician also encouraged the mother to reconnect with her siblings and her mother, who were in the community, and to reach out to them for support and understanding. The mother noticed that she was more relaxed and less stressed and that she was more able to experience enjoyable times with her sister. She also began to communicate in a more open way with her mother.

As the sisters became more involved with Isaac's family, there were more family gatherings and more opportunities for the mother to experience some relief from her caretaking obligations. Over a period of 3 months of weekly sessions and 2 months of biweekly sessions, Isaac's mother became much more relaxed, was able to obtain babysitters for her children, and got more involved in her older son's special education programs. She became more assertive about obtaining a raise at work and socialized with her colleagues. She spent more time with her family and her neighbors. She also resumed attending church, and Isaac became involved in the church-sponsored preschool kindergarten group.

The therapist stayed in touch with Isaac and his mother and heard from her that Isaac had successfully begun kindergarten

Telegram: @medical_k

www.konkur.in

during the next academic year. His behavior was much improved and his curiosity, desire to play and learn, and attentiveness to adults had helped him to learn and grow in kindergarten.

Telegram: @medical_k

Joseph was referred to the intensive in-home treatment team after his discharge from the juvenile detention facility in his community. He was 15½ years old and had been placed in the detention facility after his arrest for vandalism and breaking curfew. The vandalism involved breaking windows in his school, and well as painting graffiti on several businesses in his downtown neighborhood. Joseph lived with his mother, stepfather, 12- and 19-year-old brothers, and 17-year-old sister.

When the in-home treatment therapist went to meet Joseph and his family, the mother was at home with the younger brother. Joseph was not at home. He had told his mother that he needed to visit his friends after school and that he would be home in time for the appointment. He was late and had not informed his mother.

The history the therapist obtained was that Joseph had been a very good student and a fine boy until the age of 9, when his grandfather suddenly died and his mother moved the family into the grandmother's house to look after her. Joseph had been close to his grandfather and had reacted to his death with sadness and withdrawal from the family.

His mother noted that he began to act up at that time and said that he had started hanging around the "wrong kids" at the age of 11 and had begun truancy when in middle school. Joseph had regularly received reprimands from the school administration, mostly for fighting, defying teachers' authority, and misbehavior during recess or lunch period. Joseph's mother said that at this point she believed that Joseph was outside of her control and she had hoped that 8 weeks in the juvenile detention facility would help him to learn to manage his behavior. Because he had not come home for the therapy appointment, she was worried that perhaps things were just as bad as they were prior to his arrest and stay in the detention center.

The therapist noted that the family lived in a cramped apartment in a rundown building that needed maintenance. When the therapist asked Joseph's mother about her husband,

Telegram: @medical_k

www.konkur.in

she stated that he also was supposed to have come home for the therapy session. She said that he often stopped at the bar on his way home to hang out with his friends and drink. Joseph's mother was increasingly worried about her 12-year-old son, who seemed to be following in Joseph's footsteps, and reported that her 17-year-old daughter would likely be moving out of the home with her boyfriend when she had her baby in approximately 3 months.

Joseph's 19-year-old brother was in and out of the house, and his mother was never sure whether she could expect him home on a specific evening. She thought that Joseph's older brother was having difficulties with substance use, and she reported that there were times when she smoked marijuana or drank just to get away from her concerns and feel better for a little while. The therapist asked Joseph's mother about the family's economic situation and learned that the stepfather had a regular job as an auto mechanic but was not paid well and that the mother worked part time in a department store as a cashier.

The family had Children's Health Insurance for the children. This managed Medicaid program would provide financial support for the intensive home-based treatment program. During the first meeting, the therapist worked to understand the family's situation and recognized Joseph's mother's affection for her children and the dismay that she was experiencing because of their difficulties. The therapist spent 90 minutes getting to know Joseph's mother and her youngest son. During this first meeting, Joseph's sister came into the house during their conversation and told her mother that she had seen Joseph hanging out on the street with friends whom he used to get in trouble with before he was in the detention center.

The therapist proceeded with the assessment and commented on the strengths of the family, including their strong connections with each other, and on the hopes of the family for the futures of the younger brother and the sister. The therapist developed a deep respect for Joseph's mother and closed the first session by saying that she would come back the next day and meet with the

Telegram: @medical_k

www.konkur.in

mother again. The therapist wrote a message to Joseph, saying that she had been there and that she had heard about him and knew that she would very much enjoy meeting him and invited him to be present next evening for her visit.

Over the next 6 weeks, the therapist visited Joseph and his family in their home three to four times a week. She invited Joseph's mother to call any time if she had concerns, and she helped Joseph's mother to think about her priorities for their treatment process. Joseph's mother said that her goals included helping Joseph stay out of detention and resume school; repairing her relationship with the children's stepfather and encouraging him to take care of his chronic alcohol use; improving the family's financial situation by obtaining a full-time job; and deciding with the stepfather whether to continue to allow Joseph's older brother to come and go in the household.

Mother and stepfather set up rules and consequences for Joseph with three expectations: (1) that he would attend school all day, each school day, (2) that he would attend an afternoon program at the local Boys and Girls Club, where he could receive tutoring to complete his homework, as well as engage in basketball and video games with other young people at the center, and (3) that Joseph would return home after the Boys and Girls Club for dinner and that he would have access to his cell phone and his video game set in the evening if he followed through with the plan.

Joseph initially strongly resisted the rules and expectations, telling his mother that "she had no right telling him what to do," that he was grown, and that "he could make up his own mind and make his own decisions." The therapist helped Joseph's mother reiterate to her son that she would be happy for him to have greater freedom if he demonstrated greater responsibility and was able to comply with the house rules. The therapist also visited Joseph's school and talked to his counselor and teachers and encouraged them to be warm, engaging, and supportive of Joseph to help him know that they wanted him to be in school every day and that they wanted to get to know him and learn

Telegram: @medical_k

www.konkur.in

about him. The therapist helped Joseph to write a biography of his grandfather, which Joseph researched by talking with other community leaders and neighbors who had known him. The therapist also encouraged Joseph to resume his interest in basketball and baseball and to learn as much as he could about the history of his family and the history of his family's role in his community.

As adults who expressed interest in him and his ideas surrounded Joseph, he began significantly to improve his mood, decrease his level of anger, and increase his hopes for the future and his interest in school and his after-school program. The intensive treatment program continued to work with Joseph and his family for 3 months and encouraged the adults in Joseph's life to express more responsibility and interest in him and to offer him more opportunities to be a part of his school and a part of his neighborhood. The therapist also encouraged the mother and stepfather to resume attending their church, which the family did, and the therapist talked to the minister about being particularly welcoming for Joseph, his older sister, and his younger brother. The therapist also talked with Joseph's stepfather about his alcohol use. The stepfather was receptive to decreasing his alcohol use and being home more in the evenings and paying more attention to his family and his wife.

Together with consistent, nearly daily contact with the family, involvement with several important adults, and child-serving institutions in Joseph's community, the therapist, by creatively using Joseph's interest in his family and in his grandfather and identifying Joseph's interest in telling the stories of his family, was able to improve Joseph's school attendance, sense of himself, and the family's overall sense of well-being in the 12 weeks of contact. When the program ceased, Joseph had several adults involved in his life, his mother had a full-time job that felt rewarding, her relationship with her daughter who was about to have her first child had significantly improved, and Joseph's younger brother had resumed his academic progress and his athletic activities.

Telegram: @medical_k

www.konkur.in

A family therapist at the local mental health center was able to meet Joseph and his family for the last 3 weeks of the intensive program once a week at their clinic. That therapist continued to meet with Joseph and his family over the next several months on a weekly or bimonthly basis.

At the close of treatment, 1 year after Joseph had been discharged from the detention center, he was at home consistently, was attending school, had caught up academically, and had resumed regular activities with peers who were interested in sports and academic success. Joseph's mother and stepfather had decided to remain married and had improved their relationship.

Family Therapy for Depression

The core of treating depression in children is the consistent building of competence and connections for the child. The problem in accomplishing these goals is that the depressed child has problems with concentration, which directly interferes with competence, especially at school, and marked irritability, which greatly interferes with successful relationships with family, peers, and important adults. Furthermore, the depression creates a marked lack of motivation, which leads the child to not believe in or pursue treatment. Substance abuse is often a comorbid problem, which may leave the child feeling better in the short term but with a significant long-term problem in addition to the symptoms of depression. The longer depression persists, the more likely it is that such a child will develop significant and persistent secondary problems, including academic failure, legal difficulties, and further alienation from parents, who may also be experiencing stress.

In the face of these difficulties, family treatment offers several advantages. The parents can be asked to ensure that the child participate in treatment, even if the child would rather not, as long as the child's problems persist. Suicidal ideation, plans, and attempts can occur at this point and require specific focused attention by the therapist and the parents. Parental warmth and encouragement can

Telegram: @medical_k

www.konkur.in

be achieved by linking the child's problems to the experience of depression. Depression can be defined as a phenomenon that has taken over their child, and which is painful and hurtful while draining the child's energy and motivation. The therapist can reinforce and support the parents caring for and commitment to their child. As the parents express their care for the child, the therapist can build the child's trust in the parents.

The therapist can then encourage the parents to expect the child to participate in school, both in academics and in activities while enlisting school personnel to engage with the child and provide remedial support if needed. The therapist encourages parents to be available and attentive to the child's accomplishments and supportive of the child's emotional experience. Therapeutic support for building on the child's interests, strengths, and abilities is also important, as are efforts to build relationships with prosocial peers while also limiting substance use. Prescription of selective serotonin reuptake inhibitors (SSRIs) while monitoring suicidality can promote this process for the child and family if needed.

www.konkur.in

Lydia was a 14-year-old girl who was brought to the emergency room of her local hospital after ingesting an overdose of 15 acetaminophen tablets. Lydia had taken the overdose after an extremely difficult day in which she was teased by friends at school, was criticized by her teacher for not having completed her homework, and then engaged in an argument with her mother about her wish to go out with friends that evening. Lydia challenged her mother and threatened to leave the house. Her mother was worried that Lydia might be meeting a teenage boy and got very angry at Lydia and called her a demeaning name. During the argument Lydia rushed into the bathroom and found the bottle of acetaminophen tablets and took the overdose. She then became quite frightened and told her mother that she had taken the pills. Her mother called an ambulance, and Lydia was brought to the emergency room.

Lydia maintained consciousness and talked openly with the clinician in the emergency room about her increasing distress over the last 12 months. She had become increasingly involved with peers who were in trouble, and her performance in school had declined. She also reported that she had stopped participating in her usual activities at school, including quitting the cheerleading squad. She had been sexually active with a 16-year-old boy on one occasion and reported that the boy had stopped going out with her after they had had sex, and he had talked about the experience in an embarrassing way with other young people at her school. She had previously been a good student and popular in her class but had recently become more irritable, more isolated, and less interested in academics and her friends.

Lydia's mother reported that her daughter had changed from a happy, upbeat teenager to a surly, irritable child who was very difficult to communicate with. Lydia lived with her mother and her three younger brothers, who were 9, 7, and 5 years old, respectively. Their father had left the family to work in another community and was sending money home to the mother. He was

Telegram: @medical_k

www.konkur.in

away for several months at a time doing construction work and was only in contact with the family by phone once a week. Lydia had been very close to her father, and his recent occupational absence had been distressing for her. She had felt isolated and disconnected from her family.

Lydia's relationship with her mother had always been ambivalent; she had been very helpful but not very emotionally close to her mother and had become more quick to anger and argumentative with her mother over the last several months.

Lydia was admitted to the adolescent medical unit for monitoring because of the possibility of toxicity from the acetaminophen. While in the hospital, she and her mother were seen by a child psychiatry consultant, who invited Lydia to talk openly with her mother about why she had made the suicide attempt and what had happened that day that had so upset her. The consultant also encouraged Lydia to talk about missing her father and her recent sadness. Her mother, while being somewhat defensive, was supported by the clinician to listen to her daughter's difficulties and concerns.

Lydia was able to be open with her mother about the problems she was having in school, the difficulties that she was having with peers, and the fact that school suddenly had become very difficult for her. The clinician held daily sessions in the medical hospital over the next 3 days with Lydia and her mother to enhance the closeness and supportiveness of their relationship. He encouraged Lydia's mother to listen to her daughter in a nonjudgmental and nonreactive fashion. As the mother felt the support of the clinician and his encouragement to be clear with Lydia about her concern about the impulsive suicide attempt, her mother was also able to be more understanding and available to her daughter during these meetings. The clinician also arranged a phone session with Lydia, her mother, and her father.

After 3 days of medical hospitalization, Lydia was able to apologize to her mother for taking the overdose and to ask her for enhanced involvement and understanding at home. The family was then referred to an outpatient clinician at the local

Telegram: @medical_k

www.konkur.in

mental health center, where they were seen 3 days after discharge. Lydia reported improved mood and increased attention from her mother at home and had returned to school. The new therapist asked permission to contact Lydia's teachers to arrange more support at school. She strongly praised the enhanced closeness between Lydia and her mother.

Lydia was not initially placed on psychopharmacology. She had noted improved mood at home and had managed her behavior with less irritability and impulsivity in the initial week following her hospitalization. Future sessions were held weekly and were divided, with half the session for Lydia individually and half of the time with Lydia and her mother. The therapist focused with Lydia on her life at school, her schoolwork, and her peer relationships. The meetings between Lydia and her mother led to enhanced understanding, improved communication, and greater mutual support. Regular phone calls involved Lydia's father.

With the enhanced family support and Lydia's increasing competence as a teenager, her mood improved dramatically, and her relationship with her mother grew closer. The telephone contact between Lydia and her father re-engaged them and restored the warmth they had shared.

After 3 months of outpatient treatment, Lydia was doing well and came for sessions once every 2 weeks. The therapist noted that Lydia's mother was sad and missed her husband and offered the mother the opportunity to come for individual meetings to talk about this and how she could carry on at home while her husband was away.

Traumatic Stress in Children

Trauma-focused cognitive-behavioral therapy for children has been identified as an evidence-based treatment for traumatic stress in children. It is important to recognize that this treatment has an essential family component. Family education, emotional support for the parent who may be distancing themselves due to the child's traumatic experience, and family involvement in supporting the child

Telegram: @medical_k

www.konkur.in

while developing and sharing the trauma narrative are essential elements in this treatment. This often requires that parents accept the reality that they could not protect their child from harm or that one or both of them might actually have perpetrated the harm. Helping the parents acknowledge their feelings and the realities of their child's experience of exposure to or injury by trauma can often be quite challenging. The therapist has two goals: to support and care for the parents and to assist the child in understanding and dealing with what has happened to them. This can be horrific and is often frightening or infuriating for the therapist. Therapists in this situation often need an opportunity to discuss cases with colleagues or with a supervisor. Attention to the safety of all participants provides the foundation for engagement, and engagement builds the trust needed to share the painful, shameful, and sad aspects of trauma and its aftermath. These realities are present regardless of the source and nature of the trauma. Focusing on a successful resumption of family life founded on the belief that the trauma has led to closer relationships and greater resilience is often healing in itself. The recognition of family resiliency is then coupled with acceptance of the unpleasant emotions that are normal responses to trauma among them all. A step-by-step therapeutic approach, including the family, is extremely helpful. This approach leads from providing safety to ensuring that basic needs are met. It continues with education for understanding, behavioral competence, emotional support, and narrative creation and validation. The trauma becomes a remembered but not excessively arousing experience. As with family treatment of other child problems, the treatment can lead not only to the resolution of traumatic stress but also to an enhanced awareness of family strength among all members.

www.konkur.in

Monica was 6 years old and was referred by her pediatrician to a child psychiatrist for evaluation after she had been involved in a serious motor vehicle accident. One month prior to the referral, Monica had been riding in the car with her mother. She had been seated in a booster chair in the back seat. Their car was hit by another car that was driving very fast. Only Monica and her mother had been in the car, and Monica's mother was seriously injured in the accident. When the ambulance came to pick Monica up, they noticed that she was crying for her mother and that she was shaking in the back seat, although she did not seem to have been physically injured in the accident.

Monica's mother had lost consciousness in the front seat and needed to be taken to the emergency room in a helicopter. The police had removed Monica from the back seat, and one of the policemen held her on his lap while she was crying out for her mother. They found the mother's pocketbook and called Monica's father at work. As Monica's mother was being flown to the emergency room in the helicopter, Monica's father came to the scene of the accident and picked up his daughter.

Monica had previously been a healthy girl attending first grade. She had two younger sisters, ages 4 and 2 years, respectively. Her father was a lawyer in a firm in the community, and her mother was a part-time bookkeeper for a local physician. The family had significant resources, and the children attended either private school or private daycare.

Monica was slow to warm up and approached new situations with fearfulness and reticence. Now, 3 months into the school year, she had established friends and had a very positive relationship with her teacher. When her father brought her home and got a neighbor to stay with his three daughters while he went to the hospital, everyone noted that Monica was extremely upset.

During the mother's hospitalization, which lasted for 2 weeks, she required abdominal surgery to remove her spleen and was found to have a fractured tibia and fibula in one leg and required a cast and crutches. Monica had been able to talk with her

Telegram: @medical_k

www.konkur.in

mother by phone several times in the hospital beginning on the fourth day after the accident, and near the end of her mother's hospitalization, Monica had been able to visit her in the waiting area of the hospital.

When Monica's mother came home, she learned that Monica had been crying every morning on the way to school and also while at school. Monica also had become increasingly withdrawn at home from her younger sisters and at school from her peers and from school activities. Because of this withdrawal and problems with separation, Monica's pediatrician recommended that she and her family see a child psychiatrist.

The child psychiatrist obtained the history just described and noted that Monica's mother was also having nightmares and flashbacks of the accident and was increasingly hypervigilant. She had become frightened to drive the car. Monica's father was very concerned about his wife and about Monica and attended the initial session with them. He stated that he knew that his wife and his oldest daughter were both quiet and shy and were very much alike and very close to each other.

The child psychiatrist determined that Monica's father was deeply invested in his marriage and in wanting to help Monica and his wife recover from the physical and psychological effects of the automobile accident. During the conversation Monica's mother stated that she felt extremely guilty for having the accident and was frightened both about what had happened to her and also the possibility that the accident could have hurt her daughter. She began crying in the session and it was obvious that her distress deeply affected both Monica and her father.

The child psychiatrist talked with the family about the fact that they had a normal reaction to an extraordinarily frightening and traumatic event. He also explained that the trauma for Monica was somewhat different from the trauma for her mother. Monica's trauma involved not only the accident but also her fear of her mother's well-being and her experience of being separated from her mother at the scene of the accident and during her mother's hospitalization.

Telegram: @medical_k

www.konkur.in

The psychiatrist contrasted that with the mother's fears from her injury and treatment, her worries about her daughter, and her guilt from the car accident. The child psychiatrist also spoke about the strengths he recognized in the family: the father's intense connection to the family, his dedication to being helpful to his wife and his daughter, and their impressive closeness and love for each other. As he said this, the family relaxed. The therapist suggested realignment of the family's energy now that the threat to survival was over. He suggested that the family begin to orient themselves to resume their lives as a family while also recognizing their fragile emotional state.

The child psychiatrist recommended a family-based course of therapy over the next 8 to 10 weeks in which the mother, father, and daughter would work on reconnecting with their future lives while integrating their experience of trauma, injury, and anxiety into their past. The psychiatrist proposed homework for the family; he suggested that the father spend time alone with Monica, talking with her about the fact that her mother was better now and that it was her job to resume being a big sister to her little sisters, a student at school, and a regular 6-year-old girl. The therapist also suggested that the mother and father talk together to help the mother to accept the accident and also to appreciate that because of her appropriate attention to her child's safety, her child was in the booster seat in the back seat and was not injured. They could discuss the fact that the mother had taken very good care of Monica and that Monica was having trouble because she continued to be frightened that her mother was not all right.

Over several sessions, Monica's mother was able increasingly to reassure her daughter that she was okay and encouraged her daughter to re-engage with her school and friends and enjoyment of activities and fun as a child. She also gradually reassumed her role as an effective and caring mother for her three daughters. The father stayed actively involved with all of the children and maintained his belief in his wife's ability to recover and resume her role as his wife and their children's mother.

Telegram: @medical_k

www.konkur.in

It became apparent to the therapist and Monica's parents that they had too rigidly adopted complementary roles as breadwinner and caretaker and that some readjustment of their partnership would need to be addressed in the therapy and recovery process. Monica's mother was grateful to her husband for being more flexible and responsive to her and their children's needs. He continued to be invested in his career, but with less intensity and less single-mindedness.

After 4 weeks of treatment, Monica was increasingly acting as she had prior to the accident, as a successful student, a confident big sister, and someone who could more easily separate from her mother and the family. She had fewer episodes of tearfulness and was able to sleep through the night.

After 8 weeks, Monica's teacher reported to the parents that she had, in fact, resumed the previous functioning and had caught up academically and appeared to all to have recovered. Her mother was less frightened and was sleeping well, and had resumed work and driving. She and Monica could discuss the accident openly without crying.

Treatment of Anorexia and Substance Abuse

Family therapy–based treatment models have demonstrated effectiveness for both anorexia nervosa and adolescent substance abuse. While anorexia was formerly thought of as a disorder of middle and upper class families, it has more recently been recognized in children and adolescents of all classes and ethnicities. In both of these problems the child is involved in an engaging, self-reinforcing, and dangerous behavior. This behavior often is pursued in an extreme fashion and ultimately leads to failure to achieve other developmental skills. The lack of these skills also often renders the child anxious and further narrows the child's orientation to their life. There may be a genetic predisposition to either anorexia or substance abuse. Despite this, the child will need to learn to manage the impulse to diet or the impulse to use substances in a dangerous manner. In the majority of these situations, the parents will bring the

Telegram: @medical_k

www.konkur.in

child for treatment and will be concerned about their inability to lead their child out of their self-destructing behavior patterns. Two evidence-based family treatments have been developed for these problems, and their effectiveness has been documented through randomized, controlled treatment trials. These treatments are multidimensional family therapy for adolescent substance abuse and family-based treatment for anorexia. Both of these treatments assign responsibility to the parents for reducing the intensity of the symptomatic behaviors. In family-based treatment for anorexia, the parents are given the responsibility of helping their child gain weight with the therapist's support. As the parents take on this responsibility, the therapist helps them to be successful in attaining the child's attention and the child's compliance. The child gains greater support and autonomy as they participate in treatment. The therapist also supports the child's interest in and competence with activities and with peers. If treatment is initiated early in the course of the disorder, it can be effective and relapse is rare. Family treatment for substance abuse in adolescents is similar. However, often school failure, legal difficulties, a history of poor supervision, and the influence of negative peers complicate the clinical situation. The treatment manual for multidimensional family therapy identifies ways of addressing these challenges while simultaneously providing the supervision, support, and limits necessary to reduce substance use. Once again, the keys to treatment effectiveness are opportunities to behave in prosocial ways with intense family support for competency and success associated with consistent, unwavering expectations and reasonable but not excessive consequences.

www.konkur.in

Joan was 14 years old and lived with her parents and 12-year-old sister. She was referred to a child psychiatrist by her pediatrician, who had recently evaluated her for significant weight loss and dramatically reduced food intake.

Joan's parents were middle class, and both worked long hours. They had become concerned about her dieting and weight loss but had been unable to have it cease. When Joan and her mother met with the child psychiatrist, Joan stated very clearly that her weight was a major concern to her, that she still felt that she needed to diet and lose weight and that under no circumstances was she going to eat what the pediatrician and nutritionist had recommended. Joan's father was a busy executive who traveled twice monthly and who had grown increasingly distant from his daughters over the last year. Joan's mother stated her concern that her husband was not as involved with his daughters as he should be and that now his sole interaction with Joan concerned her eating. He yelled at her, trying to get her to eat. Joan's mother had thought that her daughter was experiencing anorexia nervosa, and the therapist concurred. The therapist strongly suggested that Joan's mother and father come to a session later that week to discuss a plan to help Joan with her anorexia. The therapist received a phone call from the father stating that he needed to be out of town on business, but the therapist firmly stated that he should postpone his trip and attend the session with his wife and daughter.

The therapist's first efforts in the meeting were to emphasize to both parents the need for them to work together and to assist Joan with rules that would encourage her to follow through with the food recommendations of her pediatrician and her nutritionist.

As the therapist helped Joan's parents plan how they would expect Joan to eat the required amount and gain weight as suggested by her pediatrician, the therapist also suggested that Joan finish her meals before she left the table and pursued other activities or completed her homework. Joan was upset and frightened at the prospect that she would gain weight. The

Telegram: @medical_k

www.konkur.in

therapist helped the parents to be understanding but firm and to reiterate their expectation of consistent weight gain. The parents were also advised to be explicit about caloric expectations and meal planning.

As Joan gained weight, she gained more freedom to choose which foods the family had in the house, but she was still required to eat the required amount of calories. Her rate of weight gain was consistently 1 lb per week, and she went from 80% of her ideal body weight to 95%. As Joan began gaining weight, the therapist noted increasing distress in her parent's relationship. The therapist suggested private couple sessions for the parents to discuss their relationship. Individual sessions were held with Joan to assist her with assertiveness, peer relationships, and ways of decreasing her perfectionism with regard to her schoolwork.

Joan participated in her individual sessions eagerly and was soon noted to be spending more time with friends and less time preoccupied with food, dieting, and weight. When she reached 100% of her ideal body weight, her menses resumed. The therapist was also meeting regularly with Joan's parents. Joan's mother expressed her concern that her husband was more involved in work than with the family and that this was not all right with her. She became assertive with him, and they began to negotiate a different approach to family and work. They also were advised to spend some time alone together. Joan's father responded well to the couple sessions, and her parent's marriage improved and became more satisfying for both of them.

Over the 8 months that therapy continued, Joan resumed normal adolescence, family relationships improved significantly, and Joan's father became more engaged with his daughters.

www.konkur.in

Stephanie was a 15-year-old girl who was referred to the substance abuse treatment program because her parents were concerned about her alcohol and marijuana use. She lived with her stepmother and biologic father. Prior to this school year, she had been a successful student and had played in her high school band.

Stephanie's biologic mother had significant trouble with alcohol and drugs when Stephanie was a preschooler. After failed attempts at treatment, Stephanie's father separated from her mother and gained full custody of his daughter. Stephanie knew that her mother was in another state and believed that she was still having trouble with alcohol use. She had not had contact with her mother for 12 months prior to her referral.

Stephanie's father had remarried when Stephanie was 6 years old, and Stephanie had two younger half-siblings, a 7-year-old brother and a 4-year-old sister. This year Stephanie had increasingly felt disconnected from her stepmother and her younger half-siblings. Her relationship with her father had begun to deteriorate as she became more defiant of rules and more involved with peers. She was home less frequently and was less involved with family activities. Stephanie's stepmother had been called by her school when she had been found somnolent and disoriented at school.

Stephanie's stepmother and father took her to the emergency room, where she was found to be intoxicated with alcohol. She said she had gotten the alcohol when she and some friends had gone to a friend's house during lunch period. Stephanie's father and stepmother had been concerned that Stephanie might be using substances frequently and in a problematic way. Over the last several months, she had been coming in late after curfew, staying over at friends' houses frequently, and had been less involved with her previous friends and more involved with a group of friends that the family did not know very well. Stephanie had also dropped out of the band and stopped playing her

Telegram: @medical_k

www.konkur.in

instrument. Her academic performance had decreased significantly.

Stephanie agreed that she was using drugs and alcohol but steadfastly stated that she did not have trouble with them and that she was only doing what her friends did. When Stephanie, her father, and her stepmother met with the family therapist at the drug treatment center, it became apparent to all that Stephanie's problems were quite significant and were seriously jeopardizing her physical safety as well as her developmental progress.

In the first session Stephanie tearfully admitted to involvement with unprotected sex, especially when she was intoxicated. With guilt and shame she admitted that she did not want to be doing what she was doing but had found it very difficult to refuse substances or affection and physical intimacy when she was with peers.

The family therapist suggested to Stephanie's father that she was scared and lost rather than defiant and delinquent. Stephanie's father, with some difficulty, acknowledged that this might be true. The family met with the therapist three times a week at the program while Stephanie participated in the adolescent after-school drug treatment groups. The therapist helped Stephanie's parents to institute a curfew and ensure adult supervision after dinner and on weekends. Stephanie reluctantly, but in fact with relief, accepted these rules and adhered.

Regular drug testing was part of Stephanie's program, and over the first month of treatment, she was consistently free of evidence of drug and alcohol use. The therapist also strongly recommended that Stephanie attend the adolescent 12-step program meetings with the teens in the treatment group. The therapist also spoke with Stephanie's counselor and teacher at school. They were advised to strongly encourage Stephanie to rejoin the band, resume her musical practice, and participate in tutoring and additional homework to improve her academic standing. Stephanie responded to this with some initial reluctance, but ultimately with the support and encouragement of her teachers, school counselor, therapist, and band leader, she

Telegram: @medical_k

www.konkur.in

was able, after a rocky period of a couple of weeks, to be more involved in school and more involved with the friends she had distanced herself from after she had gotten involved with her substance-abusing friends.

During this time, Stephanie was also seen by a child psychiatrist. The child psychiatrist reported that Stephanie was sad, but he did not believe that she warranted antidepressant medication. The child psychiatrist told Stephanie, her father, and her stepmother that he was very pleased with the progress that they were making in the intensive substance abuse treatment program.

Stephanie's mood continued to brighten. She was encouraged to have evening and weekend times with her father and stepmother. Her stepmother was advised to spend time talking with Stephanie about her friends and her activities. She was encouraged to avoid disciplining Stephanie but to inform her father about any concerns. Stephanie responded to this with improved connections with both her father and her stepmother. She also spent more time with her half-siblings.

Three months into treatment, at the time that Stephanie's discharge from the intensive treatment program was planned, her urine tested positive for alcohol. Her parents also discovered that she had come home after curfew, apparently intoxicated after attending a party without parental permission.

The therapist helped the family to recognize that Stephanie had had a difficult weekend and continued to have difficulty resisting the attraction to alcohol and the encouragement of peers to use substances. The therapist worked intensively for the next 2 weeks to reconnect Stephanie with her father and stepmother and to re-establish more-intensive supervision for Stephanie. The therapist encouraged the father and stepmother to maintain hope for Stephanie's success in the future. Stephanie asked her parents to be understanding and forgiving of her episode of alcohol abuse. Her father and stepmother realized that they could not yet expect Stephanie to be able to make

Telegram: @medical_k

www.konkur.in

mature decisions when exposed to substances and that they would need to provide intensive supervision.

The therapist also spoke with Stephanie's father and stepmother about the difficulties they were having as a blended family and worked with them to understand the challenges of that experience. They worked on building one family of five rather than two families, one with four members and another with three members. At the same time, the therapist spoke with Stephanie about her experience of abandonment and hurt in her relationship with her mother and about her worries about her mother's well-being. Stephanie talked about her fear that she would grow up to be like her mother. As Stephanie held these conversations with her therapist, she was able to be increasingly mature and thoughtful about herself and her previous experience of neglect and abandonment. She also was encouraged to speak about this with her father in a session.

The involvement of the entire family in treatment, the appreciation of the family's history and experiences, Stephanie's involvement in a teen substance use program, and the active involvement of her school had all been elements in treatment. Individual therapist support to help her to understand and accept her difficult relationship with her mother was also essential. All of this helped the family to bond together more openly and to be increasingly successful in the developmental challenges that they were facing.

Family Treatment for Divorcing and Blended Families

Family transitions occurring as a result of parental separation and divorce and remarriage are disruptive to children. If parents are able to be congenial with each other and to amicably resolve issues related to the divorce (including financial issues, grieving the end of the marriage, and child care and custody issues), the children, though they still grieve the end of their family and accommodate the changes to family life with sadness, will usually do so without significant relationship problems and persistent behavior problems.

Telegram: @medical_k

www.konkur.in

However, if significant resentment, anger, and conflicts continue between the former partners, the effect on the children can be significant and persistent. Problems with academic performance and mood and behavior problems can develop. The conflicting parents often do not manage these difficulties successfully, and family treatment can be necessary. The first step in this treatment process is to identify and support the concern that each parent has for the children and for resolving the children's problems. Parents may be motivated by different concerns—for example, one by a child's academic difficulties and the other by the child's sadness. In any event, bringing together antagonistic parents is an important element in treatment. The family therapist should work extremely hard to help the parents to understand that their children need both of them and need them to work together in parenting for the children's well-being. This process may be difficult and time-consuming, but it provides the best foundation for the children's successful outcome. As the therapist helps the biologic parents work together, they can also help the children express their concerns with each parent individually in separate therapy sessions.

Several aspects of post-divorce life can be problematic for children. Often a parent can be very involved in their life, including work and relationship building. This can lead the children to be unsupervised and to further engage in problematic behaviors. To address this, both parents (if possible) will need to supervise the children and reiterate their belief in the children's strengths and capacity to be successful.

When stepparents are involved in problematic post-divorce situations, matters can worsen. Stepparents may decide that enhanced discipline is needed and may attempt to act to deliver that. As the stepparent works to impose discipline, a child often becomes indignant and defiant. The more forceful and demanding the stepparent becomes, the more defiant the child becomes. Family therapy can reorganize this situation and lead both biologic parents to take a central role in the child's life and success and address challenging behaviors. Family therapy can also help stepparents to take a peripheral but very important role as supporter and ally for

Telegram: @medical_k

www.konkur.in

both the child and biologic parent. The stepparent can express concerns and worries about the child, but rather than to the child directly, these concerns can be expressed to the biologic parent, who can act on them in concert (if possible) with the biologic parental partner. The therapist can also encourage the stepparent to develop a warm, accepting, and caring relationship with the child based on mutual interest. This decreases the child's antagonism toward the stepparent and may significantly improve the mood of the family while also enhancing trust and attachment between the child and the biologic parent.

As time passes, the child can adapt to the changing family and maintain a supportive and engaged relationship with both biologic parents and accept stepparents and step-siblings. The therapist can also help the new partners build their relationship while they manage successful relationships with all children and with former spouses.

Kevin was an 11-year-old boy who lived with his mother, maternal grandmother, 17-year-old sister, and 14-year-old high-functioning autistic brother. Kevin was referred to see a child psychiatrist because his mother was concerned about his excessive worries. The whole family had been living with their maternal grandmother since Kevin's parents separated and divorced when he was a year old. Post-divorce, the parents had a long history of custody battles. At the time of the initial visit, the parents had shared legal custody, but the mother had physical custody. Their divorce agreement specified that if there is a disagreement regarding medical and academic needs and decisions, the mother's decision supersedes the father's preference. The father's consent to provide psychiatric treatment was received, though he did not see a reason for an evaluation. Kevin and his brother would stay with their father every other weekend and have dinner with him at least once a week.

Kevin's mother wanted him to be engaged in treatment because she believed that he suffered during the custody battles. He always had difficulty academically, but his performance deteriorated when his sister refused visitation with their father 3 years ago. When he was anxious, he would be short of breath and would pace around the house and scream. This would occur specifically when he was struggling with his homework and when he was supposed to visit his father. This behavior would take place every 3 to 4 days. Nightmares would wake him up shaking in the middle of the night.

His father was invited to participate in the evaluation and treatment. Initially, his involvement was limited, but when he realized that some of Kevin's difficulties were related to his upcoming wedding, he became more engaged.

Kevin and his father were encouraged to engage in conversations to communicate his difficulties with "his growing family." Kevin was able to feel safe in therapy to inform his father of his grievances, including his concerns about his stepmother taking over his mother's role. He worried about his mother being

Telegram: @medical_k

www.konkur.in

alone while also grieving the permanency of their divorce. With the support and involvement of his father's fiancé, his mother and his father were able to hear his concerns, to encourage him to speak-up, and to compromise when necessary. They were able to validate the loss of his original family but also to reinforce that they all had a special relationship with him individually. He was reassured that these relationships were going to remain unchanged and that one relationship could not take the place of the other. The family members were able to discuss their expectations of him in both households. They agreed to keep the rules and these expectations consistent so that it would be less confusing for Kevin. As all relationships improved, Kevin's anxiety and difficulty in school were resolved.

Family Therapy for Families from Diverse Backgrounds

Family therapists, and all providers, should be sensitive to the family's cultural norms in order to provide the best care. When discussing diversity, one often thinks of ethnicity and race exclusively. Concerns about diversity must also include differences in socioeconomic status, sexual orientation, and nontraditional family units (i.e., same-sex parents). Each family has its own culture and values that define its norms and guiding principles. Culture is the foundation that dictates one's sense of how to be, what is "normal," right and wrong, and reactions to others. The degree of assimilation to the culture of the local area (community, region, or nation) plays an important role in the family's goals for the treatment. A family's culture also influences the degree of mental health stigma and directly impacts the level of trust in mental health care. Family therapy may be tailored to increase engagement with the family to overcome distrust, mental health stigma, and past experiences of being misunderstood, misperceived, or discriminated against. Being curious about the family's history of hardships, trauma, losses, and experiences of discrimination and exclusion early in treatment helps the therapist understand the family.

Telegram: @medical_k

www.konkur.in

As the therapist engages with a family of a different culture, they will need to be aware of how the family meets three challenges that families from diverse background experience. The first challenge is to assimilate into the culture of the host country without losing their traditional values. The second challenge is to balance passing on their cultural traditions to the next generation with supporting the youth's success in the western culture. The third challenge is to manage how different family members adapt to the mainstream culture at a different pace which can result in acculturative family distancing (AFD). AFD can increase family conflicts while decreasing family cohesion through miscommunications and misunderstandings among family members.

Family therapy addresses where each family member is in their acculturation process. The therapist will also need to appreciate each member's expectations from treatment, the caretakers' parenting approach, the strengths of parent–child relationships, and parent–child conflict. The therapist can navigate AFD by highlighting the love and affection between parent and child and by creating an atmosphere of mutual acceptance and compromise, a both/and approach that is based on connection and shared commitment to family life and the development of the child's independence. By elaborating on the narratives of the parents and the child, the therapist increases mutual understanding, further fostering trust and collaboration. The therapist's task is to honor and respect how the family understands their differences. By recognizing and elaborating on the different ways family members express their love, the therapist can open the door for acceptance and growth.

Success with diverse families is defined by the family's ability to promote the value of success in America as well as their traditional cultural values, traditions, and rituals while also dealing with the presenting concerns.

www.konkur.in

Ana is a 17-year-old Mexican-American girl who was sent to the ER from her school. At school, her English teacher had raised concerns because of an essay that she submitted for an assignment. The assignment was to share reflections on a difficult moment. Ana shared her challenges at home and her struggle with living in two worlds that sometimes have opposing expectations. She also shared that she felt trapped and wished there was a way to escape her situation. Subsequently, the teacher reached out to the guidance counselor, who spoke to Ana in depth. When probed, Ana admitted to having thoughts about walking onto a high-traffic highway. She was unclear whether she wanted to die, but she was clear that she found her situation to be unbearable. The guidance counselor also felt that Ana had a flat affect, a depressed mood, and was socially isolated. The teacher had also endorsed her declining grades and decline in the quality of her class and homework. Following the school protocol, the guidance counselor called the parents, shared her concerns, and informed them that Ana could not return to school unless a psychiatrist had deemed her safe to return.

This information was surprising to the parents. As suggested by the pediatrician and the guidance counselor, they took their daughter to the nearest hospital. After prolonged waiting in the emergency room, they spoke to the psychiatrist. Ana shared her story with significant shame and guilt. She felt that she was burdening her parents, who worked hard to take care of her and her siblings. She also knew that her father had to request time off from work to be with her. Though the psychiatrist was thoughtful, the parents felt attacked, as if they were too demanding and uncaring about their daughter. They also felt a bit ashamed that they were not aware of the degree of stress on their daughter. Once the psychiatrist understood the family's concerns, she referred the family for an outpatient family therapy visit with a child psychiatrist at the same institution. She also informed the

Telegram: @medical_k

www.konkur.in

outpatient psychiatrist of the parent's experience in the emergency room and at the school.

At the first visit, it became clear that though the mother spoke English, a Spanish interpreter would be preferred so she could share her thoughts more freely. It was also apparent that the parents felt forced to engage in this service and were not happy about sharing their family stories with a stranger. Ana was palpably aware of these concerns and appeared shut down. The child psychiatrist understood these challenges and tried to gain trust by asking about their goal for the meeting. Mother and father shared that they want Ana to be safe, be less stressed but also acknowledge that the family is the most important. For them, family included her siblings but also grandparents, aunts, uncles, cousins, and sometimes even family friends. Ana's goal was to feel normal among her friends at school and be accepted by her parents. She felt that too often, her actions were divided between "an American" or "a Mexican" way of living.

Through the second, third, and fourth visits, the psychiatrist was humbly curious about the parent's experience in Mexico, their journey to America, and their hopes for their children. Ana's father came to America in his 20s in search of opportunities. He struggled with poverty and the loss of family support upon coming to America. He worked hard at a retail store, a restaurant, and as a truck driver to support his family and to make his parents proud of him. Throughout his time in America, he had been discriminated against and had to deal with prejudice. But, with hard work and dedication, he was able to bring his other siblings to America. Together, they were able to open a small business and navigate the ups and downs of the economic challenges. He married his wife when he was visiting his family in Mexico. Her transition to America was very isolating since he worked long hours, she did not have a Visa to work, and she did not speak English. Though they had been in America for over 20 years, they had adhered to their cultural values to retain their "way of life." They spent a significant amount of time with

Telegram: @medical_k

www.konkur.in

their own family members (including Ana's uncles) as a way to be protective of their culture.

The family therapist learned that Ana's parents valued family time, gender roles, and importance of cultural involvement as they had learned prior to immigration. Ana's parent's expectation of "family first"—taking care of brothers', helping with chores, and being involved with the Mexican American community—conflicted with her own desires to be more like her peers. She enjoyed American pop music and wished that her family would be accepting of her new white American boyfriend. They worried that Ana would drift away from them as she was more comfortable American culture. Furthermore, Ana would often be playing the role of translator for her mother and explaining the American cultural norms to her. This situated her in a unique position of supporting her parents to navigate American culture but, also increased the burden on her as well. She felt that they didn't understand her hopes to feel "normal" and not be isolated from and different among her peers. She also felt that the more she tried to fit- in among her peers the more isolated, disconnected, and she was in her family.

Over time, the psychiatrist was able to appreciate the parents' worries about losing their traditions and language (as Ana preferred to speak in English rather than Spanish.) He also recognized that the parents were completely dedicated to the well-being of their daughter and her future success. With the psychiatrist's support, parents were able to appreciate Ana's burden of straddling two cultures. They began to be more lenient with their expectations and allowed Anna to spend more time with her friends and boyfriend. Though they had still not met the boyfriend, they were more curious about him. They were accepting that Ana would only flourish if they embraced both cultures. The psychiatrist spent a significant amount of time processing their grief over losing some traditions while supporting their unique ways of retaining Mexican cultural values.

Ana was also encouraged to appreciate her parents' challenging journey to America in search of more opportunities

Telegram: @medical_k

www.konkur.in

and privileges for her and her siblings. She was able to respect their dilemma in holding on to their Mexican roots while trying to raise children with Mexican values and American values. Ana was proud of her parents for creating their own path to success and opportunities with limited support. She was inspired by their resilience, their dedication, and their love. This also resulted in her feeling less isolated now that her parents were accompanying her in navigating both American and Mexican cultures.

The child psychiatrist continued to support open communication between Ana and her parents. Ana reported improved mood at home and was less irritable with her parents. She also improved her grades and her participation in school. Therapy sessions were now taking place less frequently but continued meetings between Ana and her parents led to enhanced understanding, improved communication, and greater support for all to manage a bicultural lifestyle.

Family Therapy for Families with Children with Developmental or Medical Challenges

Families with children with developmental delay, autistic spectrum disorders, or chronic medical illness face unique challenges. Family therapy can help those families who are having difficulty managing emotions, behavior, and illness treatment or achieving the optimal development of the affected child or siblings. These situations often are extraordinarily sad and difficult to deal with. There can be financial challenges, career advancement can be negatively affected, illness or handicap care routines can be onerous, and opportunities for parental intimacy and family enjoyment can be threatened. Parental burden and stress can be extreme, and at times the expected positive effects of medical treatment may not occur. Marital relationships may be threatened, and siblings may not receive adequate attention and supervision. Parental isolation may also seriously jeopardize family well-being. Family therapy can address these difficulties by offering the parents, the affected child,

Telegram: @medical_k

www.konkur.in

and siblings a safe environment in which to discuss reactions to the child's problems and to collaborate on making the situation the best that it can be. Parental cooperation and parental mutual understanding are goals. All those involved can be guided by the therapist to learn about the child's condition, current and potential treatments, and prognosis. The parents, the child, and siblings can be encouraged to ask questions and to be assertive with the medical care team. The family and child can be encouraged to recognize the areas of the child's life that are not affected by the illness or handicap and the child's strengths and abilities. The therapist can also recognize the courage and care of all in dealing with the challenges of the child's condition. As the family recognizes their commitment to the affected child, they can come to see themselves as heroic and resilient, and the child can note their courage and competency regardless of the illness or handicap. The therapist can help the family work with the school and teachers and with extended family members to understand and support the affected child while also helping the child engage teachers, neighbors, peers, and extended family in an assertive, positive, and confident manner. Finally, the child's active participation in their care can be noted and recognized as a sign of competence and mastery that will help the child throughout life. The family therapist can also support the family if the child's condition fails to improve or deteriorates. The therapist elicits and ratifies legitimate responses of sadness and powerlessness and accepts their powerlessness over the illness while staying involved with and attuned to family members' sadness and grief.

Dave is a 9-year-old boy who lives with his parents and 1-year-old brother. He had been undergoing treated for high-functioning autism spectrum disorder, attention-deficit/hyperactivity disorder, and anxiety disorder for 2 years. His treatment included a low-dose atypical antipsychotic, a low-dose selective serotonin reuptake inhibitor, a stimulant, and an alpha agonist. Additionally, he was receiving individual therapy every 2 weeks to increase his coping skills. The family had been referred for family therapy but, due to both parent's full-time jobs and other commitments, they had not engaged in that treatment. The family self-referred to a different child psychiatrist because they felt that Dave's treatment had become stalled.

The family's chief complaint was Dave's explosive behavior around limit setting at home and social difficulties with his peers. His father struggled to follow through with consequences, whereas his mother was always able to do it. This inconsistency had resulted in confusion for Dave and also increased conflict between the parents. Dave's mother felt that she was not being supported by her husband. Dave's father felt that his wife was very strict with Dave and would attempt to compensate for this strictness. He felt that Dave's developmental delay made school so difficult for him that he deserved to have a less demanding environment at home. As the parents talked with the therapist they realized the need to negotiate expectations and consequences for Dave. They also recognized the need to support each other more and redevelop the warmth in their relationship. Although Dave remained difficult and challenging, he gradually improved and became much less explosive.

FUTURE DIRECTIONS

Family therapy has evolved from a therapy developed in opposition to common psychiatric care to a basic orientation to the treatment of child mental health challenges. All situations require the assessment

Telegram: @medical_k

www.konkur.in

of the involvement and education of family members. Some situations require the specific and monitored engagement of family members in the treatment plan. In many instances, treatment of the child requires the involvement of the family in the manner outlined in the manual of an evidence-based model of family intervention. Knowledge of these treatments and skills implementing them are necessary elements in child mental health care. For many child mental health problems, the problem leads to intuitive family interactions that are counterproductive and often worsen the situation. Family therapy stops these negative cycles and can introduce successful, self-reinforcing, positive family interactions that promote family life and optimal child development. These interventions can help the child's situation to improve, and the family's experience of warmth, care, and effectiveness can emerge and persist.

53.5 Pediatric Psychopharmacology

JEFFREY R. STRAWN, M.D., AND LAURA B. RAMSEY, PH.D.

Psychotropic medications play a critical role in treating many psychiatric disorders in children and adolescents. However, using these medications effectively and appropriately requires an understanding of pediatric pharmacokinetics and pharmacodynamics, in addition to the nuances of response that are revealed by numerous double-blind, placebo-controlled trials. In this chapter, we review the developmental pharmacology that is relevant to psychotropic medication use in pediatric populations and the evidence for multiple psychotropics across internalizing and externalizing disorders.

DEVELOPMENTAL PHARMACOLOGY

Pharmacokinetics and pharmacodynamics in children and adolescents differ considerably from adults, and these differences give rise to differences in dosing, differences, response, and differences in tolerability. Importantly, pharmacokinetic and pharmacodynamic factors interact (Fig. 53.5–1) and are mutually influenced by development. These pharmacokinetic factors and pharmacodynamic factors subtend differences in side effects (e.g., extrapyramidal symptoms), dosing (e.g., lithium), and efficacy (e.g., benzodiazepines) between children, adolescents, and adults.

Pediatric Pharmacokinetics

In general, metabolic capacity at birth is less than in adults and increases to levels seen in adults by approximately 2 years of age. However, near pubarche, metabolism may be greater than what is commonly observed in adults. In addition to developmental differences in hepatic metabolism, renal function, and changes in fat distribution during childhood and adolescence affect the pharmacokinetics of many medications in youths.

Telegram: @medical_k

www.konkur.in

Also, children and adolescents have greater total body water and relatively less adipose tissue compared to adults. This affects the distribution of many medications and the accumulation of lipophilic medications (and their metabolites).

FIGURE 53.5–1. Schematic representation of the components that comprise the pharmacokinetic-pharmacodynamic interface. (Reprinted with permission from Capparelli EV. Clinical pharmacokinetics in infants and children. In: Aranda JV, van den Anker JN. *Yaffe and Aranda's Neonatal and Pediatric Pharmacology: Therapeutic Principles in Practice*. 5th ed. Wolters Kluwer; 2020.)

Telegram: @medical_k

www.konkur.in

FIGURE 53.5–2. Factors affecting the rate and extent of drug distribution. (Reprinted with permission from Stancil SL, Chapron A, Abdel-Rahman AM. Drug absorption, distribution, metabolism, excretion, and transporters in newborns and children. In: Aranda JV, van den Anker JN. *Yaffe and Aranda's Neonatal and Pediatric Pharmacology: Therapeutic Principles in Practice*. 5th ed. Wolters Kluwer; 2020.)

Absorption and Bioavailability. Absorption is influenced by the route of administration of a drug and, for orally administered medications, is influenced by gastric pH and the presence of food in the stomach. Bioavailability is the fraction of the drug that reaches the systemic circulation and is also influenced by concurrently administered medications and first-pass metabolism.

Drug Distribution. Drugs are distributed throughout the body through the bloodstream, and distribution of psychotropic drugs to the site of action is affected by protein binding and transport across the blood-brain barrier. The volume of distribution (V_D) reflects the degree to which it is distributed in body tissue (rather than the plasma). Larger V_D indicates a greater amount of tissue distribution. Smaller VD suggests that the drug stays primarily in the plasma. Drugs with high lipid solubility (e.g., some benzodiazepines), low rates of ionization, or low plasma protein binding have higher volumes of distribution compared to drugs which are more polar, more ionized or those that have more plasma protein binding and differs across development (Fig. 53.5–2). Additionally, age-dependent changes in body composition can also influence distribution.

Metabolism. Many psychotropic medications are metabolized by cytochrome P450 enzymes CYP3A4, CYP2C19, or CYP2D6 in the liver. The activity of CYP2D6 is fairly constant from 1 year of age through

Telegram: @medical_k

www.konkur.in

adulthood, but the activity of CYP2C19 and CYP3A4 may be increased in children compared to adults. Drug–drug interactions can occur through inhibition or induction of these enzymes. In addition, in younger children, hepatic clearance of drugs may be increased as liver blood flow is increased compared with adults. This is largely related to the larger ratio of liver to total body mass in the children compared to adults and adolescents (Fig. 53.5–3) and, as a result, the first-pass effect of some drugs may be increased.

Excretion. Most drugs and their metabolites are excreted through the kidney or liver. Renal clearance is substantially higher in pediatric populations compared to adults and decreases from ages 2 to 20 years.

Pharmacogenetics in Children and Adolescents

Variants in the genes encoding the metabolizing enzymes (e.g., CYP2C19 and CYP2D6) influence the enzyme activity, so that patients can be poor metabolizers (with little to no activity), intermediate metabolizers, normal metabolizers, rapid metabolizers, or ultrarapid metabolizers (with more than normal activity). Dosing recommendations based on these metabolizer groups are available from the Clinical Pharmacogenetics Implementation Consortium, the Dutch Pharmacogenetics Working Group, and some are included on the FDA labels. The CYP2C19 and CYP2D6 enzyme activity affects the systemic concentration, which can be normalized with dose adjustments, using lower doses in poor metabolizers and higher doses in ultrarapid metabolizers. Individual genes should be used to adjust medication dosing rather than using combinatorial pharmacogenetic testing for medication selection.

ROLE OF PHARMACOTHERAPY IN CHILDREN AND ADOLESCENTS

While psychotropic medications often play an integral part in the treatment of children and adolescents with psychiatric disorders, they are usually used in combination with other modalities. Education about diagnosis, course of illness, prognosis, and available treatment options is important. Additionally, depending on the individual, a treatment plan may warrant individual, group, and/or family therapy; educational interventions; parent

Telegram: @medical_k

www.konkur.in

training; substance use disorder treatment; or any of several additional interventions.

FIGURE 53.5–3. Change in relative liver and kidney mass expressed as a percentage of body weight (WT) from infancy to young adulthood. (Reprinted with permission from Kauffman RE. Drug action and therapy in the infant and child. In: *Yaffe SJ, Aranda JV. Neonatal and Pediatric Pharmacology: Therapeutic Principles in Practice*. 4th ed. Wolters Kluwer; 2011.)

With all disorders and symptoms encountered in children and adolescents, thorough and developmentally sensitive assessment is critical prior to and throughout psychopharmacologic treatment. Such treatment plans are developed from comprehensive and accurate diagnostic evaluations, consideration of comorbidity, subsyndromal symptoms, family factors, personality/temperament, and learning issues (including learning disorders and learning weaknesses). Failure to address comorbidities or other factors may limit the benefits of pharmacotherapy or any therapeutic intervention.

Additionally, rating scales can be used to inform screening and diagnosis of some psychiatric disorders, although these are not a substitute for full clinical assessment by trained clinicians. Standardized

Telegram: @medical_k

www.konkur.in

measures generally provide normative data that allows a clinician to compare a particular patient's symptoms to those of children of similar age. In each section, common symptom rating scales will be discussed in addition to the evidence supporting their use.

ANXIETY DISORDERS

Selective Serotonin Reuptake Inhibitors in Anxiety Disorders

Multiple meta-analyses suggest that selective serotonin reuptake inhibitors (SSRIs) are superior to other medication classes in pediatric anxiety disorders, but patients are more like to discontinue SSRIs because of adverse events compared to SNRIs and SSRIs are more likely to produce activation in children and adolescents with anxiety disorders compared to SNRIs. To date, sertraline, fluoxetine, escitalopram, fluvoxamine, and paroxetine have been evaluated in pediatric anxiety disorders. These individual clinical trials are reviewed in detail elsewhere.

In pediatric patients with anxiety disorders, the probability of SSRI-related improvement increases over time although response is, overall, logarithmic—70% of the improvement, observed at week 8, occurred in the first 4 weeks of treatment. This trajectory may not be unique SSRIs in pediatric anxiety disorders as SSRIs appear to produce similar, early improvement in youth with major depressive disorder (MDD) and OCD. Additionally, compared to SNRIs, SSRIs produce faster and greater improvement. Only 40% of the treatment response observed for SSRIs occurs in patients receiving SNRIs by the eighth week of treatment and the divergence in SSRI–SNRI trajectory emerges near the fourth week of treatment.

SNRIs in Pediatric Anxiety Disorders

Several studies have examined venlafaxine in youth with generalized (κ = 2, pooled analysis) and social anxiety disorders (κ = 1) as well as duloxetine in generalized anxiety disorder (κ = 1) and atomoxetine in pediatric patients with ADHD and comorbid generalized, separation and/or social anxiety disorders. These studies have generally suggested benefit compared to placebo. However, meta-analyses of SSRIs and SNRIs in youth with anxiety disorders suggest that SSRIs produce faster, and greater improvements compared to SNRIs.

Telegram: @medical_k

www.konkur.in

Other Agents in Pediatric Anxiety Disorders

While SSRIs are the most commonly prescribed initial medications for children and adolescents with anxiety disorders in the United States and approximately half of these youth continue treatment for at least 6 months. However, nearly one-third of anxious who are treated with medication in the United States begin treatment with a non-SSRI medication.

Benzodiazepines in Pediatric Anxiety Disorders. Despite evidence for the use of benzodiazepines in the acute treatment of anxiety in youth, studies of chronic use of benzodiazepines in youths with generalized, separation, and social anxiety disorders have failed to show benefit.

α_2-Agonists in Pediatric Anxiety Disorders. The α_{2A}-agonist, guanfacine has been evaluated in youth with generalized, separation, and/or social anxiety disorder. Extended-release guanfacine was well tolerated although somnolence and fatigue were more frequent in GXR-treated patients compared to those receiving placebo. Differences in response were observed between placebo and extended-release guanfacine, although statistically significant differences were not observed for the dimensional measure of anxiety.

5-HT_{1A} Modulators in Pediatric Anxiety Disorders. Buspirone was evaluated in one flexibly dosed (n = 227) and one fixed-dose (n = 341) trial in children and adolescents with generalized anxiety disorder. Buspirone was not statistically superior to placebo in any of these trials. Discontinuation related to an adverse event occurred more commonly in patients treated with buspirone relative to those treated with placebo.

Tricyclics in Pediatric Anxiety Disorders. Two randomized, placebo-controlled trials evaluated imipramine in pediatric anxiety disorders. In the first study, imipramine was superior to placebo in the study's primary outcome measure (response rate: 81% vs. 47%, $p < .05$). With the exception of dry mouth, no side effects were significantly more common compared to the rates observed in patients receiving placebo. However, a second study of imipramine in children with SAD failed to replicate the earlier study's findings. Imipramine was associated with behavioral activation (e.g., "angry outbursts," irritability, etc.) and dry mouth was commonly observed.

Telegram: @medical_k

www.konkur.in

Tricyclics (i.e., tricyclic antidepressants, TCAs), have fallen out of favor since the introduction of SSRIs and SNRIs due to comparatively poorer tolerability, including anticholinergic side effects, the need for electrocardiographic monitoring as well as their narrow therapeutic index that results in an increased risk of lethality in TCA overdoses.

SSRIs + Psychotherapy in Pediatric Anxiety Disorders. Few studies have examined CBT in comparison to an SSRI or in combination with an SSRI in pediatric anxiety disorders. CAMS (*n* = 488) found CBT + sertraline to be more effective than CBT or sertraline monotherapy. Remission rates for CBT + sertraline were superior to CBT (66% vs. 35%) after 12 weeks of treatment. Yet, youth in CBT continued to improve relative to COMB such that by 24 weeks, the gap in remission rates narrowed (65% vs. 45%) with no significant difference by week 36 (67% vs. 58%). Interpretation of the effects of CBT in CAMS has always been complicated by design decisions that may have diminished the effects of CBT: (1) CBT was shortened to conform to the ethically acceptable duration of pill placebo exposure; (2) sessions focused on exposure tasks; the key ingredient in CBT were reduced. (3) At the end of CAMS' 12-week acute phase, regardless of remission status, CBT participants entered maintenance phase with a reduced visit schedule, and no initiation of any new CBT treatment potentially limiting restricting potential gains from weeks 12 to 24 and beyond. (4) CAMS CBT had no parent involvement until well into treatment, and even then, it was limited, an approach that is at odds with current practice. In youth with social anxiety disorder, Social Effectiveness Therapy for Children (SET-C) + fluoxetine and SET-C both improved anxiety symptoms relative to placebo.

Select Key Studies

The largest study of an SSRI in pediatric patients with anxiety, the Child/Adolescent Anxiety Multimodal Study (CAMS), compared sertraline (*n* = 133), cognitive-behavioral therapy (CBT) (*n* = 139), combination therapy (CBT + sertraline) (*n* = 140), and placebo (*n* = 76). CAMS included youth with separation, generalized, and/or social anxiety disorders. In CAMS, sertraline was initiated at 25 mg/day and titrated to 200 mg/day with a mean dose of 134 ± 60 mg per day in the combination-therapy group and 146 ± 61 mg per day in the sertraline group. More than half of sertraline patients (55%) exhibited improvement based on Clinical

Telegram: @medical_k

www.konkur.in

Global Impression-Improvement (CGI-I) scores while 81% of youth treated with cognitive-based therapy (CBT) + sertraline met response criteria for ($p < .001$) (compared to 60% in patients receiving CBT ($p < .001$). All active treatments were statistically superior to placebo. While this is the largest randomized controlled trial of any psychopharmacologic or psychotherapeutic combination (or their combination) in pediatric patients with anxiety disorders, there was no CBT+ placebo treatment. Some have suggested that the "absence of such a group prevented the investigators from determining whether the addition of sertraline to cognitive behavioral therapy resulted in more improvement than each treatment given separately because of an additive effect of two active treatments or because of the placebo effect of adding a pill to cognitive behavioral therapy." In this regard, those receiving CBT in conjunction with a tablet knew they were receiving active medication, thus accentuating the expectation of treatment success in patients receiving sertraline + CBT.

PHARMACOTHERAPY FOR MAJOR DEPRESSIVE DISORDER

Multiple RCTs support the efficacy of fluoxetine and escitalopram in youths with MDD—and both are FDA approved for MDD in pediatric patients. There is also support for the use of medication in conjunction with CBT for initial outcome and to reduce the risk of relapse. In an RCT of 46 adolescents who responded to 12 weeks of fluoxetine treatment, relapse-prevention–focused CBT was associated with lower relapse rates compared to medication alone. In fact, the booster effect of CBT substantially reduced the risk of relapse eightfold. Beyond fluoxetine and escitalopram, several other SSRIs have demonstrated efficacy in youth with MDD. However, interpretation of the clinical trial literature for SSRIs and SNRIs in youth with MDD is complicated by several factors. In recent meta-analyses of these medications in youth with MDD, funding source differentiated medication-placebo differences with smaller medication-placebo differences being observed in industry-funded versus federally funded trials. Thus, the impact of study sponsorship on trial outcome supports the assertion that industry-funded trials with high placebo response rates and small drug-placebo differences are "failed trials" and should not be described as "negative trials" or used to determine public

Telegram: @medical_k

www.konkur.in

health estimates of antidepressant efficacy in children and adolescents with depression.

Despite the efficacy of the SSRIs, no controlled pediatric trial data suggest benefit in pediatric patients with MDD. Monoamine oxidase inhibitors have very limited data in pediatric use, although one large, double-blind, placebo-controlled trial of transdermal selegeline recently failed to show benefit in youth with MDD, although it was compromised by a very high placebo response rate.

Treatment resistant MDD, in adolescents is prevalent and associated with a substantial psychosocial burden and mortality. In approaching medication-resistant MDD in adolescents, it may be useful to quantify the degree of treatment resistance which may help to identify treatment-responsive phenotypes, and this can be done using the Antidepressant Treatment Record (ATR), which has been evaluated in adolescents. Aside from the Treatment of SSRI-resistant depression in Adolescents (TORDIA) study described below and two recent trials, few have systematically evaluated treatments for this population. In a large study of 10-Hz transcranial magnetic stimulation (TMS) for adolescents with TRD (n = 103), daily treatments over 6 weeks failed to demonstrate superiority to a sham intervention in change in the Hamilton Depression Rating Scale score. Dwyer and colleagues examined a single intravenous infusion of either ketamine (0.5 mg/kg over 40 minutes) or midazolam (0.045 mg/kg over 40 minutes), and the alternative compound 2 weeks later in 17 adolescents and found ketamine to be well tolerated and associated with short-term (2-week) efficacy in reducing depressive symptoms compared with midazolam.

Suicidality

In 2004, an FDA advisory Committee reviewed results of a meta-analysis of 24 controlled clinical trials of 9 antidepressants, which included approximately 4,400 pediatric patients. While there were no completed suicides, the cumulative risk for suicidality (suicidal thinking or behavior) when adverse events were simply collected by spontaneous report was approximately 4% on active medication versus approximately 2% on placebo. This resulted in the FDA issuing a boxed warning that any antidepressant use in children and adolescents and young adults was accompanied by an increased risk for suicidal thinking and behavior.

Telegram: @medical_k

www.konkur.in

Subsequent meta-analyses have failed to replicate the original analyses from 2004, even as newer data were incorporated. However, there may be specific increased risks for some SSRIs. Among SSRIs, a meta-analysis found differences in suicidality, with sertraline potentially having lower rates of treatment-emergent suicidality while paroxetine had higher rates of suicidality compared to placebo. That medications within the SSRI class are differentially associated with both higher and lower rates of suicidality compared to placebo with class-wise comparisons (e.g., SSRI vs. placebo) finding no significant differences call into question the boxed warning applied to all antidepressants regardless of indication and specific medication (US Food and Drug Administration. Relationship between psychotropic drugs and pediatric suicidality: review and evaluation of clinical data. Available at: http://www.fda.gov/ohrms/dockets/ac/04/briefing/2004-4065b1-10-TAB08-Hammads-Review.pdf). However, unlike recent network meta-analyses of SSRIs and SNRIs in youth, the analyses that gave rise to the boxed warning on SSRIs and SNRIs as well as earlier analyses of suicidality utilized older meta-analytic techniques could not compare individual medications.

Select Key Studies

Treatment for Adolescents with Depression Study (TADS). In TADS, adolescents with MDD (*n* = 439) were randomized to (1) fluoxetine monotherapy (10 to 40 mg/day), (2) CBT monotherapy, (3) CBT + fluoxetine (10 to 40 mg/day), or (4) placebo. Following 12 weeks of treatment, patients who received fluoxetine + CBT were significantly more improved compared to patients who had received either CBT or fluoxetine monotherapy (Fig. 53.5–4**)**. Additionally, fluoxetine was superior to CBT and all active treatments were superior to placebo.

Telegram: @medical_k

www.konkur.in

FIGURE 53.5–4. Time course of SSRI response in NIH-sponsored trials of anxiety disorders (Child/Adolescent Anxiety Multimodal Study [CAMS]), depression (Treatment of Adolescent Depression Study [TADS]), and treatment-resistant depression (Treatment of SSRI-Resistant Depression in Adolescents [TORDIA] Study) in children and adolescents. (See eBook for color images.)

Treatment of SSRI-Resistant Depression in Adolescents (TORDIA) Study. In TORDIA, adolescents with MDD aged 12 to 18 (*n* = 334) who did not respond to an adequate dose of an SSRI, for at least 8 weeks, were randomized to one of four treatments over 12 weeks (March et al., 2004). Importantly, these patients had, on average, a more chronic course than those enrolled in TADS. In TORDIA, patients could switch to (1) a different SSRI (paroxetine, citalopram, or fluoxetine); (2) a different SSRI + CBT; (3) venlafaxine ER; or (4) venlafaxine ER + CBT. CBT + medication switch (either to another SSRI or venlafaxine ER) was associated with a marked decrease in depressive symptoms compared to simply changing medication. The two arms with CBT plus medication demonstrated a higher response rate (55%) than a medication switch alone (41%). In the original analysis, no differences in final outcome were detected between switching to venlafaxine ER relative to another SSRI, but patients who were switched to a second SSRI had less suicidal

Telegram: @medical_k

www.konkur.in

ideation than those treated with venlafaxine and fewer adverse events. Additionally, when tolerability and efficacy of the SSRIs were considered together, adolescents treated with citalopram and fluoxetine fared better than those treated with paroxetine.

Recent reanalysis of the TORDIA data, using contemporary statistical approaches, found that in patients not receiving CBT, SSRIs produced greater and faster improvement in depressive symptoms compared to venlafaxine ER. However, for CBT-treated patients, SSRIs and venlafaxine produced similar improvements in anxiety and depression.

Clinical Implications and the Role of Pharmacotherapy. For children and adolescents who present with a more complex MDD, or have a limited response to supportive psychotherapy, a more specific psychotherapy and/or an SSRI is indicated. Severe MDD and/or chronic recurring MDD will generally require pharmacotherapy, either alone or in combination with psychotherapy. For youths with SSRI-resistant depression, switching to another SSRI represents a reasonable approach and one RCT of adolescents with treatment-resistant depression, suggests that IV ketamine is superior to active placebo in the very short term (i.e., 2 weeks). However, in RCTs of adolescents with treatment-resistant depression, rTMS was not superior to sham.

PHARMACOTHERAPIES FOR BIPOLAR DISORDER

Bipolar disorder in children and adolescents is associated with significant long-term morbidity and disability. Owing to the severity and persistence of bipolar disorder into adulthood, safe and effective long-term treatments are needed.

Mixed Dopamine Serotonin Receptor Antagonists

Placebo-controlled studies suggest that multiple mixed dopamine, serotonin receptor antagonists are efficacy in pediatric patients with acute mania and six agents have received FDA approval for pediatric mania (lithium, risperidone, aripiprazole, quetiapine, olanzapine, and asenapine). In general, antimanic effects are observed within the first 2 weeks of treatment and mood stabilizers may be used as second-line treatments or in combination with mixed dopamine receptor antagonists. While monotherapy is generally preferred, combination pharmacotherapy may

Telegram: @medical_k

www.konkur.in

be required—such as a mixed dopamine receptor antagonist and mood stabilizer, or an antimanic agent with treatment for comorbid ADHD, anxiety, and/or OCD. Following initial response, most youth require ongoing treatment with medication to prevent relapse. Current recommendations suggest the regimen needed to stabilize the acute mania should be maintained for 12 to 24 months.

Mixed dopamine serotonin receptor antagonists, in youth, have been associated with changes in prolactin, fasting glucose, fasting total cholesterol, necessitating close monitoring (at least bi-yearly to yearly). Some have advocated the use of metformin to decrease weight gain and metabolic risk in youth treated with mixed dopamine serotonin receptor antagonists. Additionally, long-chain omega-3 fatty acids may decrease the risk of hypertriglyceridemia associated with some mixed dopamine receptor antagonists in youth.

Lithium

Based on two NIH-sponsored studies, the Collaborative Lithium Trials (CoLT), lithium is FDA approved for the acute (short-term) treatment of youths 7 years of age and older with manic and mixed episodes associated with bipolar I disorder and for maintenance treatment in pediatric patients ages 7 to 17 years. In the first CoLT study, children and adolescents were randomized to lithium (n = 53) or placebo (n = 28) for up to 8 weeks. Greater improvements in manic symptoms and response were observed in lithium-treated youth compared to those who receive placebo. Additionally, in the second CoLT study, responders were randomized to continue lithium or to be cross titrated to placebo for up to 28 weeks. The primary outcome measure was relative risk of study discontinuation for any reason. Significantly greater maintenance of response was observed in patients who continued lithium. In youth, the half-life of lithium is significantly shorter than in adults, largely related to increased renal clearance. In youth, pediatric trials have generally used doses of 25 to 30 mg/kg/day and average serum concentrations have been 1.05 mEq/L. Regarding the kinetics of lithium in youth, a population pharmacokinetic study found suggested a maintenance dose of 25 mg/kg/day (divided BID), although this study underscored the importance of ongoing therapeutic drug monitoring. Finally, the tolerability of lithium has been like that observed in adults with gastrointestinal side effects and elevations in TSH being common.

Telegram: @medical_k

www.konkur.in

Anticonvulsants

While the anticonvulsants likely have primary roles in the treatment of adults with bipolar disorder, these agents have produced very mixed results in youths. In this regard, improvements in manic symptoms are significantly greater for mixed dopamine serotonin receptor antagonists (approximately 0.65) compared to mood stabilizers (approximately 0.24); however, anticonvulsants are associated with less metabolic side effects in youth compared to mixed dopamine serotonin receptor antagonists. Further, their teratogenic and metabolic effects have limited their usefulness in youth.

Depression Associated with Bipolar Disorder

For youth with depression associated with bipolar I disorder, two medications have received FDA approval, olanzapine-fluoxetine combination (10 to 17 years of age) and lurasidone (10 to 17 years of age). Double-blind placebo-controlled trials of quetiapine and extended-release quetiapine have failed to demonstrate superiority to placebo in youth adolescents with bipolar depression. Open-label studies suggest that lamotrigine and lithium are associated with improvement in depressive symptoms in youth with bipolar I disorder.

Clinical Implications and the Role of Pharmacotherapy. Pharmacotherapy is the primary treatment for mania in youth. However, adjunctive psychosocial treatment may be useful to address disruptive symptoms and their sequela, which often impact family and community. These include interventions that focus on coping and emotional regulation, family therapy (including multi-family psychoeducation and family-focused treatment), CBT and there is emerging evidence that dialectical behavioral therapy may also be helpful. Due to the difficulty of stabilizing active bipolar and frequent comorbid symptoms, mixed dopamine-serotonin receptor antagonists are recommended as first-line treatments, although it is often necessary to employ combined pharmacotherapeutic strategies in these youth. As one example, multiple studies have shown that stimulants can be used in youth with stable bipolar disorder to treat comorbid ADHD.

OBSESSIVE-COMPULSIVE DISORDER (OCD)

Telegram: @medical_k

www.konkur.in

OCD affects between 1% and 2% of children and adolescents and is characterized by impairing rituals and obsessions. Pediatric OCD often continues into adulthood. Psychotherapy is recommended as first-line treatment for OCD in youth, but several pharmacotherapies have also demonstrated efficacy.

Pharmacotherapy for OCD

Several SSRIs have demonstrated efficacy and been approved by the FDA for the treatment of OCD in children and adolescents. These medications include fluvoxamine, fluoxetine, clomipramine, and sertraline. Based on the currently available evidence, the American Academy of Child and Adolescent Psychiatry recommends CBT for youth with mild to moderately severe OCD; patients with more severe symptoms of OCD, the combination of an SSRI and CBT may be more effective than CBT alone. Regarding the efficacy of SSRIs for the treatment of OCD in youth, several meta-analyses suggest benefit although the effect sizes in these studies are smaller relative to the effect sizes of these medications for patients with non-OCD pediatric anxiety disorders. The choice of antidepressant may be important; findings in one meta-analysis suggest that in pediatric patients with OCD, the tricyclic antidepressant, clomipramine—which is FDA approved for the treatment of OCD in youth—may be associated with larger effect sizes. Nonetheless, SSRIs are considered first-line psychopharmacologic interventions for youth with OCD and three SSRIs are approved for this indication in youth: fluoxetine, fluvoxamine, and sertraline.

Selected Studies

THE PEDIATRIC OCD TREATMENT STUDY (POTS). POTS randomizing 112 youths with OCD (aged 7 to 17 years) to CBT, sertraline, the combination of the CBT + sertraline and pill placebo. All active treatments were superior to placebo in reducing OCD symptoms, although remission rates for combined treatment was 53.6%, for CBT alone 39.3%, for sertraline alone 21.4%, and for placebo only 3.6%. In POTS (II), 124 youths with OCD (aged 7 to 17 years) were assigned to one of three treatment strategies, all of which included SSRIs. The positive response rates for medication management only (30%) and medication management plus instructions in CBT (34%) were significantly lower than combined medication

Telegram: @medical_k

www.konkur.in

management plus CBT (69%). These findings indicate that truncated versions of CBT are not efficacious comparatively, and that efforts should focus on making the full CBT protocol available more widely in community settings.

Clinical Implications and the Role of Pharmacotherapy. SSRIs are effective in reducing symptoms of OCD in pediatric patients and are well tolerated. However, in light of the POTS I/II findings, recommendations would be for children and adolescents with OCD to begin treatment with either CBT alone or in combination with an SSRI.

POSTTRAUMATIC STRESS DISORDER

Exposure to traumatic events, including neglect, domestic violence, as well as physical and sexual abuse, is not uncommon for many children and adolescents. A significant number of traumatized children and adolescents develop posttraumatic stress disorder (PTSD), a condition intrinsically linked to the experience of extraordinary stress and characterized by intrusive hyperarousal and avoidant/numbing symptoms. Though the prevalence varies by report, 10% of physically abused adolescents may meet criteria for PTSD. Other samples of youth exposed to urban violence suggest that PTSD rates may be as high as 24% to 34% while following a single motor vehicle accident, the prevalence of PTSD in children at 6 months is approximately 12%. Finally, pediatric patients with PTSD or clinically significant posttraumatic stress symptoms often have comorbid with depression, bipolar disorder, substance use disorders, and externalizing behavioral problems. Additionally, preschool age children with posttraumatic stress symptoms or PTSD may experience dysfunctional attachment, aggressiveness, and impulsivity.

Pharmacotherapy for PTSD

When considered, medications should be utilized adjunctively with evidence-based trauma-focused therapies. Additionally, as sleep difficulties and nightmares are common among youth with PTSD, addressing sleep is an appropriate first step when considering adjunctive pharmacotherapy.

Telegram: @medical_k

www.konkur.in

SSRIs. Clinical trials comparing adjunctive antidepressant treatment with placebo in pediatric patients with PTSD are limited and, in general, do not suggest benefit of these medications, although, SSRIs may be considered in youth with co-occurring MDD or anxiety disorders in addition to PTSD.

Antiadrenergic Agents. Medications that centrally modulate noradrenergic tone are supported by clinical research as potential treatments for PTSD. The α_1-antagonist, prazosin has been studies as a treatment for dyssomnias, including nightmares and frequent nighttime awakenings in youth with PTSD. Case reports and a retrospective case series of 34 youth ages 5 to 17 years of age suggest that prazosin, an α_1-adrenergic antagonist, may be effective and well tolerated in treating sleep disturbances in youth with most youth responding to <5 mg qHS. Prazosin should be initiated at 1 mg 30 minutes before bedtime due to concern for first-dose hypotension and may be increased by 1 mg every 3 to 4 days for the first 2 weeks, starting lower and titrating up more slowly in younger children and/or in children and adolescents experiencing nausea, dizziness, or other side effects related to changes in blood pressure. Additionally, an uncontrolled trial suggested that guanfacine may reduce intrusive and hyperarousal symptoms in children with PTSD symptoms.

Mixed Dopamine Serotonin Receptor Antagonists. Limited, uncontrolled trials of second-generation antipsychotic medications in youth with PTSD symptoms have found mixed results and high rates of treatment-emergent adverse events.

Clinical Implications and the Role of Pharmacotherapy. Current evidence for the treatment of PTSD in youth suggests that trauma-focused psychotherapies be considered first-line treatment for children and adolescents with PTSD, with SSRIs and antiadrenergics, considered potential treatment options for comorbidities and for dyssomnias.

SCHIZOPHRENIA

While the onset of schizophrenia is rare prior to 13 years of age, numbers steadily increase throughout the adolescent years, and by 18 years of age

Telegram: @medical_k

www.konkur.in

12% to 33% of patients who will ultimately develop schizophrenia will have symptoms.

Pharmacotherapy for Schizophrenia

Aripiprazole, lurasidone, olanzapine, quetiapine, risperidone, and paliperidone have received FDA approval for the treatment of adolescents aged 13 to 17 years. The mixed dopamine serotonin receptor antagonists are considered first-line medications for adolescents with schizophrenia. Studies involving clozapine in treatment-refractory early-onset schizophrenia-spectrum disorders have demonstrated superiority of clozapine compared to haloperidol and olanzapine, with regard to reduction in negative symptoms and to a certain degree with overall response. Finally, based on the results of one RCT, the use of omega-3 fatty acids may delay the onset and/or reduce the ultimate expression of psychotic symptoms in high-risk children.

Clinical Implications and the Role of Pharmacotherapy

Psychopharmacology plays a critical role in the treatment of schizophrenia, with the atypical antipsychotics considered among the first-line treatments. Fish oil may be useful in adolescents at high risk to develop fulminant psychotic symptoms. Psychosocial interventions are considered adjunctive to the medication but are strongly recommended.

EXTERNALIZING DISORDERS

Attention-Deficit/Hyperactivity Disorder (ADHD)

ADHD affects 6% to 9% of children and adolescents worldwide and persists into adulthood in roughly 50% of patients. Stimulant medications represent the first-line pharmacotherapy for ADHD, and their efficacy and tolerability are supported by multiple randomized controlled trials and meta-analyses. In recent decades the utility of stimulant medications has been boosted by the development of long-acting/delayed/extended-release preparations. These newer formulations have allowed patients to sustain treatment effects throughout the day and lower potential abuse liability. Similarly, there have been successes in the development of novel medications and devices for the treatment of ADHD.

Telegram: @medical_k

www.konkur.in

Pharmacotherapies for ADHD. Stimulant medication—including both amphetamine- and methylphenidate-based agents are highly efficacious in treating youth with ADHD. In general, 65% to 75% of stimulant-treated youth response and response rates are similar for methylphenidate and amphetamine in immediate-release as well as extended-release preparations.

STIMULANTS. For ADHD core symptoms, amphetamines and methylphenidate are associated with improvement relative to a placebo, and this efficacy has been demonstrated in multiple meta-analyses. While network meta-analyses have failed to detect differences in efficacy between one amphetamine derivative over another or between amphetamines and methylphenidate, their tolerability may differ considerably, and there may also be differences in response at the individual level.

Immediate-release stimulant medications must be taken BID or TID and are both rapidly absorbed and metabolized which results in their therapeutic effects wearing off within several hours. To address these limitations, sustained-release formulations were developed, although in some cases "acute tolerance due to a lack of a steep absorption phase and a flat (i.e., zero-order) drug delivery profile" potentially degraded response. Given this, modified extended-release formulations have been develop which include varying amounts of immediate- and extended-release stimulant and which produce ascending (e.g., first-order) delivery profiles (Table 53.5–1). Longer-acting formulations are considered the first-line stimulant formulation and enhance adherence. However, it is not uncommon to need a "booster" dose of a stimulant in the afternoon with many extended-release proportions to extend the duration of coverage. Dosing is important with stimulant medication and in general, adequate trials of methylphenidate consist of >0.8 mg/kg/day while 0.5 mg/kg is often considered an adequate trial for mixed amphetamine salt-based preparations.

Table 53.5–1. Common Stimulant Medications and Formulations

Proprietary Name	FDA-Approved Age Range	Formulation	Route	Immediate Release/Extended Release	Molecule
ADHANSIA XR	≥6 years	Capsule (composite beads)	Oral (whole or sprinkled)	IR 20%; ER 80%	d,l-MPH
APTENSIO XR	≥6 years	Capsule (composite beads)	Oral (whole or sprinkled)	IR 40%; ER 60%	d,l-MPH
Azstarys	≥6 years	Capsule (composite beads)	Oral (whole or sprinkled	IR 30%, pro-drug 70%	Ser-d-MPH/d-MPH
CONCERTA	≥6 years ≤65 years	Tablet	Oral (whole)	IR 22%; ER 78%	d,l-MPH
COTEMPLA XR-ODT	6–17 years	Orally disintegrating tablet	Oral (whole)	IR 25%; ER 75%	d,l-MPH
DAYTRANA	≥6 years	Transdermal	Topical (hip)	N/A	d,l-MPH
FOCALIN XR	≥6 years	Capsule (mixed beads)	Oral (whole or sprinkled)	IR 50%; ER 50%	d-MPH
JORNAY PM	≥6 years	Capsule (composite beads)	Oral (whole or sprinkled)	N/A	d,l-MPH
METADATE CD	6–15 years	Capsule (mixed bead)	Oral (whole or sprinkled)	IR 30%; ER 70%	d,l-MPH
QUILLICHEW ER	≥6 years	Chewable tablet	Oral (chewed)	IR 30%; ER 70%	d,l-MPH
QUILLIVANT XR	≥6 years	Liquid oral suspension	Oral	IR 20%; ER 80%	d,l-MPH
RITALIN LA	≥6 years	Capsule (mixed beads)	Oral (whole or sprinkled)	IR 50%; ER 50%	d,l-MPH
ADDERALL XR	≥6 years	Capsule (mixed beads)	Oral (whole or sprinkled)	IR 50%; ER 50%	Mixed salts of d- and l-AMP (ratio of 3:1)
ADZENYS ER	≥6 years	Liquid oral suspension	Oral	IR 50%; ER 50%	Mixed salts of d- and l-AMP (ratio of 3:1)
ADZENYS XR-ODT	≥6 years	Orally disintegrating tablet	Oral (whole)	IR 50%; ER 50%	Mixed salts of d- and l-AMP (ratio of 3:1)
DYANAVEL XR	≥6 years	Liquid oral suspension	Oral	NR	Mixed salts of d- and l-AMP (ratio of 3.2:1)
MYDAYIS	≥13 years	Capsule (mixed beads)	Oral (whole or sprinkled)	NR	Mixed salts of d- and l-AMP (ratio of 3:1)
VYVANSE	≥6 years	Capsule (powder)	Oral (whole or sprinkled)	N/A	d-AMP

While stimulants are generally well tolerated in youth with ADHD, side effects, including decreased appetite, sleep difficulties, rebound hyperactivity or irritability, headache, and gastrointestinal symptoms, can become problematic. A meta-analysis of appetite loss associated with stimulant medications in pediatric patients with ADHD suggests that nearly half of methylphenidate-treated patients will experience appetite loss (compared to approximately 15% of placebo-treated patients); however, “serious” appetite loss occurs in 10.5% of stimulant-treated youth (compared to approximately 2% of placebo-treated youth). Stimulant-induced appetite decreases appear to be dose related. Several strategies have been proposed for the management of stimulant-induced appetite loss, including careful monitoring of appetite, weight, and body mass index, administration of medication after breakfast, and the use of calorically dense snacks (or fourth meals) later in the day or early evening.

There has been considerable debate about the management of cardiovascular side effects of stimulant medications, and, at times, conflicting recommendations have been provided. Stimulants have been

Telegram: @medical_k

www.konkur.in

associated with elevations in mean blood pressure (<5 mm Hg) and heart rate (<10 beats/min). A subset of individuals (5% to 10%) may have an even greater increase in heart rate or blood pressure. Although there are limited prospective data related to the relationship between cardiac risk factors and outcomes in stimulant-treated youth, prudent recommendations from the American Heart Association and the American Academy of Pediatrics recommend obtaining a thorough history to identify high-risk youth with potential cardiac abnormalities or pre-existing cardiac disease prior to initiation of stimulant pharmacotherapy. Routine screening electrocardiography is *not* indicated in the absence of other cardiac risk factors.

NOREPINEPHRINE REUPTAKE INHIBITORS (NRIS). The NRI atomoxetine has demonstrated efficacy in multiple controlled trials, although its efficacy is less than that of the stimulants. One meta-analysis reported atomoxetine's effect size as 0.62, while the stimulants were from 0.91 (immediate release) to 0.95 (sustained release). However, atomoxetine exposure varies substantially (30-fold) across individuals, and part of this variability is explained by CYP2D6 activity. Dosing recommendations are available for atomoxetine when the CYP2D6 genotype/phenotype is known.

The second NRI to be approved for children and adolescents with ADHD is viloxazine which also has *in vitro*, antagonistic activity at 5-HT2B and agonistic activity at 5-HT2C receptors (and has high receptor occupancy at clinical doses).

α-AGONISTS. Multiple RCTs support the efficacy of extended-release preparations of clonidine and guanfacine as monotherapy in children and adolescents with ADHD. Typically, extended-release clonidine is administered BID, and the extended-release guanfacine is given either qHS or qAM with equal efficacy throughout the day. Extended-release α-agonists are FDA approved as monotherapy as well as in combination with stimulants. Moreover, in youth who have a partial response to stimulants, α-agonists may boost ADHD response. Immediate-release formulations of clonidine and guanfacine are also used off-label in the treatment of youth with ADHD.

Selected Studies

MULTIMODAL TREATMENT STUDY OF CHILDREN WITH ADHD (MTA). In MTA, children were randomized to one of four groups: medication treatment alone (with a structured algorithm-based approach), psychosocial treatment alone, algorithm-driven medication management, psychosocial treatment, or "community treatment." The treatment algorithm involved monthly appointments with a physician during which the stimulant was titrated based on parent and teacher ratings. Treatment-related improvements were observed across all groups (at 14 months relative to baseline). However, algorithm-driven medication management was superior to intensive behavioral treatment alone and community treatment. It is noteworthy that the community treatment group had more limited physician follow-up, and, in this group, the average daily stimulant dose was significantly lower than in the algorithmic medication management group. Finally, approximately a quarter of youth who were randomized to behavioral management treatment required pharmacologic treatment secondary to a lack of effectiveness of the behavioral treatment. This finding highlights the role of pharmacotherapy in the management of many pediatric patients with ADHD.

PRESCHOOL ADHD TREATMENT STUDY (PATS). The Preschool ADHD Treatment Study (PATS) was also a large federally funded 14-month study designed to examine medication efficacy for younger children. All children and their parents first participated in a pre-trial, 10-week behavioral therapy, and training course. Only those children who still demonstrated significantly impairing ADHD symptoms were then randomized to receive immediate-release methylphenidate or placebo. Methylphenidate was significantly more effective than placebo at treating preschoolers with ADHD. However, at lower weight-adjusted, smaller effect sizes compared with school-aged children. In this regard, the mean optimal dose of methylphenidate was 14 mg/day (0.7 mg/kg/day), which is lower than the mean optimal dose of 1 mg/kg/day in the MTA study. In terms of tolerability, spontaneously reported moderate to severe adverse effects were present in approximately one in three preschoolers, including emotional outbursts, initial insomnia, repetitive behaviors/thoughts, decreased appetite, and irritability. Moreover, one in ten children discontinued treatment because of intolerable methylphenidate adverse effects (vs. <1% of school-age children in the MTA study).

Clinical Implications and the Role of Pharmacotherapy. Pharmacotherapy is a fundamental component of ADHD treatment in children and adolescents and is superior to behavioral therapy alone. Stimulant medications are among the most effective pharmacotherapies, although they vary considerably in release properties and duration of action. Additionally, in patients who have an incomplete or partial response to stimulants, adjunctive atomoxetine, guanfacine, and clonidine may boost response.

AUTISM SPECTRUM DISORDERS (ASD)

Pharmacotherapy for Autistic Spectrum Disorders (ASD)

ASDs, including autistic disorder, are characterized by impaired socialization, communication, and behavioral problems, frequently presenting with anxiety, irritability, aggression, and inattention/impulsivity-related symptoms. Psychosocial interventions include social skills training and applied behavioral analysis for youth with ASDs, while the role of psychopharmacologic interventions is frequently focused on target symptoms (e.g., irritability, disruptive and aggressive behaviors, impulsivity). Risperidone and aripiprazole have been approved by the FDA for the treatment of irritability associated with autistic disorder in children and adolescents.

Mixed Dopamine Serotonin Receptor Antagonists. Both risperidone and aripiprazole are FDA approved for the treatment of irritability associated with an autism spectrum disorder. In addition, quetiapine, olanzapine, ziprasidone, and paliperidone are commonly used clinically to manage irritability and aggressive behavior in youths with ASD; however. Meta-analyses of pediatric patients with autism (higher functioning) demonstrated improvement in behavioral symptoms associated with mixed dopamine serotonin receptor antagonists but confirmed the significant metabolic liability (e.g., weight gain) associated with this class of medications.

Additionally, first-generation antipsychotic medications (i.e., dopamine receptor antagonists) have been used to manage irritability and aggression in children with ASD. However, comparative data suggest that the mixed dopamine serotonin receptor antagonists are potentially more effective and may have fewer extrapyramidal side effects. More recently,

there have been several observational studies examining long-acting injectable forms of the mixed dopamine SSRIs, and these may be particularly helpful when children struggle with swallowing tablets and adherence.

Clinical Implications and the Role of Pharmacotherapy

SSRIs are modestly effective in improving global functioning and specifically improve repetitive behaviors, anxiety, irritability, and hyperactivity in children with ASD. Mixed dopamine serotonin receptor antagonists are commonly used for affective dysregulation, including irritability, aggression, and self-injurious behaviors. The mixed dopamine serotonin receptor antagonists may improve both the affective symptoms as well as—in some samples—ritualistic behaviors. For ADHD, as well as symptoms of inattention and distractability, stimulants are commonly used; however, the degree of stimulant-related improvement for these target symptoms is less than that which is associated with idiopathic ADHD.

SLEEP-RELATED DISORDERS

Insomnia is common in the general pediatric population and is certainly more common in youth with psychiatric disorders due to the disorders themselves as well as a sequela of the medications prescribed to treat the primary disorder. Pharmacologic treatment may be indicated if children do not show significant improvement following behavioral intervention. However, excluding other primary causes of dyssomnia (e.g., obstructive sleep apnea, iron deficiency anemia) is critical prior to pursuing pharmacotherapy, as pharmacotherapy could mask an underlying disorder.
